Action of Bases on the Salt: The Dimolecular Anhydride (IX).—The usual method of obtaining pseudo bases by shaking the salts with sodium hydroxide in the presence of ether was inapplicable in this case because extraction is too slow and the product is rapidly decomposed by the hydroxide. When benzene was substituted for the ether the result was more satisfactory. Thus one gram of the salt was shaken with 10 cc. of benzene and one gram of sodium hydroxide in 20 g. of ice and water until all of the salt was decomposed. The benzene layer was then decanted, dried and evaporated. It left a solid which was recrystallized from benzene and ether. It separated in colorless prisms melting at 148°.

Anal. Calcd. for $C_{34}H_{32}O_3N$: C, 79.0; H, 6.2; mol. wt., 516. Found: C, 79.0; H. 6.2; mol. wt., 488.

Ozonization.—A solution of 0.7 g. of the substance in 10 cc. of carbon tetrachloride was ozonized for forty-five minutes. The solvent was pumped off and the residual oil shaken with ice water in the usual manner, but the water solution was treated directly

---

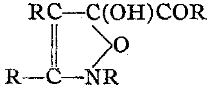
[4] Kohler and Davis, *ibid.*, 52, 4527 (1930).

with phenylhydrazine hydrochloride. A yellow precipitate formed which was identified as the phenylhydrazone of phenyl glyoxylic acid by comparison with an authentic sample.

Cleavage of Bases.—A solution of a small quantity of the dimolecular compound in methyl alcohol containing a trace of sodium hydroxide was boiled down, cooled and diluted with water. It deposited the unsaturated amino ester VI. The filtrates from the ester later also deposited a small quantity of desoxybenzoin. This unsaturated amino ester was obtained also when the ferric chloride double salt was shaken with ice and methyl alcoholic sodium hydroxide. In this case the yield of ester was 82%.

Summary

1. In the pseudo bases which are formed from isoxazolinium salts that are completely substituted and have an acidic group in the 5-position, the hydroxyl group occupies the 5-position:



Owing to the ease with which they are cleaved, their behavior is quite different from that of the pseudo bases derived from other tri-substituted isoxazoles.

2. The pseudo bases derived from β,γ-diphenyl isoxazole likewise have an hydroxyl group in the 5-position. They undergo a characteristic rearrangement into open-chained compounds.

THE INFLUENCE OF ACID CHLORIDES AND OF PYRROLE ON THE COLOR TEST FOR REACTIVE ORGANOMETALLIC COMPOUNDS. THE CONSTITUTION OF PYRRYLMAGNESIUM HALIDES

By Henry Gilman and Lloyd L. Heck

Received August 16, 1930 Published December 18, 1930

Introduction

In continuation of studies[1] on the reaction between acid halides and the Grignard reagent, it was noted that some acid chlorides appeared to interfere with the sensitive color test[2] for reactive organometallic compounds. This prompted an investigation of the effect of several typical acid halides on the color test. It has been found that such interference is not general.

Fortunately, the occasional interference of acid halides need not be of serious consequence for several reasons. First, the reaction between RMgX

compounds and acid halides is rapid.[3] Second, it is possible to use equivalent quantities of acid halide and Grignard reagent, the former being weighed out and the latter titrated before use. Third, in reactions involving alkylmagnesium halides having an alkyl group of low weight, it is possible to detect a slight excess of such an RMgX compound by observing the evolution of gas when a small sample of the reaction mixture is removed and hydrolyzed.

However, in a very special and rarely met with case there is another source of interference with some acid halides. Such interference might arise when a part or all of the commonly used diethyl ether is replaced by an amine like dimethylaniline.[4] Amines of this type may give, in some cases, products with acid halides whose color might interfere with the colors developed in testing for reactive organometallic compounds.[5] These are considered in the "Experimental Part."

We have had occasion to test the reliability of the color reaction with an unusually comprehensive and varied series of compounds. In addition to the occasional interference of acid halides, we directed attention recently[2'] to the infrequent interference of a few amino compounds by the production of colors which obscure those otherwise normally developed. The peculiar effects of pyrrole are of considerable interest in connection with the constitution of pyrrylmagnesium halides. It is known that when an RMgX compound reacts with a compound containing active hydrogen, the hydrogen is replaced by the –MgX group. Accordingly, the structure of a pyrrylmagnesium halide should be that represented by Formula (A). However, pyrrylmagnesium halides give reaction products which generally have the new grouping attached to carbon and not to nitrogen, and most frequently attached to an α-carbon atom. Consequently, a question has been raised[6] concerning the possibility of such types having Formula (B), either prior to or during its reaction with other compounds like carbon dioxide.

---

[3] See Gilman, Heck and St. John, *Rec. trav. chim.*, 49, 212 (1930), for the relative rates of some reactions involving organomagnesium halides. Obviously, the rate of reaction might be affected considerably in some cases by steric influences of groups about the acid halide grouping.

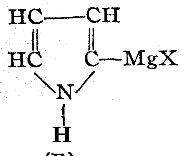
(A)



(B)

It has been suggested[6b] that the pyrrylmagnesium iodides might be represented in accordance with Formula (B) because they, unlike the related indylmagnesium halides, give a color test. This is an ingenious application of the color test. However, it may be open to the criticism that a compound of Formula (A) might give the color test, not because of the –NMgX grouping (which is known not to give a color test) but because the amine itself (which is liberated from –NMgX compounds by hydrolysis incidental to the completion of the color test) might be the cause of the color. Actually, pyrrole (in the absence of Grignard reagent) does give a blue coloration with iodine and glacial acetic acid, the reagents used to develop the color in testing for reactive organometallic compounds. However, because a more marked color is obtained from a mixture of an RMgX compound and an excess of pyrrole, it appears that the –MgX group is attached to carbon and not to nitrogen. This must not, however, be construed to mean that Formula (B) is necessarily the correct one *prior* to its reactions with a miscellany of compounds. It is entirely possible that no chemical reaction can differentiate between (A) and (B), because the product of reaction gives us no clue as to the original position of the –MgX group. We need only recall a simple illustration: namely, sodium acetoacetic ester which has the sodium attached to oxygen, and yet which (in a reaction with an RX compound) gives a product with the R group attached to carbon and not to oxygen.[7]

Another suggestion for deciding between Formulas (A) and (B) involves the chemiluminescence induced by the oxidation of organomagnesium halides. McCay and Schmidt[8a] observed no luminescence when a small stream of oxygen was played on pyrrylmagnesium iodide. This observation has been confirmed by us in connection with a miscellany of studies on the chemiluminescence of Grignard reagents.[8] We have

[7] This is open to two usual reservations. First, the sodium used need not be attached to oxygen, electronically speaking—in the same way that some would consider no formal valence bond between sodium and chlorine in sodium chloride. Second, some RX compounds react with sodium acetoacetic ester to give an R–O and not an R–C combination.

[8] Gilman, McGlumphy and Fothergill, *Rec. trav. chim.*, 49, 526 (1930). Also Gilman, Fothergill and McGlumphy, *ibid.*, 49, 726 (1930). Other references are to be found in these papers. The *p*-chlorophenylmagnesium bromide was selected because it gives an intense luminescence with oxygen. An answer to the question of the position of the –MgX group in pyrroles and related compounds may be found in absorption spectra studies.

shown that when a known excess of dry and freshly distilled pyrrole is treated with methylmagnesium iodide, phenylmagnesium iodide and p-chlorophenylmagnesium bromide, respectively, and oxygen is then passed into the mixture there is no chemiluminescence. These observations, however, are not to be taken as incontrovertible evidence for the –NMgX linkage, because there is still a possibility that a pyrrole –CMgX linkage may not luminesce

Perhaps the best present way of deciding the position of the –MgX group is by means of the Zerewitinoff reaction. If the –MgX is attached to carbon in accordance with Formula (B), then pyrrole should show at least two active hydrogen atoms inasmuch as another active hydrogen (–NH) is present when the –MgX group in Formula (B) is attached to carbon. If Formula (A) is correct, then but one equivalent of methane should be liberated when pyrrole is treated with an excess of methylmagnesium iodide. Using di-n-butyl ether as a solvent, the number of active hydrogens determined at 29° with freshly distilled pyrrole was 1.049 and 1.045. At a more elevated temperature (heating in a boiling water-bath for one hour) the number was 1.125 and 1.216. These values confirm other related studies.[9] From them one may conclude with definiteness that the –MgX group is attached to nitrogen in accordance with Formula (A), and that in a reaction of the pyrrylmagnesium halide the substituent finds itself generally on the a-carbon atom. This applies to pyrrylmagnesium iodide in di-n-butyl ether under the temperature conditions stated above.

Experimental Part

To those who may be unfamiliar with the carrying out of the color test, it might be stated that it is done very simply by adding a very small volume[2c] of the organometallic mixture to be tested to Michler's ketone in benzene, hydrolyzing with water, and then developing the color with a glacial acetic acid solution of iodine. In the results to be described, no organometallic compound was used. Unless otherwise stated, *a* benzene solution of Michler's ketone was used.

Acetyl Chloride.—Michler's ketone in benzene and acetyl chloride gave a pale blue color which disappeared in one-half minute. The ketone in dimethylaniline with acetyl chloride gave a dark blue color which did not disappear on standing; however, the addition of water destroyed the color. No color was observed when dimethylaniline and acetyl chloride stood for fifteen minutes.

Benzoyl Chloride.—With benzoyl chloride and the ketone a blue color only developed after five minutes. The same mixture with water gives a blue color which reaches maximum intensity in five minutes, and the addition of iodine in glacial acetic acid gives a deeper color, which changes rapidly to brown on the further addition of iodine–glacial acetic acid solution and so would not be confused with the colors given by reactive organometallic compounds.

---

[9] Oddo, *Ber.*, 44, **2048** (1911); Ciusa, *Gazz. chim. ital.*, 50, **II**, *53* (1920); *(Chem. Abstracts*, 15, *837* **(1921))**; Fischer and Postowsky, *Z. physiol. Chem.*, 152, *300* **(1926).** See also, Chelintzev and co-workers, *J. Russ. Phys.-Chem. Soc.*, *47*, 1224 (1915); 48, 127 (1916).

Essentially the same color effects were noted when Michler's ketone was replaced by its ethyl homolog, *p,p'*-tetraethyldiaminobenzophenone. Both ketones in dimethylaniline give colors which are destroyed by the iodine solution.

No color was observed after ten minutes, with a mixture of dimethylaniline, benzoyl chloride and water.

Benzoyl Bromide.—Benzoyl bromide appears to have a more pronounced interfering effect than benzoyl chloride.

Furoyl Chloride, C_4H_3OCOCl.—A mixture of the ketone, furoyl chloride and water gave, after ten minutes, a pale green color to the upper layer. This would not be confused with a positive test for an organometallic compound because of the long time required for the development of color subsequent to hydrolysis.

Phosgene, $COCl_2$.—The phosgene solution was that used earlier in a related study.[2e] The colors noted with phosgene may be definitely stated to interfere.

Oxalyl Chloride, $(COCl)_2$.—There is an unmistakable color interference with oxalyl chloride. It is interesting to note that as small a quantity as 0.05 cc. of a 1% solution of oxalyl chloride in benzene gives a pale but distinct blue color with 1 cc. of a 0.01 M solution of Michler's ketone.

Benzene **Sulfochloride,** $C_6H_5SO_2Cl$.—The colors obtained with benzene sulfochloride and Michler's ketone (and *p,p'*-tetraethyldiaminobenzophenone, respectively) should not interfere because they are not the greens and blues obtained with RMgX compounds. Furthermore, even these colors disappear when sufficient iodine–glacial acetic acid solution is added ultimately.

Thionyl Chloride, $SOCl_2$.—A very poor but positive color test is obtained with 1 cc. of a saturated Michler's ketone solution and 0.1 cc. of a 1% thionyl chloride solution in benzene. The color is more pronounced with a larger quantity of thionyl chloride.

Sulfur Chloride, S_2Cl_2.—Neither Michler's ketone nor its ethyl homolog in benzene or dimethylaniline gives a positive or conflicting test with sulfur chloride.

Chloromethyl Sulfate, $ClCH_2OSO_2OCH_3$.—A reddish-purple color is obtained with chloromethyl sulfate.

Phosphorus Pentachloride.—The blue-green color obtained with phosphorus pentachloride definitely interferes in the sense that it would be mistaken for a positive color test with reactive organometallic compounds. This interference was noted with both Michler's ketone and its ethyl homolog.

Pyrrole.—The following facts clarify the observations reported previously.[2f] First, pyrrole and Michler's ketone in benzene give no characteristic color; second, pyrrole and iodine in glacial acetic acid give a blue coloration which might be mistaken for a positive test; third, pyrrole and glacial acetic acid give no characteristic color; and, fourth, an organomagnesium halide (ethylmagnesium chloride or phenylmagnesium bromide) and a definitely known excess of pyrrole with Michler's ketone and glacial acetic acid (without iodine) give what can be regarded as an excellent test.

Miscellaneous.—The following compounds gave no interfering colors: concd. hydrochloric acid, phosphorus trichloride, antimony tri-iodide, anhydrous aluminum chloride, sulfuryl chloride, vanadium oxytrichloride,[10] picryl chloride, di-chloromethyl sulfate $[(ClCH_2)_2SO_4]$, cinnamoyl chloride $[C_6H_5CH{=}CHCOCl]$, tetranitromethane and *p*-toluene sulfochloride.

Summary

A study has been made of the possible interference of some acid halides on the sensitive color test for organometallic compounds. In connection with interfering colors, evidence has been presented for the attachment of

---

[10] Kindly provided by Dr. F. E. Brown and F. A. Griffitts.

the –MgX group to nitrogen in pyrrylmagnesium halides. The ultimate disposition of substituents on the α-carbon is accordingly no proof for a –CMgX linkage.

A NEW SERIES OF HALOGENATED SULFONEPHTHALEINS

BY WILLIAM CLOUSER BOYD WITH ALLAN WINTER ROWE

RECEIVED AUGUST 28, 1930 PUBLISHED DECEMBER 18, 1930

Introduction

Sulfonephthaleins with halogen substituted in the phenolic residues have been prepared by several investigators since the initial discovery of the parent body by Remsen.[1] Since certain of the phthaleins and sulfonephthaleins have interesting application as dyes, as indicators, and in certain clinical procedures, a study was begun in 1927 of the preparation of a series of sulfonephthaleins having halogen substituted in the *o*-sulfobenzoic anhydride residue. The selective elimination by the kidney of phenolsulfonephthalein offered a potential lead to direct pyelography if this property were retained in compounds rendered opaque to x-rays by substituted halogen.

In 1929 there appeared a paper by Harden and Drake[2] describing some work on such a series, including four of the compounds described here. They gave but meager details of the preparation, however, and it was felt that the compounds and methods described below might still prove of interest.

Preparation and Properties of the Parent Substances (Tetra-iodo-o-sulfobenzoic Anhydride and Tetrabromo-o-sulfobenzoic Anhydride.—As has evidently been the experience of other workers, it was found that halogen could be not introduced directly into the o-sulfobenzoic anhydride residue of a sulfonephthalein. Attempts to do so resulted in the destruction of the molecule. Consequently the halogen was substituted in the o-sulfobenzoic anhydride molecule before condensation, using a slight modification of the Juvalta method, as described by Pratt and Shupp.[3] Iodine and bromine derivatives were thus prepared with comparative ease. No attempt was made to prepare the fluorine or chlorine derivatives, though the latter could doubtless have been made, as Harden and Drake[2] report the preparation of some of them.

[2] Harden and Drake, *ibid.*, 51, 562 (1929).

[3] Pratt and Shupp, ibid., 40, 254 (1918).

Tetra-iodo-o-sulfobenzoic Anhydride.—108 g. of o-sulfobenzoic anhydride (Eastman, practical grade) and 300 g. of powdered iodine (4 moles of iodine per 1 mole of anhydride) were mixed in a long-necked flask (an 800-cc. Kjeldahl flask serves very well), and 500 cc. of fuming sulfuric acid containing 50% free SO_3 was added, with stirring. Acid of this strength is ordinarily partly or completely solid. and may require melting. The flask, into the neck of which, to prevent the escape of too much iodine or sulfuric acid, a test-tube was loosely fitted by means of a winding of asbestos cord, was slowly heated in an oil-bath, and the temperature kept between 110 and 120" until the evolution of sulfur dioxide had practically ceased (five to ten hours). The temperature was then raised to 175–180° and held for about thirty minutes. The whole apparatus was then allowed to cool, and when cool the practically solid contents poured into about 1.5 liters of water, and washed with successive portions of water containing sulfurous acid to remove the excess iodine. It was allowed to stand overnight with the final portion of wash water, the solid filtered off, washed with a little water, and dried in air; yield, **333** g. or 88%, calculated on the basis of the amount of o-sulfobenzoic anhydride used. The product so obtained is pure enough for making sulfonephthaleins.

Tetra-iodo-o-sulfobenzoic anhydride is somewhat soluble in water, acetic acid, tetrachloro-ethane, chloroform and benzene. It is quite soluble in acetone and in alcohol, but cannot be recrystallized from either. When dissolved in acetone it forms a dark brown mass, owing, apparently, to the formation of an addition product, since tetra-iodo-o-sulfobenzoic anhydride cannot be recovered from the mass except by the action of some drastic reagent, such as warm nitric acid. In alcohol it supersaturates, forming, when concentrated, a yellow varnish-like mass, which is quite unmanageable. When recrystallized from chloroform it has a melting point of 132" (uncorr.), as against the melting point of the crude product of about 260°, indicating the probable formation of some sort of addition product.

It can, however, be recrystallized from a mixture of alcohol and acetic acid (60 g. will require about 350 cc. of a mixture consisting of 100 cc. of 95% ethyl alcohol and 250 cc. of glacial acetic acid).

The purified product so obtained does not melt, but decomposes at from 305 to 310°. It is somewhat lighter in color than tetra-iodophthalic anhydride, resembling iodoform, except for a slight greenish tinge. The crystals, when examined under the microscope, are seen to be small, imperfect platelets, more opaque than the coffin-shaped crystals of tetra-iodophthalic anhydride.

The compound was analyzed for iodine by the method of Baubigny and Chavanne,[4] other methods, including that of Carius, proving unsatisfactory.

Anal. Calcd. for $C_7O_4I_4S$: I, 74.0; S, 4.6. Found: I, 73.8, 74.1; S, 4.8.

The toxic dose for a rabbit appeared to lie in the vicinity of 0.2 g. per kilogram of body weight when injected intravenously. The substance is not bacteriocidal for B. *coli* except in very high concentrations. One of us (B) took 0.5 g. by mouth without ill effect; subsequently, it could not be demonstrated in the urine.

Tetra-bromo-o-sulfobenzoic Anhydride.—Twenty-five grams of o-sulfobenzoic anhydride, 1 g. of iodine, and 125 cc. of fuming sulfuric acid containing 50% free SO_3 were mixed together in a long-necked flask of about 300 cc. capacity. About **39** cc. (124 *g.)* of bromine was measured out into a flask and added as described below.

About two-thirds of the bromine was added, and the mixture heated to 80° in an oil-bath until the bromine was all absorbed. The apparatus was then allowed to cool to room temperature, when two-thirds of the remaining bromine was added, and the mixture heated to 100° until the bromine was absorbed, as before. The apparatus was again

---

[4] Lassar-Cohn, "Organic Laboratory Methods," Oesper–Adams–Clarke, Williams and Wilkins, Baltimore, 1928, p. 443.

allowed to cool, two-thirds of the remaining bromine added, the mixture heated to 130° until absorption of the bromine took place, and again allowed to cool. The next time all of the remaining bromine was added, and the mixture heated to 170° for thirty minutes, and finally allowed to cool. The treatment from this point on is the same as for the iodine derivative; yield, 56 g., or 81%.

The crystals, after washing and drying the crude preparation, have a faint brownish color which deepens on exposure to light, but the pure compound (recrystallized three times from glacial acetic acid) is pure white. The crystals are easily seen under the low power of the microscope to be small, imperfect, hexagonal prisms. After the recrystallized product had been dried in a desiccator over sodium hydroxide to remove traces of acetic acid, the melting point was found to be **219"** (uncorr.).

The neutral equivalent was found to be 258, which corresponds to the calculated molecular weight of 516. The compound was analyzed for bromine by the method of Carius.

Anal. Calcd. for $C_7O_4I_4S$: Br, 61.9. Found: Br, 61.8, 61.8.

The substance is soluble in alcohol, acetone, glacial acetic acid and to some extent in water.

Preparation and Properties of the Halogenated **Sulfonephthaleins.**—For the condensation of the parent substances with phenols, the best condensing agent, both with respect to quantity and to quality of product, was found to be fuming stannic chloride. These anhydrides are much more difficult to condense than the corresponding phthalic anhydride derivatives, and the actual yields were all small.

The decision as to the best condensing agent and also as to optimum temperature was made by treating equal volumes of a standard mixture of melted phenol and anhydride with different reagents at different temperatures, dissolving the product in a slight excess of alkali, diluting to a definite volume, and comparing the resultant colors in the colorimeter.

The preparation of phenol-tetra-iodo-sulfonephthalein may be taken as typical.

Properties of the New Series.—Practically all of these sulfonephthaleins decompose gradually at very high temperatures, but have no real melting points, so as a rule melting points are not given.

PH ranges were determined either by adding a given amount of an alcoholic solution of the substance in question to buffered solutions prepared according to the directions of Folin,[5] or by adding a given amount of 0.04% aqueous solution of the sodium salt of the phthalein. Results obtained by these two methods were identical for the purpose in question.

The buffer mixtures were prepared according to the directions of Clark[6] except that in the PH range 4.6–5.6 the acetic acid mixtures described by Folin[5] were used.

Into these tetra-iodo and tetra-bromosulfonephthaleins more halogen

---

[5] Folin, "Laboratory Manual of Biological Chemistry," 4th ed., Appleton and Co., New York, 1925, pp. 49–53.

[6] Clark, "The Determination of Hydrogen Ions," 3d ed., Williams and Wilkins Co., Baltimore, 1928, pp. 192–220.

can be introduced. Bromine can be introduced by boiling the phthalein in acetic acid solution with a slight excess of bromine, pouring into water, extracting with alkali and purifying, as before. Iodine can be introduced, in alkaline solution, by adding a solution of iodine in potassium iodide solution.

Phenol-tetra-iodo-sulfonephthalein.—Eighty grams (0.12 mole) of tetra-iodo-*o*-sulfobenzoic anhydride was dissolved in 320 g. (3.4 moles) of freshly distilled, melted phenol, 80 g. of fuming stannic chloride added, and the mixture heated in an oil-bath for about eight hours. The flask was kept closed by a ground-glass stopper carrying a sealed-in glass tube. Moisture was excluded by a calcium chloride tube.

At the end of about eight hours the mixture was poured into about 6 liters of hot water, and washed repeatedly by decantation and boiling with fresh water. This washed raw product was then extracted with 2% sodium hydroxide solution until only an insoluble residue remained, the extract filtered, and the pbthalein precipitated by the addition of hydrochloric acid. This precipitate was then washed with hot water, as before, and this alternation of solution in alkali, precipitation and washing repeated until the product remained solid in hot water, and was completely soluble in alkali. It was then recrystallized from glacial acetic acid. Harden and Drake report recrystallization from benzene, but this in the experience of the present writers was unsuccessful.

Phenol-tetra-iodo-sulfonephthalein, when pure, consists of small imperfect crystals of a reddish-black color. It decomposes at about 210°. The crystals contain 8 to 10% moisture, which can be driven off by prolonged heating at 180°.

It is readily soluble in methyl alcohol, ethyl alcohol, ethyl acetate, acetone and acetic acid. It is somewhat soluble in benzene, carbon tetrachloride, tetrachloroethane, chloroform and ether. It is only very slightly soluble in water. It dissolves in alkali with an intense purplish color. By dissolving the compound in the calculated amount of alkali and evaporating the solution to dryness, the disodium salt can be obtained, as a dark reddish-black mass, with a bluish tinge. The phthalein dissolves, apparently without permanent change, in concentrated sulfuric acid, with the formation of an intense purplish color. The compound has a useful *P_H* range of 7.0 to 8.2.[7] Its color changes in this interval from a brownish-yellow to a wine-purple.

Phenol-tetra-iodo-sulfonephthalein will dye silk a color which varies from brownish-yellow to reddish-walnut, depending upon the method of application. " Dyeing from a 5% aqueous acetic acid solution is perhaps the simplest laboratory method.

Injected intravenously, as the disodium salt, it is, in part, eliminated through the kidney. It is not toxic to rabbits in doses of 0.2 g. per kilogram of body weight.

Anal. Calcd. for $C_{19}H_{10}O_5I_4S$: I, 59.3. Found: I, 59.0, 58.8, 59.1.

Tetra-iodo-phenol-tetra-iodo-sulfonephthalein.—This compound consists of small, irregular crystals of a reddish-brown color. It is soluble in alcohol, methyl alcohol, ethyl acetate, acetone and acetic acid, but in all to a less extent than is phenol-tetra-iodo-sulfonephthalein. It dissolves in alkali with a green color, and will dye silk a greenish-brown color. It is but slightly soluble in water (the disodium salt) and this renders it unsuited for the ultimate purpose of the study.

The *P_H* range is from 6.2 to 7.0 but as the color simply ranges from one shade of green to another, it is hardly possible that the compound could be of value as an indicator.

Anal. Calcd. for $C_{19}H_6O_5I_8S$: I, 74.6. Found: I, 74.4, 74.2.

Tetra-nitro-phenol-tetra-iodo-sulfonephthalein.—This compound crystallizes in

---

[7] Harden and Drake (Ref. *2)* report for the crude product *P*_H 6.4–8.0.

small brown crystals, melting with decomposition at 190°. It dyes silk a peculiar greenish-black. It dissolves in alkali with a purple color. Its *PH* range is probably between 6 and 7, but it is quite unsuited for use as an indicator. It can be analyzed for nitrogen by the Kjeldahl method by first adding zinc dust to the digestion mixture, so as to bring the nitrogen into the reduced form.

Anal. Calcd. for $C_{19}H_6O_{13}I_4N_4S$: N, 5.39. Found: N, 5.20, 5.23.

Diacetyl-phenol-tetra-iodo-sulfonephthalein.—This substance is light brown in color and melts at 136° (uncorr.). It is soluble in the usual organic solvents but practically insoluble in water.

Anal. Calcd. for $C_{23}H_{14}O_7I_4S$: I, 54.0. Found: I, 53.8.

Tetra-bromo-phenol-tetra-iodo-sulfonephthale ($C_{19}H_6O_5Br_4I_4S$).—This substance is brown in color, gives a green color in alkali and dyes silk a greenish-brown color, similar to that given by tetra-iodo-phenol-tetra-iodo-sulfonephthalein, but greener. The disodium salt is practically insoluble in water.

o-Cresol-tetra-iodo-sulfonephthalein.—The properties of this compound are not essentially different from those of phenol-tetra-iodo-sulfonephthalein. It gives a similar purple color in alkali, and dyes silk a shade darker. Its *PH* range was found to be 8.8–9.6.[8] The water solubility is low.

Anal. Calcd. for $C_{21}H_{14}O_5I_4S$: I, 57 4. Pound: I, 57.0, 57.2.

Resorcin-tetra-iodo-sulfonephthalein (**Tetra-iodo-sulfonefluorescein**).—This compound is very difficult to obtain in crystalline form. After washing, on spreading the crystals out to dry, they liquefy to a viscous mass and eventually harden again to a black mass. The solid material is black. It is soluble in the usual solvents. Its solution in alkali is red with a splendid greenish fluorescence. Its *PH* range is about 8 to 10, but it would be quite valueless as an indicator. It dyes silk a golden-reddish-brown.

Anal. Calcd. for $C_{19}H_8O_6I_4S$: I, 58.4. Found: I, 58.4.

Salicylic-acid-tetra-iodo-sulfonephthalein—This compound consists of small, imperfect crystals of a rose-beige color. It is soluble in ethyl alcohol, methyl alcohol, acetone and ethyl acetate. It is not as soluble in acetic acid, chloroform and ether as the compounds previously described. It dyes silk a golden-brown.

Its useful *PH* range is 7.2–8.0, the color changing from yellow-brown to pink. It might prove moderately satisfactory as an indicator.

Anal. Calcd. for $C_{21}H_{10}O_9I_4S$: I, 53.7. Found: I, 53.6.

Phenol-tetra-bromo-sulfonephthalein.—This substance gives very small reddish-black crystals of high but indefinite melting point; its properties are very similar to those of phenol-tetra-iodo-sulfonephthalein. It gives a purple color in alkali, and a golden-yellow on silk. Its PH range was found to be shorter than that of phenol-tetra-iodo-sulfonephthalein, its color changing between *PH* 7.2 and 8.0[9] from a light brown to a purple, so abruptly that its turning point might almost be fixed at *PH* 7.4. It might possibly be of some value as an indicator.

Anal. Calcd. for $C_{19}H_{10}O_5Br_4S$: Br, 47.7. Found: Br, 47.5.

Tetra-bromo-phenol-tetra-bromo-sulfonephthalein.—This substance dissolves in alkali with a bluish-green color, and dyes silk a similar shade, but is not otherwise very different from phenol-tetra-bromo-sulfonephthalein. It is less soluble in the usual solvents.

Its *PH* range was found to be 5.6–7.0,[10] but the colors are a series of shades of bluish-

---

[8] Harden and Drake report *PH* 7.0–8.6.

[9] Harden and Drake give *PH* 6.6–8.2.

[10] Harden and Drake report PH 3.0–4.6.

green at all the hydrogen-ion concentrations within this range, so its usefulness as an indicator would probably be small.

Anal. Calcd. for $C_{19}H_6O_5Br_8S$: Br, 64.8. Found: Br, 64.6.

Resorcin-tetra-bromo-sulfonephthalein.—This substance is a black solid, with a greenish sheen. It is soluble in the usual solvents, dissolving in alkali to give a red solution with a magnificent greenish fluorescence. It dyes silk a light reddish-brown. The PH range was difficult to determine, but was about 8–10. The compound would hardly be useful as an indicator.

Anal. Calcd. for $C_{19}H_8O_6Br_4S$: Br, 46.7 Found: Br, 46.5.

o-Cresol-tetra-bromo-sulfonephthalein was also prepared but offered nothing distinctive in its properties.

Tetra-iodo-saccharin.—This compound is not really a member of the present series, but was made while working on the parent substances. It can be prepared by the Juvalta method as described for them.

The substance consists of silky greenish-yellow crystals, somewhat soluble in acetone, and practically insoluble in everything else, including sodium hydroxide solution. It has a faint bitter taste.

The crystals did not melt or otherwise alter even at 345°. They contained carbon, sulfur, iodine and nitrogen, as demonstrated by the usual tests. Analysis for nitrogen was carried out by the Kjeldahl method, a rather long time being required for digestion.

Anal. Calcd. for $C_7HO_3I_4NS$: N, 2.03. Found: N, 1.99.

Attempts to condense this substance with phenolic substances were made, but unlike saccharin itself the substance would not condense.

Summary

Methods of preparing the parent substances of a new series of sulfonephthaleins having halogen substituted in the o-sulfobenzoic anhydride residue are described, together with methods of preparing the phthaleins themselves.

Certain properties of members of the new series, and of another substance, tetra-iodo-saccharin, are given.

THE CUPRO-POTASSIUM CARBONATE SOLUTION IN THE DETERMINATION OF REDUCING SUGARS

BY H. A. SCHUETTE AND JENNETTE N. TERRILL

RECEIVED AUGUST 29, 1930 PUBLISHED DECEMBER 18, 1930

In view of the revival of interest[1] in the use of the so-called cupro-potassium carbonate solution[2] in the determination of reducing sugars, there exists an evident need for more data and for a corroboration of some of those now extant. These ends have in part been approached in this Laboratory by the determination (1) of the dextrose equivalents of four modifications of this solution in which the concentration of copper sulfate is the only variant, and (2) of the levulose equivalent, as affected by change in method of reduction, of still other modifications[3] containing materially less copper than any of the others and, finally, by a study of the action of dextrose upon one of the latter. The presentation of these data is the object of this communication.

Reagents

Six sugar-oxidizing solutions of the type in question were made of such concentrations of copper sulfate, potassium bicarbonate and potassium carbonate as directed by their sponsors. The observed instability[1b,c] of four of these solutions—all statements in the literature to the contrary notwithstanding—made it necessary to prepare them in two parts each of such a concentration of copper sulfate and alkaline salts, respectively, as would produce, when used in the ratio of one volume of the first to four of the second, a reagent of the same composition as that used by its originator. Although a twenty-seven month period of observation on the stability of the fifth member[3] of this group has to date brought out no visible sign of decomposition, yet because of a desire to maintain uniformity in procedure, this reagent also was made up in two parts without, however, disturbing the original proportions of its constituents. The compositions of the copper solutions which were used throughout this study are given in Table I.

In the preparation of solutions "B" of the above reagents (Ost's and Nyns' modifications) the normal carbonate was slowly added to about 700 cc. of water at, or near, its boiling point. Complete solution of this salt was then effected by the addition of the acid carbonate. The same tech-

TABLE I

COMPOSITION OF CUPRO-POTASSIUM CARBONATE SOLUTIONS

Sponsor	Solution A $CuSO_4 \cdot 5H_2O$, g. per liter	Solution B K_2CO_3	 $KHCO_3$ g. per liter
Ost[4]	117.8	312 5	125
Ost[5]	87.5	312 5	125
Reyersdorfer[3]	15.71	312.5	125
Beyersdorfer[3]	3.14	312.5	12.5
Nyns[1]	75.0	312.5	125
Nyns[1]	126.5	312 5	125

nique was followed in making the Beyersdorfer modifications except that the water was brought to a temperature of only 60° before the carbonates were added in the same manner and order.

The dextrose used in this study was obtained from the Bureau of Standards (standard sample 41), and the levulose from the Eastman Kodak Company. The latter was found to have the same copper equivalent as a sample obtained from the former source.

Experimental Procedure

Exactly 20 cc. of the reducing solution, containing varying amounts of sugar, was added to 50 cc. of the freshly mixkd cupro-potassium carbonate reagent combined in the proportion of 10 cc. of solution A and 40 cc. of solution B. The dextrose–copper equivalents were determined for the two solutions of Ost[4,5] and the two of Nyns[1] by the procedure described elsewhere.[1c,d] Reductions were carried out for two and one-half hours at a temperature of 48.9 ± 0.1°, in stoppered Erlenmeyer flasks immersed to within 3 cm. of the top. The precipitated cuprous oxide was determined gravimetrically. Duplicate determinations run side by side checked excellently.

The levulose–copper equivalents of Beyersdorfer's stronger solution[3] were determined by three methods of reduction in which time and temperature were the variants, the approximate relationship between these factors being an inverse one. The conditions were met by following the *modus operandi* of Munson and Walker,[6] Defren[7] and Nyns,[1] respectively, for effecting the reduction of the copper solution. The phenomenon of delayed flocculation'' of part of the cuprous oxide was not detectable in this series of reductions.

Inasmuch as the graph of the observed reducing sugar–copper equivalents of the oxidizing solutions proved to be a straight line, there was derived for each a mathematical expression for the dual purpose of dis-

tributing the experimental errors over the whole range and of calculating the sugar equivalents for any weight of copper. It is in this form that the data obtained in this investigation are recorded (Tables II and III).

TABLE II

THE DEXTROSE EQUIVALENT OF THE CUPRO-POTASSIUM CARBONATE SOLUTION

Copper content, mg per cc.	Range of concn. of dextrose (x) in 20 cc., mg.	Equation for calculating Cu equiv.	Mean deviation $Cu_{obs.} - Cu_{calcd.}$, mg.
19.1'	60–140	$0.2254x - 4.3725$	±0.21
22.3[5]	60–140	$.2276x - 5.2175$	± .14
27.9[4]	60–140	$.2220x - 2.5700$	± .47
39.3[1]	20–140	$.2198x - 0.6650$	± .50

x = mg. of dextrose; y = mg. of copper.

TABLE III

THE LEVULOSE EQUIVALENT OF THE CUPRO-POTASSIUM CARBONATE SOLUTION (BEYERSDORFER)

Method	Time of reduction, min.	Equation for calculating levulose equiv. (x) from Cu	Mean deviation $Cu_{obs} - Cu_{calcd.}$, mg.
Over a free flame[6]	6	$2.485x - 2.255$	±0.20
In a boiling water-bath'	15	$2.391x - 1.034$	± .43
In a water-bath at 48.9°[1]	120	2.549~ – 1.464	± 51

The assertion by Nyns,[1] now known to be erroneous,[1b,c] that the cupro-potassium carbonate solution under closely guarded conditions as to time, temperature and concentration is a selective reagent for levulose to the exclusion of dextrose, suggested the desirability of observing what action, if any, the latter has upon Beyersdorfer's alternative modification[3] of this oxidizing agent which contains but one-fifth as much copper. To that end a series of dextrose solutions (**0.3** g. in **100** cc.) of **20** cc. each was added to 50-cc. portions of the copper solution which had been mixed as above described and then brought to the reaction temperature (48.9'). The amount of copper reduced was determined at one-half hour intervals until a reaction time of two and one-half hours was reached. Data are presented in the form of a graph (Fig. **1**).

Discussion

The maximum quantity of dextrose which any of the four reagents relevant to this study will oxidize is of the order of magnitude of **140** mg. On comparing the several dextrose–copper equivalents as calculated by means of the corresponding equation (Table II) it will be noted that there exists an exception to the generalization that the oxidizing power of the cupro-potassium carbonate reagent rises with an increase in the concentration of the copper. The situation which obtains is that the Ost solution[6] in which there are 22.3 mg. of copper per cc. will oxidize less dextrose than that one of Nyns[1] in which the concentration is less, or 19.1 mg. Inasmuch as the equilibrium conditions within this reagent are apparently not much better understood now than at the time of its introduction by Soldaini,[8] no explanation of this phenomenon suggests itself except that it is perhaps its hydrogen-ion concentration which is the significant factor.

The application of the Ost solutions to the determination of dextrose under the unified conditions of this study is new for data obtained by their sponsor were based on a larger volume of reactants (150 cc.) when boiled for at least ten minutes. In view of the data communicated herein it appears that, as between these two reagents for the determination of dextrose under the conditions proposed by Nyns,[1] preference should be given the weaker solution[6] because of its greater sensitiveness and the fact that the mean deviation between observed and calculated weights of reduced copper was materially less for this modification.

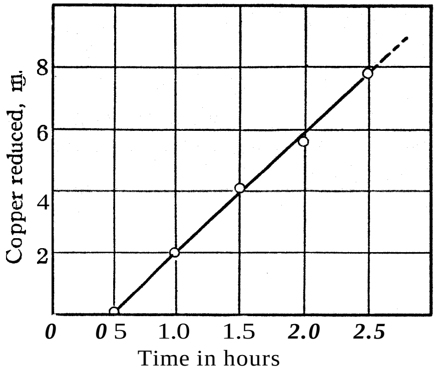

Fig. 1.—Action of dextrose upon Beyersdorfer's cupro-potassium carbonate reagent.

No claim had ever been advanced by its sponsor that the weakest copper solution[3] which has been used in this study is quite indifferent in the presence of dextrose. Beyersdorfer, it is true, carried out his reductions in a short time, compensating for brevity of reaction by recourse to higher temperatures. The rather high ratio of the relative reducing effects of dextrose and levulose upon Nyns' stronger solution—10 mg. of copper was found to be equivalent to 3.5 mg. of levulose'' or 48.5 mg. of dextrose[9]—raised the hope that, by applying his conditions to a reagent of still lower copper content, it might be demonstrated that it shows a selective reactivity for the latter sugar and therefore could be developed as a serviceable tool in the determination of this ketose in the presence of dextrose, a situation which obtains in the analysis of honey. This hope was not realized (Fig. 1). No reduction which is measurable by macro-chemical means had taken place at the end of the first half-hour of the reaction period, but after that it progressed arithmetically.

It is not improbable, however, that with the establishment of the above-mentioned ratio with respect to this reagent it will be possible to calculate

---

[8] Soldaini, *Pubb. Instit. studi Sup. Firenzi Sez. med. chir.*, **1**, 232 (1876); *Gazz. chim. ital.*, **6**, 322 (1876).

[9] This ratio is in good agreement with that reported by Jackson[1b] who found that 13 mg. of dextrose precipitate the same weight of copper as 1 mg. of levulose.

the percentage of these two sugars in a mixture, although such a procedure bids fair to be a laborious task, one that will involve many approximations.

Beyersdorfer's stronger reagent has not heretofore been put to a comparative test as to its levulose oxidizing powers when time and temperature of reaction are made to vary. As a result of such a study it appears (Table III) that no very material differences exist in the levulose–copper equivalents as between a reaction period of six minutes at the temperature obtainable by interposing an asbestos gauze between a beaker and a Bunsen burner,[6] by extending that period to fifteen minutes and reducing the temperature to that of a boiling water-bath,' or by allowing the reduction to proceed slowly.[1] The levulose equivalents of 10 mg. of copper are, under the above conditions and in the order given, 4.9, 4.6 and 4.5, respectively.

Choice of method of reduction will therefore be determined to some extent by (1) the smallest mean deviation between observed and calculated values, (2) convenience of operation, **(3)** reproducibility of results and (4) probable popularity among analysts. The mode of reduction of Munson and Walker[e] fulfils these requirements.

Summary

In a re-investigation of the so-called cupro-potassium carbonate solution of Soldaini[8] as modified in turn by Ost[4,5] and by Nyns,[1] there have been obtained data on the dextrose equivalents of four forms of this reagent of a copper content lying between the limits of 19.1 and **39.3** mg. per cc. These data are presented in the form of mathematical expressions and are pertinent to a temperature of 48.9° maintained for two and one-half hours. It was also found that this sugar, under the aforesaid conditions, has a reducing action upon that modification by Beyersdorfer[3] which contains but 0.8 mg. of copper per cc. This observation casts some doubt upon the acceptance of this solution as a selective reagent for levulose when both are present in the same solution.

Mathematical expressions also have been derived for calculating the levulose–copper equivalents of another reagent of this type (copper content 4.03 mg. per cc.) when either one of three modes of reduction is used, the relevant variants being time and temperature so adjusted as to bear to each other a relationship which is approximately an inverse one. It has been pointed out that there exist no very material differences in the levulose equivalents of a given weight of cuprous oxide when the latter is precipitated by either one of these procedures.

SOME GAMMA-NITRO-BETA-FURYLBUTYROPHENONES[1]

BY NATHAN L. DRAKE AND H. W. GILBERT

RECEIVED AUGUST 30, 1930 PUBLISHED DECEMBER 18, 1930

The addition of nitromethane and phenylnitromethane to α,β-unsaturated ketones such as benzalacetophenone has been studied extensively by Kohler and his pupils.[2] The work herein described is concerned with the preparation of certain γ-nitro-β-furylbutyrophenones, prepared by means of the addition of nitromethane and phenylnitromethane to furfuralacetophenone and furfural *p*-bromo-acetophenone.

Furfuralacetophenone has been prepared by Kostanecki and Podrajansky[3] and by Semmler and Ascher[4] but in each investigation the substance was obtained as an oil which apparently was not obtained in crystalline form. After considerable difficulty our oily product, prepared by condensation of furfural and acetophenone by means of 10% sodium hydroxide, was induced to crystallize. It formed long blunt yellow crystals which turned red on standing, and darkened rapidly in the sunlight. No difficulty was encountered in obtaining crystalline furfural-*p*-bromo-acetophenone. The latter substance also darkens on standing, but is much more stable than furfuralacetophenone.

The addition of nitromethane to the above-mentioned unsaturated ketones was carried out in a manner similar to that used in the case of benzalacetophenone. The furfural derivatives, however, are much more soluble in the reaction mixture than are the benzal derivatives, and consequently must be precipitated at the completion of the reaction by the addition of water. The use of a large excess of nitromethane was found necessary to give the best yields. Both products are very soluble in methyl and ethyl alcohols, ether and acetone, but sparingly soluble in petroleum ether.

The addition products of phenylnitromethane crystallize readily and were prepared with far less difficulty than the corresponding nitromethane addition products.

Experimental

Furfuralacetophenone.—A solution of 22 g. of stick sodium hydroxide in 196 cc. of water and 100 cc. of 95% ethyl alcohol were introduced into a beaker loosely covered

with a disk of cardboard and provided with an efficient mechanical stirrer. Into the alkaline alcoholic solution was poured **52 g.** of acetophenone, the stirrer was started and **42** g. of freshly distilled furfural was added slowly. Considerable heat was evolved at first and ice cooling was necessary to prevent the temperature from rising too high. After ten minutes the ice was replaced by water and the water-bath kept at 20–30° for three hours to complete the condensation. The water was then replaced by an ice and salt mixture, and after the temperature of the reaction mixture had become constant, a seed of furfuralacetophenone was added. Stirring was continued during the separation of the yellow granular condensation product. One-half hour was sufficient for crystallization. The crude product was sucked as dry as possible on a *cold* Büchner funnel and then dissolved in chloroform. After having been dried over sodium sulfate the chloroform was distilled off and the residue distilled *in vacuo*. Eighty grams of product was obtained. Furfuralacetophenone melts at 26°, and boils at 179° at **7** mm. pressure. Under **764** mm. pressure, the substance distils with considerable decomposition at 319°.

Furfural-*p*-bromo-acetophenone.—This substance was prepared as described above for furfuralacetophenone The crude material boiled at 210–217° under **16–18** mm. pressure and melted at **79–80°**. Recrystallization from hot ethyl alcohol yielded a product melting at 80–81°.

Anal. Calcd. for $C_{13}H_9O_2Br$: C, **56.3**; **H, 3.25.** Found: C, **56.2,** 56.2; H, 3.6, 3.5.

γ-Nitro-β-furylbutyrophenone.—To **35** g. of furfuralacetophenone in **50** cc. of dry methanol in a covered beaker provided with an efficient mechanical stirrer and heated in a beaker of boiling water was added rapidly a suspension of sodium nitromethane prepared by the addition of **40 g.** of nitromethane to a well-cooled solution of **11** g. of sodium in **175** cc. of dry methanol. The container from which the suspension was added was rinsed with **100** cc. of dry methanol and the rinsings added to the reaction mixture. The latter was kept hot and stirred to insure the rapid course of the addition, which was marked by the disappearance of the solid. When all of the sodium nitromethane had disappeared, the mixture was cooled *immediately* in an ice and salt bath and acidified *very slowly* (over about forty-five minutes) with **60** cc. of glacial acetic acid. Stirring was continued for thirty minutes longer, the solution was then seeded with a crystal of the addition product and **150** cc. of water was added slowly to precipitate the nitro ketone. After thirty minutes the solid was filtered off, washed on the funnel with **500** cc. of water and three ***50-cc.*** portions of 75% ethyl alcohol; **40** g. of a crude product, melting at 48°, was obtained. This was purified by dissolving it in the minimum quantity of 95% ethyl alcohol, adding **3** g. of norite and stirring the mixture for five hours. The charcoal was then filtered off and the product caused to crystallize by adding water. Thirty-five grams of material melting at 49.5–50° was obtained in this way.

Anal. Calcd. for $C_{14}H_{13}O_4N$: C, **64.85;** H, **5.02.** Found: C, **65.0, 64.9;** H, **5.17, 5.20.**

γ-Nitro-β-furyl-*p*-bromobutyrophenone.—This substance was prepared by the method described above for γ-nitro-β-furylbutyrophenone. For purification a charcoal treatment of a solution of the ketone in a mixture of one part acetone to nine parts of ethyl alcohol was used. The yield of purified material corresponded to **75%** of that theoretically possible. The product melted from **72** to 73°.

Anal. Calcd. for $C_{14}H_{12}O_4NBr$: C, **49.7;** H, **3.55.** Found: *C*, 49.9, 49.8; H, **3.84, 3.78.**

γ-Phenyl-γ-nitro-β-furylbutyrophenone.—19.8 grams of furfuralacetophenone was dissolved in **100** cc. of dry methanol in a round-bottomed flask fitted with a reflux condenser. To the solution was added **13.7** g. of phenylnitromethane dried over phosphorus pentoxide. The mixture was made alkaline by adding a solution of 0.5 ***g.*** of sodium in **10** cc. of dry methanol, then refluxed for three hours, and cooled in an ice and salt mixture with occasional shaking. The product which crystallized was sucked as dry as possible on a funnel and washed with **25** cc. of 95% ethyl alcohol which had been cooled on an ice and salt bath; **25** g. of a product melting from **90** to 105° was obtained. Recrystallization from alcohol yielded 18 g. of nitro ketone, melting at **153** to **153.5°**.

Anal. Calcd. for $C_{20}H_{17}O_4N$: C, **71.7**; H, **5.07**. Found: C, **71.7, 71.8**; H, **5.11, 5.20.**

γ-Phenyl-γ-nitro-β-furyl-*p*-bromobutyrophenone.—This ketone was prepared as described for γ-phenyl-γ-nitro-β-furylbutyrophenone. **A 29%** yield of product melting at **87** to 88.5° was obtained.

Anal. Calcd. for $C_{20}H_{16}O_4NBr$: C, **58.0**; H, **3.86**. Found: **C, 57.8, 57.8; H, 3.81, 3.75.**

Summary

The addition products of nitromethane and phenylnitromethane to furfuralacetophenone and furfural-*p*-bromo-acetophenone are described.

College Park, Maryland

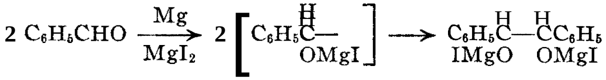
[Contribution from the Chemistry Laboratory of the University of Michigan]

THE REACTION BETWEEN THE BINARY SYSTEM MAGNESIUM + MAGNESIUM IODIDE AND AROMATIC ALDEHYDES

By M. Gomberg and W. E. Bachmann

Received September 8, 1930 Published December 18, 1930

From the behavior of ketones, benzils and acids toward a mixture of magnesium and magnesium halide[1] it was inferred that the carbonyl group in aldehydes as well would be affected in a similar manner. Thus, benzaldehyde, the aldehyde which we have studied most in detail, should react as follows



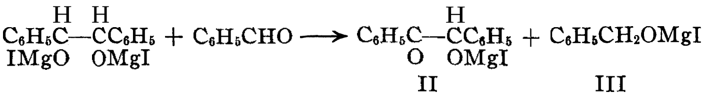
$$2\,C_6H_5CHO \xrightarrow[MgI_2]{Mg} 2\left[\begin{matrix}C_6H_5\overset{H}{C}— \\ \quad OMgI\end{matrix}\right] \longrightarrow \begin{matrix}C_6H_5\overset{H}{C}—\overset{H}{C}C_6H_5 \\ IMgO\quad OMgI\end{matrix} \qquad (1)$$

I

It was found that the binary system reacts with benzaldehyde. Although, in reality, no hydrobenzoin to correspond to compound (I) is obtainable on the hydrolysis of the reaction mixture, there is nonetheless every reason to assume that the reaction indicated actually represents the first stage of the process. The disappearance of this intermediate product (I) is brought about by reactions subsequent to that given as the first step (Equation 1). We found, namely, that this hydrobenzoinate salt, which readily can be prepared directly from hydrobenzoin itself by treatment with methylmagnesium iodide, rapidly and completely reduces benzaldehyde to iodomagnesium benzylate (111), and thus becomes oxidized to iodomagnesium benzoate (II).

---

[1] Gomberg and Bachmann, This Journal, 49, 236 (1927); 49, **2584 (1927); 50,2762 (1928);** Gomberg and Bailar, *ibid.*, **51,2229 (1929);** Gomberg and Van Natta, *ibid.*, **51,2238 (1929);** Bachmann and Shankland, *ibid.*, 51,306 **(1929).**

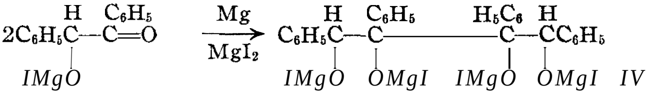


$$C_6H_5\underset{\text{IMgO}}{\overset{\text{H}}{C}}-\underset{\text{OMgI}}{\overset{\text{H}}{C}}C_6H_5 + C_6H_5CHO \longrightarrow \underset{\text{II}}{C_6H_5\underset{\text{O}}{C}-\underset{\text{OMgI}}{\overset{\text{H}}{C}}C_6H_5} + \underset{\text{III}}{C_6H_5CH_2OMgI} \qquad (2)$$

The speed of Reaction 2 is ever so much greater than that of 1, so that in the reaction between benzaldehyde and the binary system no appreciable amount of hydrobenzoinate can remain present as such. As soon as formed it becomes oxidized by the portion of the aldehyde which is still unchanged.

However, when the reactants are taken in the proportion indicated jointly by Equations 1 and 2 (*i. e.*, 3 moles of aldehyde + 1 atom of magnesium), then the final reaction mixture, hydrolyzed, still contains invariably some unchanged aldehyde; the amount of benzoin is only about half of that calculated, and there is present, in addition, nearly an equal amount of a resinous substance of approximately the same composition as benzoin but of a much higher molecular weight than the latter. On the other hand, when, instead of one atom, an excess of metallic magnesium is taken, the total consumption becomes finally 1.5 atoms of the metal for 3 molecules of the aldehyde, and no more than that even when the reaction period is allowed to extend for two years. The reaction mixture yields now the calculated amount (1 mole) of benzyl alcohol, but no benzoin, while the polymerized resin is proportionately larger in amount. Obviously the resinous substance must be continually being formed at the expense of the benzoinate salt (II) through a third step in the process, which step is brought about, like the first step, again by the binary system.

Indeed, the benzoinate salt, as a ketone, should be susceptible to reduction



$$2C_6H_5\underset{\text{IMgO}}{\overset{\text{H}}{C}}-\overset{C_6H_5}{C}{=}O \xrightarrow[\text{MgI}_2]{\text{Mg}} C_6H_5\underset{\text{IMgO}}{\overset{\text{H}}{C}}-\underset{\text{OMgI}}{\overset{C_6H_5}{C}}-\!\!-\!\!-\underset{\text{IMgO}}{\overset{H_5C_6}{C}}-\underset{\text{OMgI}}{\overset{\text{H}}{C}}C_6H_5 \quad \text{IV} \qquad (3)$$

That salt, prepared directly from benzoin itself by the use of just enough methylmagnesium iodide to affect only the hydroxyl group, was found to react, although somewhat slowly, with the binary system. While the amount of metallic magnesium consumed corresponds near enough to that required by Equation 3, the quantity of tetraphenylerythritol produced is only 5 to 12% of the calculated, the rest consisting of polymerized resin which, however, appears to be identical with that obtainable when one starts with benzaldehyde itself,

The conclusion, therefore, seems justified that the mechanism of the reaction between the binary system and benzaldehyde consists in three consecutive steps, and these commence to overlap each other soon after the reaction ensues: (1) reduction by the binary system, in moderate speed, of the aldehyde to hydrobenzoin salt; (2) very rapid oxidation of the salt produced by still unchanged aldehyde to the salt of benzoin;

(3) slow reduction of the latter again by the binary system, with simultaneous, or subsequent, polymerization or condensation. The relative proportions of benzoin and polymer will depend in each case upon the comparative speeds of Reactions 1 and 3, respectively, and upon how nearly the amount of magnesium consumed approaches the ratio of 1.5 atoms for 3 moles of aldehyde.

It still remains to determine the constitution of the polymer and the factors which induce its fortnation from the tetraphenylerythritol salt (IV). Nor can we offer at this time any explanation why, when starting with pure iodomagnesium benzoinate, one gets on reduction with MgI, in addition to the resin, at least 5–10% of tetraphenylerythritol, while when starting with benzaldehyde, the final reduction product consists wholly of the polymerized resin. Other aromatic aldehydes that have been investigated in this Laboratory by Mr. R. V. Shankland were found to react with the binary system essentially in the same manner as benzaldehyde.

The fact that the binary system—with the surmised MgI as the real active reducing agent—is generally very analogous in its effects to that of metallic sodium, suggests that the mechanism of the much discussed reaction between sodium and aldehydes is fundamentally similar to that between our binary system and aldehydes.

Experimental

Numerous experiments were carried out, varying the relative amounts of the principal reactants, using small amounts and large amounts of magnesium iodide, and allowing the reaction to run for periods from a few hours to two years. Only a few experiments, typical of the others, are here described.

It was established that benzaldehyde and magnesium iodide, in the absence of metallic magnesium, form merely a molecular complex, which, in the form of an etherate, separates as a heavy oil insoluble in the ether–benzene mixture employed as a solvent. On hydrolysis the complex is resolved completely into its components. With magnesium bromide, a crystalline complex is formed which, by coating the metallic magnesium, greatly slows down the reaction although in the end the same reduction product is formed. For this reason, magnesium iodide is to be preferred.

Benzaldehyde (3 Moles) + **Mg** (1 Atom) + **MgI_2.**—To a filtered solution of magnesium iodide, prepared from 70 g. of iodine and excess magnesium powder, in a mixture of 125 cc. of absolute ether and 150 cc. of dry benzene, were added 53 g. of benzaldehyde and 4.1 g. of magnesium ribbon. The jar was tightly closed with a stopper and placed on a shaking machine. After several days the insoluble oil, the complex of benzaldehyde and magnesium iodide, nearly all disappeared, and by the end of two weeks all the magnesium had dissolved. The solution, hydrolyzed with dilute acid and additian of more benzene, was extracted with a solution of sodium carbonate (yield of benzoic acid, 12 g) and the solvents, ether and benzene, were removed by distillation under reduced pressure. The residue was digested with ether, the precipitated benzoin. only slightly soluble in ether, was removed by filtration; to the filtrate was added some petroleum ether, which induced separation of more benzoin. In all, 15.1 g. of benzoin was obtained. Distillation of the filtrate under a pressure of 1 mm. on a steam-bath gave 15 g. of an oil, from which, by use of sodium bisulfite, there were obtained 3 g. of benzaldehyde and 11 g. of benzyl alcohol. The non-volatile portion of the reaction mixture, the polymerized resin, weighed 15 g.

In another experiment, with only 3.6 g. of metallic magnesium, the reaction was finished after the mixture was heated on a steam-bath for twelve hours. The result was 17.5 g. of benzoin, 4 g. of unchanged aldehyde, 10 g. of benzyl alcohol and 15 g. of resin.

In experiments in which only small amounts of magnesium and magnesium iodide were employed, considerable quantities of benzyl benzoate were formed. The condensation of the aldehyde to the ester is here brought about in virtue of the catalytic influence of iodomagnesium benzylate, an effect similar to that of sodium benzylate.

Benzaldehyde (3 Moles) + Mg (1.5 Atom) + MgI_2.—Benzaldehyde, 106 g., was added to a solution of 150 g. of magnesium iodide in a mixture of 200 cc. of ether and 300 cc. of benzene. Magnesium turnings, 12.2 g., were introduced and the mixture, protected from access of air by a mercury trap, was boiled under a reflux condenser. After twenty hours of heating, the magnesium was nearly all gone. The mixture was hyrolyzed, the mixed solvents removed by distillation and replaced by ether alone, but no precipitation of benzoin occurred. The ether was then evaporated, the benzyl alcohol distilled under 1 mm. pressure and the non-volatile material extracted repeatedly with petroleum ether. There were isolated: benzaldehyde, none; benzoin, 2.5 g.; benzil, 1 g.; benzyl alcohol, 30 g.; resin, 65 g.

In another experiment, with the reactants in the same amounts as above and the magnesium in long ribbon strips, the mixture was placed in a one-liter graduated cylinder and the reaction allowed to proceed at room temperature. The magnesium was all dissolved in ten weeks. No benzaldehyde was left and no benzoin obtained, the reaction products consisting solely of benzyl alcohol and the resin.

Benzaldehyde + Mg (Excess) + MgI_2.—A mixture, in ether–benzene, of 53 g. of benzaldehyde, 75 g. of magnesium iodide and 8 g. of metallic magnesium was boiled for thirty hours. However, the amount of magnesium that reacted was only 6.35 g., i. e., 1.5 atoms for 3 moles of the aldehyde, and the reaction products were benzyl alcohol, 15.2 g., and polymerized resin.

In a series of experiments, with 53 g. of aldehyde in each and with large excess of magnesium in form of strips, the reaction was allowed to proceed at room temperature from a year to eighteen months, but the loss in weight of magnesium was again about the same, namely, 6.36, 6.7, 6.36, 6.77 g., respectively. In still another experiment, the mixture was allowed to stand for two years—the loss in weight of the metal was 6.42 g., and the magnesium hydroxide produced on hydrolysis of the reaction mixture required 135 cc. of 4 N acid instead of the calcd. 132 cc. The products were benzyl alcohol and resin.

Oxidation of Iodomagnesium Hydrobenzoinate by Benzaldehyde to Iodomagnesium Benzoinate (Equation 2).—While hydrobenzoin itself is without effect upon benzaldehyde, the salt readily reduces it to benzyl alcohol. The salt was prepared by adding solid hydrobenzoin to a solution of methylmagnesium iodide until evolution of methane no longer took place.

$$C_6H_5CH(OH)CH(OH)C_6H_5 + 2CH_3MgI = C_6H_5CH(OMgI)(IMgO)CHC_6H_5 + 2CH_4$$

To such a solution, prepared from 10.6 g. of hydrobenzoin, 5.3 g. of benzaldehyde was added. The reaction was complete after the mixture had been warmed for five to ten minutes. From the mixture, hydrolyzed, there was isolated 9.5 g. of benzoin and 3 g.

of benzyl alcohol. In many experiments on a larger scale the yields also of alcohol obtained were much nearer to those calculated.

The reduction of benzaldehyde by the hydrobenzoinate salt consists in the transfer of an H and MgI from the salt to the aldehyde. That only one of the two groups (HCOMgI) is involved in this transfer has been proved in several ways, (a) Were the second group also involved, the reaction would then become as follows

$$C_6H_5COCH(OMgI)C_6H_5 + C_6H_5CHO = C_6H_5COCOC_6H_5 + C_6H_5CH_2OMgI \quad (4)$$

In reality, however, the reverse of this occurs—iodomagnesium benzylate reduced benzil to the benzoinate salt, itself becoming oxidized to aldehyde. In an experiment with iodomagnesium benzylate from 8 g. of alcohol with 8 g. of benzil, there was isolated 4.6 g. of benzoin and 1.9 g. of benzaldehyde. (b) Whether we start with benzaldehyde and the binary system, or with the aldehyde and the hydrobenzoinate salt, the actual presence of iodomagnesium benzoinate as one of the main resulting products has been confirmed by subjecting the mixture of the reaction products, prior to hydrolysis, to the action of phenylmagnesium iodide. In each case, then, after hydrolysis, triphenylethylene glycol resulted.

$$C_6H_5COCH(OMgI)C_6H_5 + C_6H_5MgI = (C_6H_5)_2C(OMgI)CH(OMgI)C_6H_5 \quad (5)$$

In one experiment, using 21 g. of benzaldehyde, 5.2 g. of pure triphenylethylene glycol was obtained, m. p. 168°. In another experiment, starting with 2.4 g. of hydrobenzoin, 2.5 g. of the same glycol was isolated from the mixture of the reaction products.

Reduction of Iodomagnesium Benzoinate by Mg + MgI_2.—To a solution of 20 g. of benzoin and 16.5 g. of magnesium iodide in a mixture of 30 cc. of ether and 80 cc. of benzene, a concentrated ether solution of ethylmagnesium iodide was gradually added until no more ethane was being evolved. Magnesium powder, 2.5 g., was now added and the mixture refluxed on a steam-bath for fifteen hours. The solution was filtered and decomposed with dilute acid. Fine threads of tetraphenylerythritol crystallized from the solution, and some more from the filtrate, 2.8 g. in all, which is 14% of that possible. The remaining 17 g. of product consisted of the polymerized resin. Other similar experiments varied in yield of tetraphenylerythritol from 3 to 20% of the calculated. The erythritol compound melted at 236°, and is identical with that which Kaufmann[2] obtained by electrolytic reduction of benzoin. By oxidation with copper sulfate in pyridine it gives benzil, almost weight for weight.

The Resinous Component of the Reaction Mixture.—This material, whether obtained in the process of reduction by means of the binary system either of benzaldehyde or of iodomagnesium benzoinate, has the consistency of a thick sirup if the removal of the benzyl alcohol has been done merely by distillation under reduced pressure. The last traces of alcohol are best removed by steam distillation. If the resinous mass is now dissolved in ether and, after thorough drying of the solution, is completely freed from the solvent, it is obtained as a yellow, transparent, solid, brittle mass of the appearance of rosin. It softens at about 50° and is all molten at about 60–65°. It is insoluble in petroleum ether. It remains entirely dissolved in ethyl ether when the solution is fairly concentrated—about 1 to 5—but on further dilution there separates, about 10% by weight, an amorphous white powder which is only very slightly soluble in ether and which melts at 160 to 180°. The original resinous mass is probably a mixture of several individual substances. It has an average molecular weight of 600 to 800 and a percentage composition of carbon and hydrogen not far from that of tetraphenylerythritol itself. Treatment with acids or alkalies, or acetylation, gave unsatisfactory results. While the erythritol (m. p. 236°) gives on oxidation with copper sulfate in pyridine benzil almost quantitatively, the resin is unaffected by that reagent, which makes it appear hardly probable that the resin contains stereoisomers of this crystalline erythritol.

---

[2] Kaufmann, *Z. Elektrochem.*, 4, 461 (1898).

Various Aromatic Aldehydes and the System **$MgI_2 + Mg$.**[3]—Other aromatic aldehydes were found to react with the binary system essentially in the same manner as benzaldehyde. When excess of magnesium was employed and the reaction was allowed to go to completion, just slightly more than 0.5 gram atom of magnesium dissolved for each mole of aldehyde reduced. Under those circumstances no corresponding benzoin was obtained, the only products being the primary alcohol and viscous oil analogous to the resin resulting from benzaldehyde. If, however, the reduction was only allowed to proceed until the complex of the aldehyde with magnesium iodide had disappeared, during which time approximately two-thirds of the maximum amount of metallic magnesium had dissolved, or when only that limited amount of magnesium was used for the reaction, then a fair yield of the corresponding benzoin resulted. These substituted benzoins, unfortunately, proved, in general, so soluble that they could not be separated readily from the viscous condensation products which always accompanied the other products. It was found advantageous to treat the mixture of the benzoin and the viscous oil with a solution of cupric sulfate in pyridine, thus obtaining the corresponding benzils. These proved usually only sparingly soluble in benzene or acetic acid and could, therefore, be more readily separated. The results are summarized in Table I. Excess of magnesium iodide was used in each case, while the amount of magnesium was one-third of an atom to a molecule of the aldehyde. The solvents used for each experiment comprised 75 cc. of ether and 150 cc. of benzene.

TABLE I

REDUCTION OF ALDEHYDES BY BINARY SYSTEM

Aldehyde reduced	Moles	G.	Alcohol obtained	G.	Benzoin isolated as	G.
a-Naphth-	0.1	15.6	α-Naphthenyl	4.1	a-Naphthil	5.3
p-Tolu-	.25	30.0	p-Methylbenzyl	7.5	p-Tolil	7.0
p-Anis-	.25	34.0	*p*-Anisalcohol	10.0	*p*-Anisil	8.2
p-Bromobenz-	.25	45.3	p-Bromobenzyl	11.3	4,4′-Dibromobenzil	13.0
p-Chlorobenz-	.25	35.1	p-Chlorobenzyl	8.5	4,4′-Dichlorobenzil	8.4

Summary

Benzaldehyde is reduced by a mixture of magnesium and magnesium iodide to the iodomagnesium derivative of hydrobenzoin, $C_6H_5CH(OMgI)-(IMgO)HCC_6H_5$, thus using up two molecules of the aldehyde.

The iodomagnesium hydrobenzoinate so produced reacts immediately with a third molecule of the aldehyde, with formation of the salts of benzoin and benzyl alcohol, $C_6H_5COCH(OMgI)C_6H_5$ and $C_6H_5CH_2OMgI$.

The benzoinate salt suffers further, partial or complete, reduction by the binary system to tetraphenylerythritol and a polymer, or condensation product, of the latter.

Other aromatic aldehydes are affected by the binary system, i. e., by MgI, in a manner essentially similar to that in which benzaldehyde is affected.

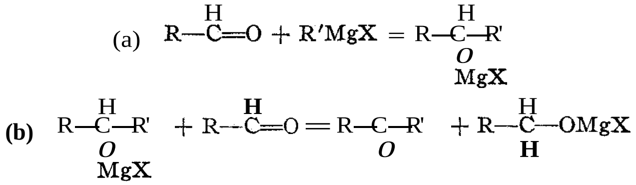
THE REDUCING ACTION OF COMPOUNDS CONTAINING THE GROUP >CHOMgI[1]

BY R. V. SHANKLAND AND M. GOMBERG

RECEIVED SEPTEMBER 8, 1930 PUBLISHED DECEMBER 18, 1930

Aliphatic Grignard reagents have long been known to be capable of exerting a reducing action on aldehydes and ketones, the carbonyl group being reduced to a carbinol group while from the Grignard reagent saturated or unsaturated hydrocarbons, or both, were formed. In some of the cases, however, the by-product is neither saturated nor unsaturated hydrocarbon, and this is particularly so when aromatic Grignard reagents are employed. Instead, the oxidation product is a ketone, namely, that ketone which corresponds to the secondary alcohol which would be the result of the normal addition product of the aldehyde and Grignard reagent. Although several complicated theories have been proposed to account for the formation of these anomalous products, the mechanism of the reaction is, no doubt, relatively simple. In these cases, as was first shown by Marshall,[2] and as has been concurred in, finally, by Meisenheimer,[3] the reductions cannot be ascribed to the Grignard reagent itself, but rather to the primary normal addition product of that reagent with the aldehyde, according to the equation



$$\text{(a)}\quad R-\overset{H}{C}=O + R'MgX = R-\underset{\underset{MgX}{O}}{\overset{H}{C}}-R'$$

$$\text{(b)}\quad R-\underset{\underset{MgX}{O}}{\overset{H}{C}}-R' + R-\overset{H}{C}=O = R-\underset{O}{C}-R' + R-\underset{H}{\overset{H}{C}}-OMgX \qquad (1)$$

The oxidation and reduction reaction involves thus merely the transfer of H and MgX from one molecule to another, although the exact mechanism of this transfer still remains uncertain.

We converted secondary aromatic alcohols to their iodomagnesium derivatives and the latter were then treated with aldehydes. We found, in agreement with Meisenheimer's experiment on phenylethylcarbinol,[4] that the aldehydes were reduced to primary alcoholates, while the secondary alcoholates were oxidized to ketones.

The reducing action upon aldehydes, and also upon certain other compounds containing the carbonyl group, is not limited, however, to secondary

[4] Ref. 3, p. 84.

alcohols; primary alcohols act more slowly, while dihydroxy secondary alcohols, glycols, are even more effective than monohydroxy secondary alcohols. Gomberg and Bachmann[5] found that the iodomagnesium derivative of hydrobenzoin reduces benzaldehyde to benzyl alcohol very rapidly, itself becoming oxidized to benzoin

$$C_6H_5CHO + C_6H_5CH(OMgI)(IMgO)CHC_6H_5 = C_6H_5CH_2OMgI + C_6H_5CO(IMgO)CHC_6H_5 \quad (2)$$

In other words, hydrobenzoin, although a di-secondary alcohol, functions in this reaction only through one of its two alcohol groups, just as if it were a monohydroxy alcohol. The ketone which results here, benzoin, can be isolated readily and the amount of it accurately established. This fact offered an opportunity to determine by means of hydrobenzoins on various aldehydes the extent of the possible occurrence of step (b) in Equation 1. Further quantitative evidence could thus be supplied in regard to Marshall's explanation concerning the apparently anomalous results in the Grignard reaction with aldehydes, especially when the aldehyde is employed in excess.

Experimental

Reduction of Benzaldehyde by **Iodomagnesium Hydrobenzoinate.**—The reduction of benzaldehyde by iodomagnesium hydrobenzoinate is very rapid. The rapidity of the reaction can be judged from the following set of experiments. Hydrobenzoin, prepared in 60% yield according to the procedure described by Danilov,[6] was converted into the iodomagnesium salt by adding 10.7 g. (0.05 mole) of the glycol to a standardized solution of ethylmagnesium iodide containing 0.1 mole of the Grignard reagent. To each sample was added a solution of 4.85 g. of benzaldehyde in benzene, and at the end of predetermined periods the reaction products were hydrolyzed and the components determined as described by Gomberg and Bachmann. The measure of oxidation–reduction that has occurred is based on the yield of benzoin. The results are given in Table I.

TABLE I

REDUCTION OF BENZALDEHYDE BY IODOMAGNESIUM HYDROBENZOINATE

Time	Temperature	Yield of benzoin Calcd., g.	Found, g.	%
5 Min.	Refluxing	9.70	7.10	73 2
15 Min.	Refluxing		9.2	95 3
30 Min.	Refluxing		8 95	92 3
5 Min.	Room temp.		5.82	00.0
30 Min.	Room temp.		8.40	86.6
4 Hrs.	Room temp.		8 45	87.1
42 Hrs.	Room temp.		9.05	93.3

Reduction of Various Aldehydes and of Ketones by **Hydrobenzoin.**—The reduction of aldehydes by iodomagnesium hydrobenzoinate proved to be a general method for the preparation of primary alcohols. The method might prove particularly useful in the preparation of primary unsaturated alcohols, since the ethylene bond remains unaffected

---

[5] Gomberg and Bachmann, THIS JOURNAL, 52,4967 (1930).

[6] Danilov, *Ber.*, 60, 2393 (1927).

by the hydrobenzoinate salt. Although ketones, in general, proved unsuited for reduction by the glycolate, cyclohexanone and benzil were quantitatively reduced. The reduction of benzil by the glycolate is of especial interest as the oxidation product and reduction product are both iodomagnesium benzoinate. When acetophenone was treated with the glycolate a fair yield of benzoin was ohtained but no α-phenylethyl alcohol could be detected. Attempts to reduce p-dimethylaminobenzaldehyde by this method were unsuccrssful. Other methods of reduction are known to have failed in the case of that aldehyde; in fact, there is still some uncertainty as to the properties of *p*-dimethylaminobenzyl alcohol.[7] Iodomagnesium benzoate was not affected by the glycolate.

A summary of the results obtained appears in Table II. The solvent used in all experiments consisted of a mixture of one part absolute ether and two parts anhydrous benzene, and a total of 225 cc. of the solvent was used when 0.1 mole of the aldehyde was employed for the experiment, which amount was generally used except in Experiment 20, when 0.05 mole of each reactant was taken. In Experiment 7 hydrolysis was accomplished by means of ammonium acetate solution, while in Experiments 16, 17 and 18, water alone, followed by steam distillation, hydrolyzed the reaction product; in all other cases a mixture of ice and a slight excess of hydrochloric acid was used.

In Experiments 11 and 12, due to the relatively high boiling points of the alcohols formed, practically all of the benzoin was directly precipitated by adding petroleum

TABLE II

REDUCTION OF ALDEHYDES AND KETONES BY IODOMAGNESIUM HYDROBENZOINATE

ether to the freshly hydrolyzed reaction product. After filtration, the solvents were removed by distillation and the residue was fractionated, yielding the alcohol. In Experiments **16** and 17 steam distillation separated the alcohol from the benzoin; the distillate was extracted with ether and benzene and the alcohol obtained from these by fractionation of the dried solution. In Experiment **18,** after the ether and benzene were removed by steam distillation, the residue in the distilling flask was filtered from the water, the solid was washed with warm water and the aqueous filtrate extracted with ether and benzene. The furfuryl alcohol was obtained by distillation of the ether–benzene extract In Experiment 6, although good yields of benzoin were obtained, none of the pure alcohol to correspond to piperonal could be isolated. Apart from these exceptions, all experimental details were similar to those described under the reduction of benzaldehyde, and the alcohols formed were separated from the benzoin by distillation under highly diminished pressure. The alcohols were identified by their boiling points, mixed melting points if solid and by their naphthylurethans.

Reductions by Substituted **Hydrobenzoins.**—A summary of these reductions is given in Table III. Equimolecular quantities of oxidizing agent and reducing agent were used in each experiment. Since *p*-toluoin, unlike benzoin, is very soluble in ether and benzene, none precipitated on hydrolysis of the reaction mixture. The ether–benzene solution, after hydrolysis, was fractionated under reduced pressure; after the alcohol had distilled the p-toluoin came over at 210° under a pressure of **1** mm., and was finally purified by crystallization from alcohol. Dichlorobenzoin is also quite soluble in all ordinary solvents. After the alcohol had been distilled, the residue was dissolved in boiling benzene; on cooling the solution, **0.35** g. of the 4,4'-dichlorobenzil, m. p. 195°, separated, due to the ready oxidation of the benzoin by air. The benzene was removed by distillation and the residue was dissolved in boiling aqueous alcohol, an atmosphere of nitrogen being maintained over the surface of the liquid. On cooling, the dichlorobenzoin crystallized in the form of fine needles. In the experiment with methylhydrobenzoin, the reaction product was hydrolyzed as usual and the ether-benzene solution was extracted with a saturated solution of sodium bisulfite, after which the organic solvents were allowed to evaporate spontaneously. The residual mass was digested with cold water until partial solidification took place. The mixture was filtered through a sintered glass filter. From the solid, recrystallized, the methylbenzoin, melting at 65.6°,[8] was obtained; the liquid yielded the corresponding benzyl alcohol. Under similar conditions of experiment, phenylhydrobenzoin, as well as tetraphenylerythritol, did not reduce aldehydes.

TABLE III

REDUCTION OF ALDEHYDES BY SUBSTITUTED HYDROBENZOINS

Hydrobenzoin used	Benzaldehyde reduced	Benzoin obtained	Yield. %	Yield of alcohol obtained, %
4.4'-Dimethyl-	4-Methyl-	4,4'-Dimethyl-	84.6	81.8

Reductions by Iodomagnesium Derivatives of Secondary Alcohols.—A summary of the results obtained with benzhydrol as the reducing agent appears in Table IV. Besides reducing aldehydes, this alcohol was found capable of reducing benzil also, to idomagnesium benzoinate. The oxidation product was in all cases benzophenone; that the ketone was formed directly as such was proved by the fact that when the still

---

[8] Roger, *J. Chem. Soc.*, 12'7, 518 (1925).

unhydrolyzed reaction product was subjected to the action of the binary system $MgI_2 + Mg$, good yields of benzopinacol were obtained.[9] Since the pinacol is quite insoluble in alcohol and could therefore be separated readily from other products of the reaction, the treatment with the binary system afforded a better method of estimating the yield of ketone formed than isolation of benzophenone itself. In the case of the reduction of benzil by the iodomagnesium derivative of benzhydrol, since the binary system would attack both benzil and iodomagnesium benzoinate, that method of estimating the yield of benzophenone was not used. One-tenth mole of each reactant was used except in Experiment 6, in which case 0.05 mole of each reactant was taken.

TABLE IV

REDUCTION BY BENZHYDROL

	Carbonyl compound reduced	Yields Benzophenone, %	Yields Alcohol, %
1	Benzaldehyde	83.7	71.7
2	*p*-Tolualdehyde	80.8	72.2
3	o-Chlorobenzaldehyde	71.7	73.0
4	p-Chlorobenzaldehyde	79.7	75.8
5	p-Bromobenzaldehyde	77.5	72.7
6	Benzil	82.4	79.2 (benzoin)

Table V contains the yields of the products obtained when the iodomagnesium derivatives of two other secondary alcohols were used as reducing agents. The reaction of the iodomagnesium derivative of benzpinacolin alcohol with benzaldehyde was of especial interest, as it furnished the explanation why Schmidlin[10] and Chichibabin[11] failed to obtain benzopinacolin alcohol (unsym.-tetraphenyl alcohol) by the action of triphenylmethylmagnesium halides on benzaldehyde, the explanation being that the excess of aldehyde oxidized the alcohol so formed to the corresponding ketone, *i. e.*, the pinacolin

$$C_6H_5CHO + C_6H_5CH(OMgCl)C(C_6H_5)_3 = C_6H_5CH_2OMgCl + C_6H_5COC(C_6H_5)_3$$

Our low yields of acetone, obtained when iodomagnesium isopropylate was used, were due to the occurrence of condensations of aldehyde with the acetone formed in the reaction; in fact, styryl methyl ketone, 7 g., was isolated in the experiment with benzaldehyde. The amounts of the reducing alcohols used were 0.05 mole.

TABLE V

REDUCTION BY VARIOUS SECONDARY ALCOHOLS

Secondary alcohol	Aldehyde	Oxidation product	Yield, %	Reduction product, alcohol	Yield, %
Benzopinacolin	Benz-	Benzopinacolin	80.0	Benzyl	78.0
Benzopinacolin	o-Chlorobenz-	Benzopinacolin	77.3	o-Chlorobenzyl	75.0
Isopropyl	Benz-	Acetone	30.0	Benzyl	52.0
Isopropyl	o-Chlorobenz-	Acetone	20.4	o-Chlorobenzyl	71.0

Reductions by **Iodomagnesium** Derivatives of Primary Alcohols.—Primary alcohols, in the presence of a small amount of aluminum, or halogenomagnesium, alcoholate salt as catalyst, are known to be capable of reducing aldehydes and some other carbonyl compounds[12]

$$RCH_2OH + R'CHO \rightleftharpoons RCHO + R'CH_2OH$$

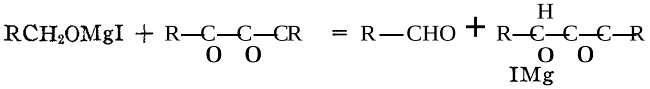
This reaction is reversible, but if, for instance, iodomagnesium benzylate be treated with a susceptible carbonyl compound whose reduction product is not affected by benzaldehyde, then the reaction should go to completion. Benzils are such compounds



$$RCH_2OMgI + R-\underset{O}{C}-\underset{O}{C}-CR = R-CHO + R-\overset{H}{\underset{\underset{IMg}{O}}{C}}-\underset{O}{C}-C-R$$

In two experiments of this nature, using benzyl and chlorobenzyl alcohol, respectively, and benzil as the oxidizing compound, we obtained an 85% yield of the corresponding aldehydes and 90% of benzoin.

Summary

To a still greater extent than the iodomagnesium salts of monohydroxy alcohols, the similar salts of hydrobenzoin and of substituted hydrobenzoins have been found effective in reducing saturated and unsaturated, aromatic and aliphatic aldehydes to their corresponding primary alcohols. Only one of the two alcohol groups in the hydrobenzoins is involved in this reaction, the hydrobenzoins becoming oxidized by the aldehydes to benzoin~just as secondary alcohols become oxidized to ketones.

The mechanism of this oxidation–reduction reaction consists in the transfer of an H and MgI from the group >CHOMgI in the alcohol to the carbonyl group of the aldehyde.

The results of this investigation supply further evidence in favor of Marshall's explanation in regard to the apparently anomalous formation of primary alcohols and ketones in the course of the Grignard reaction on aldehydes: namely, the normally produced addition product, RR'CHOMgI, is liable to become oxidized by the excess of aldehyde to the ketone RCOR', and the aldehyde reduced to RCH_2OMgI.

THE PYROLYSIS OF PROPYLENE[1]

BY CHARLES D. HURD[2] AND RICHARD N. MEINERT[3]

RECEIVED SEPTEMBER 9, 1930 PUBLISHED DECEMBER 18, 1930

That hydrocarbons of different types differ quite widely from each other in their behavior on pyrolysis has been demonstrated in earlier papers of this series. Normal and isobutane[4] both undergo primary changes into

---

[1] This paper contains results obtained in an investigation on "The Pyrolysis of Pure Hydrocarbons," listed as Project No. 18 of American Petroleum Institute Research. Financial assistance in this work has been received from a research fund of the American Petroleum Institute donated by the Universal Oil Products Company. This fund is being administered by the Institute with the cooperation of the Central Petroleum Committee of the National Research Council.

simpler substances. Isobutylene[5] not only yields simpler gaseous products but also gives rise to liquids which are aromatic in character. Methylacetylene was found to rearrange into allene, and allene,[6] in turn, pyrolyzes almost exclusively into allene polymers. These polymers are liquids of an entirely different nature from the liquids produced from isobutylene.

The subject of this study, propylene, has been investigated previously only by Frey and Smith.[7] They observed that about one-third of the propylene was decomposed at 575° with a reaction time of four minutes, in a silica bulb. Among the products of the reaction were hydrogen, ethylene, ethane and propane in small amounts. They also reported the presence of butylene and of small amounts of paraffin hydrocarbons containing as high as eight carbon atoms. The same workers showed that propylene reacts with hydrogen at 575° to form some propane.

Preliminary experiments in this Laboratory[8] indicated that propylene was not appreciably changed at temperatures below 525° in pyrex glass apparatus when the hot contact time was fifty seconds. The present study revealed that there was practically no change below 600° even with contact times of two minutes. At 600' the change was only 4% with a contact time of thirty seconds but it increased to about 30% with a contact time of 158 seconds. At 650° and 120 seconds the amount of propylene pyrolyzed was 60%, while at the same temperature and a contact time of thirty seconds it was 16%. At 700° the change was 51% with a contact time of only twenty-five seconds, but it reached 72.5% by doubling the contact time. In quartz tubes with a contact time of about one-half second, the propylene was 90 to 95% pyrolyzed when the temperature was 900 to 950°. The course of the reaction was similar to the results in pyrex wherein a lower temperature but a longer contact time was used.

The reaction in pyrex was predominantly homogeneous and unimolecular, since dilution of the gas with nitrogen, or creation of an increased surface by packing the tube with pyrex glass, had a negligible effect on the fraction of propylene decomposed in a given time.

The larger part of the propylene which disappeared in the reaction was broken down into simpler gases. Methane, ethylene, hydrogen and paraffins higher than methane (consisting principally of ethane) were found in the ratio of 3:3:1:1. As would be expected, the quantity of methane, hydrogen and total gas was found to increase with increasing temperature or with increasing contact time. This is evidently due not only to a greater extent of pyrolysis but also to secondary reactions which involve the breakdown of C_2 hydrocarbons.

[8] Hurd and Spence, unpublished results.

In pyrex or in quartz about one-fifth to one-fourth of the propylene used was converted into aromatic liquids. Benzene and toluene were identified and more complex substances, such as naphthalene and phenanthrene, were indicated. The last two are not considered to be primary products of the pyrolysis since they could arise by interaction of the simpler aromatic hydrocarbons with olefins at the high temperatures in question.

When small volumes of propylene were pyrolyzed no feasible method suggested itself of obtaining the weight of the liquids, but with larger runs this could be done although quantitative precision was, necessarily, not realized. Thus, it was possible to account for the hydrogen within fairly satisfactory limits. In two runs at 700°, the check was 100–104% of the theoretical and in one run at 955° the value was 107%. In one run at 650° only 88% of the hydrogen was accounted for, and in one at 600° the value dropped to 81%. Probably these variations are the result of experimental error due to the smaller quantity of liquid product which was formed in these lower temperature experiments. Similar calculations on the carbon balance were of value in estimating the limit for the quantity of carbon which may have been liberated in the various runs.

When a mixture of approximately equal parts of hydrogen and propylene was pyrolyzed, it was noticed that the amounts of ethylene and methane formed were greatly increased. Little or no propane was formed. This indicates a tendency for the hydrogen to cause a scission of the propylene molecule, thus

$$CH_3{-}CH{=}CH_2 + H_2 \longrightarrow CH_4 + CH_2{=}CH_2$$

Such a reduction may be preceded by the division of propylene into the methyl and vinyl radicals.

The pyrolytic behavior of propylene in monel metal was also investigated. Here the almost exclusive change was a decomposition into hydrogen and a sooty form of carbon. Moreover, the rate of decomposition was much greater than when pyrex or quartz tubes were employed. Thus, with the same hot contact periods, much more propylene decomposed in monel at 350° than in pyrex at 650°.

A peculiarity about the reaction in monel metal was that it was autocatalytic. The carbon formed and deposited on the walls of the tube near the beginning of the experiment catalyzed the reaction so that it proceeded much more rapidly after about twenty minutes. A number of experiments at different temperatures showed conclusively that this was the case. Both in appearance and in quantity was the carbon from the monel tube in decided contrast to the shiny, hard flakes of carbon which were deposited on the walls of the pyrex tube.

The pyrolysis in monel metal tubes started at a temperature of 350°. At 375°, with a contact time of about half a minute, it was practically complete. No liquids or tarry products were formed in the reaction at any temperature from 300 to 650°. About one liter of hydrogen and one-half liter of a mixture of paraffin hydrocarbons resulted from each liter of propylene consumed at 375°. With increasing temperature, the amount of hydrogen formed per liter of propylene increased to 1.7 liters at 650°, while the amount of paraffins (chiefly methane) formed decreased to 0.2 liter.

The fact that the production of hydrogen increased with increasing temperature while the production of paraffins decreased indicates that the first step in the reaction is probably a splitting into compounds that are simpler than propylene, but which are themselves unstable at higher temperatures and also break down into their elements.

Propylene, Isobutylene and Allene Compared.—It is interesting to compare the relative stability in pyrex of propylene and isobutylene, since both are olefin hydrocarbons which have been studied under analogous conditions. In Table I it is shown that at the same temperature and contact time, the amount of pyrolysis is about the same for the two hydrocarbons. The isobutylene data are from the paper of Hurd and Spence.[9]

TABLE I

RELATIVE STABILITY OF PROPYLENE AND ISOBUTYLENE

Isobutylene			Propylene		
Temp., °C.	Contact time, sec.	Extent of pyrolysis, %	Temp., °C.	Contact time, sec.	Extent of pyrolysis, %
600	200	20.0	600	190.0	24.3
650	27	22.7	650	26.8	16.7
			650	30.0	16.0
700	25	51.4	700	25.0	50.8

The mechanism which has been developed for isobutylene adequately explains the data in the pyrolysis of propylene. The former was reported to produce methane, propylene, hydrogen and isobutane at 600° in the ratio (approximately) of 10:5:3:4. At 700° there was more methane and considerably less propylene in the off-gas. From the results obtained in this work, it would be expected that propylene formed from isobutylene would break down rather rapidly at 700°. Aromatic liquids were found to the extent of 23 to 63%, depending on the temperature and the contact time. Similar liquids were formed from propylene in 15–28% yields.

To explain the pyrolysis of i-butylene, Hurd and Spence suggested that heat may rupture the single C—C or C—H bonds and that it may activate the C=C double bonds. Gaseous products were regarded as coming from the first process and liquids from the last. Evidently the same mechanism applies with the pyrolysis of propylene. The general experimental data for both propylene and isobutylene were very similar.

Propylene and allene are both C_3 hydrocarbons, but their mode of pyrolysis is quite different. The former is considerably the more stable of

---

[9] Hurd and Spence, THIS JOURNAL, **51**, 3561 (1929).

the two and it changes into gases and aromatic liquids. The latter gives but small amounts of gases and large quantities of non-aromatic liquids. No allene or polymers of allene were found (except possibly in traces) among the products of pyrolysis of either propylene or isobutylene.

Experimental Part

Apparatus.—An apparatus similar to the one described by Hurd and Spence for use with *i*-butylene[10] was constructed for this study. The dimensions of the various reaction tubes were as follows:

Tube	Total length, cm.	Inside diameter, cm.	Length in furnace, cm.
Pyrex	90	2.5	75
Quartz	85	0.45	75
Monel	92	2.0	75

A 15-cm. length of 7-mm. tubing was sealed into the bottom of the pyrex tube. It was attached to a trap immersed in ice water which served to condense the liquid products of the reaction. The thermocouple was placed inside the pyrex tube and was protected by a pyrex sheath.

Temperature measurements of the quartz tube were made by placing the thermocouple in another quartz tube having walls of the same thickness and having one end closed. The two tubes were suspended side by side in the furnace with the end of the thermocouple about two-thirds of the way down.

With the monel metal tube the thermocouple was placed inside the tube with a porcelain insulator as its only covering. The ends of the thermocouple were exposed directly to the hot gases and the leads were run through the rubber stopper which closed the top end of the tube. To prevent the conduction of heat to the rubber stoppers, tight spiral coils, consisting of right turns of 5-mm. copper tubing, were wound around both ends of the monel tube. With water circulating through these coils the ends of the monel metal tube were kept quite cool by this device.

The gases were analyzed as previously outlined by Hurd and Spence.[11]

Source of Propylene.—The propylene used in these experiments was generously furnished by E. R. Squibb and Sons. Analysis showed that it contained less than 1% of impurities.

The Pryolysis of Propylene in Pyrex.—Preliminary experiments, with temperature varying between 550 and 700° and the contact time varying between twenty-five and one hundred fifty seconds, were made to determine the best conditions for the pyrolysis. The results are given in Table II, and the data make it evident that increasing either the temperature or the contact time gives rise to a marked increase in the amount of propylene decomposed. The results show further that the temperature range between 600 and 700° offers the best opportunity for studying the mechanism of the reaction. Below 600° the pyrolysis is negligible, while above 700° the reaction is complicated by secondary reactions, consisting of the decomposition of the products of the primary reactions.

It will be noted that the relative amounts of the various products formed

from each liter of propylene pyrolyzed are not greatly affected either by changing the temperature or the contact time. This matter will be discussed in more detail in a later section.

Effect of Dilution on **the** Reaction.—Several runs were made with either hydrogen or nitrogen added to the propylene in order to find out the effect of dilution of the propylene. The results are shown in Table III.

TABLE III

EFFECT OF DILUTION ON THE PYROLYSIS OF PROPYLENE

Paraffins	375	500	388	747
n in C_nH_{2n+2}	1.54	1.42	1.42	1.25

[a] 387 cc. of hydrogen were used up for each liter of propylene pyrolyzed.

Examination of Runs 5 and 12 shows a somewhat smaller percentage of pyrolysis in the latter case. Whether or not this is a significant difference is open to question since in high temperature experiments which are carried out under seemingly identical conditions it is the customary experience that precise duplication of data is only rarely achieved. We are inclined to believe that the values 29 and 23 are sufficiently near each other to indicate a predominantly unimolecular reaction, although strict interpretation of the values would indicate a reaction order between first and second. Some of the other differences which are noticeable in these two runs may be accounted for by the fact that in Run 12 almost no liquid reaction products were formed whereas in Run 5, with no dilution, about 20% of the propylene pyrolyzed was recovered as liquids. The nitrogen would act to lessen the formation of liquids by diluting the primary reaction products and hindering them from undergoing polymerization.

When Runs 10 and 11 are compared, the percentage of pyrolysis is a little higher (rather than lower) in the dilution experiment. The order of magnitude is similar, however. As in the nitrogen dilution experiment, the amounts of ethylene and of paraffins formed are much larger than in runs where there was no dilution. Again, with a smaller liquid yield, the gaseous products showed up correspondingly when calculated on the basis of cc. of each product formed per liter of propylene pyrolyzed.

A striking result when Runs 11 and 10 are compared is the change in the n in the paraffin formula. The volume of the paraffins formed is greatly increased, relatively more so than the volume of ethylene, but the n is decreased by adding hydrogen to the entering gas. This indicates the formation of methane, probably by hydrogenation of the CH_3- radicals formed when the propylene is split at the single bond. Apparently not much propylene is hydrogenated to propane; otherwise the n would be higher than it is. This is an important point when considering the mechanism of the reaction, for it is best interpreted by considering that the CH_3- residue is present in the hot zone, at least momentarily.

Effect of Increased Surface.—Experiments were made at 600 and 650° to determine whether or not increasing the surface in the reaction tube had any effect on the amount of propylene pyrolyzed. The method consisted of packing the tube with long pieces of capillary tubing made by heating sections of large capillary tubing and drawing them out to a diameter of about one millimeter. Rough calculation showed that the surface in the reaction tube was about trebled. Table IV shows the results of the experiments. The calculation for the contact time took account of the decrease in the volume of the tube due to the packing. Evidently the increased surface in the tube had no appreciable effect upon the amount of propylene pyrolyzed. Therefore, the decomposition of propylene is apparently unimolecular and homogeneous.

TABLE IV

EFFECT OF INCREASED SURFACE

	Unpacked	Packed	Unpacked	Packed
Run number	20	25	21	26
Temperature, °C.	600	600	650	650
Contact time, sec.	139	150	90.2	115
Percentage pyrolysis	18.7	17.0	41.8	44.2

Gaseous Products Obtained in the Reaction.—The gaseous products of the pyrolysis of propylene were measured, collected and analyzed. From the percentage of propylene in the off-gas, the amount of undecomposed propylene was determined, and this, subtracted from the propylene passed into the tube, gave the amount of propylene changed in the pyrolysis. The percentage of pyrolysis could then be readily calculated.

From the analysis of the off-gas and the volume of the off-gas, the total volume of each component present was found. This was divided by the number of liters of propylene actually changed and the result expressed as the number of cc. of each component per liter of propylene pyrolyzed. The advantage of this method of calculating the results is apparent, for it puts all the experimental data on *a* common basis.

Table V shows some of the representative data at various temperatures and contact times. The table includes data with both pyrex and quartz reaction tubes.

Sufficiently large samples of propylene were used in Runs 11, 7, 4, 8 and 29 so that it was possible to check the hydrogen (free or combined) in the final gaseous products with the combined hydrogen in the original propylene, correction being made in the latter for the propylene which was found to change into liquid products. In these runs the liquid could be weighed satisfactorily although high precision in this regard was impossible. This, no doubt, was the major cause for the discrepancies which were noted in the hydrogen balance. In Runs 5, 24, 3 and 23 the original quantity of propylene was too small to yield a satisfactory volume of liquid. In Run 28 the liquid product was not worked up.

In Run 11, 1906 out of a possible 2370 units of hydrogen were found in the gaseous products per liter of propylene pyrolyzed; in Run 7, 2233 out of 2538; in 4, 2276 out of 2172; in 8, 2281 out of 2280; and in 29, 2553 out of 2376. In making these calculations, the gas which was "absorbed in 62.5% H_2SO_4" was assumed (with no especial justification) to be C_4H_8, and the "acetylenes" were assumed to be C_2H_2. To illustrate the method of calculation in Run 11, 49 cc. of $C_2H_2 \Bumpeq$ 49 cc. of H_2; 22 cc. of $C_4H_8 \Bumpeq$ 88 cc. of H_2; 340 cc. of $C_2H_4 \Bumpeq$ 680 cc. of H_2; 388 cc. of $C_nH_{2n}+$, where $n = 1.42 \Bumpeq$ 970 cc. of Hz, which with 119 cc. of H_2 totals 1906 cc. Supposedly, this volume originated from 79% of 1000 cc. of C_3H_6, which is equivalent to 2370 cc. of hydrogen. The check is only 81% of the theoretical, but in the other four cases it is better, namely, 88, 104, 100 and 107%.

The carbon content of the gaseous products was always less than the carbon content of the original propylene, corrected as before for the portion which changed into liquids. The two chief causes for this difference were carbon formation and the experimental difficulty in collecting and weighing the small volume of liquid. Thus, in Runs 11, 7, 4, 8 and 29 the units of carbon in the gas at the end and at the beginning, respectively, were 1417/2370, 1474/2538, 1580/2172, 1514/2280, 1553/2376. If these differences are interpreted as being solely due to carbon formation, the values would indicate, respectively, 0.51, 0.57, 0.32, 0.41 and 0.45 g. of carbon.

The Liquid Portion.—In addition to the gaseous products, about 20% by weight of each liter of propylene pyrolyzed was recovered as liquid products. In the cases where the temperatures were low and the contact time short, the decomposition of the propylene was very small; consequently it was difficult to weigh the liquids which were obtained, as they amounted to less than a gram, and some of the liquid stuck to the walls of the reaction tube. But with three runs, one at 650° with a contact time of 150 seconds, and two at 700° and a contact time of thirty-six and fifty-two seconds, respectively, several grams of liquids were obtained and these runs averaged a liquid formation of 22% by weight of the propylene actually pyrolyzed.

A portion (12.5 g.) of these liquids, being the aggregate of several runs, was fractionated with a Vigreux fractionating column. The results were as follows.

Fraction number	Roiling point, °C	Weight, g.
1	70–85	2.34
2	85–107	2.04
3	107–160	2.41
4	160–200	1.58
5	200–210	0.90
Residue		2.90
Loss		0.31
		12 48

Fraction 5 partially solidified on cooling. All these fractions had an aromatic odor resembling that of toluene.

Fractions 1, 2 and 3 were fractionated into three fractions and the refractive indices of these portions were determined. For reference, the refractive index of benzene, n_D^{20}, is 1.501, and for toluene, 1.495.

Fraction	Boiling point, °C.	n_D^{20}
A	75	1.490
B	75–85	1.499
C	85–128	1.502

Most of the fraction B boiled between 83 and 85° and most of fraction C boiled above 118°. The refractive indices, together with the boiling points, indicate that these compounds are aromatic, presumably benzene and toluene with some higher homologs. Fraction A and B nitrated readily and, in experiments described below, it was confirmed that the former was the nitro derivative of benzene. The higher-boiling fractions could not be obtained pure and were not identified.

Besides the gaseous and liquid products, there was always a thin deposit of carbon formed in the reaction tube. This carbon was in the form of graphite and could be removed by scraping it from the tube, but it was more completely removed before each run by burning it out. There was also a small amount of heavy tar which collected on the sides of the tube, which was removed from time to time by dissolving it out with acetone.

The Effect of Shorter Contact Times and Higher Temperatures upon the Pyrolysis of Propylene.—The results are summarized in Runs 25 and 26 of Table V. A quartz tube was used instead of the pyrex tube. The gas was passed through the apparatus as rapidly as possible so that the hot contact time would be very short. The temperature was 950°. This was the maximum temperature of the furnace.

Comparison of these runs with the others shows that pyrolysis at 950° in quartz with a hot contact time of one-half second gives about the same results as pyrolysis at 700° in pyrex with a contact time of fifty-three seconds. The percentage of propylene pyrolyzed is about 90 instead of 73, but the products formed are very much the same. There is about the same percentage of unrecovered propylene which is converted into liquids in each case, *viz.*, 20–25%. In both cases liquids are aromatic hydrocarbons and in both the gaseous products are the same. More hydrogen and methane are formed at the higher temperatures but this would be expected, since the secondary reactions would also be more rapid at high temperatures.

The liquids obtained from the 950° experiments were fractionally distilled as carefully as the small volume would permit, with these results.

Fraction	Volume, cc.	B. p., °C.	n_D^{20}
A	2.0	78–97	1.5025
B	0.8	97–130	1.5140
C	1.0	130–180	1.5465

Fraction A had an odor very much like that of benzene, fraction B an odor somewhat resembling that of toluene and fraction C smelled like tar. The properties of these liquids were almost identical with those of the liquids obtained from propylene in pyrex apparatus at 700°. Nitration of fraction A yielded m-dinitrobenzene.

Experiments with a Monel Metal Tube.—A summary of data is given in Table VI. It will be seen that the effluent reaction products were gaseous, but in addition there was always a large amount of carbon deposited in the tube. In some cases this deposit was so thick that it closed

the tube completely and stopped the flow of the gas. This carbon was not graphitic as was the carbon deposited when propylene was pyrolyzed in a pyrex tube, but it had the appearance of soot and could be scraped easily from the walls of the tube. No liquids were obtained.

It was noticed in these experiments that the ratio of the off-gas to the entering gas began to increase after the first five or ten minutes of the run and finally reached a constant value. This points to the fact that the action is autocatalytic, the carbon deposited on the walls acting as the

catalyst so that the full rate of the reaction is not reached until the tube has been coated with carbon. The increase of the ratio of the off-gas to the entering gas is shown in Table VII. The data are given as taken from Runs 1, 3, 6 and 7. In the first column the elapsed time from the beginning of the run is given; in the second column, the total volume of the entering gas from the beginning of the run and in the fourth column the total volume of the off-gas from the beginning of the run. The figures in column three, *(a)*, represent the differences between successive figures in column two. Similarly, column five, (b), gives the differences between the readings in the fourth column. The ratio b/a, given in column six, represents the ratio of off-gas to entering gas over the period of time between successive readings of the wet-test meters which measured the entering and exit volumes. It is to be noted that these readings were not taken at regular intervals but this does not affect the ratios.

It can be seen readily that the ratios increase until a maximum is reached, and the maximum is reached in a shorter time at high temperatures than at low temperatures.

All the volumes in Table VII are expressed in cubic feet. The time is in minutes.

Summary

Propylene is rapidly decomposed at temperatures above 600° in pyrex or quartz. The gaseous products are largely hydrogen, methane and ethylene with smaller amounts of acetylene and ethane. Aromatic liquids (benzene, toluene, etc.), comprise approximately 25% of the total reaction products. The reaction has been shown to be predominantly homogeneous and unimolecular. A mechanism for the reaction is suggested.

Under comparable conditions in monel metal, decomposition of propylene begins at a much lower temperature, namely, 350°. The products are largely carbon and hydrogen and the reaction is autocatalytic.

As compared with isobutylene, propylene has been shown to undergo an almost identical type of pyrolysis.

CARBITHIOIC ACID STUDIES.
II. CYCLOHEXYLCARBITHIOIC ACID AND VARIOUS DERIVATIVES

BY R. W. BOST AND W. W. WILLIAMS

RECEIVED SEPTEMBER 10, 1930 PUBLISHED DECEMBER 18, 1930

A number of carbithioic acids have been reported; however, the chemistry of these compounds seems to have been neglected. Recently Bost and Mattox[1] studied tolyl-4-carbithioic acid and found that the –CSSH group showed a striking resemblance to the –COOH group in some cases, while in others a great dissimilarity was noted.

In view of the fragmentary knowledge of the reactions of the –CSSH group, and of carbithioic acids in general, work has been extended to a new acid, cyclohexylcarbithioic acid. Its synthesis, its chemical and physical propetties, and certain derivatives are described.

Cyclohexylcarbithioic acid resembles its oxygen analog in the formation of salts, esters and toluides. It yields neither an acid chloride nor a thioamide. Oxidizing agents convert it into hexahydrobenzoic acid. The thioacyl peroxide was not obtainable.

Experimental Part

Cyclohexylcarbithioic Acid.—The Grignard reagent was made in the usual way from 0.5 mole of cyclohexyl bromide and 12.2 g. of magnesium. To this was added **38.1** g. of carbon disulfide and the method adopted by Bost and Mattox[1] in the preparation of tolyl-4-carbithioic acid followed, both in the preparation of the acid and in its purification.

Cyclohexylcarbithioic acid is a reddish-brown liquid with a putrid odor, and slowly decomposes on exposure to air. It distils with decomposition. It is soluble in most of the organic solvents. The acid is rather stable in ether solution. All its salts are stable. The sodium salt was used in the preparation of most of the derivatives.

Silver Salt of Cyclohexylcarbithioic Acid.—A saturated solution of silver acetate was added slowly, with stirring, to an ether solution of the acid until precipitation was complete. The precipitate was filtered, washed with water, alcohol and toluene, and dried. It is slightly soluble in hot alcohol and toluene.

Preparation of Esters.—The methyl and ethyl esters were made from the sodium salt of the acid and the corresponding alkyl sulfates. The propyl and butyl esters were made by refluxing equivalent quantities of the sodium salt and the corresponding alkyl bromides. The esters were purified by the usual method.

p-Toluide of Cyclohexylcarbithioic Acid.—Ten grams of *p*-toluidine, 6 g. of the dry sodium salt and 6 ml. of concentrated hydrochloric acid were heated to gentle boiling in a beaker for thirty minutes. The mass was extracted with 50 ml. of hot toluene, boiled with charcoal, filtered and allowed to crystallize. The toluide separated in large colorless needles. It is soluble in hot alcohol, toluene and benzene.

Attempt to Prepare the **Thioamide.**—The method adopted by Bost and Mattox[1]

---

[1] Bost and Mattox, THIS JOURNAL, 52,332 (1930).

in the preparation of the amide of tolyl-4-carbithioic acid was used. After a few days a solid separated. It consisted of white glistening leaflets melting at 185–187°. The product contained nitrogen but no sulfur. Further investigation showed the substance to be the amide of hexahydrobenzoic acid.

Action of Oxidizing Agents.—To an ether solution of the acid at room temperature was added concentrated nitric acid with stirring until the color was discharged. After several hours the product was extracted with ether and purified through its sodium salt. It melted at 28° and gave negative tests for sulfur. Other tests showed the substance to be hexahydrobenzoic acid.

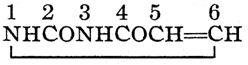
RESEARCHES ON PYRIMIDINES. CXIX. DETERMINATION OF THE CONSTITUTION OF ALKYLATION PRODUCTS OF PHENYLURACIL AND PHENYLHYDROURACIL[1]

BY JANET EVANS AND TREAT B. JOHNSON

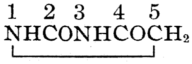
RECEIVED SEPTEMBER 17, 1930 PUBLISHED DECEMBER 18, 1930

In uracil, as in hydantoin, the hydrogen atoms attached to each nitrogen atom can be replaced with alkyl or substituted alkyl groups by appropriate methods. If only one group is substituted, it enters the hydantoin molecule in the 3-position.[2] This is not always true of the pyrimidine series, mixtures of N-1 and N-3 substitution products being formed in some cases.[3,4] The position of the entering group in hydantoin can be determined directly by identifying the a-amino acids formed when the molecule undergoes complete hydrolysis.[2] On the other hand, the double bond of uracil is not easy to reduce,[5] and hydrouracils are hydrolyzed either only partially with the formation of the ureido acids, or are broken down completely, probably because the β-amino acids which would be formed are more unstable[6] than the a-amino acids which result from the hydrolysis of hydantoins. The present investigation was undertaken with a view to establish some method for the determination of the position of an entering group.



$\underbrace{\overset{1}{\mathrm{N}}\mathrm{H}\overset{2}{\mathrm{C}}\mathrm{O}\overset{3}{\mathrm{N}}\mathrm{H}\overset{4}{\mathrm{C}}\mathrm{O}\overset{5}{\mathrm{C}}\mathrm{H}{=}\overset{6}{\mathrm{C}}\mathrm{H}}$

Uracil



$\underbrace{\overset{1}{\mathrm{N}}\mathrm{H}\overset{2}{\mathrm{C}}\mathrm{O}\overset{3}{\mathrm{N}}\mathrm{H}\overset{4}{\mathrm{C}}\mathrm{O}\overset{5}{\mathrm{C}}\mathrm{H}_2}$

Hydantoin

Since uracil and hydantoin are somewhat related and since comparison of the ultraviolet absorption spectra of hydantoin compounds had proved useful in the identification of substituted hydantoins,[7,8] it seemed advisable to prepare a series of substituted uracils and to study their spectra in the ultraviolet. Uracils isomeric with hydantoins, whose spectra[8] had been determined, were chosen so that structural differences between uracils and hydantoins could also be studied. The absorption spectra will be published in a later paper.

Another consideration which led to the choice of this series of uracil

compounds for synthesis was the fact that in the course of the synthesis of methyl N-1-methyl-5-benzalhydantoin-N-3-acetate[9]

$$\underbrace{N(CH_3)CON(CH_2COOCH_3)COC}=CHC_6H_5$$

it was noted that the two isomeric esters of this constitution (m. p. 66" and 98°) suffer a transformation to the same compound (m. p. 278°) when they are allowed to stand in the light. This new compound is extremely insoluble as well as high melting, and its analysis showed it to have the same empirical formula as the esters from which it was obtained. The acid corresponding to the esters and melting at 198–199.5° was similarly transformed by light to an insoluble substance at 310°.

At the time the possibility of a rearrangement from a five- to a six-membered ring with the formation of the isomeric substituted uracil was considered.[9] Synthesis of the pyrimidine to which the ester and acid might rearrange and comparison of their properties with those of the compounds melting at 278 and 310° would definitely prove whether a change in the number of atoms in the ring had taken place.

The present experimental evidence can lead us to no such conclusions. The uracil derivative, methyl N-1-methyl-6-phenyl-uracil-N-3-acetate, VI (see chart), has properties differing widely from those of the product formed by the action of light on the isomeric hydantoin. The former has a melting point of 159° and is very soluble in alcohol, whereas the latter melts at 278°, and is practically insoluble. The corresponding acid melts at 261°, in contrast to 310°, and is moderately soluble in alcohol. No evidence of the true structure of the compounds melting at 278 and 310° has as yet been obtained.

The compound methyl N-1-methyl-6-phenyl-uracil-N-3-acetate, VI, was synthesized by three different series of transformations, one of which definitely proves its structure. The course of the transformations and other minor relationships can be visualized by reference to the chart. The methods will be discussed separately.

In carrying out the first series, it was found that alkylation of 6-phenyluracil, with either methyl iodide or ethyl chloro-acetate, resulted in the formation of but one monosubstitution product, numbered, respectively, I and III. Another product was isolated from the treatment with methyl iodide, and was proved to be dimethyl-6-phenyluracil, II. That the positive methyl group and the less positive ethyl acetate residue enter the same position in the ring is proved by the following facts.

The methyl derivative, I, prepared by the alkylation of 6-phenyluracil has very different properties from those of the I-methyl-6-phenyluracil, XVIII, synthesized from benzalmethylamine. The former crystallizes in glistening leaves and melts at 228–230°, whereas the latter occurs in long

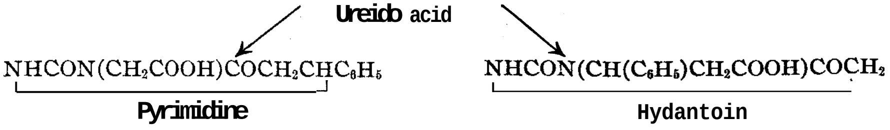
slender needles and melts at 194–195°. The nitrogen content of the two compounds is identical. Since the method of preparation of the latter substance requires that the methyl group must be in the 1-position, it follows that the hydrogen in the 3-position of the former compound must have been replaced by a methyl group.

Similarly, the methyl derivative, V, of ethyl 6-phenyl-uracil-N-3-acetate, III, which was prepared by alkylation of the corresponding acid, IV, with dimethyl sulfate and subsequent esterification, was shown by mixed melting point determinations and analyses to be the same compound as that prepared from 1-methyl-6-phenyluracil, XVIII, by treatment with ethyl chloro-acetate. On saponification, a sample of the ester formed from 1-methyl-6-phenyluracil was transformed into the corresponding acid, which has the same properties as those of the acid prepared by methylation of the 6-phenyl-3-acetic acid, IV. Thus the acetic acid or ester residue is in the 3-position, which is the same position entered by the methyl group.

The yield of substituted 6-phenyl-uracils was very low; moreover, it was found that reduction to the corresponding saturated compounds could not be effected by ordinary means. The saturated compounds were therefore prepared by alkylation of phenyl-hydrouracil. Their relationships to the unsaturated compounds were demonstrated by the substitution of bromine in position 5 of the ring,[10] and subsequent expulsion of hydrogen bromide. The products were identical with those prepared by alkylation of phenyluracil.

The hydrolysis of these saturated compounds cannot be used to determine their constitution. It was found that 3-methyl-6-phenyl-5,6-dihydrouracil VIII is rather readily hydrolyzed to the corresponding ureido acid IX, but prolonged action of boiling barium hydroxide solution at atmospheric pressure failed to complete the hydrolysis. When the compound was heated with barium hydroxide solution in a sealed tube at 150°, complete destruction of the molecule resulted.

Alkylation of 6-phenyl-5,6-dihydrouracil with ethyl chloro-acetate resulted in the formation of a mixture of which the major portion was identified as ethyl-6-phenyl-5,6-dihydrouracil-N-3-acetate. Two acids were obtained by the saponification of this ester in either acid or alkaline solution. Of these, the one, XII, melting at 231°, is that related to the original ester since it reverts to that ester on treatment with absolute alcohol and dry hydrogen chloride. The formation of the other acid may be accounted for by the following mechanism



$$\mathrm{HOOCCH_2NHCONHCH(C_6H_5)CH_2COOH}$$

$$\mathrm{\underline{NHCON(CH_2COOH)COCH_2CHC_6H_5}} \qquad \mathrm{\underline{NHCON(CH(C_6H_5)CH_2COOH)COCH_2}}$$

---

[10] Fischer and Roeder, *Ber.*, **34**, 3763 (1901).

Hydrouracils can be hydrolyzed to the corresponding ureido acids, and reclosure of the ring effected by heating in acid solution. Two possibilities for ring formation from the ureido acid in question are evident. The validity of this explanation has not been determined.

The synthesis of N-1-methyl-6-phenyl-5,6-dihydrouracil, XVI, which now became essential for the proof of the structure of the whole series, depends on the fact that β-amino acids react with potassium cyanate[11] in water solution and then undergo rearrangement to *β-ureido* **acids,** which form hydrouracils on the closure of the ring. Accordingly the acid β-N-methylamino-β-phenylpropionic acid, XIV, had to be synthesized.

A modification of the recent method of Rodionow for the synthesis of β-amino acids[12] seemed the most promising for the synthesis of β-N-methyl-β-phenylpropionic acid, especially since it offered a plausible mechanism of his reaction. Rodionow discovered that the reaction of alcoholic solutions of ammonia or amines with aldehydes and malonic acid is more complicated than Knoevenagel[13] supposed and results in the formation of β-amino acids as well as cinnamic acids.

The repetition of Knoevenagel's experiments with acid and neutral ammonium malonate and benzaldehyde in the present investigation shows that besides the cinnamic acid, which was formed in slightly smaller amounts than those reported by him, the corresponding 8-amino acid was isolated in yields corresponding to slightly more than 50% of the calculated amount. Ammonium acetate was also used very successfully as a source of ammonia with benzaldehyde and malonic acid in alcoholic solution.

The reaction of malonic acid with benzalmethylamine, the aliphatic analog of Knoevenagel's benzalaniline, proceeds to form β-methylamino-β-phenylpropionic acid, XIV, and cinnamic acid in approximately equal amounts. The intermediate addition product, XIII, of benzalmethylamine and malonic acid was isolated in pure condition. On heating, it undergoes decomposition, giving a mixture of 8-amino acid and cinnamic acid.

The isolation of this amine dicarboxylic acid addition product offers some positive evidence in support of Rodionow's postulation[14] that the formation of β-amino acids from an aldehyde, ammonia and malonic acid proceeds in the following order: first, condensation of aldehyde and ammonia to form an imine; second, addition of malonic acid to the double bond; and, finally, loss of carbon dioxide. This mechanism is the most plausible one suggested. The relative yields of β-amino acid and cinnamic acid depend on the stability of the former.

N-1-methyl-6-phenyl-dihydrouracil, XV, was formed without difficulty

from the β-amino acid by the use of potassium cyanate in neutral solution and could be made to condense quantitatively with ethyl chloro-acetate in the presence of sodium ethylate to form the disubstituted saturated uracil, XIX.

N-1-methyl-6-phenyl-hydrouracil, XVI, is converted quantitatively by the action of bromine in chloroform solution under pressure into the 5-bromine substitution product, XVII, which loses hydrogen bromide on heating at its decomposition point and forms the theoretical amount of 1-methyl-6-phenyluracil, XVIII. Condensation of the latter compound with ethyl chloro-acetate in the presence of sodium ethylate results in nearly quantitative formation of ethyl N-1-methyl-6-phenyl-uracil-1-acetate, VII. Saponification of the ester obtained by this method results in the formation of the acid V. Both acid and ester are identical in properties with the products obtained by direct substitution of phenyluracil.

The synthesis from benzalmethylamine in addition to its inherent theoretical interest, and its being absolute proof of the structure of the disubstituted uracils, was also the most efficient method for their preparation, since the yields of each of the intermediate products were extremely good.

Experimental Part

A. Derivatives of 6-Phenyluracil

The 6-phenyluracil, used as a starting point in this investigation was prepared according to the method of Johnson and Hemingway.[15] This method involves the condensation of ethyl benzoylacetate[16] and thiourea to form 6-phenyl-2-thiouracil and the subsequent desulfurization of this compound. The 6-phenyluracil obtained in this way was recrystallized once before using for syntheses.

N-3-methyl-6-phenyluracil, I, (m. p. 228–230°), and **N-1-3-dimethyl-6-phenyluracil, II,** (m. p. 122–122.5°) were prepared simultaneously by treating 6-phenyluracil with methyl iodide in alkaline solution.

The general method is illustrated by the following experiment. Ten grams of 6-phenyluracil (m. p. 269–270 5°) was refluxed on the steam-bath for six hours with a solution of 1.2 g. of sodium in 100 cc. of methyl alcohol. Excess methyl iodide was added and refluxing continued for twenty-four hours or until the sodium salt had disappeared and the solution had become neutral. On evaporation, 5 g. of material melting from 110 to 210° and 4 g. melting from 89 to 125° were obtained. Since it was found that the substituted uracils are much more soluble in boiling chloroform than the unsubstituted phenyluracil, separation of these mixtures could be accomplished with comparative ease. Extraction of these two successive precipitates with boiling chloroform gave in the first case, 2 g. of almost pure mono-methyluracil (m. p. 225–228°); and in the second case, 3 g of dimethyluracil, m. p. 106–118°. The combined residues, insoluble in chloroform, amounted to 4 g. of unsubstituted phenyluracil fm. p. 265–269°). Evaporation of the mother liquor gave products contaminated with iodine and which could not be further purified. Iodoform separated in several cases and was identified by mixed melting point determinations. Only one monomethyl derivative was ever isolated from the reaction mixture although diligent search was made for another.

[15] Johnson and Hemingway, THIS JOURNAL, 37,379 (1915).

[16] Wahl and Doll, Bull. *soc. chim.*, [4]13,265 (1913).

N-3-methyl-6-phenyluracil, I, m. p. 228–230°, was also prepared by treating N-3-methyl-6-phenyl-5,6-dihydrouracil, VIII, with bromine. Equal molecular quantities of bromine and hydrouracil were heated for one hour in a sealed tube with acetic acid as a solvent. Half of the product consisted of N-3-methyl-6-phenyluracil, m. p. 224–229°, which does not lower the melting point of the product obtained by direct methylation of phenyluracil. The rest of the product was a mixture, m. p. 140–155°, which contained the original N-3-methyl-6-phenyl-dihydrouracil.

After four recrystallizations from boiling alcohol, its melting point remained constant at 228–230°. It is soluble in boiling alcohol and precipitates in the form of large glistening leaves. It is also soluble in boiling chloroform.

Anal. Calcd. for $C_{11}H_{10}O_2N_2$: N, 13.86. Found: N, 13.80, 13.75.

N-1-3-dimethyl-6-phenyluracil, II, m. p. 122–122.5°, is soluble in chloroform and in boiling alcohol. After four recrystallizations from alcohol, from which it precipitates as small glistening leaves, a sample melting at 122–122.5° was used for analysis.

Anal. Calcd. for $C_{12}H_{12}O_2N_2$: N, 12.96. Found: N, 13.01, 13.17.

Potassium 6-phenyluracil was prepared by boiling 15 g. of 6-phenyluracil with a solution of one equivalent of potassium hydroxide in 150 cc. of water and filtering out the undissolved uracil. Its melting point lies above 300°. After one recrystallization from boiling water the salt was analyzed.

Anal. Calcd. for $C_{10}H_8O_2N_2K$: N, 12.33. Found: N. 12.61, 12.63.

Ethyl-6-phenyluracil-N-3-acetate, III, m. p. 205–206°, was prepared from 6-phenyluracil by treatment with sodium ethylate and ethyl chloro-acetate. In a sample experiment, 25 g. of 6-phenyluracil was refluxed for three-quarters of an hour with a solution of 4 g. of sodium in 300 cc. of absolute alcohol. Twenty-five grams of ethyl chloroacetate was added and the refluxing continued until the solution was practically neutral, which required ten days. Nearly complete precipitation was brought about by the addition of an equal volume of water and a few drops of hydrochloric acid. Boiling chloroform extracted 4.3 g. of ester from this precipitate, leaving 19 g. of unchanged phenyluracil. Although the ester was prepared several times with variations in the length of time of heating, no better yields were obtained. No evidence of the formation of the isomeric N-1 substituted compound was obtained. When two equivalents of sodium was used with 35 g. of phenyluracil, the yield of ester was increased to 8 g., and 19.7 g. of phenyluracil was recovered unchanged. On long standing, additional precipitates were obtained from the mother liquor aggregating 7.6 g., m. p. 75–220°. This gave more ester on extraction with chloroform.

Anal. Calcd. for $C_{14}H_{14}O_4N_2$: N, 10.22. Found: N, 10.19, 10.42, 10.49.

The ester passes quantitatively into the salt of the corresponding acid IV, m. p. 305°, on saponification with potassium hydroxide. The ester is soluble in boiling alcohol from which it can be conveniently recrystallized. It forms as fine colorless needles.

6-Phenyluracil-N-3-acetic, IV, m. p. 304–305°, was obtained in quantitative yield by boiling the corresponding ester with about six equivalents of dilute potassium hydroxide for one and one-half hours and acidifying the resulting solution with hydrochloric acid. It is insoluble in water and only very slightly soluble in boiling alcohol and acetone. It can be recrystallized most conveniently irom boiling glacial acetic acid, in the form of tiny clear cubes.

Anal. Calcd for $C_{12}H_{10}O_4N_2$: N, 11.39. Found: N, 11.12, 11.27.

The acid can be esterified by treatment of its suspension in absolute alcohol with dry hydrogen chloride, when it passes quantitatively to the ester, III, m. p. 205–206°. When treated with dimethyl sulfate it yields the N-1-methyl derivative, V. The acid is also formed when ethyl 6-phenyl-5,6-dihydrouracil-3-acetate, X, is treated with bromine in a sealed tube.

N-1-methyl-6-phenyluracil-N-3-acetic acid, V, m. p. 261–263°, was readily prepared by treating **6-phenyluracil-N-3-acetic** acid, IV, with dimethyl sulfate. For example, 7 g. of acid, m. p. 303–305°, was dissolved in a solution of somewhat more than two equivalents of potassium hydroxide in 100 cc. of alcohol. About 9 moles of dimethyl sulfate (15 cc.) was added dropwise and alternately with a solution of potassium hydroxide to keep the reaction mixture alkaline. The mixture was refluxed for half an hour to destroy any excess dimethyl sulfate, evaporated to small volume, diluted with water and acidified with hydrochloric acid. An immediate precipitate of 7.3 g. of an acid resulted.

Anal. Calcd. for $C_{13}H_{12}O_4N_2$: N, 10.77. Found: N, 10.63, 10.67.

The acid is very slightly soluble in boiling water, but it is soluble in boiling glacial acetic acid and in boiling ethyl alcohol, from which it crystallizes in the form of small clear cubical crystals.

Methyl-N-1-methyl-6-phenyluracil-N-3-acetate, VI, m. p. 157–157.5°, was formed quantitatively by alternately saturating with hydrogen chloride and refluxing a suspension of the corresponding acid, V, in methyl alcohol.

Anal. Calcd. for $C_{14}H_{14}O_4N_2$: N, 10.21. Found: N, 10.06, 10.21.

The ester is very soluble in boiling alcohol, but is much less soluble in cold alcohol. It crystallizes in stout colorless needles. On saponification with concentrated hydrochloric acid the ester reverts quantitatively to the acid V.

Ethyl-N-1-methyl-6-phenyluracil-N-3-acetate, VII, m. p. 109–110, was prepared from the acid, V, by the above method using absolute ethyl alcohol in place of methyl alcohol. The yield was quantitative, 2.9 g. of ester resulting from the esterification of 2.6 g. of acid. Its analysis is given below (a). This ester was also prepared by treating 2.8 g. of N-1-methyl-6-phenyluracil, XVIII, with 0.4 g. of sodium in 40 cc. of absolute alcohol, and 0.8 g. of ethyl chloro-acetate. The sodium salt, which precipitated immediately on the addition of the uracil to the sodium ethylate solution, was refluxed for fifteen minutes before the addition of the ethyl chloro-acetate, and refluxing continued for four hours thereafter, or until the solution had become neutral to litmus. Water was added causing successive precipitates which aggregated 3.1 g. of fairly pure ester. After four recrystallizations it was analyzed (b).

Anal. Calcd. for $C_{15}H_{16}O_4N_2$: N, 9.72. Found: (a) N, 9.85, (b) N, 9.98.

The ester is very soluble in boiling alcohol and in 50% alcohol, from which it crystallizes in clusters of long, very fine silky needles. On saponification with concentrated hydrochloric acid it passes quantitatively into the corresponding acid, V.

Reduction of N-1-methyl-6-phenyl-N-3-acetic acid or its methyl ester could not he accomplished by catalytic methods, nor by the use of hydrogen iodide, both of which had proved successful in reducing the isomeric hydantoins.[8] Units of 1.5 g. of acid or ester were used and recovered quantitatively in each of the four experiments. In two cases, one with the acid and one with the ester, hydrogen was used with colloidal palladium as a catalyst.[17] In the third the acid was heated for two hours at 120–130" with 5 cc. of hydrogen iodide, 0.5 g. of red phosphorus and 20 cc. of acetic acid. In the fourth, the acid was heated for five hours at 140–145° with 1.0 g. of red phosphorus and 30 cc. of hydrogen iodide, sp. gr. 1.70.

B. Derivatives of 6-Phenyl-5,6-dihydrouracil

6-Phenyl-5,6-dihydrouracil was prepared by heating cinnamic acid with urea, the general method of Fischer and Roeder.[10] Their procedure was modified by decreasing

---

[17] Hahn and Gilman, THIS JOURNAL, 47, 2948 (1925).

the temperature from 250 to 190°, and increasing the length of time of heating from one to six hours, whereby the yields were nearly tripled. From 50 g. of cinnamic acid and 30 g. of urea yields of 22–24 g. of phenyldihydrouracil, m. p. 215–217°, were obtained. This melting point agrees with that given by Posner[18] and by Dakin,[19] 216–217°, rather than that obtained by Fischer,[10] 202–203°.

6-Phenyl-5,6-dihydrouracil was also prepared by treating a solution of β-phenyl-β-aminopropionic acid with potassium cyanate and evaporating to dryness.'' The product was dissolved in a little water and acidified with hydrochloric acid. The precipitate, m. p. 183–186°, proved to be the ureido acid and passed quantitatively into phenyl-hydrouracil (m. p. 215–217°) on heating with 10% hydrochloric acid. Mixed melting point determinations demonstrated the identity of these compounds with those obtained by Fischer's synthesis.

The β-phenyl-β-aminopropionic acid used in the above synthesis was prepared by treatment of 3 g. of benzaldehyde with 3 g. of malonic acid, 4.5 g. of ammonium acetate and 25 cc. of absolute alcohol. The materials were refluxed for two hours, during which time carbon dioxide was evolved. On coding, 3.2 g. of amino acid decomposing at 213–215° precipitated, and from the filtrates, 1.2 g. of cinnamic acid, m. p. 128–131°.

In several experiments ammonium malonate was used in place of malonic acid and ammonium acetate. The ammonium malonate was prepared by treating a solution of malonic acid in dry ether with a stream of dry ammonia gas.[20]

From 10 g. of the mono-ammonium malonate refluxed for two hours with 10 g. of benzaldehyde and 25 cc. of absolute alcohol, 6 g. of amino acid and 3.2 g. of cinnamic acid were obtained; from 6 g. of the mixture of mono and di-ammonium malonate refluxed for three and one-half hours with 4.6 g. of benzaldehyde and 25 cc. of absolute alcohol, 3.2 g. of amino acid and 2.8 g. of cinnamic acid were obtained. After recrystallization from boiling alcohol, the amino acid melted at 215–216°. Since the melting point does not agree with that given by Posner,[18] 231°, or Rodionow,[12] 228°, the identity of the compound was established by an analysis.

Anal. Calcd. for $C_9H_{11}O_2N$: N, 8.49. Found: N, 8.48.

N-3-methyl-6-phenyl-5,6-dihydrouracil, VIII, m. p. 149–150.5°, was prepared by the following method. The sodium salt of 6-phenyl-5,6-dihydrouracil was formed by refluxing 17.5 g. of the hydrouracil with a solution of 2.3 g. of sodium in 300 cc. of absolute alcohol for one hour. The addition of 20 g. of methyl iodide caused almost immediate solution of the salt. Refluxing was continued for one-half hour. On standing for twenty-four hours and further evaporation, 14 g., m. p. 145–149°, precipitated and a small amount of unchanged hydrouracil was recovered. The methylated compound was purified by recrystallization from boiling water and alcohol, from which it precipitates in the form of needles.

Anal. Calcd. for $C_{11}H_{12}O_2N_2$: N, 13.73. Found: N, 13.88, 13.86.

On treatment with bromine, in sealed tubes, N-3-methyl-6-phenyl-5,6-dihydrouracil can be transformed into the corresponding unsaturated compound, I. On hydrolysis at atmospheric pressure the corresponding ureido acid IX is formed.

Hydrolysis of N-3-methyl-6-phenyl-5,6-dihydrouracil, VIII.—The hydrolysis was conducted both at atmospheric pressure and at elevated pressures. In the first case, 6.4 g. of hydrouracil was digested with 50 g. of barium hydroxide, 100 cc. of water and 100 cc. of methyl alcohol for one hundred hours. After removing the solid barium

---

[18] Posner, Ber., 38, 2316 (1905).

[19] Dakin, J. Biol. Chem., 8, 39 (1910).

[20] McMaster, Am. Chem. J., 49, 295 (1913).

hydroxide by filtration, the solution was distilled into weak hydrochloric acid. A very small amount of methylamine hydrochloride contaminated with ammonium chloride was isolated from the distillate. The residue in the flask was exactly neutralized with sulfuric acid and filtered from the barium sulfate. A precipitate of 2.6 g. of coarse needles which decompose at 178° resulted after further evaporation. This compound reverted quantitatively to the original hydrouracil on treatment with 10% hydrochloric acid. This result and the following analysis of the product decomposing at 178° established the fact that the hydrouracil is hydrolyzed with the formation of the ureido acid IX, on prolonged treatment with barium hydroxide and that complete hydrolysis cannot be effected by this means.

Anal. Calcd. for $C_{11}H_{14}O_3N_2$: N, 12.61. Found: N, 12.70, 12.74.

The molecule degenerated completely when N-3-methyl-6-phenyl-5,6-dihydrouracil (3.5 g.) was heated at 150° for seventy-two hours in a sealed tube with excess barium hydroxide and a little water and subsequently treated as described above. The acid distillate yielded 1.5 g. of solid which was extracted with absolute butyl alcohol and found to consist of nearly the theoretical quantities of ammonium chloride and methylamine hydrochloride. After the barium had been removed from the reaction mixture and the filtrate evaporated to dryness only 0.5 g. of a substance, m. p. 115–120°, remained. This was found to be neither benzoic acid nor cinnamic acid. The peculiar odor and lachrymal effect of the vapors indicate that the other products of this profound decomposition are volatile with steam. It is evident that this method cannot be used for the determination of the position of the methyl group.

Ethyl-6-phenyl-5,6-dihydrouracil-N-3-acetate, X, m. p. 154.5–156°, is the major product formed when the sodium salt of phenyl-dihydrouracil is treated with ethyl chloro-acetate. Twenty grams of phenyl-dihydrouracil was refluxed for four hours with two equivalents of sodium (4.8 g.) in 250 cc. of absolute alcohol; 40 g. of ethyl chloro-acetate was added and refluxing continued for nine hours or until the solution was neutral. The addition of an equal volume of water caused the precipitation of 10.4 g., m. p. 135–170°. The filtrate was evaporated to dryness and extracted with chloroform and then alcohol. From the chloroform solution 2.7 g. of a mixture, m. p. 110–128°, was obtained. This mixture was never resolved, though several attempts with chloroform, water and alcohol were made. The alcohol extraction yielded 3,4 g. of original hydrouracil. The ester was obtained by extraction of the first precipitate with chloroform, leaving a residue of 1.7 g. of the original hydrouracil. The extract was recrystallized from boiling alcohol, giving 5.1 g., m. p. 148–151°. After several recrystallizations from boiling alcohol, from which it precipitates as fine white needles, its melting point remained constant at 154.5–156°.

Anal. Calcd. for $C_{14}H_{16}O_4N_2$: N, 10.15. Found: N, 10.15, 10.17.

On hydrolysis the ester is converted into a mixture from which the acid, XI, m. p. 228–231°, can be isolated. Treatment with bromine also results in the formation of a mixture from which a bromine compound, XII, and the corresponding unsaturated acid, IV, were isolated.

Bromination of **ethyl-6-phenyl-5,6-dihydrouracil-N-3-acetate** was carried out at 100° in a sealed tube. Three grams of the hydrouracil was heated with 1.5 moles of bromine in glacial acetic acid for three hours. After neutralization, a precipitate of 2.8 g. which decomposed at 212–235° was obtained. This was recrystallized from boiling alcohol, giving 0.8 g. of a bromine compound, XI, which forms in spongy balls and melts at 259–261° with decomposition.

Anal. Calcd for $C_{14}H_{15}O_4N_2Br$: N, 7.89. Found: N, 7.61, 7.63.

From the filtrate, 0.35 g. of original ester and 1.3 g. of a mixture melting from 80° to above 267° were obtained.

In a second experiment the heating at 100° was continued for seven hours and resulted in the formation of another mixture. In this case, however, no pure bromine compound could be isolated but a small amount (0.8 g.) of material melting at 350° was obtained by recrystallization. It was proved to be 6-phenyluracil-N-3-acetic acid, IV, by a mixed melting point determination. The remainder of the material consisted of a mixture melting from 180 to 275" with decomposition. Although this method is not feasible for the preparation of the acid, IV, the relationship between the two compounds has been definitely established.

6-Phenyl-5,6-dihydrouracil-N-3-acetic acid, XII, m. p. 228–231°, can be isolated from the mixture formed when the corresponding ester, X, is hydrolyzed in either acid or alkaline solution. The proportion of it is practically the same in either case. When 0.5 g. of pure ester was boiled with 30 cc. of concentrated hydrochloric acid for two hours, 0.2 g., m. p. 228–231°, and 0.2 g., m. p. 165–215°, were obtained. The product melting at 228–231° passed quantitatively to the ester, m. p. 154.5–156°, on treatment with absolute ethyl alcohol and dry hydrogen chloride. On esterification of the mixture, both the original ester, m. p. 148–152°, and a new ester, m. p. 132–135°, were obtained. This latter ester was not obtained in large enough quantities for analysis.

When 5 g. of ester, m. p. 154.5–156°, was refluxed with potassium hydroxide for one and one-half hours and the resulting solution acidified, 4.2 g., m. p. 180–220°, precipitated. This was resolved into two products, 2.6 g., m. p. 228–231°, and 1.0 g., m. p. 170–180°, by one recrystallization from boiling alcohol. Further recrystallization from boiling alcohol failed to alter the melting point.

Anal. Calcd. for $C_{12}H_{12}O_4N_2$: N, 11.29. Found: N, 11.07, 11.19.

C. Derivatives of Benzalmethylamine

β-N-methyl-benzylmalonic acid, XIII, decomposition point 147°, is the primary product of the action of malonic acid on benzalmethylamine. It is formed with the evolution of heat and begins to precipitate from the reaction mixture almost immediately. On further heating it loses carbon dioxide to form the corresponding β-aminopropionic acid, XIV, and cinnamic acid. It was recrystallized once from boiling alcohol.

Anal. Calcd. for $C_{11}H_{13}O_4N$: N, 6.28. Found: N, 6.53.

β-N-methyl-β-phenylpropionic Acid, XIV, m. p. 168.5–169°.—Benzalmethylamine (20 g.), malonic acid (16.7 g.) and absolute alcohol (80 cc.) were mixed and warmed gently on the steam-bath. After five to ten minutes the solution was filled with the feathery white crystals of the malonic acid addition product and carbon dioxide was being given off. The refluxing was continued, causing the gradual disappearance of the precipitate. At the end of three hours solution was complete and evolution of carbon dioxide had ceased. The solution was cooled in a freezing mixture and the product precipitated slowly as a white powder by addition of ether or by seeding. The precipitate obtained by seeding always contained some cinnamic acid. The yield of β-amino acid was 12 g., and of cinnamic acid obtained from the ether solution, 9 g. Small amounts of benzaldehyde and benzoic acid were also detected.

Anal. Calcd. for $C_{10}H_{13}O_2N$: N, 7.82. Found: N, 7.72, 7.71.

The acid precipitates as feathery crystals from pure boiling alcohol, in which it is less soluble than it is in the reaction mixture. It is extremely soluble in hydrochloric acid. From the latter, the hydrochloride crystallizes in clusters of needles.

β-Phenyl-β-N-1-methyl-ureido-propionic acid, XV, m. p. 165–167°, could be prepared in good yield by the treatment of β-phenyl-β-N-methylpropionic acid with the calculated amount of potassium cyanate in a small quantity of water. Thus, 2.5 g. of the amino acid dissolved in 15 cc. of water was treated with 2 g. of potassium cyanate. The solution was heated on the steam-bath for one and one-half hours, cooled, acidified and filtered immediately. The yield was 2.0 g., m. p. 165–167°. When the hydrochloride of the amino acid was used the product of the reaction was a mixture of the ureido acid, the corresponding hydrouracil, and a little cinnamic acid. The mixture melts from 130–150° with decomposition.

The ureido acid can also be prepared by the partial hydrolysis of the corresponding hydrouracil with dilute alkali.

N-1-methyl-6-phenyl-5,6-dihydrouracil, XVI, m. p. 158–159.5°.—Closure of the ring was brought about quantitatively by heating either the pure ureido acid, XV, or the mixture with 10% hydrochloric acid. The product is soluble in boiling water, from which it crystallizes in long fine needles, and in alcohol, from which it crystallizes in short heavy needles.

Anal. Calcd. for $C_{11}H_{12}O_2N_2$: N, 13.73. Found: N, 13.72, 13.56.

N-1-methyl-6-phenyl-5,6-dihydrouracil can be transformed readily into the corresponding unsaturated compound by treatment with bromine and subsequent expulsion of hydrogen bromide. An ethyl acetate residue can be readily substituted for hydrogen in the N-3-position.

N-1-methyl-6-phenyl-5-bromo-5,6-dihydrouracil, XVII, m. p. 214–215°.—Bromination of N-1-methyl-6-phenyl-5,6-dihydrouracil was brought about in sealed tubes at 100°. When acetic acid was used as solvent, the major product was the 5-bromo compound, but a small quantity of another mono-bromo compound which crystallizes in long needles, m. p. 240–242° without decomposition, was also formed. It was found more convenient to brominate in chloroform solution by the following method. Bromine (4.5 g.) in 40 cc. of alcohol-free chloroform and 5 g. of dihydrouracil were sealed in a Carius tube and heated at 100° for one and one-half hours. After cooling, the solution was diluted to 200 cc. and extracted with a solution of sodium bicarbonate until free from acid. The chloroform was evaporated and the product (6.9 g.) recrystallized several times from boiling alcohol. It precipitates as glistening leaflets which decompose at 214–215°. None of the compound melting at 240–242" was formed.

Anal. Calcd. for $C_{11}H_{11}O_2N_2Br$: N, 9.93. Found: 214–216°, N, 9.92, 10.19; 240–242°, N, 9.95, 10.18.

Boiling the bromine compound for four hours with an equivalent of pyridine in absolute alcohol produced no change. Hydrogen bromide could, however, be driven off by heating, as described below.

N-1-methyl-6-phenyluracil, XVIII, m. p. 194–195°, was prepared by heating the bromine derivative, XVII, at its decomposition point, 215°. Hydrogen bromide is given off, the reaction being complete in fifteen minutes. The yield is quantitative, 3 g. of bromine derivative giving 2.1 g. of uracil. The product was purified by recrystallization from boiling alcohol and from water. No test for bromine could be obtained by fusion with sodium.

Anal. Calcd. for $C_{11}H_{10}O_2N_2$: N, 13.86. Found: N, 13.79, 13.84.

On treatment with sodium and ethyl chloro-acetate the N-3-ethyl acetate derivative, VII, is formed.

Ethyl **N-1-methyl-6-phenyl-5,6-dihydrouracil-N-3-acetate,** XIX, m. p. 70–71°, resulted in good yield from the treatment of N-1-methyl-6-phenyl-5,6-dihydrouracil with sodium and ethyl acetate in the usual manner. The reaction is complete half an hour after the addition of ethyl chloro-acetate. The ester could not be induced to crystallize from the reaction mixture. It was therefore evaporated to dryness and extracted with ether, leaving behind sodium chloride and unchanged N-1-methyl-6-phenyl-5,6-dihydrouracil. The ester was obtained in crystalline form after evaporation of the ether and stirring. From 7.8 g. of N-1-methyl-6-phenyl-5,6-dihydrouracil, 6.6 g. of ester was obtained. The ester is exceedingly soluble in boiling alcohol, but it was purified for analysis by recrystallizations from slightly more dilute solutions in this solvent. Water can be added to precipitate the remainder of the ester.

Anal. Calcd. for $C_{15}H_{18}O_4N_2$: N, 9.66. Found: N, 9.52, 9.42.

Summary

1. The pyrimidine methyl N-1-methyl-6-phenyluracil-N-3-acetate has been synthesized by three series of transformations using 6-phenyluracil, 6-phenyl-5,6-dihydrouracil and benzalmethylamine as starting points.

2. The structure of methyl N-1-methyl-6-phenyluracil-N-3-acetate has been definitely established by its synthesis from benzalmethylamine. The structures of the other uracils and hydrouracils have also been proved by relationships to this ester.

3. β-Phenyl-β-aminopropionic acid has been prepared by the reaction of benzaldehyde, malonic acid and ammonium acetate.

4. The preparation of β-phenyl-β-methylaminopropionic acid from benzalmethylamine is evidence that the formation of β-amino acids from ammonia or amines with aldehydes and malonic acid may take place with the intermediate formation of an imine.

THE DECOMPOSITION OF ETHYL NORMAL-BUTYLACETOACETATE INTO CAPROIC ACID AND METHYL NORMAL-AMYL KETONE

BY NATHAN L. DRAKE AND R. W. RIEMENSCHNEIDER[1]

RECEIVED SEPTEMBER 17, 1930 PUBLISHED DECEMBER 18, 1930

A number of methods for the preparation of n-caproic acid have appeared in the literature from time to time.[2] Of the various schemes which have been suggested, the synthetic method described in the article mentioned,[2] starting from ethyl malonate, is the most useful. By use of this method, yields of 74% of the theoretical were obtained.

A synthesis of caproic acid from ethyl n-butylacetoacetate is possible and, inasmuch as ethyl malonate has a molecular weight of 160 compared to 130 for ethyl acetoacetate, the acetoacetic ester method appears at first sight attractive. Prices of raw materials are also much in favor of this method.[3] Consequently, if satisfactory yields can be obtained, the de-

[1] From a thesis submitted to the Graduate School of the University of Maryland by R. W. Riemenschneider in partial fulfilment of the requirements for the degree of Master of Science.

[2] See Adams and Marvel, THIS JOURNAL, 42, 317–319 (1920), for a brief summary of these methods.

[3] Eastman's "List No. 21" quotes the following: ethyl acetoacetate $7.00 per kg.; ethyl acetoacetate (pract.) $3.00 per kg ; ethyl malonate, $12.00 per kg.; ethyl malonate (techn.) $10.00 per kg.

composition of ethyl n-butylacetoacetate should offer a more economical method of preparing caproic acid than the decomposition of ethyl n-butylmalonate.

Considerable quantities of caproic acid were necessary in a research being conducted in this Laboratory, and it was decided, therefore, to study the reaction mentioned above.

Methyl n-amyl ketone can be prepared in approximately a 60% yield by the decomposition of ethyl *n*-butylacetoacetate[4] under appropriate conditions, and the present paper is a report of a series of experiments on factors affecting the yields of this ketone and caproic acid when ethyl n-butylacetoacetate is decomposed by alkali.

The effect of varying concentrations of alkali on the decomposition of many mono-substituted ethylacetoacetates has been studied, but ethyl n-butylacetoacetate is not among them.

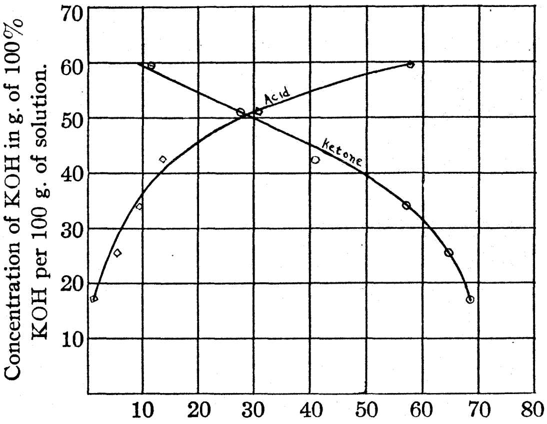

Fig. 1.—The effect of potassium hydroxide concentration on the decomposition of ethyl n-butylacetoacetate (T, 105°).

Experimental

Decomposition of the Ester.—In a round-bottomed three-necked flask fitted with a reflux condenser, a mercury-sealed mechanical stirrer and a separatory funnel, were placed the desired amount of water and potassium hydroxide. The reaction flask was then heated to the desired temperature by means of an oil-bath and the ester[5] added over a period of an hour. The temperature of the oil-bath was read from time to time and the temperatures given in the figures are oil-bath temperatures. Stirring was continued for five hours.

[5] Prepared according to "Organic Syntheses," John Wiley and Sons, Inc., New York, 1927, Vol. VII, p. 36, b. p. 112–117° at 16 mm. pressure.

Isolation of Methyl *n*-Amyl Ketone.—The alkaline reaction mixture was diluted with 250 cc. of water, except in those cases where dilute alkali was used, and the alcohol and ketone which had been produced were distilled off. Distillation was continued until no more water-insoluble material passed into the distillate. The ketone layer was separated, washed twice with one-half its volume of saturated calcium chloride solution and dried over anhydrous calcium chloride. The water layer of the distillate was again distilled until about half its volume of distillate was collected. From this second distillate the ketone was separated and the distillation process repeated until no appreciable amount of ketone separated from the distillate.

Isolation of n-Caproic Acid.—The alkaline solution from which the ketone had been distilled was acidified with 50% sulfuric acid, with care not to allow the mixture to become unduly hot during acidification. The caproic acid was then extracted with three 100-cc. portions of ether, the combined extracts dried over sodium sulfate and the ether distilled off on a steam-bath. The sodium sulfate used for drying the extracts was washed with a small portion of anhydrous ether which was added to the dried extract. The crude caproic acid remaining was distilled under reduced pressure from a Claisen flask. The fraction boiling from 105 to 110° under 16 mm. was collected. No appreciable quantity of ketone was obtained during this treatment.

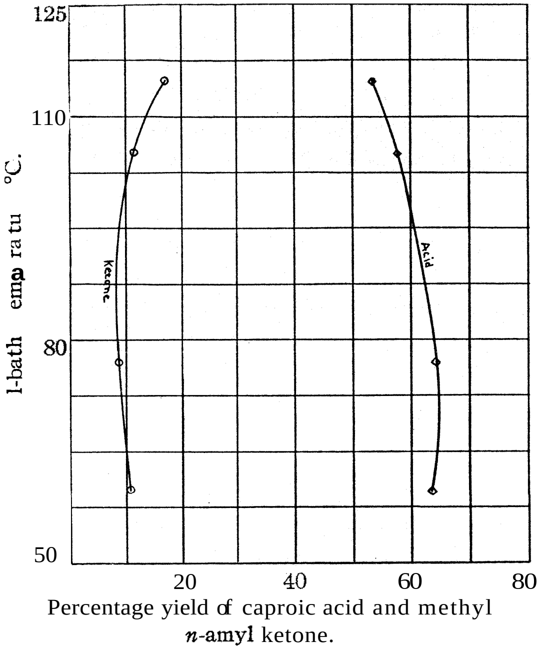

Fig. 2.—The effect of temperature on the decomposition of ethyl n-butylacetoacetate (KOH concentration, 59.5 g. per 100 g. of solution).

Discussion of Results

Figure 1 shows the effect of several concentrations of alkali on the yield of ketone and acid. In the six experiments represented by these curves, the oil-bath temperature was 105° and twelve moles of potassium hydroxide per mole of ester was used. Fifty grams of ester was used in each experiment.

Appreciable formation of acid took place only in the more concentrated solutions. It is interesting to note that increasing the alkali concentration from 51 to 59.5 g. of hydroxide per 100 g. of solution caused an increase in yield of acid from **30.5** to 57.7%.

Best yields of ketone were, of course, obtained in the more dilute solutions. The best yield of ketone obtained here was about 8% higher than that mentioned above.

Figure 2 shows the effect of temperature on the decomposition. It can be seen that the temperature of decomposition is not without effect on the yield, although the effect is not great. The optimum temperature for acid production is about 75°. At this temperature an increase in acid yield from 57.7%, the optimum of Fig. 1, to 64.6% was obtained. The experiments represented by Fig. 2 were carried out using 12 moles of hydroxide per mole of ester and a concentration of 59.5 g. of alkali per 100 g. of solution.

Figure **3** represents a series of experiments carried out to determine the effect of decreasing the number of moles of hydroxide per mole of ester. The temperature of the oil-bath was 75° and the initial concentration of alkali 59.5 g. of hydroxide per 100 g. of solution. Little increase in yield of acid was obtained by using more than eight moles of hydroxide per mole of ester, but a decrease below eight resulted in a very considerable drop in acid yield with a simultaneous rise in the yield of ketone.

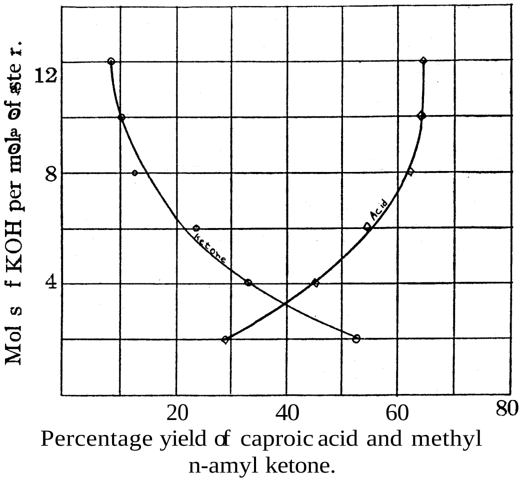

Fig. 3.—The effect of excess alkali on the decomposition of ethyl n-butylacetoacetate (oil-bath temperature, 75°).

In all of the experiments mentioned above the stirring of the reaction mixture was continued for five hours to allow the decomposition of ester to proceed to completion. It is reasonably certain, however, that this period could be considerably shortened. One experiment was conducted in which the time of heating was one hour; the yield of caproic acid was 55.5%. It seemed to us that efficiency of stirring was very important, although no experiments to verify this idea were conducted, and it is believed that with very efficient stirring one hour would have been sufficient to bring the decomposition to completion.

Summary

1. The effects of alkali concentration, excess of alkali and temperature on the decomposition of ethyl n-butylacetoacetate have been studied.

2. Formation of caproic acid in satisfactory yield is possible only in very concentrated alkali.

SOME NEW MONOSUBSTITUTION DERIVATIVES OF RETENE

BY GUST. KOMPPA AND ERIC WAHLFORSS[1]

RECEIVED SEPTEMBER 18, 1930 PUBLISHED DECEMBER 18, 1930

Introduction and Historical

Retene is a hydrocarbon derived from pine tar. This compound, 8-methyl-2-isopropylphenanthrene, m. p. 98–99°, exhibits many peculiarities in its behavior toward ordinary chemical reagents. It is quite stable under certain conditions and will frequently react only if brought into solution and agitated vigorously.

Although a number of investigators have studied the effect of various reagents upon retene, the preparation of only one crystalline mono-substituted product has been reported. This, a monocarboxylic acid, $C_{18}H_{17}$-COOH, m. p. 121–123°, was obtained by Liebermann and Zsuffa[2] by the action of oxalyl chloride, in the presence of aluminum chloride, on a solution of retene in carbon disulfide. Repetition of this experiment from the meager description given resulted, in this research, in the formation of a well-characterized monocarboxylic acid, which after thorough purification and recrystallization melted over 100° higher, 229–231°.

Ekstrand[3] obtained a yellowish oil analyzing for a monochlororetene, $C_{18}H_{17}Cl$, by the action of chlorine gas on crystalline retene. No other monohalogen substitution products of retene have been reported.

The action of nitric acid on retene has been investigated extensively. Concentrated as well as fuming nitric acid readily attacks retene but no crystalline nitro derivatives have thus far been obtained.

The effect of sulfuric acid on retene has been studied by a number of investigators. Knauss[4] observed that sulfur dioxide was evolved when retene was heated with concentrated sulfuric acid above 100". Apparently, however, no sulfonic acid was formed as no soluble barium salt could be isolated. Fritzsche[5] was able to isolate the barium salt of a disulfonic acid, $C_{18}H_{16}(SO_3H)_2$, obtained by the action of a mixture of concentrated and fuming sulfuric acid on retene. Ekstrand[3] was able to identify the free disulfonic acid and its chloride. All his attempts to prepare a monosulfonicacid, despite the use of the most diverse experimental conditions, were fruitless.

Results and Discussion

A well-characterized monocarboxylic acid, $C_{18}H_{17}COOH$, m p. 229–231° was prepared by the method of Liebermann and Zsuffa.[2]

The methyl ester of this acid, $C_{18}H_{17}COOCH_3$, m. p. 96–97°, and the amide, $C_{18}H_{17}CONH_2$, m. p. 224–226°, were prepared. A monocarboxylic acid of retenequinone, $C_{18}H_{15}O_2COOH$, m. p. above 237°, was prepared by the action of chromic acid on the monocarboxylic acid dissolved in glacial acetic acid. This shows that the carboxyl group does not enter the 9- or 10-position in retene.

Attempts to chlorinate retene at 120–130 and 170–180° and to brominate retene dissolved in carbon tetrachloride both in the presence and absence of iodine resulted in the formation of a great variety of products with varying halogen contents but no definite compound could be isolated.

A viscous yellowish oil was obtained when retene dissolved in carbon tetrachloride was chlorinated with chlorine gas. Analysis indicated the formula $C_{18}H_{17}Cl$ for this product. It distilled at a constant temperature of 350–351° at atmospheric pressure but a high percentage of the original oil resinified. The wide range of boiling point, 195–205°, when this product was distilled at 10 mm. pressure would indicate the presence of a mixture. The insolubility of this oil in alcohol together with its analysis and its behavior when subjected to sulfonation indicated that it was at least not a mixture of retene and higher chlorinated derivatives. Oxidation of monochlororetene with chromic acid in acetic acid solution resulted in the formation of retenequinone. This indicates that the chlorine substitutes in the 9- or 10-position in retene.

Boiling the chlorinated product with alcoholic potassium hydroxide and with quinoline did not split off hydrogen chloride. The chlorine atom could not be replaced by iodine by treatment with sodium iodide in acetone or glacial acetic acid solution. No crystalline products were obtained when the monochlororetene was nitrated or sulfonated. Attempts to obtain monohydroxyretene from monochlororetene by Grignard's reaction resulted in the formation of traces of oil which were insoluble in water, aqueous sodium carbonate and mineral acids but soluble in aqueous sodium hydroxide. This oil gave the Liebermann test for phenols.

Methylretene, which could be considered as a link between retene and the resin acids, is of considerable theoretical significance. Attempts to prepare this compound from monochlororetene and methyl iodide with sodium in absolute ether were, however, unsuccessful.

Attempts to prepare a crystalline nitro derivative of retene by the action of nitric acid on retene dissolved in glacial acetic acid; acetyl nitrate in acetic anhydride solution and benzoyl nitrate in carbon tetrachloride solution were all unsuccessful. In one case traces of a yellow nitro derivative, 0.01 g., m. p. 154.5–156.5°, were obtained from 5 g. of retene by the action of acetyl nitrate in carbon tetrachloride solution.

Although retene was sulfonated with chlorosulfonic acid in boiling chloroform solution, no pure crystalline monosulfonic acid was obtained in this research. Two isomeric monosulfonic acids, $C_{18}H_{17}SO_3H$, designated as A-retenesulfonic acid and B-retenesulfonic acid, were obtained by adding concentrated sulfuric acid to vigorously stirred melted retene. Lower temperatures favored the formation of the A-retenesulfonic acid, m. p. 188–189°, and higher temperatures favored the formation of the B-retenesulfonic acid, m. p. 121–123°.

Attempts to isolate and separate the two monosulfonic acids by means of the alkaline earth and lead salts were unsuccessful as, contrary to the general rule for sulfonic acids, these salts are only very slightly soluble in hot water. The sodium, potassium and ammonium salts, however, differ enough in solubility from the other products formed during sulfonation to permit separation. The salts of the B-retenesulfonic acid are much more soluble than the corresponding salts of the A-retenesulfonic acid. The free B-retenesulfonic acid was obtained by the action of sulfuric acid on its barium salt. A-retenesulfonic acid again was isolated directly from the sulfonation mixture.

The formation of quinones, $C_{18}H_{15}O_2SO_3H$, when both the A-retenesulfonic acid and B-retenesulfonic acid were oxidized with chromic acid in acetic acid solution shows that the sulfonic acid group does not enter the 9- or SO-position in retene. Alkaline permanganate is decolorized by the potassium salts of the retenesulfonic acids but no crystalline oxidation products could be isolated.

A number of metallic salts of both retenesulfonic acids were prepared and analyzed. They crystallize with varying amounts of water of crystallization. Fusion of the ammonium sulfonates with alkali leads to the formation of monohydroxy derivatives. The term *retenol* is suggested for monohydroxyretene, $C_{18}H_{17}OH$, in analogy with the corresponding term for monohydroxyphenanthrene.

The methyl ester, $C_{18}H_{17}SO_3CH_3$, m. p. 164–166°, and A-retenol, $C_{18}H_{17}OH$, m. p. 200–202°, were obtained in good yields from the ammonium salt of A-retenesulfonic acid. The picrate of A-retenol melted at 151–152'.

A number of derivatives of B-retenesulfonic acid were prepared. The chloride, $C_{18}H_{17}SO_2Cl$, m. p. 146.5–148°; the amide, $C_{18}H_{17}SO_2NH_2$, m. p. 206–207.5°; the methyl ester, $C_{18}H_{17}SO_3CH_3$, m. p. 117–119° and the potassium salt of the quinone, $C_{18}H_{15}O_2SO_3K$, were obtained in crystalline form. B-retenol, $C_{18}H_{17}OH$, m. p. 158.5–159°, was prepared by fusing the ammonium salt of B-retenesulfonic acid with potassium hydroxide. Its picrate melted at 145–146°, and its acetyl compound, $C_{18}H_{17}OCOCH_3$, at

132–134°. B-retenol when coupled with diazobenzenesulfonic acid developed an orange-red color.

Two attempts to acetylate retene with acetyl chloride in carbon disulfide solution in the presence of aluminum chloride gave no positive results. These, together with other experiments of a negative nature, are omitted from the Experimental Part.

The following derivatives have been prepared in this investigation

Derivatives	Melting point, °C.		
	A =	B =	
$C_{18}H_{17}SO_2OH$	188–189	121–123	
$C_{18}H_{17}SO_2Cl$		146.5–148	
$C_{18}H_{17}SO_2NH_2$		206–207.5	
$C_{18}H_{17}SO_2OCH_3$	164–166	117–119	
$C_{18}H_{17}OH$	200–202	158.5–159	
$C_{18}H_{17}OH$ picrate	151–152	145–146	
$C_{18}H_{17}OCOCH_3$		132–134	
$C_{18}H_{17}COOH$			229–231
$C_{18}H_{17}CONH_2$			224–226
$C_{18}H_{17}COOCH_3$			96–97

Experimental Part

The retene used in these experiments was obtained from that fraction of pine tar boiling above 300°. After purification it possessed a uniform melting point of 98–99°.

Monochlororetene.—A solution of 40 g. of retene in 200 g. of carbon tetrachloride to which a trace of iodine had been added was cooled to 0°. Chlorine gas was then passed through the solution until an increase in weight of 12.2 g. was noted. The solution was allowed to stand overnight at room temperature and was then washed successively with aqueous sodium bisulfite, sodium hydroxide and water. After drying with calcium chloride, the solvent was distilled off and the residue was rectified under reduced pressure. In this way 36.5 g. (79.5% yield) of a yellowish oil boiling at 195–205° (10 mm.) was obtained.

Anal. (Carius) Calcd. for $C_{18}H_{17}Cl$: Cl, 13.20. Found: Cl, 13.13.

This product is nearly insoluble in alcohol but is soluble in ether and petroleum ether. It distilled at 350–351° at atmospheric pressure (747.6 mm.) without appreciable decomposition but left a considerable residue of tar in the distilling flask. A small amount of chlorine-free substance crystallized out on standing. After one recrystallization from alcohol this melted at 94–97°. Mixed with retene, m. p. 98.5°, it melted at 96–97". The distillate was boiled with alcohol to remove any traces of retene. The residue, d_4^{20} 1.1359, was analyzed for chlorine.

Anal. Calcd. for $C_{18}H_{17}Cl$: Cl, 13.20. Found: Cl, 13.30.

The results of refluxing this product for twenty-five hours with 33% alcoholic potassium hydroxide and for half an hour with quinoline indicated that it was not a mixture of retene and retene dichloride.

Oxidation of Monochlororetene.—A solution of 1.1 g. of monochlororetene in 3.5 g. of glacial acetic acid was treated with a solution of 1.9 g. of chromic acid in 10 g. of glacial acetic acid. The mixture was refluxed for half an hour. On cooling 0.4 g. (37.0% yield) of red chlorine-free needles separated out. The melting point, 190–192°, and appearance indicated that this was retenequinone.

Reteoecarboxylic Acid and Derivatives

Retenecarboxylic Acid.—To a solution of 10 g. of retene in 75 cc. of freshly purified carbon disulfide, cooled to $-4°$, were added *23.4* g. of oxalyl chloride and *5* g. of finely pulverized aluminum chloride. After three hours an additional *75* cc. of carbon disulfide and *10* g. of aluminum chloride were added. The mixture was then left at room temperature. When after two weeks no more hydrogen chloride was evolved, the carbon disulfide was filtered off and the residue extracted with ether. The solvent was distilled and the residue boiled with aqneous sodium carbonate. The sodium salt of the carboxylic acid separated out from the solution; yield, *4.4* g. (31.6%). The free carboxylic acid was obtained by boiling the aqueous solution of the sodium salt with very dilute hydrochloric acid. After three crystallizations from benzene the acid melted at *229–231°*. The acid is difficultly soluble in ether, more easily soluble in boiling benzene. It was titrated in alcohol solution with $N/10$ potassium hydroxide: calcd. for *0.1130* g. $C_{18}H_{17}COOH$: *4.06* cc.; found: *3.95* cc.

Sodium Salt.—This salt was prepared by neutralizing an alcohol solution of the free acid with $N/10$ aqueous sodium hydroxide.

The alcohol was distilled off and the salt recrystallized from water. The shining silver scales thus obtained were difficultly soluble in cold water but more easily soluble in hot water. They contain five molecules of water of crystallization. all of which are entirely lost below 136°. After drying the salt was analyzed.

Anal. Calcd. for $C_{18}H_{17}COONa$: Na, *7.66*. Found: Na, *7.50*.

Methyl Ester.—This compound was prepared by refluxing the sodium salt with dimethyl sulfate for five minutes. After recrystallization from alcohol a 51.7% yield of fine, slightly yellow scales, m. p. 96–97°, was obtained.

Anal. Calcd for $C_{20}H_{20}O_2$: C, *82.15;* H, *6.90*. Found: C, *81.70;* H, *6.75*.

Amide.—This compound was prepared from the acid chloride. A mixture of *0.24* g. of retenecarboxylic acid, 1 g. of phosphorus oxychloride and *0.5* ***g.*** of phosphorus pentachloride was heated on a water-bath for ten minutes. The resulting mixture was cooled and poured into ice water. The undissolved part was filtered off, washed, dried in a desiccator and extracted with ether. The ether extract was washed with water, and the ether evaporated, leaving the solid acid chloride; yield, *0.14* g. (54.7%). It was dissolved in benzene and shaken with concentrated ammonium hydroxide. The precipitated amide was filtered off and recrystallized from benzene, m. p. *224–226°*.

Retenequinonecarboxylic Acid.—To a solution of *0 2* g. of the dried sodium salt in *1* g. of glacial acetic acid was added in small portions a solution of *0.38* ***g.*** of chromic acid in *3.5* g. of glacial acetic acid. The mixture was refluxed for twenty minutes. On cooling the retenequinonecarboxylic acid separated out in long needles; yield, *0.13* g. *(63.4%)*. This substance was boiled with hydrochloric acid and recrystallized from glacial acetic acid; m. p. 237–240°. Owing to the dark red color of the acid it was difficult to determine the melting point. When dried for two days over sulfuric acid no loss in weight was observed. The acid was slightly soluble in water and ether, somewhat more soluble in alcohol. It was titrated in very dilute alcohol solution with $N/100$ potassium hydroxide: calcd. for *0.0423* g. of $C_{18}H_{15}O_2COOH$: *13.7* cc.; found: *13.0* cc.

Monosulfonic Acids and Derivatives

A-Retenesulfonic Acid.—To 10 g. of retene heated on an oil-bath to 99° was added *10* g. of sulfuric acid (sp. gr. *1* 84). The acid was at room temperature and was added slowly, with vigorous stirring, to the melted retene. The sulfonation was completed in five minutes, as was indicated by complete solution of a sample in hot water. The sulfonation mixture was poured into *200* g. of hot water. allowed to cool to about 70°

and filtered. After some time a gelatinous mass formed and this was filtered off. The residue was washed first with very dilute sulfuric acid and then with cold water. After drying in a desiccator it was extracted with ether and the residue recrystallized from glacial acetic acid. This gave well-developed scales melting at 188–189°. The acid was titrated in alcohol solution with $N/10$ sodium hydroxide: calcd. for 0.1530 g. of $C_{18}H_{17}SO_3H$: 4.87 cc.; found: 4.75 cc.

Ammonium Salt.—The sulfonation mixture, prepared as above, was poured into 300 g. of hot water, cooled and extracted with ether. The aqueous solution was reheated and concentrated ammonium hydroxide was added. The thick precipitate of ammonium A-retenesulfonate which thus formed was filtered off, washed with water and dried at 135°; yield, 3.85 g. (28.4%).

Methyl Ester.—This compound was prepared by refluxing potassium A-retenesulfonate with dimethyl sulfate. This salt had been obtained by neutralizing an alcohol solution of the free acid with potassium hydroxide. An 88.2% yield was obtained. The thin small scales of the methyl ester after recrystallization from methyl alcohol melted at 164–166°.

Anal. Calcd. for $C_{19}H_{20}SO_3$: C, 69.46; H, 6.14. Found: C, 69.33; H, 6.02.

Potassium A-Retenequinonesulfonate.—To a solution of 0.9 g. of A-retenesulfonic acid in 25 g. of glacial acetic acid was added in small portions a solution of 0.9 g. of chromic acid in glacial acetic acid. The solution was refluxed for half an hour and allowed to cool. As nothing crystallized out, it was evaporated to 10 cc. and again cooled. As precipitation still did not take place the solution was heated and a slight excess of potassium hydroxide was added. On cooling a red substance precipitated. This was washed with cold water and dried in a desiccator; yield, 0.5 g. (45.7%). This product, potassium A-retenequinonesulfonate, was easily soluble in hot water.

Anal. Calcd. for $C_{18}H_{15}O_5SK$: K, 10.23. Found: K, 9.99.

A-Retenol.—To 10 g. of potassium hydroxide and a few drops of water, heated in a nickel crucible to 220°, was added slowly 1 g. of ammonium A-retenesulfonate. The temperature was then increased to 270° and the fused potassium compound of A-retenol floated to the top. Not more than fifteen minutes should elapse from the time of the first addition of the salt. The entire mixture was then poured on to a copper plate, allowed to cool and dissolved in 1000 cc. of hot water.

The solution was filtered through a warm water filter and the phenol was precipitated with dilute sulfuric acid. After carefully decanting the supernatant liquid, the precipitated A-retenol could readily be filtered. It was washed thoroughly with water and with dilute aqueous sodium carbonate, dried in a desiccator and extracted with ether. The ether solution was thoroughly washed with water and aqueous sodium carbonate. The ether extract gave 0.4 g. of solid phenol (53.0% yield). Fine yellowish needles melting at 200–202" were obtained after three crystallizations from xylene. A-retenol is easily soluble in ether, boiling benzene and xylene, soluble in warm alkali and alcohol, but insoluble in aqueous sodium carbonate and sodium bisulfite. The picrate of A-retenol was obtained by mixing equivalent quantities of alcohol solutions of the components. The ruby red needles of this compound melted at 151–152°. A-retenol gave a positive Liebermann test for phenols. Ferric chloride imparted a slightly green color to an alcohol solution of the phenol.

Anal. Calcd. for $C_{18}H_{18}O$: C, 86.35; H, 7.25. Found: C, 86.13; H. 7.22.

B-Retenesulfonic Acid.—To 10 g. of retene heated on an oil-bath to 200° was added 10 g. of sulfuric acid (sp. gr. 1.84). The acid was at room temperature and was added slowly with vigorous stirring. The sulfonation was completed in two minutes. The product was poured into 300 g. of hot water. The solution was boiled and an excess of concentrated ammonium hydroxide was added. It was cooled, allowed to stand for twenty-four hours and filtered. The precipitated ammonium salt was washed with cold water and dried; yield, 5.0 g. (35.4%). The salt was redissolved in hot water and boiled with aqueous sodium hydroxide. An excess of barium chloride was added to the solution of the sodium salt, made slightly acid with hydrochloric acid, and the barium salt was filtered off and washed thoroughly. After treatment with the calculated amount of sulfuric acid, the free B-retenesnlfonic acid was obtained in the form of colorless scales. These, when dried for two weeks in a desiccator, melted at 121–123°. The acid was titrated with $N/10$ potassium hydroxide: calcd. for 0.1154 g. of $C_{18}H_{17}SO_3H$: 3.67 cc.; found: 3.65 cc.

Salts.—A number of salts of B-retenesulfonic acid were prepared and analyzed.

Ammonium Salt.—Prepared from the free acid, m. p. 121–123°, and ammonium hydroxide. Solubility: 0.1082 g. of salt in 100 g. water at 17°; more soluble at 100°. The salt, which crystallized without water of crystallization, was dried at 150" and analyzed. Calcd for $C_{18}H_{21}SO_3N$: C, 65.21; H, 6.39; S, 9.68; N, 4.23; found: C, 65.09; H, 6.34; S (Carius), 9.60; N (Kjeldahl), 4.11.

Sodium Salt.—Prepared from the free acid and aqueous sodium hydroxide. Crystallized from water in white scales, which, air dried, contained three molecules of water. Two molecules were lost at 110° and the third at 150". Solubility: 0.0726 g. of the anhydrous salt in 100 g. of water at 17°; more soluble at 100". The salt was dried at 150° and analyzed. Calcd. for $C_{18}H_{17}SO_3Na$: Na, 6.84; found: Na, 6.96.

Potassium Salt.—Prepared from the free acid and aqueous potassium hydroxide. Crystallized from water as crystalline powder without water of crystallization. Solubility: 0.0824 g. of salt in 100 g. of water at 17°; only slightly more soluble at 100°. The salt was dried at 150° and analyzed. Calcd. for $C_{18}H_{17}SO_3K$: K, 11.10; found: K, 11.00.

Barium Salt.—Prepared from the sodium salt and barium chloride. Precipitated as a crystalline powder which, air dried, contained two molecules of water; both were lost when dried over sulfuric acid. Solubility: 0 0848 g. of anhydrous salt in 100 g. of water at 17°; sparingly soluble at 100". The salt was analyzed. Calcd. for $(C_{18}H_{17}SO_3)_2Ba$: Ba, 17.99; found: Ba, 17.70.

Strontium Salt.—Prepared from the sodium salt and strontium chloride. Precipitated as a crystalline powder, which, air dried, contained four molecules of water; all four molecules were lost when dried over sulfuric acid. Solubility: 0.1016 g. of anhydrous salt in 100 g. of water at 17°; sparingly soluble at 100°. The salt was anzlyzed. Calcd. for $(C_{18}H_{17}SO_3)_2Sr$: Sr, 12.27; found: Sr, 12.28.

Calcium Salt.—Prepared from the sodium salt and calcium chloride. Precipitated as a crystalline powder, which, air dried, contained four molecules of water; all four molecules were lost when dried over sulfuric acid. Solubility: 0.1166 *g.* of anhydrous salt in 100 g. of water at 17°; sparingly soluble at 100°. The salt was analyzed. Calcd. for $(C_{18}H_{17}SO_3)_2Ca$: Ca, 6.01; found: Ca, 6.00.

Copper Salt.—Prepared from the free acid and copper carbonate. Crystallized as light green scales, which, air dried, contained five molecules of water: all five molecules were lost below 150°. Solubility: 0.1572 g. of anhydrous salt in 100 g. of water at 17°; more soluble at 100°. The salt was analyzed. Calcd. for $(C_{18}H_{17}SO_3)_2Cu$: Cu, 9.21; found (CuO): Cu, 8.91.

Chloride.—Prepared from potassium B-retenesulfonate in a manner similar to that described for the chloride used in the preparation of retenecarboxylic acid amide; yield, 68.8%. Recrystallization from benzene gave colorless prisms, m. p. 146.5–148°.

Anal. (Carius) Calcd. for $C_{18}H_{17}SO_2Cl$: Cl, 10.66; S, 9.64. Found: Cl, 10.55; S, 9.79.

Amide.—Prepared from the chloride of B-retenesulfonic acid and ammonium hydroxide; yield, 31.9%; colorless scales, m. p. 206–207.5".

Anal. Calcd. for $C_{18}H_{19}SO_2N$: N, 4.47. Found: N, 4.16.

Methyl Ester.—Prepared from ammonium B-retenesulfonate and dimethyl sulfate; yield, 73.8%. Recrystallization from methyl alcohol gave colorless needles, m. p. 117–119°.

Anal. Calcd. for $C_{19}H_{20}SO_3$: C, 69.46; H, 6.14. Found: C, 69.39; H, 6.02,

Potassium **B-Retenequinonesulfonate.**—To a solution of 2 g. of potassium B-retenesulfonate in 10 g. of glacial acetic acid was added, in small portions, a cold solution of 3.8 g. of chromic acid in 35 g. of glacial acetic acid. The solution was refluxed for about half an hour and on cooling 1.2 g. (55.3% yield) of orange colored scales crystallized out. This product, potassium B-retenequinonesulfonate, was easily soluble in hot water.

Anal. Calcd. for $C_{18}H_{15}O_5SK$: K, 10.23. Found: K, 10.01.

B-Retenol.—Prepared from ammonium B-retenesulfonate by the method used for A-retenol. The temperature, however, was not allowed to exceed 240°; yield, 66.37%. Recrystallization from xylene gave slighly yellowish scales, m. p. 158.5–159°. B-retenol is easily soluble in ether, alcohol, benzene and nitrobenzene; soluble in aqueous sodium hydroxide, but insoluble in sodium carbonate and sodium bisulfite. The picrate of B-retenol, small orange-red scales, melted at 145–146°. B-retenol gave a positive Liebermann test for phenols. Ferric chloride imparted a green color to an alcohol solution of the phenol.

Anal. Calcd for $C_{18}H_{18}O$: C, 86.35; H, 7.25. Found: C, 86.14; H, 7.26.

Acetyl-B-retenol.—Prepared from B-retenol, alkali and acetic anhydride. Recrystallization from alcohol gave fern-like crystals, m. p. 132–134°.

Anal. Calcd. for $C_{20}H_{20}O_2$: C, 82.15; H, 6.90. Found: C, 82.09: H. 7.00.

B-Retenol Sodium Azobenzenesulfonate.—B-retenol readily coupled with diazo benzenesulfonic acid, giving a red dye which dyed, wool and silk cherry-red.

Summary

Only two mono-substituted derivatives prepared from retene have been reported previously in the literature: monochlororetene and a monocarboxylic acid, m. p. 121–123°. The preparation of mono-substituted products of retene has been the object of this investigation.

Sulfonation gave two well-defined monosulfonic acids. They were isolated by means of the ammonium or sodium salt. These were used in the preparation of a number of derivatives; the most interesting was the monohydroxy derivative, retenol. Only one retenol coupled with diazo compounds. An attempt to determine the position of the sulfonic acid group by oxidation with chromic acid resulted in the formation of retenequinonesulfonic acid, showing that this group did not enter the 9- or 10-position in retene. Chlorination of retene resulted in an oil, monochlororetene, the individuality of which was not definitely established. Oxidation of this product with chromic acid gave retenequinone. Action of oxalyl chloride on retene resulted in the formation of a monocarboxylic acid, m. p. **229–**

231°. A few derivatives were prepared. Oxidation with chromic acid gave retenequinonecarboxylic acid.

THE FORMATION OF A COMPLEX MIXTURE OF MANY RMgX COMPOUNDS FROM THE REACTION BETWEEN A SIMPLE RX COMPOUND AND MAGNESIUM

BY HENRY GILMAN AND NINA B. ST. JOHN

RECEIVED SEPTEMBER 18, 1930 PUBLISHED DECEMBER 18, 1930

Introduction

The simplest expressions for the reaction between an RX compound and magnesium in ether are the following

$$RX + Mg \longrightarrow RMgX \qquad (I)$$

$$2RX + Mg \longrightarrow R{\cdot}R + MgX_2 \qquad (II)$$

Reaction II is the chief side reaction in the preparation of Grignard reagents, and the extent of this reaction varies markedly with the nature of the RX compound, the relative proportions of reactants and experimental conditions.[1] The hydrocarbon (or their equivalent) by-products are not pure R·R compounds, but may contain R(+H) and R(–H) compounds[2] as well as R·R compounds having R-groups unlike those contained in the original RX compound.[3]

Furthermore, Reaction I gives an incomplete picture of the more important compounds contained in Grignard solutions inasmuch as these reagents are involved in the following equilibria[4]

$$2RMgX \rightleftarrows R_2Mg + MgX_2 \qquad (III)$$

$$RMgX \rightleftarrows R- + -MgX \qquad (IV)$$

In short, a Grignard reagent is not simply an RMgX compound, but a mixture of RMgX, R_2Mg, MgX_2, R– and –MgX[6] in a series of equilibria

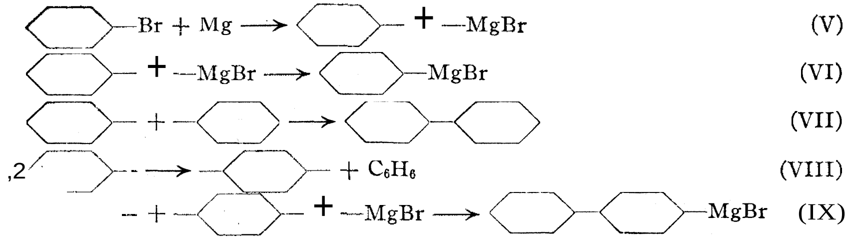
[5] Gilman and Brown, *ibid.*, 52, 1128 (1930). This article contains leading references to the chemistry of the interesting magnesious halides or the binary systems (MgX_2 + Mg) of Gomberg and co-workers. Better reviews of these systems are to be had in the chapters entitled "Metallo-Organic Compounds," in Vol. III (1927–1928) and Vol. IV (1928–1929) of the Annual Survey of American Chemistry, published for the National Research Council by the Chemical Catalog Co. of New York.

with only additional experiments to determine the extent of the equilibrium in Reaction III and the degree of dissociation illustrated by Reaction IV.

When the halide used to prepare the Grignard reagent contains two or more halogens which are reactive toward magnesium, then it is theoretically possible to have an infinite number of Grignard reagents. This[6] development has been illustrated with the relatively simple *p*-dibromobenzene, BrC_6H_4Br. Obviously, with an infinite number of organomagnesium halides derivable from a simple dihalogen compound, there is also present an infinite number of equilibria and dissociation reactions (III and IV).

This very complex state of affairs is apparently not restricted to organomagnesium halides prepared from a polyhalogen compound. It now appears that the reaction of a simple RX compound, having but one halogen, can give rise to a very complex mixture of RMgX compounds. The explanation for such mixtures almost certainly lies with the initial and intermediate formation of free radicals. If we select the reaction between bromobenzene and magnesium as a type, we have the following general representation[7]



That is, the first[8] step in the reaction between an RX compound and magnesium is the formation of free radicals. These radicals may unite (Reaction VI) to give the RMgX compound; or the R-groups may unite to give the coupling (R·R) compound (Reaction VII); or the radical may disproportionate to give new free radicals, like the *p*-phenylene radical in Reaction VIII; and the radicals (mono or polyvalent) may combine with each other and with the –MgX (or its equivalent, MgX_2 + Mg) or with magnesium to give a miscellany of Grignard reagents.

[7] Gomberg and Bachmann, THIS JOURNAL, 49, 236 (1927); Gilman and Zoellner *ibid.*, 52, 3984 (1930); and, particularly, Bachmann and Clarke, *ibid.*, 49, 2089 (1927), for an excellent theoretical and experimental development of the mechanism of the Wurtz-Fittig reaction.

[8] We are omitting here the probable prior formation of oxonium compounds with ether and the several possible coordination formations involving each of the participating elements [Gilman and Fothergill, *ibid*, 51, 3149 (1929)]. See, also, Gilman and Zoellner, *ibid.*, 52, 3984 (1930), and Gilman and Brown, *ibid.*, 52, 5045 (1930), for that interpretation involving combination of free radicals with magnesium.

We have illustrated the formation of but one RMgX compound other than phenylmagnesium bromide: namely, *p*-biphenylmagnesium bromide (Reaction IX). This has been done advisedly because we now have experimental evidence for the formation of *p*-phenylbenzoic acid, *p*-$C_6H_5C_6H_4$-COOH, when carbon dioxide is passed into a Grignard reagent (or reagents) prepared from bromobenzene and magnesium.

There is no reason, a *priori,* for confining consideration to the reactions (V) to (IX) as we have done. For example, it appears altogether probable that two phenyl radicals might disproportionate to give not only *p*-phenylene (Reaction VIII), but also a lesser quantity of *o*-phenylene.[3] Furthermore, multiples of these phenylene radicals might unite with a phenyl radical and $-MgBr$ (Reaction IX) to give $C_6H_5(C_6H_4)_nMgBr$.[9] Many other combinations are possible, such as the union of a phenylene radical with two $-MgBr$ groups to give $BrMgC_6H_4MgBr$.

The theoretical possibilities of even more complex mixtures are patent with the use of halides like the mono-bromotoluenes or benzyl chloride, inasmuch as we have here the opportunity of free radicals formed from the side chain as well as from the nucleus. Finally, we are unaware of any valid objection to a like condition with *alkyl*magnesium halides. A good case has been made for the short life of alkyl radicals,[10] and their disproportionation,[2] as well as for the disproportionation and rearrangements of arylalkyl radicals such as benzyl.[3] If we grant the possibility of an alkyl radical to disproportionate to an alkylene[11] radical by analogy with Reaction VIII, and to rearrange to a different free radical, then there exists the same opportunity for the formation of a complex mixture of Grignard reagents from a simple mono-halogen[12] alkyl halide.

The above development has a theoretical reasonableness and part of it, as mentioned, has found experimental confirmation. Fortunately, the extent of these many possible side reactions leading to the formation of complex mixtures of RMgX compounds is strictly limited because of preferential reactions. If a so-called single Grignard reagent is in reality very slightly contaminated with many other RMgX compounds, then the products obtained from them and reactants are also approximately of a like

---

[9] Actually, the residues which yielded *p*-phenylbenzoic acid contained highly complex, intractable materials which so far have resisted purification, primarily because of the small quantities of starting materials used.

[10] Paneth and Hofeditz, *Ber.,* **62B, 1335** (1929).

[11] The general evidence for alkylene (or bivalent) radicals is at present hardly as convincing as that for alkyl (or trivalent) radicals and although there is essentially no experimental evidence for monovalent carbon radicals, one can conceive of an alkylene group acting as a donor of hydrogen in its disproportionation reactions.

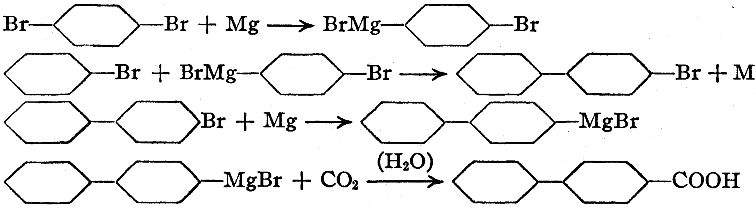
[12] With polyhalogen-alkyl compounds there is, of course, the same opportunity for an infinite number of Grignard reagents that is present in the case of *p*-dibromobenzene (see **Ref. 6** of this paper).

degree of impurity. One important conclusion to be drawn from the several studies is that the world of organic chemicals is relatively "impure." This is hardly a situation peculiar to organomagnesium compounds[2] because it is altogether likely that most reactions of organic chemistry are accompanied by side reactions which give rise to slight impurities. Ordinarily these trivial side reactions deserve no consideration and get no consideration partly because the extent of impurities appears to be of no apparent consequence[13] and partly because we are blissfully ignorant of the impurities for the reason that our present analytical procedures do not reveal them.[14]

Discussion of Results

The isolation of *p*-phenylbenzoic acid came as a result of studies on the purported addition of RMgX compounds to an ethylenic linkage. In order to determine whether phenylmagnesium bromide might add to 1,1-diphenylethylene, $(C_6H_5)_2C{=}CH_2$, in solvents other than ether, the reactants were heated, and then the mixture was carbonated. If no addition took place, then benzoic acid alone should result: However, if some addition occurred a new Grignard reagent would result and this on carbonation would reveal itself by affecting the melting point and neutralization equivalent of the benzoic acid formed from the excess of phenylmagnesium bromide.[15] The acid obtained from this reaction was impure, and in order to identify the acidic impurity the benzoic acid was carefully removed, leaving a small quantity of p-phenylbenzoic acid.

The p-phenylbenzoic acid was also obtained in a like very small quantity when no diphenylethylene was present. There is a possibility that the *p*-phenylbenzoic acid, or the *p*-biphenylmagnesium bromide from which it was formed, came from impurities in the bromobenzene. The following reactions illustrate one of several possible methods for its formation.



(X)

(XI)

(XII)

(XIII)

---

[13] We say "no apparent consequence" advisedly, because there is always the irritable or pleasant phenomenon of catalysis due to small impurities to plague or to delight us depending on one's point of view.

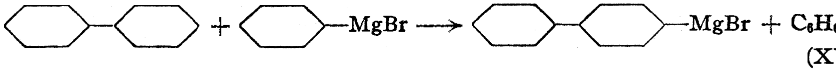
[14] We are confident that other Grignard reagents postulated as being formed in small quantities will be characterized in large-sized runs. In this connection see Footnote 10 of Ref. 3 of this paper on the special contributions to be made to such problems by manufacturers and dealers in research chemicals.

[15] Leading references to the application of this and other devices to establish the non-addition of RMgX compounds to an ethylenic linkage may be traced from an article by Gilman and Schulz, THIS JOURNAL, 52,3588 (1930).

Reaction X is plausible because small quantities of *p*-dibromobenzene might be present in supposedly pure bromobenzene, and if so it would readily react with magnesium to give the mono-Grignard reagent.[6] However, Reactions XI and XII are less reasonable because they take place with uncommon difficulty and to a limited extent.[16] The bromobenzene used by us was highly purified. Not content with this, we prepared some bromobenzene by a reaction other than that used technically (the bromination of benzene): namely, a Sandmeyer reaction starting with freshly distilled and pure aniline. We do not say that no *p*-dibromobenzene is formed in such a reaction, but it does appear to be distinctly superior to the reaction of direct bromination and should yield a bromobenzene as pure and as free of dibromobenzene as that obtained by any reaction. This bromobenzene also yielded p-phenylbenzoic acid.

There is another possible explanation for the *p*-biphenylmagnesium bromide and this is illustrated by the reactions

(XIV)



(XV)

The diphenyl of Reaction XIV is always formed to a small extent[17] in the preparation of phenylmagnesium bromide, and Reaction XV has been postulated in an interpretation of the Wurtz reaction using sodium.[18] However, the metathesis pictured in Reaction (XV) has been shown not to apply with Grignard reagents, even at elevated temperatures.[19] To further test the unlikelihood of this reaction, the phenylmagnesium bromide was prepared and heated in the presence of a large quantity of diphenyl, but there was no increase in the yield of p-phenylbenzoic acid on subsequent carbonation.

No p-phenylbenzoic acid was isolated from a 0.5 mole preparation of phenylmagnesium bromide in ether. Very likely the preparation of this Grignard reagent at more elevated temperatures, with no ether, and with an uncommonly large initial excess of bromobenzene gives a higher concentration of phenyl radicals.

---

[16] This applies to reactions in ether and not to those in the absence of ether and in the presence of an excess of hot bromobenzene, the condition of our experiments The difficulty mentioned here is even greater when chlorobenzene is used because of its distinctly lesser activity than bromobenzene to magnesium. Notwithstanding this, we did get a small quantity of p-phenylbenzoic acid from the preparation of phenylmagnesium chloride in the absence of ether.

[17] The extent of this side reaction can be markedly decreased with the use of an excess of magnesium; see Gilman and Fothergill, *Iowa State Coll. J. of Science*, **4**, **351** (1930).

[18] Bachmann and Clarke, This Journal, 49,2089 (1927).

[19] Gilman and Leermakers, *Rec. trav. chim.* **48**, 577 (1929); see also, Gilman and Leermakers, *ibid.*, 49, 208, **532** (1930).

Phenylmagnesium chloride prepared in the absence of ether also gave some p-phenylbenzoic acid.[20]

Experimental Part

In a typical preparation, 470.7 g. (3.0 moles) of bromobenzene was refluxed with 6.1 g. (0.25 atom) of magnesium and a crystal of iodine for one hour in a flask provided with a trap[21] to exclude air. The mixture was cooled and then carbonated. A positive color test[22] for Grignard reagent was obtained even after an eighteen-hour passage of carbon dioxide. The weight of crude benzoic acid was 10.05 g. or 32.93%, and it melted at 104–106". Purification by crystallization from hot water gave benzoic acid melting at 122" and a dark brown oily residue which was essentially insoluble in water. This residue on crystallization from benzene gave 0.15 g. of p-phenylbenzoic acid. The p-phenylbenzoic acid was converted to its methyl ester and the identity of both the acid and the ester was confirmed by respective mixed melting point determinations with authentic specimens. Wherever elsewhere p-phenylbenzoic acid was isolated it was identified by a mixed melting point determination.

In order to test the validity of Reaction XV, 50 g. (0.32 mole) of diphenyl was added to 470.7 g. (3 moles) of bromobenzene and 6.1 g. (0.25 atom) of magnesium. After refluxing the mixture for twelve hours it was cooled to 0° and then carbonated for twelve hours. The viscous violet colored mixture gave a negative test for Grignard reagent.[22] The products recovered were a few crystals (not weighed) of p-phenylbenzoic acid, 4.23 g. of benzoic acid and 43.6 g. or 87.2% of the diphenyl.

Using the same proportions of reactants (but omitting the diphenyl) the yield of p-phenylbenzoic acid was 0.02 g. In this experiment the bromobenzene was that prepared from aniline.[23]

Phenylmagnesium bromide (0.3 mole) was prepared in a sealed tube[24] by heating for one hour at 150°, extracted by ether and then carbonated.[25] The yield of *p*-phenylbenzoic acid was 0.6 g. In this method of preparation the reaction between bromobenzene and magnesium is unusually rapid, and actually appears to proceed of itself on the local application of heat. The preparation in an open flask (in the absence of ether) goes much more slowly and so may give rise to a lower concentration of phenyl radicals.

Phenylmagnesium chloride was prepared20 in a like manner from 21.8 g. (0.25 mole) of chlorobenzeneand 7.3 g. (0.3atom) of chlorobenzene, transferred to a flask containing 337.5 g. (3.0 moles) of chlorobenzene, refluxed for thirty minutes and then cooled and carbonated. The yield of crude benzoic acid melting at 104–105° was 9.26 g. (30.35%), and from this was isolated a very small quantity of p-phenylbenzoic acid. It is interesting to note that phenylmagnesium chloride in chlorobenzene is carbonated more rapidly than is phenylmagnesium bromide in bromobenzene.

Summary

The carbonation of phenylmagnesium bromide and of phenylmagnesium

---

[20] It has been suggested that it would be interesting to know how iodobenzene and magnesium behave in this reaction, With sodium and chlorobenzene (see Ref. 18 of this paper), there is formed a relatively large quantity of o-phenylene radicals.

[21] Gilman and Hewlett, *Rec. trav. chim.* 48, 1124 (1929).

[22] Gilman and Schulze, THIS JOURNAL, 47,2002 (1925).

[23] This bromobenzene was synthesized by Catherine Vinton.

[24] See, Gilman and Brown, THIS JOURNAL, 52,3330 (1930), for a description of this method for the preparation of some Grignard reagents.

[25] This experiment was carried out by K. E. Marple.

[26] By R. E. Brown.

chloride, each prepared in the absence of ether, gave in addition to benzoic acid very small quantities of *p*-phenylbenzoic acid, $C_6H_5C_6H_4COOH$. The formation of the latter acid is almost certainly due to free phenyl radicals initially developed in the preparation of the C_6H_5MgX.

Attention is directed to the theoretical, and in some cases practical, formation of a large and complex variety of Grignard reagents starting with a single and simple RX compound. Although the degree of these side reactions is fortunately very limited and in most cases insignificant, it emphasizes the difficulty or impossibility of preparing absolutely pure compounds. This difficulty is undoubtedly not confined to organo-magnesium compounds.

THE CHEMISTRY OF THE LIPOIDS OF TUBERCLE BACILLI. XXI. THE POLYSACCHARIDE OCCURRING IN THE PHOSPHATIDE FROM THE HUMAN TUBERCLE BACILLI[1]

BY R. J. ANDERSON AND E. GILMAN ROBERTS[2]

RECEIVED SEPTEMBER 18, 1930 PUBLISHED DECEMBER 18, 1930

Introduction

Previous investigations in this Laboratory of the water-soluble constituents which are obtained on hydrolyzing the phosphatide **A-3** from the human tubercle bacillus have shown that mannose,[3] inosite[4] and some other reducing sugar, probably invert sugar,[5] are present in about equal amounts in the aqueous solution. The phosphatide fractions isolated from the avian and bovine tubercle bacilli also yielded mannose and inosite on hydrolysis.[6]

In all of these cases prolonged boiling of the phosphatides with dilute acid was necessary before reducing sugars appeared in the solution. It seemed evident, therefore, that the various sugars which were liberated on complete hydrolysis existed in the original phosphatide molecules in firm chemical combination; possibly sugar complexes or polysaccharides

might be present with which the fatty acids were combined in the form of esters.

We were naturally interested in discovering some evidence of the existence of complex carbohydrates or polysaccharides in the bacillary phosphatides but for a long time we had to be content with the identification of the simple sugars which appeared as cleavage products after hydrolysis. It was difficult to discover a method by which a partial hydrolysis of the phosphatide could be effected without at the same time disrupting the carbohydrate groups.

In the analysis of the so-called purified tubercle bacilli wax[7] we found when this substance was saponified with dilute alcoholic potassium hydroxide that an alcohol-insoluble carbohydrate complex was obtained, while when the wax was hydrolyzed by boiling with acid–alcohol reducing sugars appeared in addition to fatty acids and so-called unsaponifiable wax. Further studies which have not yet been published on the water-soluble cleavage products obtained from the purified wax and from the bovine phosphatide made it seem probable that the polysaccharides or carbohydrate complexes that were present were very stable since only partial hydrolysis could be effected by means of acid–alcohol treatment.

A study has now been made of the cleavage products which are formed when the phosphatide A-3 derived from the human tubercle bacillus is boiled with dilute alcoholic potassium hydroxide. The results obtained were very interesting and entirely unexpected. The phosphatide is insoluble in alcohol but when it is boiled with dilute alcoholic potassium hydroxide the material gradually disintegrates, giving a soap solution of the fatty acids and leaving an amorphous mass of insoluble matter on the bottom of the flask, The latter is easily soluble in water and consists of two components: (a) the potassium salt of an organic phosphoric acid and (b) a neutral carbohydrate. The two products can be separated by dissolving the mixture in water and adding a solution of neutral lead acetate, when the organic phosphoric acid is precipitated as an insoluble lead salt, leaving the carbohydrate in solution. The carbohydrate is precipitated by alcohol as a gummy mass from the aqueous solution after the lead has been removed. The product can be converted into a snow white amorphous powder by pouring its aqueous solution with stirring into absolute alcohol. The substance does not reduce Fehling's solution but after it has been boiled with dilute acid reducing sugar is liberated and after complete hydrolysis it yields about equal parts of mannose and inosite.

The nature of the new compound has not been established definitely but the results so far obtained indicate clearly that the phosphatide contains a new type of polysaccharide. So far as we are aware this is the

[7] Anderson, *J. Biol. Chem.*, **83**, **505** (1929).

first time that a compound of the nature of a polysaccharide or possibly a glucoside composed of mannose and inosite has been found in nature and we propose to name this substance maninositose.

It is an interesting fact that the action of dilute acid and dilute alcoholic alkali upon the phosphatide produces such different cleavage products. When the phosphatide is boiled with dilute acid the molecule is completely disrupted with the formation of fatty acids and glycerophosphoric acid together with reducing sugar and inosite. By the action of hot dilute alcoholic alkali only the fatty acids are split off; the polysaccharide binding is not disturbed and no reducing sugar is liberated. It seems probable, therefore, that the fatty acids are combined as esters with hydroxyl groups in the polysaccharide and the fact that no free glycerophosphoric acid can be isolated from the saponification mixture makes it probable that this substance is also linked in ester combination with the sugar .molecules.

The organic phosphoric acid referred to above was converted into a barium salt. The barium salt is very soluble in water but it is insoluble in alcohol and up to the present time it has been obtained only as a snow white amorphous powder. The substance does not reduce Fehling's solution but after it has been boiled for some time with dilute acid some reducing sugar is liberated. The composition of the substance does not agree with any ordinary hexosemonophosphate since the relation of carbon to phosphorus is approximately C : P = 9 : 2. It is not impossible that it represents a compound of a hexosephosphate with glycerophosphoric acid.

The discovery of maninositose, a bacterial polysaccharide or glucoside of mannose and inosite will open up a new chapter in the study of the function of inosite in cell metabolism. It should also lead to interesting experiments in the synthesis of similar combinations between hexoses such as glucose or mannose and inosite. Biological values or reactions of maninositose are still unknown but various experiments are planned and will be carried out as soon as possible.

Experimental Part

The general properties of the cleavage products obtained on saponification together with methods of separating the organic phosphoric acid and the neutral polysaccharide were worked out in preliminary experiments. Three separate saponifications were conducted in the course of which the various cleavage products were isolated. In all of these experiments very similar results were obtained both qualitatively and quantitatively. The experimental procedure outlined below can, therefore, be recommended as the shortest and most satisfactory.

Saponification of the Phosphatide.—The phosphatide had been prepared by the H. K. Mulford Company from the human tubercle bacillus, strain H-37, according to our original method.[8] The product was a white amorphous powder and its properties were identical with those that we described for the phosphatide A-3. We desire to express our thanks to the H. K. Mulford Company who generously supplied this expensive material.

The saponification[9] was carried out by refluxing a mixture of 18 g. of the phosphatide and 600 cc. of 1% alcoholic potassium hydroxide on the steam-bath for twenty-four hours. The phosphatide agglutinated to a solid mass on the bottom and sides of the flask and the alcoholic solution became slightly straw colored. After the mixture had cooled the insoluble product was a hard brittle mass which could be easily rubbed to a powder. The supernatant liquid was decanted, the flask was rinsed several times with hot alcohol and the solution was reserved for the isolation of the fatty acids.

Examination of the Alcohol-Insoluble Residue.—The material which was insoluble in alcohol was dissolved in 100 cc. of water and the solution was acidified with acetic acid, when a slight scummy precipitate was obtained which consisted mainly of fatty acids which had been occluded in the amorphous mass. The precipitate was filtered off, washed with ether and the extract was combined with the fatty acids obtained from the alcoholic solution.

The aqueous solution and washings, after they had been concentrated under reduced pressure to a volume of about 30 cc., were mixed with 400 cc. of alcohol, when a sticky mass was precipitated. The mixture was allowed to stand until the supernatant liquid was clear; the solution was decanted, and the precipitate was washed with alcohol and dried. The material was dissolved in 10 cc. of water, precipitated by adding alcohol and the supernatant liquid was decanted. After the precipitate had been washed with alcohol and dried, it was dissolved in 60 cc. of water and a slight excess of neutral lead acetate solution was added. The dense amorphous precipitate was filtered off and washed thoroughly with water. The filtrate and washings were saved for the isolation of maninositose.

Isolation of the Organic Phosphoric Acid.—The lead salt was suspended in water, decomposed with hydrogen sulfide and the lead sulfide was filtered off and washed with water. The filtrate, after it had been concentrated under reduced pressure to a volume of about 50 cc., was neutralized with barium hydroxide. A slight amount of an amorphous precipitate separated which was filtered off and washed with water.

This precipitate, which gave a strong reaction for inorganic phosphoric acid, evidently consisted of barium phosphate and it was discarded. The colorless filtrate was mixed with an equal volume of 95% alcohol, when a white amorphous precipitate seprated. The latter was filtered off, washed with 60% alcohol and with alcohol. After the substance had been dried *in vacuo* it weighed 3.15 g. The barium salt was dissolved in a few cc. of water and the perfectly clear solution, after it had been diluted to 40 cc. with water, was precipitated by adding 40 cc. of alcohol. The snow white product after it had been filtered, washed and dried, weighed 3.1 g.

The substance did not directly reduce Fehling's solution but after it had been boiled with an acid for some time it did reduce Fehling's solution.

For analysis the barium salt was dried at 105° *in vacuo* over dehydrite.

Anal. Subs., 0.2223: $BaSO_4$, 0.1481; $Mg_2P_2O_7$, 0.0715. Subs., 0.1722: H_2O, 0.0479; CO_2, 0.0997. Found: C, 15.79; H, 3.11; P, 8.96; Ba, 39.20.

The analytical values agree approximately with the formula $C_9H_{20}O_{14}P_2Ba_2$, which might represent a mixture of equal parts of a hexosemonophosphate and glycerophos-

---

[8] Anderson, *J. Biol. Chem.*, 74,525 (1927).

[9] Throughout the various operations air was displaced by nitrogen or carbon dioxide until the fatty acids had been isolated. Freshly distilled solvents were used and the alcohol had been distilled over potassium hydroxide.

phate. It is evident, however, that the substance does pot contain any ordinary hexosemonophosphate, because it does not reduce Fehling's solution until after it has been boiled for some time with an acid. It appears most reasonable, at present, to assume that the compound contains a complex binding which is broken on boiling with acid, yielding a reducing sugar. Further work on this subject will be necessary before we can determine the definite formula of the acid as well as of its cleavage products.

Isolation of **Maninositose.**—The filtrate from the lead acetate precipitation was freed of lead by means of hydrogen sulfide and the lead sulfide was filtered off and washed with water. The clear colorless filtrate was concentrated to a sirup under reduced pressure and the sirup was washed into a beaker with 30 cc. of water. The solution was acidified with 2 cc. of glacial acetic acid and poured with constant stirring into 400 cc. of absolute alcohol, when an amorphous precipitate was obtained. The product was collected on a Buchner funnel, washed thoroughly with absolute alcohol and finally dried in a vacuum desiccator. The snow white amorphous powder weighed 4.4 g. For further purification the product can be reprecipitated a number of times in the same manner but it is recovered practically quantitatively.

The substance is optically active and on moist litmus paper it shows a neutral reaction. It has no definite melting point. When heated it begins to sinter at 100°; it begins to swell or froth at 150° without showing any noteworthy change on further heating, but above 250" it slowly darkens. When the substance is ignited it swells up and burns, leaving a very light voluminous white ash which on further heating forms a fused mass. The ash consists principally of potassium phosphate.

Rotation. 0.5998 g. of substance dried at 60° *in vacuo* over dehydrite was dissolved in water at 23° and made up to 10 cc. In a 1-dm. tube a $= +3.42°$; hence $[\alpha]^{23}_{D}$ $+57°$.

For analysis the substance was dried at 105" *in vacuo* over dehydrite. The loss in weight was 3.5%.

Anal. Found: ash, 16.27; P, 2.33; K, 3.92.

The phosphorus is present in organic combination but it is impossible to state definitely, at present, whether the phosphorus content is due to incomplete removal of the organic phosphoric acid compound or forms an integral part of the carbohydrate molecule.

Hydrolysis of **Maninositose.**—A sample of the neutral carbohydrate which had been repeatedly precipitated from dilute acetic acid with absolute alcohol was hydrolyzed. The snow white amorphous powder, which weighed 1.1 g., was refluxed with 100 cc. of 5% sulfuric acid for four hours. The faintly straw-colored solution was freed of sulfuric acid quantitatively with barium hydroxide and the barium sulfate was removed. The filtrate was concentrated under reduced pressure to 50 cc. and the solution, which showed a slight acid reaction, was neutralized with barium hydroxide. The addition of two volumes of alcohol caused a small amount of an amorphous precipitate to separate. The latter was filtered off, washed with alcohol and dried. The white powder weighed only 0.15 g. and contained organic phosphorus. The properties of the substance resembled those of barium glycerophosphate but the small quantity of the material prevented its definite identification.

Isolation of **Mannose Phenylhydrazone.**—The filtrate from the above-mentioned barium salt was freed of barium quantitatively with sulfuric acid and, after removing the barium sulfate, the filtrate was concentrated to 30 cc. On adding 1 g. of phenylhydrazine dissolved in 2 cc. of alcohol a crystalline precipitate began to separate immediately. After the mixture had stood overnight the crystals were filtered off, washed with water, alcohol and ether. The dried crystals were slightly straw-colored and they weighed 0.55 g. The substance was recrystallized from 50 cc. of hot 60% alcohol and as the solution cooled there separated slowly large colorless rhombic plates which were filtered off, washed and dried. The crystals weighed 0.35 g. and the optical properties were identical with those of mannose phenylhydrazone. The substance melted with decomposition when rapidly heated at 195–196° and there was no depression of the melting point when some of the substance was mixed with a sample of pure mannose phenylhydrazone. The crystal form and melting point definitely identify the substance as mannose phenylhydrazone.

Isolation of Inosite.—The filtrate from the crude mannose phenylhydrazone was shaken with an excess of benzaldehyde for several hours and the precipitated hydrazone was removed by filtration. The solution, after it had been extracted several times with ether, was concentrated under reduced pressure to a sirup and the latter was dried in a vacuum desiccator. A snow-white crystalline residue, free from any sirupy admixture, was obtained that weighed 0.25 g. It was dissolved in a little dilute acetic acid and brought to crystallization by the addition of alcohol. Colorless prismatic needles were obtained that weighed 0.2 g. The crystals gave the Scherer reaction and melted at 225°. There was no depression of the melting point when the substance was mixed with pure inactive inosite prepared from phytin.

It is evident from the results of this analysis that the only products obtained on hydrolyzing the neutral carbohydrate were: (a) a small quantity of a barium salt of an organic phosphoric acid which resembled barium glycerophosphate, (b) mannose, isolated as mannose phenylhydrazone, and (c) inactive inosite. We are forced to the conclusion, therefore, that the carbohydrate consists of a combination of mannose and inosite in the form of a polysaccharide or a glucoside. For want of a better name we designate the substance by the name maninositose.

Isolation of the Fatty Acids.—The alcoholic soap solution, obtained on saponifying the phosphatide, was concentrated to a volume of about 200 cc., diluted with water, acidified with hydrochloric acid, and the fatty acids were extracted with ether. The aqueous solution was saved and examined for glycerol. The ether extract was washed with water until the washings were neutral to litmus and the ether was distilled off. The residue, consisting of the mixed fatty acids, weighed 10.8 g. after it had been dried *in vacuo.* The fatty acids were not separated at this time but they were preserved for future use.

Examination of the Aqueous Solution for Glycerol and Glycerophosphoric Acid.—The acid aqueous solution, which remained after the fatty acids had been extracted, was concentrated to dryness under reduced pressure and the residue was extracted with absolute alcohol. The insoluble potassium salts were removed by filtration, the alcohol was evaporated and the residue was again extracted with absolute alcohol, filtered and diluted with an equal volume of water. The mixture was made faintly alkaline with barium hydroxide when a very slight amorphous precipitate was obtained. The precipitate was filtered off, washed with alcohol and dried. The amount of the substance was very small and since it gave a reaction for inorganic phosphoric acid it evidently consisted of barium phosphate.

The filtrate from the barium precipitate was concentrated to dryness in *vacuo.* The residue was extracted with absolute alcohol, the extract was filtered and the alcohol was distilled off when a slight sirupy residue was obtained. The sirup gave no reduction on boiling with Fehling's solution but when it was heated with acid potassium sulfate a strong odor of acrolein was noted, thus indicating the presence of glycerol.

The alcohol-insoluble potassium salts, which were mentioned above, were dissolved in water and the solution was made faintly alkaline with barium hydroxide. A slight amount of an amorphous precipitate was obtained but there was no further precipitate on adding alcohol. The precipitate gave a reaction for inorganic phosphate and it evidently consisted of barium phosphate. The results of the examination indicate that the aqueous solution contained some free glycerol and some free phosphoric acid but no glycerophosphoric acid could be isolated.

Summary

1. A study has been made of the action of hot dilute alcoholic potassium hydroxide on the phosphatide A-3 from the human tubercle bacillus. When treated in this manner the phosphatide is saponified, yielding an alcoholic soap solution of the fatty acids together with small amounts of free glycerol and phosphoric acid, while an alcohol-insoluble residue remains which consists of a mixture containing a complex organic phosphoric acid and a neutral carbohydrate.

2. The organic phosphoric acid has not been studied fully but when it is boiled with dilute acid it is hydrolyzed with the formation of a reducing sugar which has not yet been identified.

3. The neutral carbohydrate, called maninositose, represents a new type of polysaccharide or a glucoside which on hydrolysis with dilute acid yields mannose and inosite.

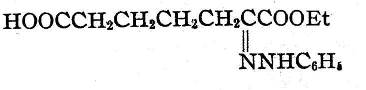
THE SYNTHESIS OF INDOLYL-BUTYRIC ACID AND SOME OF ITS DERIVATIVES

BY RICHARD W. JACKSON AND RICHARD H. MANSKE

RECEIVED SEPTEMBER 18.1930 PUBLISHED DECEMBER 18, 1930

The interest which has of late centered in the metabolism of certain indole derivatives[1,2,3] has made it desirable to prepare new members, particularly some of the higher homologs, of an already known series. For example, to make available a sequence of 3-indolyl acids among which indolyl-propionic acid has heretofore been the highest known homolog, it became desirable to construct the corresponding butyric, valeric and caproic acids. At the same time, the chemical aspects of the syntheses presented several interesting features.

The recently much exploited[4] Japp and Klingemann reaction, when applied to ethyl cyclohexane-1-one-2-carboxylate, produces an excellent yield of the half ester of the phenylhydrazone of α-ketopimelic acid (I)



$$HOOCCH_2CH_2CH_2CH_2\underset{\underset{NNHC_6H_5}{\|}}{C}COOEt$$

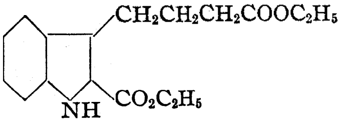
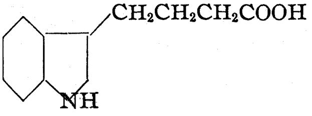
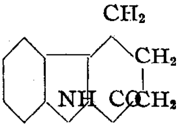
The alternative product, cyclohexane-1,2-dione monophenylhydrazone (11), is formed in only small amounts if at all. Esterification and indole ring closure of the ester (I) take place readily when it is heated in alcohol with sulfuric acid. The dibasic ester (III) thus obtained yields, on hydrolysis and decarboxylation, y-3-indolyl-butyric acid (IV)



III



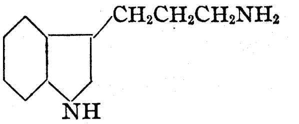
IV



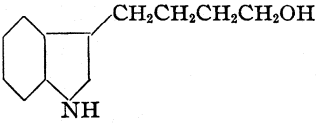
V

2-Ketotetrahydrocarbazole (V) is obtained in small amount during the decarboxylation of the dibasic acid. The temperature required for decarboxylation is presumably sufficient to induce the elimination of water—which is obviously possible and undoubtedly dependent upon the reactivity of the 2-hydrogen atom.

We have converted the indolyl-butyric acid into y-3-indolyl-propylamine (VI) via the methyl ester, the hydrazide, the azide, the urea or the urethan and the phthalimide, and thus there is established a connection between this chain of synthetic products and a substance already known (VI)[5]



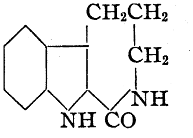
VI



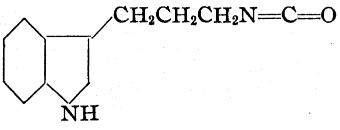
VII

Again, reduction of the ester with sodium and alcohol was found to yield δ-3-indolyl-butyl alcohol (VII); and to make the series more complete, we have, *inter alia*, prepared γ-3-indolyl-propyl alcohol by the reduction of methyl β-3-indolyl-propionate. The preparation of a lower homolog, β-3-indolyl-ethyl alcohol (the tryptophol of Ehrlich) has recently been placed on record by one of us.[6]

Lastly we attempted to synthesize the homo-3-carboline (VIII) by ring closure of the intermediary isocyanate (IX) obtained by heating the azide in an inert medium



VIII



IX

Although the similar synthesis of 2-keto-tetrahydro-3-carboline proceeds with unusual ease from the lower homologous azide,[7] our experiments in

[7] Manske and Robinson, *J. Chem. Soc.*, 240 (1927).

the present case have resulted in only a small amount of the product, which appears, nevertheless, to be the desired substance. Apparently the seven-membered ring is considerably more difficult to form.

Experimental Part

Ethyl **γ-(2-Carbethoxy-3-indolyl)butyrate.**—It was found essential to avoid delay during this preparation as far as the isolation of the phenylhydrazone. To a mixture of 76.8 g. of aniline and 200 cc. of hydrochloric acid (sp. gr. 1.2), 56 g. of solid sodium nitrite was gradually added with constant stirring. Crushed ice was kept floating in the reaction flask during the diazotization. Meanwhile an ice-cold solution of 200 g. of potassium hydroxide in 500 cc. of water was prepared; 136 g. of ethyl cyclohexanone-carboxylate was now poured over 400–500 g. of ice; to this mixture of the ester and ice were added alternately (about ten portions of each) the solutions of the potassium hydroxide and benzenediazonium chloride such that the alkali was always present in excess. Efficient stirring was provided to prevent the formation of any localized acid regions of appreciable extent, and sufficient ice was added from time to time to keep the solution quite cold. None, or at the most only a trace, of the solid potassium salt of the cyclic ester remained at the end of the condensation. The reaction mixture was next acidified with 160 cc. of hydrochloric acid (sp. gr. 1.2) previously diluted and chilled. After standing for a short while, the half ethyl ester phenylhydrazone of a-ketopimelic acid crystallized and could then be filtered and thoroughly washed by suction. It was dried first in the air and then in a vacuum desiccator. A small quantity was recrystallized with some difficulty several times from benzene; it then consisted of an orange colored powder melting at 142–143°.[8] The yield of dried product was uniformly 200 to 204 g. The Fischer indole ring closure and attendant esterification of the free carboxyl group were conveniently effected by refluxing for two and one-half hours with 500 cc. of absolute alcohol and 55 cc. of sulfuric acid (sp. gr. 1.84). The excess alcohol was next largely distilled off under reduced pressure. The oily residue was dissolved in ether–benzene, washed with water and with aqueous sodium bicarbonate and dried over calcium chloride; after the removal of the solvent, the residue was distilled *in vacuo.* The main fraction, obtained at 235° and 7 mm., crystallized on cooling. In order to remove a small amount of oil, the distillates from three runs were united, warmed with 100 cc. of benzene to dissolve nearly all of the ester, cooled and cautiously treated with 400 cc. of petroleum ether. When crystallization was complete, the solid was filtered off and washed with petroleum ether. The yield of colorless product melting at 75–76" was 278 g. (38% of the theoretical calculated on the amount of cyclic ester employed). Recrystallization from benzene–petroleum ether yielded the ester in long needles, melting sharply at 76°.

Anal. Calcd. for $C_{17}H_{21}O_4N$: C, 67.33; H, 6.93; N, 4.62. Found: C, 67.54; H, 7.09; N, 4.75.

The methyl **ester,** although never obtained in as good yield, was prepared from methyl cyclohexanone-carboxylate in a strictly analogous way. The recrystallized ester consisted of colorless fine elongated plates melting at 64°.

Anal. Calcd. for $C_{15}H_{17}O_4N$: N, 5.09. Found: N, 4.74.

During the early part of the distillation of the ethyl and methyl esters described above a colorless crystalline substance sublimed into the condenser and the top of the distillation flask. The identity of the products secured from the two distillations was suspected from their appearance and proved by a mixed melting point determination.

---

[8] All recorded melting points are corrected.

Furthermore, the same substance was obtained during the preparation of the lower homologous ester from ethyl cyclopentanone-carboxylate, and a compound of analogous nature was obtained during the course of some unpublished work on the preparation of several methoxy-indole compounds.

Analytical figures and subsequent mixed melting point determination proved the substance in question to be *sym.*-diphenyl-urea (m. p. 240°).

Anal. Calcd. for $C_{13}H_{12}ON_2$: C, 73.58; H, 5.66; N, 13.21. Found: C, 73.82; H, 5.86; N, 13.18.

At present we are not prepared to submit a rational mechanism to account for the universal production of ureas under the conditions of our experiments.

γ-(2-Carboxy-3-indolyl)-butyric Acid.—The hydrolysis of the methyl and ethyl esters of this acid proceeded readily in dilute alcoholic alkali. Subsequent acidification gave quantitative yields of the acid. It was obtained from approximately 50% acetic acid in minute stout prisms melting at 193–194° with loss of carbon dioxide.

Anal. Calcd. for $C_{13}H_{13}O_4N$: N, 5.67. Found: N, 5.56.

Methyl γ-3-Indolyl-butyrate.—The dibasic acid (106 g.) was decarboxylated by heating in an oil-bath at 220° until the evolution of carbon dioxide slowed down somewhat; the decomposition of the melt was completed by elevating the temperature of the bath to 230° for fifteen minutes. The product was esterified by heating under reflux for two hours with 200 cc. of absolute methyl alcohol and 4 cc. of sulfuric acid. The ester isolated in the usual way distilled at 230° at 6 mm.; the yield was 83 g. A small amount of unchanged acid was recovered from the alkaline wash water. The ester solidified completely on cooling and when recrystallized from benzene–petroleum ether was obtained in colorless glistening plates which melted at 73–74°.

Anal. Calcd. for $C_{13}H_{15}O_2N$: C, 71.89; H, 6.91. Found: C, 72.28; H, 7.01.

γ-3-Indolyl-butyric Acid.—The crude decarboxylation residue obtained as described above is difficult to purify directly. It was found more convenient to prepare the monobasic acid by hydrolyzing the distilled methyl ester with alcoholic potash. The acid regenerated from the alkaline solution by acidification was first recrystallized from a large volume of water or from dilute alcohol but the product then tenaciously retained small quantities of water which depressed the melting point several degrees. Recrystallization from a mixture of benzene and petroleum ether gave colorless plates melting sharply at 124°.

Anal. Calcd. for $C_{12}H_{13}O_2N$: N, 6.90. Found: N, 6.77.

The hydrolysis of the monomethyl ester yielded in addition to the acid a small amount of unsaponifiable product which proved to be 2-keto-2,3,4,5-tetrahydrocarbazole the properties of which were first placed on record by Coffey.[9] Recrystallized from alcohol, it melted at 166°. The azine melted at 248°. These melting points agree with those reported by Coffey.

γ-3-Indolyl-butyric Hydrazide.—A mixture of 40 g. of 50% hydrazine hydrate, 54 g. of methyl indolyl-butyrate and 60 cc. of alcohol was placed in a flask equipped with an air-cooled reflux condenser and gradually heated in an oil-bath until the temperature rose to 130°. At the end of an hour, the condenser was removed and the temperature of the bath raised to 140–150° to effect the removal of water, alcohol and excess hydrazine. The product, which crystallized upon standing, was filtered off and washed with cold alcohol. In addition to the first yield of 35 g., a small amount was recovered by evaporating the filtrate. After one recrystallization from alcohol, the hydrazide melted sharply at 112°.

---

[9] Coffey, *Rec. trav. chim.*, **42**, 531 (1923).

Anal. Calcd. for $C_{12}H_{16}ON_3$: N, 19.36. Found: N, 19.27.

Di-(γ-3-indolyl-propyl)-urea.—A cooled solution of 10 g. of the above hydrazide in 50 cc. of acetic acid was treated in rapid succession with 200 g. of ice and 4 g. of sodium nitrite dissolved in a small volume of water. The precipitated and washed azide was added in small portions to boiling water and the mixture finally heated until no more decomposition was apparent. The oily urea was washed by decantation and then freed of remaining acid and easily saponifiable matter by heating for a short time with alcoholic potash. The product precipitated by the addition of water was washed with water, dried and then heated under reflux with norite in a large volume of ethyl acetate. The clear filtered solution on evaporation yielded a pale oily residue which crystallized on cautious treatment with ether. The crystals were filtered off, washed with a mixture of ethyl acetate and ether and recrystallized from the same solvents. The yield was 2.3 g. As thus obtained the urea consists of pale yellow plates melting at 124°.

Anal. Calcd. for $C_{23}H_{26}ON_4$: N, 14.97. Found: N, 14.73.

Methyl y-3-Indolyl-propyl-carbamate.—The azide prepared as described above was dissolved in benzene. The solution was clarified with sodium sulfate and then evaporated under reduced pressure at room temperature with frequent addition of dry benzene until all moisture had been removed. The pale yellow residue was treated with 75 cc. of absolute methyl alcohol. The solution was gently warmed until the first vigorous evolution of nitrogen subsided and then heated under reflux for twelve hours with a generous amount of norite. The clear filtrate was then repeatedly evaporated with dry benzene to remove the excess methyl alcohol. The resulting oily residue was taken up in 250 cc. of dry ether. A small amount of insoluble material was filtered off and the filtrate evaporated. Treatment with alcoholic potash removed only inappreciable impurities. Since the urethan could not be induced to crystallize, it was finally distilled in *vacuo* to give 8 g. of an almost colorless and very viscous sirup. This set to a glass on cooling and failed to crystallize in contact with various solvents. Its conversion to the phthalimide is proof of its structure.

γ-3-Indolyl-propyl-phthalimide.—For this preparation, both the urea and the urethan were found to suffice. A mixture of either substance with an equal weight of phthalic anhydride was heated in an oil-bath, finally at 230°, until effervescence ceased. The partially cooled mixture was dissolved in alcohol. The phthalimide was precipitated, while acid products were held in solution, by cautious treatment with sodium carbonate solution. The crystallized product was filtered off, thoroughly washed and recrystallized from hot alcohol, in which it is sparingly soluble. The yield of pure product consisting of pale yellowish plates and melting at 132° was nearly the theoretical amount. It is almost insoluble in ether.

Anal. Calcd. for $C_{19}H_{16}O_2N_2$: N, 9.21. Found: N, 9.03.

The mother liquors from the preparation of the urea were also suitable for making the phthalimide, which in this case was quite pure after two recrystallizations.

γ-3-Indolyl-propyl-amine.—Hydrolysis of the phthalimido compound to the amine was readily accomplished by heating with a slight excess of hydrazine in dilute alcohol. When solution was completed, the alcohol was evaporated and the aqueous solution clarified by filtration through a layer of norite. The phthalyl hydrazide obtained on acidification was filtered off. The amine was then extracted from the basified filtrate. The ethereal extract was dried over potassium hydroxide and concentrated. The residue dissolved in a small volume of acetone was carefully neutralized with dry hydrogen chloride in ether. The crystalline hydrochloride was filtered off and washed with acetone and with ether. A very good yield was secured. In agreement with data reported by Majima and Hoshino,[5] the hydrochloride melted sharply at 170°.

Anal. Calcd. for $C_{11}H_{14}N_2 \cdot HCl$: N, 13.30. Found: N, 13.06.

γ-3-Indolyl-propyl Alcohol.—To 10.2 g. of methyl β-3-indolyl-propionate dissolved in 250 cc. of absolute alcohol[10] was added 17 g. of sodium. The reaction finally was completed by heating for a short time on a steam cone. Water was added and the alcohol distilled off. The alkaline solution was extracted with ether. The residue secured by the evaporation of the ether was distilled *in vacuo* to give 6 g. of a colorless viscous oil. Further purification was effected by conversion to the picrate which on two recrystallizations from benzene was obtained in brick-red stout needles melting at 101°. The alcohol regenerated from the picrate by decomposition with alkali and distilled a second time *in vacuo* was an almost colorless oil which crystallized completely at 0° but which became liquid again at room temperature.

Anal. Calcd. for $C_{11}H_{13}ON$: N, 7.99. Found: N, 7.83.

The alcohol was further characterized by conversion to the phenylurethan formed when the alcohol was heated with a slight excess of phenyl isocyanate. The reaction mixture crystallized readily after it was washed several times with petroleum ether. The derivative was crystallized from hot benzene, in which it is only moderately soluble when cold, to give colorless plates melting at 94°.

Anal. Calcd. for $C_{18}H_{18}O_2N_2$: N, 9.52. Found: N, 9.38.

δ-3-Indolyl-butyl Alcohol.—The reduction of methyl y-3-indolyl-butyrate (85 g.) with sodium (92 g.) and absolute alcohol (1100 cc.) in the manner described above for the lower homolog yielded 57 g. of practically colorless distillate which, on cooling and seeding with a crystal previously prepared from a specimen regenerated from the purified picrate, set to a solid mass of crystals. The material developed a slight reddish color after standing for some time.

The picrate crystallized first from dilute alcohol and then twice from benzene was obtained in ruby-colored needles melting at 102°. The alcohol liberated from the picrate by treatment with alkali was obtained as a colorless oil which slowly crystallized. A small portion plated out on porous tile melted at 32–33°.

Anal. Calcd. for $C_{12}H_{15}ON$: N, 7.40. Found: N, 7.34.

The phenylurethan recrystallized from benzene–petroleum ether melted at 88°. It is readily soluble in the ordinary organic solvents except petroleum ether.

Anal. Calcd. for $C_{19}H_{20}O_2N_2$: N, 9.11. Found: N, 9.14.

There was recovered 13 g. of indolyl-butyric acid on acidifying the alkaline solution remaining from the preparation of the corresponding alcohol. The yield of alcohol based on the ester actually used up was, therefore, 89%.

2-Keto-2,3,4,5-tetrahydro-homo-3-carboline (VIII).—The dried benzene solution of the azide prepared as described under preparation of the methylurethan (p. 5033) was gently heated on the steam-bath until evolution of nitrogen was complete. A stream of dry hydrogen chloride was passed into the solution and heating continued. A considerable amount of resin was precipitated. The clear benzene solution was evaporated to a thin sirup and the crystalline product which separated in the course of several days filtered off and washed with cold alcohol. It was recrystallized first from hot alcohol and then from acetone and was obtained in fine microcrystalline needles melting at 220". The yield was only about 5% of the theoretical. It does not give a color with Ehrlich's reagent immediately but on prolonged boiling a cherry-red color is slowly developed. This behavior is interpreted to signify the opening of the lactam ring with subsequent decarboxylation, the latter process being analogously observed with the similar treatment of other 3-alkylated indole-2-carboxylic acids.

Anal. Calcd. for $C_{12}H_{12}ON_2$: C, 71.96; H, 6.05; N, 13.99. Found: C, 72.12; H, 6.26; N, 13.97.

---

[10] Smith, *J. Chem. Soc.*, 1288 (1927).

Experiments are in progress for converting the indolyl-butyl alcohol into the *p*-toluenesulfonyl derivative with the object in view of condensing the latter with ethyl sodio-malonate[11] to obtain indolyl-caproic acid on hydrolysis and decarboxylation. We have succeeded, thus far, in securing a small amount of δ-3-indolyl-butyl malonic acid. It consists of colorless crystals melting at 177°.

Anal. Calcd. for $C_{15}H_{17}O_4N$: C, 65.43; H, 6.23; N, 5.09. Found: C, 65.47; H, 6.23; N, 5.10.

The main product by far from these reactions, however, was found to be present in a neutral fraction secured by ether extraction of an alkaline hydrolysate. The residue from this ether when distilled *in vacuo,* plated out on a porous tile and finally recrystallized from 70% alcohol yielded glistening, colorless plates which alone, or admixed with an authentic specimen of tetrahydrocarbazole prepared for comparison, melted at 117°. Further comparison of the neutral material by means of Ehrlich's color reaction failed, likewise, to disclose any difference.

Whether the ring closure is effected by the action of the acyl chloride directly on the alcohol or whether the toluene-sulfonyl ester eliminates toluene-sulfonic acid in the presence of the hot alcoholic sodium ethylate, we are not prepared to say at present. The latter course would appear to be the more likely one. In any case, however, the mechanism appears to he much the same. We are not familiar with strictly analogous examples of ring closure; the paucity of reactions of this kind is due not only to the lack of suitable orientation but also, we believe, to the absence of sufficient reactivity on the part of the hydrogen atom which must be eliminated along with the hydroxyl group as water.

Summary

1. The synthesis of indolyl-butyric acid has been effected through a procedure involving the application of the Fischer indole ring closure to the phenylhydrazone secured by subjecting ethyl cyclohexanone-carboxylate to the Japp and Klingemann reaction.

2. Along with various other derivatives, indolyl-propyl and -butyl alcohols and 2-keto-2,3,4,5-tetrahydro-homo-3-carboline were prepared. Indolyl-propylamine was synthesized via a new group of indole compounds.

3. The reactivity of the 2-hydrogen atom in the indole ring has been emphasized in light of the formation of 2-ketotetrahydrocarbazole and tetrahydrocarbazole as by-products of certain reactions employed.

4. Indolyl-butylmalonic acid has been synthesized.

THE REPLACEMENT OF HALOGEN BY HYDROGEN IN ALPHA HALO-KETONES UNDER THE INFLUENCE OF THE GRIGNARD REAGENT

BY C. HAROLD FISHER, THOMAS S. OAKWOOD AND REYNOLD C. FUSON

RECEIVED SEPTEMBER 18,1930 PUBLISHED DECEMBER 18, 1930

The action of the Grignard reagent on certain alpha halo-ketones has been under investigation in this Laboratory in connection with the study of the coupling action of the Grignard reagent on certain types of halogen compounds.[1] The results obtained so far have been to some extent anticipated by Lowenbein and Schuster[2] in an article which has just appeared. For this reason our work, although not fully completed, is being reported in its present form.

In our work the original object in view was to extend if possible the coupling reaction to other types of active halogen compounds. Only the benzyl halides and their derivatives had been used in previous studies. Inasmuch as a-halo-ketones have a very reactive halogen atom, it seemed likely that the coupling reaction might take place when compounds of this type were treated with the Grignard reagent. Experiments with w-bromo-acetophenone showed that the great rapidity with which the carbonyl group was attacked by the Grignard reagent precluded the possibility of testing the behavior of the a-halogen atom toward this reagent. It was found possible, however, to get around this difficulty by introducing substituents into the two ortho positions, thus effectively inhibiting the tendency of the carbonyl group to undergo addition reactions. Further, in order to avoid the possibility of enolization, the a-hydrogen atoms were replaced by methyl groups. The compound eventually obtained which fulfilled all of these requirements was α-3,5-tribromo-2,4,6-trimethylisobutyrophenone (III).

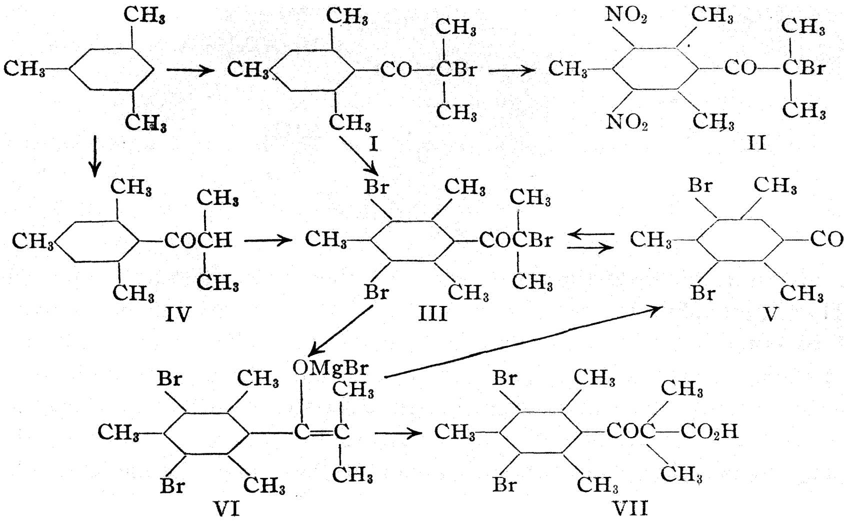
This compound was prepared in two ways. The method first used involved the synthesis of α-bromo-2,4,6-trimethylisobutyrophenone (I) from mesitylene and a-bromoisobutyryl chloride by use of the method of Friedel and Crafts. The monobromo compound was low-melting and for this reason difficult to study. Its dinitro derivative (II) was prepared as a check on the structure. By direct bromination of I was obtained the tribromo compound (III) which was used in the Grignard study. This compound was prepared more advantageously from isobutyrylmesitylene (IV) by direct bromination.

When this a-bromo ketone was treated with methylmagnesium chloride or ethylmagnesium bromide neither coupling nor alkylation was observed.

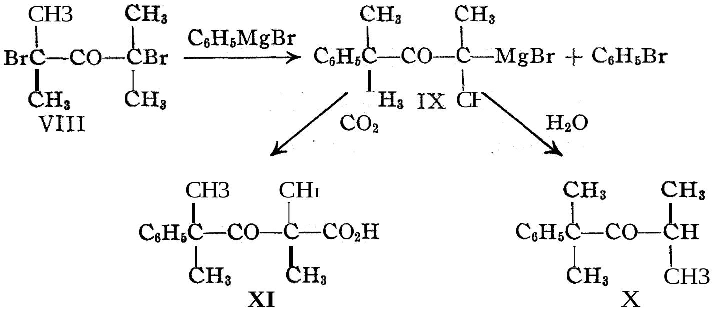
---

[1] For earlier papers in this field see Fuson, THIS JOURNAL, 48, 830, 2681, 2937 (1926).

[2] Lowenbein and Schuster, Ann., 481, 106 (1930).

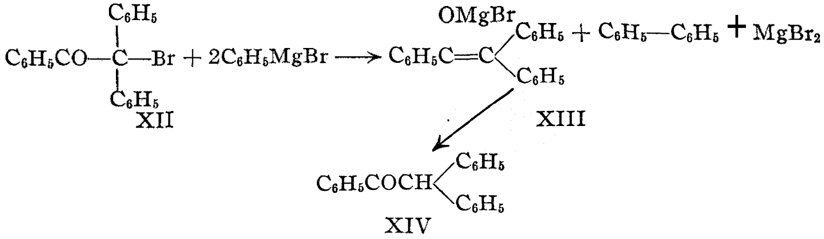


Instead the bromine was smoothly replaced by hydrogen. This result resembles that obtained by Umnova[3] who showed that when α,α'-dibromoisobutyrone (VIII) was treated with phenylmagnesium bromide there resulted a Grignard reagent having the formula IX. The simultaneous production of bromobenzene seems to establish this reaction as one of alkylation and radical interchange. The structure of IX was assigned on the basis of its reaction with water and with carbon dioxide* followed by water. In the first case the product was α-phenylisobutyrone (X) and in the second, α,α,γ-trimethyl-γ-phenyl-β-keto-valeric acid (XI).



Lowenbein and Schuster, in the investigation mentioned above, worked with benzoyldiphenylmethyl bromide (XII). With phenylmagnesium bromide this compound reacted to give diphenyl and the bromomagnesium enolate of triphenylethanone (XIII). The last-named compound when treated with water gave triphenylethanone (XIV).

[3] **Umnova,** *J. Russ. Phys.-Chem. Soc.*, 45,881 (1913).



It will be noted that these authors write their intermediate compound (XIII) as an enolate instead of as a true Grignard reagent such as Umnova used to explain the reaction with carbon dioxide (IX). Our results in the present work with α,3,5-tribromo-2,4,6-trimethylisobutyrophenone seem to parallel those of Lowenbein and Schuster rather than those of Umnova. When treated with methylmagnesium chloride or with ethylmagnesium bromide, the tribromo compound (III) gave the enolate, VI. This when treated with water gave 3,5-dibromo-2,4,6-trimethylisobutyrophenone (V). The structure of V follows from the fact that bromination converted it into α,3,5-tribromo-2,4,6-trimethylisobutyrophenone, from which it could be regained by reduction with zinc dust. Treatment with carbon dioxide, however, failed to convert VI into α,α-dimethyl-β-keto-β-(2,4,6-trimethyl-3,5-dibromophenyl)-propionic acid (VII). The reaction of our intermediate compound (VI) with benzoyl chloride, carbon dioxide and other typical reagents for the detection of the Grignard reagent is being further investigated.

Experimental Part

a-Bromoisobutyrylmesitylene (I).—A mixture of 50 g. (0.22 mole) of a-bromoisobutyryl bromide, 26 g. (0.22 mole) of mesitylene and 170 g. of carbon disulfide was placed in a 500-cc. three-necked flask equipped with a mercury-sealed stirrer and a reflux condenser with a tube to carry off the evolved hydrogen chloride. Through the remaining side neck of the flask was added in small portions over a period of one and one-half hours 40 g. of anhydrous aluminum chloride. The reaction flask was kept in an ice-water bath and the stirring was continuous throughout the period of addition of the aluminum chloride and for an hour afterward. A dark red color developed during the addition; this color gradually faded to a light red toward the end of the reaction.

The product was poured on cracked ice and a vigorous reaction took place. The crude product when distilled came over at 145–175° at 24 mm. Redistillation gave 41 g. of a golden-brown oil boiling at 160–170° at 24 mm. The yield was 69.5% of the theoretical. On long standing the oil deposited crystals of the α-bromoisobutyryl mesitylene, melting at 27°.

Anal. Calcd. for $C_{13}H_{17}OBr$: Br, 29.79. Found: Br, 29.22.

α,3,5-Tribromo-2,4,6-trimethylisobutyrophenone (III).—The a-bromoisobutyrylmesitylene described above was brominated by treatment with bromine in ice water. The oil boiling at 160–170° at 24 mm. was covered by a layer of water and cracked ice and an excess of bromine was added. During the addition of the bromine the mixture was shaken vigorously. The oil became very viscous and finally set to a solid. This was treated with a solution of sodium bisulfite to remove excess bromine. The product crystallized from 95% alcohol in colorless needles melting at 106–107° (corr.). The yield was nearly quantitative.

Anal. Calcd. for $C_{13}H_{15}OBr_3$: Br, 56.2. Found: Br, 56.1.

α-Bromo-3,5-dinitro-2,4,6-trimethylisobutyrophenone (II).—Four and one-half grams of a-bromoisobutyryl mesitylene was added slowly with agitation to a mixture of 10 cc. of concentrated nitric acid and 15 cc. of concentrated sulfuric acid. The temperature rose but was kept below 60° by immersion of the container in cold water. On standing for fifteen minutes the emulsion which had formed separated into two layers; the upper layer was orange in color and contained a finely divided solid, The reaction mixture was poured into cold water; a white solid came out. Thick needles melting at 117.8–118.5° were obtained after several recrystallizations from alcohol.

Anal. Calcd. for $C_{13}H_{15}O_5BrN_2$: Br, 22.3. Found: Br, 22.4.

α,3,5-Tribromo-2,4,6-trimethylisobutyrophenone (III) (Second **Method).**—It was found that this preparation could be carried out more conveniently by direct bromination of isobutyrylmesitylene. The procedure used was essentially that described in the preparation by the first method. A mixture of the products from the two sources showed no depression of the melting point.

The Action of **Methylmagnesium** Chloride on **α,3,5-Tribromo-2,4,6-trimethyliso**-butpophenone.—A solution of 9 5 g. (0.022 mole) of the tribromo ketone in 125 cc. of ether was added dropwise and with stirring (mercury-sealed stirrer) to a three-fold excess of the Grignard reagent contained in a three-necked flask. During the addition, which required about thirty minutes, the reaction mixture boiled gently without external heating. When the addition was complete the stirring and refluxing (from external heat) were continued for two and one-half hours. Cold dilute hydrochloric acid was added; this caused violent refluxing if added rapidly. The clear, colorless ether layer was washed twice with water and the ether carried off by a stream of air, leaving a white solid. All of the solid dissolved in hot 70% alcohol. On cooling the solution deposited a crystalline solid which melted at 62–64". Further recrystallization from methyl alcohol changed the melting point to 70–71° (corr.). This product was found to be 3,5-dibromo-2,4,6-trimethylisobutyrophenone (IV) by the reaction described below. The yield was 5.5 g. or 71% of the theoretical.

3,5-Dibromo-2,4,6-trimethylisobutyrophenone.—Five-tenths gram of the pulverized product and an excess of bromine were intimately mixed in a test-tube cooled by an ice–salt mixture. After ten minutes a solution of sodium bisulfite was added to remove excess bromine. After one recrystallization from alcohol 0.6 g. of a solid melting at 102–104.5" was obtained. This was shown to be α,3,5-tribromo-2,4,6-trimethylisobutyrophenone by the method of mixed melting points

Anal. Calcd. for $C_{12}H_{16}OBr_2$: Br, 46.0. Found: Br, 45.7

Reduction of α,3,5-Tribromo-2,4,6-trimethylisobutyrophenone with Zinc and Acetic Acid.—The method used was similar to that which Stephen and Weizmann[4] used to reduce ω-chloro-2,4-dihydroxy-acetophenone. One and one-half grams of the tribromo ketone, 4 cc. of glacial acetic acid, 16 cc. of water, and 100 cc. of 95% ethyl alcohol were placed in a 200-cc. flask fitted with a reflux condenser, and the temperature of the water-bath surrounding the flask was brought to 60°. Five grams of zinc dust was added and the temperature of the water-bath maintained at 60° for one hour, when 16 cc. of water and 4 cc. of acetic acid were again added. The temperature was kept at 60° for five additional hours.

The zinc dust was filtered, part of the solvent evaporated and water added, which

---

[4] Stephen and Weizmann, J. Chem. *Soc.*, **105,** 1050 (1914).

caused the precipitation of a fine white solid. Two extractions with ether were made and the ether was allowed to evaporate. The residue after several recrystallizations from methyl alcohol melted at 69–70°. This was shown to be 3,5-dibromo-2,4,6-trimethylisobutyrophenone by the method of mixed melting points.

The Action of Ethylmagnesium Bromide on α,3,5-Tribromo-2,4,6-trimethylisobutyrophenone.—Several experiments similar to that described for methylmagnesium chloride were run with ethylmagnesium bromide. The tribromo compound was in all cases smoothly converted into the dibromo compound. In two runs the reaction mixture was treated for long intervals with carbon dioxide before being decomposed with water. The product was the same as in those runs in which no carbon dioxide was used. No acid could be isolated in any case.

Summary

α,3,5-Tribromo-2,4,6-trimethylisobutyrophenone (III) has been prepared by the bromination of isobutyrylmesitylene (IV) and of α-bromoisobutyrylmesitylene (I).

Treatment with methylmagnesium chloride or ethylmagnesium bromide transformed the tribromo compound (III) into an enolate (VI) which reacted with water to give 3,5-dibromo-2,4,6-trimethylisobutyrophenone (V).

The structure of the dibromo compound (V) was proved by its synthesis from III by zinc reduction and by the fact that bromination reconverted it into the tribromo compound.

THE NITRATION OF SYM.-DIPHENYLETHANE[1,2]

BY WM. H. RINKENBACH[3] AND H. A. AARONSON[4]

RECEIVED SEPTEMBER 19, 1930 PUBLISHED DECEMBER 18, 1930

Although various workers have reported the preparation and properties of a number of nitro derivatives of symmetrical diphenylethane (dibenzyl), it was considered advisable to carry out a more thorough investigation of the nitration of this compound. The object of this study was to determine the practicability of preparing the symmetrical hexanitro derivative by direct nitration, although it was considered probable that steric hindrance would prevent the formation of a high yield of hexanitrodiphenylethane.

Several dinitrodiphenylethanes are recorded in the literature, the 4,4′-dinitro compound being the most important. Stelling and Fittig[5] prepared this compound by the direct nitration of diphenylethane with nitric acid (sp. gr. 1.52) and reported the simultaneous formation of the 2,4′-

[5] Stelling and Fittig, Ann., 137, 260 (1866).

dinitro compound. It has been found possible to obtain 4,4'-dinitrodiphenylethane with a yield of 95% of the theoretical by the use of nitric acid having a specific gravity of only 1.42 according to the following procedure.

Thirty-five grams of diphenylethane was added to 105 g. of nitric acid (sp. gr. 1.42). There was no appreciable evolution of heat. The mixture was slowly heated and the temperature was maintained between 70 and 80° for six hours while being stirred. At the end of this time an oily layer below the spent acid was visible. After cooling, the mixture was drowned in ice water, filtered on a Büchner funnel and the retained nitro compound was washed thoroughly with water, air-dried and weighed; yield, 50.0 g. as compared with 52.5 g. calcd. This material was purified by repeated recrystallization from ethanol.

The pure 4,4'-dinitrodiphenylethane so obtained was in the form of light yellow needles which were found to melt at 180.5° (corr.). The melting point of this compound has been reported as being 178[6] 180–182[7] and 182°[8] by various workers, and particular care was taken in determining the above value with a thermometer calibrated by the U. S. Bureau of Standards.

Braun and Rawicz[9] reported the preparation of 2,4,2',4'-tetranitrodiphenylethane, obtaining a 70% yield of this compound when diphenylethane was added to ten times its weight of fuming nitric acid (sp. gr. 1.53) at −15°, allowing to stand at room temperature for one hour, and drowning in ice water. It was found possible to obtain 2,4,2',4'-tetranitrodiphenylethane with a yield of 90 to 95% by the use of the following procedure: 50 g. of diphenylethane was added slowly to 500 g. of fuming nitric acid (95%) which was stirred continuously and maintained at a temperature lower than 30°. When the mixing was complete the temperature was slowly raised to about 70° in the course of two and one-half hours, and maintained at this point for four hours. After cooling and standing overnight, heating at 70° was continued for two hours. Stirring was continued for two hours during cooling. The mixture was then drowned in ice water and filtered through a Büchner funnel. The retained solid was washed thoroughly with water to remove acid and with alcohol to remove any unnitrated diphenylethane. air-dried and found to weigh 91 g. Repeated recrystallizations of this material from benzene and toluene yielded pale yellow needles.

The pure compound so prepared was found to melt at 170.9° (corr.) as compared with the value 168–169° reported by Braun and Rawicz. It is insoluble in hot or cold ethanol, slightly soluble in ether or chloroform and appreciably soluble in hot benzene, toluene, acetone, acetic acid, ethylene dichloride or acetylene tetrachloride. It is nonhygroscopic and explodes in five seconds when heated at 380°. In spite of this, the compound is not detonated by the impact of a 2 kg. weight falling 34 inches; nor is it detonated by 0.4 g. of mercury fulminate or by 0.4 g. of tetryl with 0.23 g. of mercury fulminate in the sand test. However, when 0.40 g. of cyclotrimethylenetrinitramine with 0.23 g. of mercury fulminate is used, detonation takes place and the tetranitrodiphenylethane is found to crush 21 g. of sand as compared with 30 g. crushed by the same weight of trinitrotoluene.

Several attempts to prepare 2,4,2',4'-tetranitrodiphenylethane by the use of mixtures of sulfuric and nitric acids gave negative results. The diphenylethane was dissolved in 95% or in fuming (103%) sulfuric acid by heating to 110° and, after cooling,

---

[6] Leppert, Ber., 9, 15 (1876)

[7] Green, Davies and Horsfall, J. Chem. *Soc.*, 91, 2079 (1907).

[8] W. Will, *Ber.*, 47, 704 (1914).

[9] Braun and Rawicz, *ibid.*, 49, 802 (1916).

a mixture of 95% sulfuric and fuming nitric (95%) acids or of fuming sulfuric and fuming nitric acids was added. After heating at 80 to 100° for from two to four hours, the mixture was cooled and drowned in ice water. Very little separation of solid material resulted and only a small quantity of the tetranitro compound was recovered. Only traces of other compounds were obtained by extracting the water solutions with organic solvents, neutralizing with sodium carbonate and extracting again. It would appear that the use of mixed acids for nitration results in almost complete decomposition of the diphenylethane.

The only reference to a nitro derivative of diphenylethane higher than the tetranitro compound found in the literature is a statement by Will[8] that 2,4,6,2',4',6'-hexanitrodiphenylethane is readily formed by the nitration of the dinitro compound and can also be prepared by the oxidation of 2,4,6-trinitrotoluene in the presence of alkalies. He gave no details of either method, but gave the melting point of the hexanitro compound as 212°.

Further nitration of tetranitrodiphenylethane by the use of fuming nitric acid or mixtures of fuming nitric and sulfuric acids caused no additional nitration, the unchanged tetranitro compound being recovered in each case. A number of attempts to prepare the hexanitro compound by the oxidation of trinitrotoluene in the presence of alkalies, using the method of Green, Davies and Horsfall,[7] gave negative results, even with the addition of ammonium persulfate to the solution. An effort to replace one or more hydrogen atoms of the methylene groups with the nitrate group was made, using the method of Walther and Wetzlich.[10] These workers found that hydrobenzoin dinitrate was formed by boiling diphenylethane with silver nitrate in glacial acetic acid; but when 2,4,2',4'-tetranitrodiphenylethane was substituted for diphenylethane in this procedure, only the unchanged tetranitro compound was recovered.

It was considered possible that a preliminary sulfonation of tetranitrodiphenylethane over an extended period might render nitration possible. A new compound was prepared by the following procedure: 142 g. of tetranitrodiphenylethane was added to 100 g. of fuming sulfuric acid (103%), and the temperature was maintained at 85° for four days. After cooling, 500 g. of fuming nitric acid (95%) was added, and the temperature was slowly raised to 85°. This temperature was maintained for two days, and the mixture was then cooled and drowned in ice water. The separated solid was caught on a Büchner funnel, washed thoroughly with water and air-dried. The weight was found to be 100 g.

On recrystallizing from toluene, the solution became black and the deposited crystals were contaminated with a dark material. Washing with alcohol and with ether removed this and when the alcohol and ether solution was evaporated to dryness, a few grams of a black, gummy residue was obtained. Repeated recrystallization of the crystalline material from toluene gave a pure product consisting of fine, pale cream-colored needles which melted at 187.3'.

Because of the melting point, the material prepared as described above was thought to be a new compound, and investigation showed it to be α-2,4,5-trinitrophenyl-β-2,4-dintrophenylhydroxyethane. The constitution of the compound was established by analysis.

Anal. Calcd.: C, 39.38; H, 2.14; N, 16.56. Found: C, 39.58; H, 2.38; N, 16.56.

From these results the empirical formula $C_{14}H_{10}N_5O_{11}$ was calculated, while that of the pentanitrohydroxy compound is $C_{14}H_9N_5O_{11}$. Since the empirical formula of the tetranitro compound is $C_{14}H_{10}N_4O_8$, it appeared probable that the new compound contained only nine hydrogen atoms, since

---

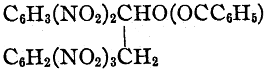
[10] Walther and Wetzlich, J. *prakt. Chem.*, 61, 174 (1854).

one nitrogen and three oxygen atoms had been added. The value found by the determination of hydrogen is believed to be high because of the difficulty in obtaining accurate results with so small a percentage present, but is within the experimental error. If this is granted, it is apparent that either a nitrate (NO_3) group has replaced one of the hydrogen atoms of the ethylene linkage, or a nitro (NO_2) group has replaced a hydrogen atom in one of the benzene rings and an oxygen atom has been added to the ethylene linkage or formed a phenol derivative.

Molecular weight determinations, with trinitrotoluene as the solvent, gave values of 417 and 427 (av., 422) as compared with 423 for α-2,4,5-trinitrophenyl-β-2,4-dinitrophenylhydroxyethane and 407 for pentanitrodiphenylethane. This confirms the presence of eleven oxygen atoms instead of the ten required for a pentanitro derivative.

A diphenylamine–sulfuric acid test for the presence of a side-chain nitrate or nitrite group gave a negative result. The sodium hydroxide test for a phenolic group[u] also gave a negative result. These results indicate that a nitro group has been substituted in one of the benzene rings and that the additional oxygen is attached to the ethylene linkage, probably to form a –CHOH– group.

The presence of a non-phenolic hydroxyl group was confirmed by treatment with benzoyl chloride in pyridine solution. A brownish powder melting at about 200° with decomposition was obtained. This was found to have a nitrogen content of 13.68% as compared with a theoretical value of 13.3% for



$$\begin{array}{l} C_6H_3(NO_2)_2CHO(OCC_6H_5) \\ \qquad\qquad\quad | \\ C_6H_2(NO_2)_3CH_2 \end{array}$$

These results indicate that two nitro groups are attached to one benzene ring, three to the other, and that one of the CH_2 groups had been oxidized to a CHOH group. The problem of determining the position of the third nitro group in one benzene ring and the position of the CHOH group with reference to the trinitrophenyl group was attacked as follows.

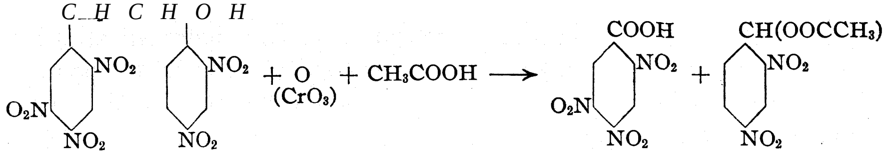
A portion of the pentanitrohydroxy compound was placed in a solution of chromic oxide in glacial acetic acid and the solution was boiled under a reflux condenser for sixty-two hours. After cooling, two compounds were isolated. One was slightly contaminated with the second, but melted at 188° and had a nitrogen content of 16.08%. This is believed to be sufficient identification as 2,4,5-trinitrobenzoic acid, which melts at 190–191° and has a nitrogen content of 16.35%.

The second compound did not melt even when heated to 275° and contained 11.16% of nitrogen. That it was an acetic ester was shown by hydrolyzing it with sulfuric acid in the presence of ethanol, when ethyl acetate was formed. This indicates that this compound has the constitution $C_6H_3(NO_2)_2CH(OOCCH_3)$, the theoretical nitrogen content of which is 11.72%.

---

[11] Mulliken, "Identification of Pure Organic Compounds," John Wiley and Sons, Inc., New York, Vol. I, p. **87.**

The foregoing facts indicate that the compound under investigation is α-2,4,5-trinitrophenyl-β-2,4-dinitrophenyl-hydroxyethane and that treatment with chromic oxide and glacial acetic acid gave rise to the reaction



This compound is very slightly soluble in alcohol or ether, but is appreciably soluble in hot benzene, toluene, acetone, ethylene dichloride or acetylene tetrachloride. When heated at 360°, it explodes in five seconds and explodes when subjected to the impact of a 2-kilogram weight falling 18 inches or more. It cannot be detonated by 0.4 g. of mercury fulminate, but when initiated with 0.25 g. of tetryl and 0.25 g. of mercury fulminate in the sand test, it crushes 21 g. of sand.

The formation of α-2,4,5-trinitrophenyl-β-2,4-dinitrophenylhydroxyethane is of unusual interest, as the direct effects of steric hindrance are easily recognizable. It is thought probable that prolonged sulfonation does no more than serve to introduce a nitro group in the 5-position instead of the 6-position normally substituted in the trinitration of monoalkylbenzene compounds. The introduction of the nitro group in the 5-position prevents oxidation of the adjacent β-methylene. The oxidation of the methylene group is evidently limited to one stage by the steric hindrance effect of the nitro groups already present in the compound and evidently is subsequent to the introduction of one of the nitro groups; otherwise both methylene groups would be oxidized and no nitration would take place, as the introduction of a third nitro group is more difficult than the oxidation of a methylene group.

The limitation of oxidation as an effect of steric hindrance is confirmed by results obtained in efforts to condense two molecules of α-2,4,5-trinitrophenyl-β-dinitrophenylhydroxy-ethane with the elimination of one molecule of water from the two hydroxyl groups. When the compound was dissolved in and heated with 95% sulfuric acid or a mixture of fuming sulfuric acid and phosphorus pentoxide, the unchanged compound was recovered. As such condensations are relatively easy when less complex hydroxy compounds are used, and the 2,4-dinitro compound recovered on splitting with chromic oxide was esterified by the glacial acetic present, the inhibitive effect of steric hindrance in α-2,4,5-trinitrophenyl-β-2,4-dinitrophenylhydroxyethane is great, although the preparation of a benzoate was not difficult.

In the course of this study, the pentanitrohydroxy compound was prepared several times. From the products of nitration in one case, using 140 g, of tetranitrodiphenylethane, there was isolated about 0.5 g. of a compound melting at 209°, and having a nitrogen content of 18.48%. This is undoubtedly the symmetrical hexanitrodiphenylethane mentioned by Will[5] as melting at 212° (18.59% N). In spite of repeated attempts to prepare more of this material, none was obtained. It is apparent that this compound is formed in very small amount under even the most favorable conditions.

Summary

1. Modified methods of preparing 4,4′-dinitro- and 2,4,2′,4′-tetranitrodiphenylethane with high yields have been developed. Accurate melting point determinations of these pure compounds, as well as other properties, have been recorded.

2. A new compound has been prepared by the nitration of tetranitrodiphenylethane and identified as α-2,4,5-trinitro-phenyl-β-2,4-dinitrophenylhydroxyethane. The important properties of this compound have been determined.

3. 2,4,6,2′,4′,6′-Hexanitrodiphenylethane is formed in very small amount under even the most favorable conditions of nitration.

4. The effects of steric hindrance in the formation of nitro derivatives of diphenylethane have been evaluated.

MAGNESIUM DIALKYLS. AN HISTORICAL NOTE ON THE FIRST PREPARATION OF AN ALKYLMAGNESIUM HALIDE

BY HENRY GILMAN AND ROBERT E. BROWN

RECEIVED SEPTEMBER 19, 1930 PUBLISHED DECEMBER 18, 1930

Introduction

In extension of studies concerned with the preparation of phenylmagnesium chloride in the absence of a solvent,[1] some apparently anomalous reactions were observed when alkyl halides were heated with magnesium. This necessitated an investigation of the related magnesium dialkyls.

Hallwachs and Schafarik[2] were the first to prepare an organomagnesium compound, and this they did by heating ethyl iodide with magnesium. The solid reaction product when heated gave a colorless, volatile liquid which they said contained traces of the magnesium diethyl. Then Cahours,[3] by a like reaction, obtained an entirely volatile product which he considered magnesium diethyl. At a much later time, Lohr[4]

[1] Gilman and Brown, THIS JOURNAL, 52, 3330 (1930).

[2] Hallwachs and Schafarik, *Ann.*, 109, 206 (1859).

[3] Cahours, *ibid.*, 114, 227, 240 (1860).

[4] Löhr, *ibid.*, 261, 48, 72 (1891). *See*, also, Fleck, *ibid.*, 276, 129 (1893), who used the mercury diethyl method of preparation described by Lohr. Extensive studies on the direct action of RX compounds and magnesium have been made by Spencer and co-workers, J. Chem. *Soc.*, 93.68, 1821 (1908).

prepared magnesium diethyl by heating ethyl iodide with magnesium and also by heating mercury diethyl with magnesium. In both cases the product was a non-volatile solid. This was subsequently confirmed? and then it was shown, incidental to other studies, that magnesium dimethyl[6] and magnesium di-n-butyl[7] were solids. There is a possibility that some higher, possibly branched-chain magnesium dialkyls might be liquids because although beryllium dimethyl is a solid, beryllium di-n-butyl is a liquid.[8]

Strictly speaking, the known magnesium dialkyls are volatile to a certain extent, for recent studies[9] have shown that these organomagnesium compounds can not only be sublimed in a high vacuum but also distilled in a stream of ether. Furthermore, the earlier literature[10] on these studies is incorrect in describing the magnesium dialkyls as being essentially insoluble in ether. They are distinctly soluble in ether. Possibly the higher magnesium dialkyls might be found to be sparingly soluble in ether, which is the case with magnesium diphenyl.[11] Other general observations on magnesium dialkyls are contained in the Experimental Part.

Undoubtedly Hallwachs and Schafarik[2] were the first to prepare an organomagnesium compound.[12] They may have been the first to prepare a so-called "individual" or ether-free organomagnesium halide, because either one, or both, of the following reactions can be used to account for their product.

$$2C_2H_5I + 2Mg \longrightarrow (C_2H_5)_2Mg + MgI_2 \qquad (I)$$

$$C_2H_5I + Mg \longrightarrow C_2H_5MgI \qquad (II)$$

There is not now[13] available a reaction for differentiating between ($R_2Mg + MgX_2$) and RMgX. Once the reaction product is dissolved, in a solvent such as ether, then the following equilibrium occurs.[14]

$$2C_2H_5MgI \rightleftharpoons (C_2H_5)_2Mg + MgI_2 \qquad (III)$$

In view of this equilibrium it is inconsequential whether Reaction I or Reaction II occurred, because in either case the equivalent of ethylmagnesium iodide is obtained.[15]

[11] Hilpert and Griittner, *Ber.*, 46, 1675 (1913). Gilman and Brown, *Rec. trav. chim.*, *49*, *202* (1930).

[12] We refer here not to carbides or to acetylides, but only to those types having an alkyl or aryl group attached directly to magnesium.

[13] Gilman and Brown, This Journal, 52, 1181 (1930). This refers to ether solutions. An x-ray investigation of the crystal structure of these two types should prove of assistance in differentiation.

[14] Leading references to related studies may be traced back from a recent article by Gilman and St. John, *ibid.*, 52, 5017 (1930).

[15] It is interesting to note that it was about forty years later that Grignard first

With the application of heat, the condition used in most of these preparations, the RMgX compound might have formed first and then have been converted to the R_2Mg compound, in accordance with Reaction III. It is known that such a transformation does occur on heating.[6,16] Also, it has been generally assumed that in the formation of other organometallic compounds, the organometallic halide (RMeX) is first formed and then is converted to the organometallic compound (R_2Me): as, for example, in the formation of zinc diethyl from ethyl iodide and zinc through the ethyl zinc iodide stage.

Even though the equilibrium pictured in Reaction III probably applies to a great many, if not all, organometallic combinations it is not necessary to assume that the first stage in the formation of an R_2Metal compound is the RMetalX type. The reaction might occur as follows, using magnesium as the metal.[17]

$$2RX + Mg \longrightarrow 2R- + MgX_2 \qquad (IV)$$

$$2R- + Mg \longrightarrow R_2Mg \qquad (V)$$

Previously, it was assumed that RMgX or ($R_2Mg + MgX_2$) compounds were formed as follows:

$$RX + Mg \longrightarrow R- + -MgX \qquad (VI)$$

$$R- + -MgX \longrightarrow RMgX \qquad (VII)$$

This latter interpretation has some objections,[17] not the least of which is its lack of comprehensiveness, as in a reaction between mercury diethyl and a metal, where no halogen is present. Admittedly, both types of reaction might take place concurrently.

Experimental Part

The technique employed was that described earlier[1] in the preparation of phenylmagnesium chloride, a water pump being used to evacuate the tubes prior to sealing at the vapor pressure of the liquid. The magnesium was freshly ground and of 30-80 mesh. The qualitative color test, quantitative acid titration and characteristic derivatives were those used in other related studies in this Laboratory.

Methyl iodide showed no reaction even after heating at 140–150° for twelve hours. We have no explanation for the vigorous reaction reported by Cahours.[3] However, because he describes his magnesium dimethyl as a volatile, inflammable liquid, we are inclined to the opinion that his magnesium might have contained significant quantities of metallic impurities, such as zinc.

Ethyl iodide reacts at room temperatures, and the yield of organometallic compound at the end of seven days was 46%. When one equivalent of ethyl iodide was heated at 120–130° for four hours with two equivalents of magnesium, the yield was 61%. When two equivalents of ethyl iodide are used with one equivalent of magnesium no

---

prepared ether solutions of RMgX compounds. But it was just this operation of Grignard in preparing the RMgX compounds in ether which made it possible for these reagents to find their wide application.

[16] Giman and Fothergill, THIS JOURNAL, 51, 3149 (1929).

[17] This interpretation is developed in a paper by Gilman and Brown, Rec. *trav. chim.*, 49 (1930).

organometallic compound results. This is undoubtedly due to a secondary reaction between ethylmagnesium iodide or magnesium diethyl and the excess of ethyl iodide.

n-Butyl iodide appears to react more readily than ethyl iodide at room temperature. It is interesting to note that so far we have obtained no reaction under moderate conditions between trimethylene chloro-iodide, $ClCH_2CH_2CH_2I$, and magnesium.

Ethyl bromide did not react at room temperatures in seven days. When heated at 120–130° for four hours a reaction occurred with the formation of magnesium bromide and gaseous products, but no color test was obtained. Very probably an organometallic compound will be obtained from ethyl bromide under intermediate conditions. Essentially the same results were obtained with n-butyl chloride and n-butyl bromide

Methyl[18] and ethyl acetates have pronounced catalytic effects in initiating reaction, particularly with an iodide like ethyl iodide. They have practically no effect with methyl iodide.

Magnesium diethyl and magnesium di-n-butyl are very soluble in ether. Magnesium dimethyl is somewhat less soluble than the other two magnesium dialkyls, and a solution of it in ether contained in a sealed tube, deposited fine needle crystals after about six months' standing. The approximate solubility of magnesium dimethyl in ether is 0.08 mole per 100 cc. of solvent. These crystals of magnesium dimethyl (or its etherate) are markedly similar in appearance to the related beryllium dimethyl.8 The three magnesium dialkyls just described were prepared from the corresponding mercury dialkyls. The product obtained from ethyl iodide and magnesium is only slightly soluble in pure ethyl iodide.

In general, the organomagnesium compounds prepared from magnesium and a mercury dialkyl appear to be more reactive to atmospheric oxygen and moisture than the corresponding compounds prepared from magnesium and an alkyl iodide. Whenever the dry powders, prepared from the mercury dialkyls, are allowed to come in contact with water the mixture almost always takes fire. Ether solutions of the magnesium dialkyls take fire with water, but not so readily as the dry powders. The dry powders sometimes took fire in air, but no definite data are at hand because these compounds were always manipulated in an atmosphere of nitrogen or hydrogen. **A** high humidity was conducive to such combustion when the powders were exposed to the air.

Summary

A description is given of some general properties of magnesium dialkyls prepared from magnesium and mercury dialkyls, and organomagnesium compounds prepared from alkyl iodides and magnesium (with no solvent). The first organomagnesium halide, or its equivalent, was prepared by Hallwachs and Schafarik in 1859 in ***the absence of ether,*** but the use of ether by Grignard first made possible the extensive applications of these compounds.

THE SYNTHESIS OF GLUCOSIDOFERULIC ACID

BY RAYMOND M. HANN

RECEIVED SEPTEMBER 27, 1930 PUBLISHED DECEMBER 18, 1930

The natural occurrence of hydroxycinnamic acids and their internal lactones, the coumarins, in the free state and in glucosidic combinations has been demonstrated repeatedly. While ferulic acid (3-methoxy-4-hydroxycinnamic acid) has been observed in the free state by Ponti[1] in the extract from the macerated plants of *Ajuga iva*, the isolation of its glucoside does not seem to have been reported. Power and Tutin,[2] however, have shown it to be an integral portion of the chalcone, homoeriodictyol (2,4,6-trihydroxyphenyl-4-hydroxy-3-methoxystyryl ketone) in Eriodictyon *californicum*, and the occurrence of its related alcohol, coniferyl alcohol (3-methoxy-4-hydroxycinnamyl alcohol) in the glucoside coniferin is well known. The present communication describes the synthesis of ferulic acid d-glucoside. The procedure adopted in this study was that of the interaction of the sodium salt of the methyl ester of ferulic acid with acetobromoglucose in cold alcoholic solution. This plan materially shortened the usual method of agitation of an ether solution of the acetylated sugar halide with an alkaline aqueous solution of the phenolic acid ester. The resulting tetra-acetylglucosidoferulic acid methyl ester was simultaneously de-esterified and de-acetylated by treatment with cold barium hydroxide, yielding directly the desired glucosidoferulic acid, which was obtained in crystalline form. Its rotation shows it to be the β-glucoside, as would be expected from its synthesis from acetobromoglucose.

Experimental

Methyl Ferulate.—Ferulic acid was prepared by the Knoevenagel condensation of vanillin with malonic acid in the presence of pyridine and piperidine according to the directions of Robinson and Shinoda.[3] The acid (4 g.) was esterified by boiling for four hours under a reflux condenser with 25 cc. of absolute methyl alcohol and 1 cc. of concd. sulfuric acid. The oily ester was precipitated by addition of 75 cc. of water, then extracted with ether and the ether solution was washed with dilute sodium carbonate, dried over calcium chloride, and evaporated until free of ether. The oily ester (3.6 g. or 84% of the theoretical) was used directly in the condensation with acetobromoglucose.

Methyl Tetra-acetyl-β-*d*-glucosidoferulate (Methyl **3-Methoxy-4-tetra-acetylglucosido-cinnamate).**—A solution of 3.4 g. of methyl ferulate in 25 cc. of absolute alcohol was treated with an amount of alcoholic potassium hydroxide (17.6 cc. containing 0.0517 g. per cc.) sufficient exactly to neutralize the phenolic hydroxyl. The solution was cooled in ice and an ether solution of 6.7 g. of acetobromoglucose rapidly added.

---

[1] Ponti, *Gazz. chim. ital.*, **39**, II, 349 (1920).

[2] Power and Tutin, J. *Chem. Soc.*, 91, 887 (1907).

[3] Robinson and Shinoda, ibid., 127, 1973 (1925).

Following an immediate cloudiness a rapid precipitation of potassium bromide took place. Following a period of standing the salt was removed and the ether–alcohol solution evaporated to a sirup by an air current. Upon standing crystallization occurred, which was aided by cautious addition of 50% ethyl alcohol. The separated crystals were filtered off, washed and recrystallized from 50% ethyl alcohol; yield 5.6 g. (64% of the theoretical).

Methyl tetra-acetylglucosidoferulate separated from its solutions in 50% ethyl alcohol in colorless brilliant platelets, almost needle-like in character. It melts to a clear oil at 142–143° (corr.). A determination of its rotation in chloroform gave a value of $[\alpha]_D^{20}$ $-32.3°$ (0.2408 g. in 25 cc. of $CHCl_3$ solution gave a reading of 0.623° to the left in a 2-dm. tube). An acetyl determination by the method of Kunz[4] indicated that simultaneous de-acetylation and de-esterification took place (0.2304 g. substance consumed 10.8 cc. of $N/5$ NaOH; calcd., 10.7 cc.). A micro combustion was performed by Dr. R. T. K. Cornwell, to whom thanks are herewith expressed.

Anal. Subs., 3.943 mg.: CO_2, 8.095 mg.; H_2O, 1.943 mg. Calcd. for $C_{25}H_{30}O_{13}$: H, 5.62, C, 55.74. Found: C, 55.99; H, 5.51.

β-*d*-Glucosidoferulic Acid (3-Methoxy-4-β-d-glucosido-cinnamic Acid).—For saponification and de-acetylation of the tetra-acetylated methyl ester glucoside an aqueous 6% solution of barium hydroxide was used. Two grams of the finely powdered acetylated glucoside was shaken with 100 cc. of the alkali solution for eighteen hours, when solution was complete. The barium was precipitated successively as the carbonate and sulfate and the precipitate thoroughly extracted with boiling water. Upon concentrating the filtrate and washings under reduced pressure at 40° to a small volume, the glucoside of ferulic acid separated in colorless needles. It is almost insoluble in cold water. It was repeatedly recrystallized from boiling water for purification; yield, 1.1 g.

Glucosidoferulic acid crystallizes from boiling water, in which it is readily soluble, in colorless, brilliant, long, acicular needles containing one molecule of water of crystallization. This is retained at room temperature and ordinary humidity, but is rapidly lost over calcium chloride even at room temperature, the brilliancy of the crystal being replaced by a dull cottony appearance. Upon heating the glucosido acid in *vacuo* at 110° some loss of carbon dioxide occurs and at 180° an amount comparable to one molecule, although partial sublimation of the residue prevented an accurate determination. It is conceivable that the corresponding styrene derivative is formed as has been demonstrated in the case of caffeic acid (3,4 dihydroxycinnamic acid).[5]

The acid melts at 198–199° (corr.) without appreciable decomposition to a colorless oil. Its solutions rotate the plane of polarized light to the left, its $[\alpha]_D^{21}$ value being $-36.6°$ (0.2433 g. in 10 cc. of absolute alcohol solution gave a value of $-0.890°$ in a 1 dm. tube). A micro analysis was carried out.

Anal. Subs., 6.549 mg.: CO_2, 12.302 mg.; H_2O, 3.489 mg. Calcd. for $C_{16}H_{20}O_9 \cdot H_2O$: C, 51.31; H, 5.93. Found: C, 51.22; H, 5.96.

The writer takes this opportunity to express to Dr. C. S. Hudson his appreciation of the many kindnesses extended during the course of this research.

Summary

By the interaction of acetobromoglucose and the sodium salt of methyl ferulate, crystalline methyl ferulate β-*d*-glucoside-tetra-acetate has been

---

[4] Kunz and Hudson, THIS JOURNAL, 48, 1982 (1926).

THE TOXICITY OF ROTENONE, ISOROTENONE AND DIHYDROROTENONE TO GOLDFISH[1]

BY W. A. GERSDORFF

RECEIVED OCTOBER 2, 1930 PUBLISHED DECEMBER 18, 1930

The method used by the author for the study of toxicity in which the goldfish serves as the test animal has been described in a previous paper.[2] This method was used in studying the relative toxicities of rotenone, and two of its derivatives, isorotenone and dihydrorotenone. These substances were prepared by F. B. LaForge and L. E. Smith of this Division[3] in their researches to determine the chemical structure of rotenone.

The chemical structure of these compounds is not yet known. The empirical formula of rotenone is $C_{23}H_{22}O_6$. It possesses a ketone group, two methoxyl groups, a lactone group and an oxygen atom which is probably in the form of an ether linkage. LaForge and Smith reported that dihydrorotenone was one of the products of the catalytic reduction of rotenone, the reaction involving the simple reduction of an unsaturated bond in the rotenone molecule. It is now known that the double bond reduced is that in an isopropylene group. Isorotenone differs from rotenone in the position of its double bond. The double bond of the isopropylene group in rotenone has migrated and an isopropyl group has formed. The chemical relationship of these compounds will be discussed in a forthcoming paper by H. L. Haller of this Division.

The data are given in Tables I to III. The survival time curves and velocity of fatality curves which were plotted from these data are given in Figs. 1 to 3. In the former the ordinates are survival times in minutes; in the latter, the reciprocals of the survival times multiplied by 100. In both kinds of curves the abscissas are concentrations in milligrams per liter.

These curves resemble those given by Powers[4,5] to show the general type of toxic action to goldfish and that given by Carpenter[6] to show the

general type of effect which was marked by the formation of film over gills and skin and resulted in death by suffocation. When less than a certain amount of metallic ion was present the film was shed and complete recovery took place. In the tests with rotenone, isorotenone and dihydrorotenone no such film formation was apparent.

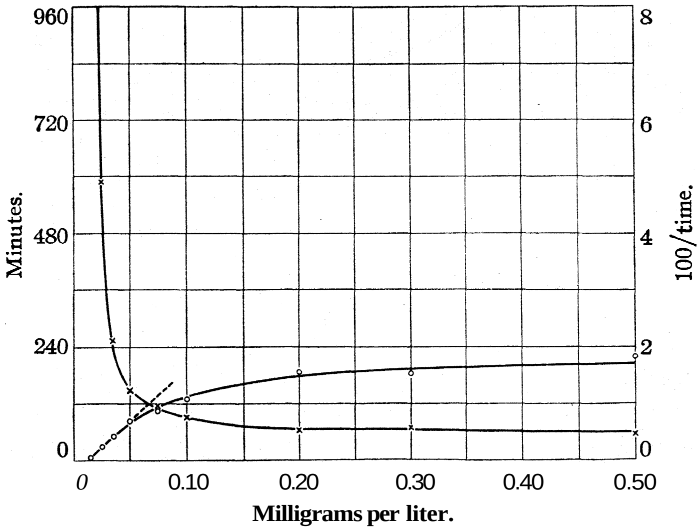

Fig. 1.—Toxicity curves for rotenone.

As Osterhout[7] pointed out, the values for the relative toxicities of substances will vary according to the criterion used. There are serious ob-

---

[7] W. J. V. Osterhout, "The Measurement of Toxicity," J. Biol. Chem., 23, 26–70 (1915).

jections to the comparison of the survival times at a given concentration, to the comparison of the concentrations necessary to produce death (or any other phenomenon used as the criterion) in any arbitrarily fixed time, and to the comparison of the concentrations necessary to just cause death (threshold of toxicity concentration). These are easily seen in an inspection of the survival time curves. Limiting concentrations vary so that the relative toxicities of two substances, when compared by the first method, will change, depending on the concentration used. For example, as seen in the data, at 4 mg. per liter, rotenone is apparently two and one-half times as toxic as isorotenone; at 0.20 mg. it is three times, at 0.10 mg. four times and at 0.075 mg. nearly six times as toxic, whereas at 0.050 mg. its toxicity becomes indefinitely greater since at this concentration isorotenone is no longer toxic at all. Similarly, the relative toxic values vary when the concentrations necessary to kill in an arbitrarily chosen survival time are compared, and they become worthless if they are obtained from data falling on either that portion of the survival time curve approaching the horizontal or that portion approaching the vertical. If substances are compared by this single survival time method, this survival time should fall on the middle portion of the curve, that is, the portion that approaches an equilateral hyperbola. The third method, the comparison of the concentrations necessary to just cause death, involves the determination of values very difficult to obtain with precision and in addition deals only with one factor in toxicity, the threshold of toxicity. From the velocity of fatality curves it is seen that there are at least two variables in toxicity and these apparently vary independ-

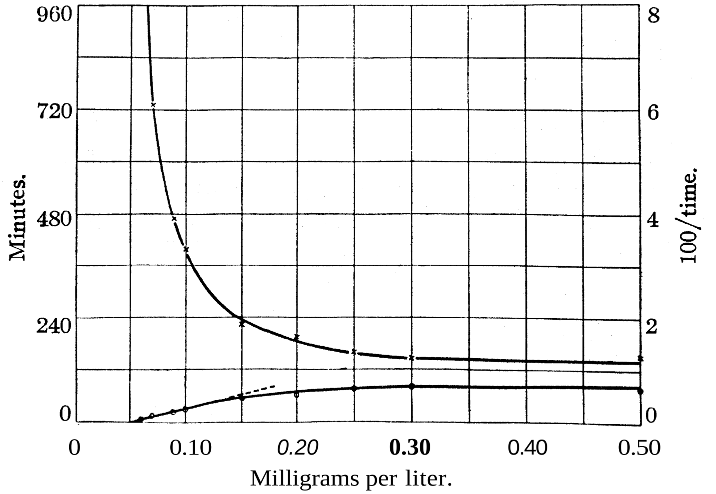

Fig. 2.—Toxicity curves for isorotenone.

ach other. They are the threshold of toxicity concentration te of increase of the velocity of fatality. Powers[4] adopts as a toxicity a value based on the reciprocal relation of these two 1 calculated from the equation, toxicity = $\sqrt{\tan \theta / a}$, where esents the slope of that portion of the velocity of fatality curve oaches a straight line and a its point of intersection, when proth the x-axis. Powers designated this straight line as the velocity of fatality curve and the concentration represented nt *a* as the theoretical threshold of toxicity concentration.

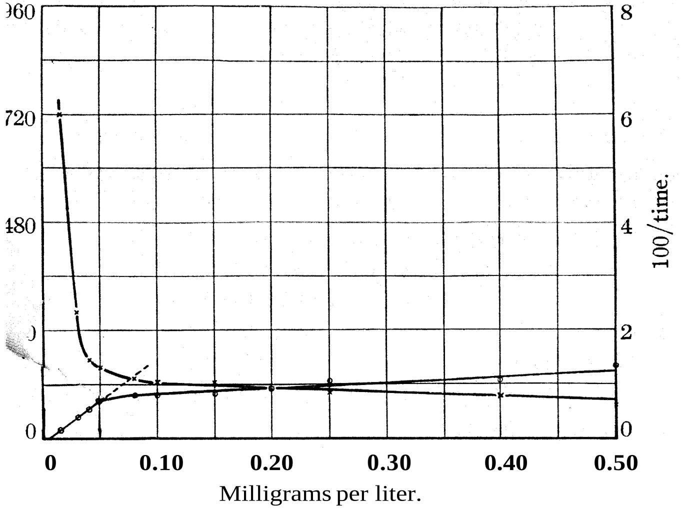

Fig. 3.—Toxicity curves for dihydrorotenone.

nparative toxicities of the substances considered here, derived to this equation, are shown in Table IV.

TABLE IV

'E TOXICITIES TO GOLDFISH OF ROTENONE, ISOROTENONE AND DIHYDRO-ROTENONE AT 27

THE RESOLUTION OF 1-(ALPHA-1-PIPERIDYLBE NAPHTHOL[1]

BY WALLACE R. BRODE AND JOSEPH B. LITTMAN

RECEIVED OCTOBER 2, 1930 PUBLISHED DECEMBER 18, 193

In a previous article on the condensation of secondary naphthols and aldehydes[2] a description was given of the pi 1-(α-1-piperidybenzyl)-2-naphthol. This asymmetric amine series of amines which are being prepared and tested as reso At the present time only one synthetic amine, namely, α- amine, has been used to any great extent for this work, most b agents being alkaloids, where only one of the two possible is available for use.

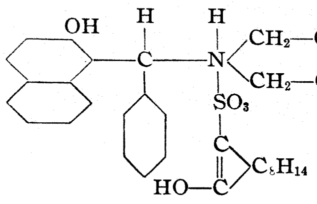
---

[1] An abstract of a portion of a thesis submitted by Joseph B. Litt fulfilment of the requirements for the degree of Doctor of Philosophy at University.

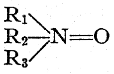
[2] Littman and Brode, THIS JOURNAL, 52, 1655 (1930).

dl-1-(α-1-Piperidylbenzyl)-2-naphthol can be resolved easily by means of d-camphorsulfonic acid. It has a high specific rotation, $[\alpha]_D$ −211°. Its use as a resolving agent, however, seems to be limited to strongly acidic compounds. Its solubility properties are poor for an ideal resolving agent but it does have acceptable qualities in its ease of crystallization, stability in the presence of common reagents and resistance to oxidation. In these latter qualities it is a marked improvement over the parent substance from which it is derived, 1-(α-aminobenzyl)-2-naphthol.[3,4]

From a comparison of the structural formula of 1-(α-1-piperidylbenzyl)-2-naphthol-d-camphorsulfonate (A) with the general formula of the amine oxides (B) which have been resolved by Meisenheimer,[5] it would appear



A



B

that there was a close relation in their configuration and one might possibly expect an asymmetric nitrogen atom in the first compound. Careful fractionation and a study of the rotation of various fractions failed to show any evidence of more than the two expected fractions in the resolution of a compound containing a single asymmetric atom. In similar attempts Barrowcliff and Ripping[6] did not succeed in resolving benzylmethylpiperidium-d-bromocamphorsulfonate and Wedekind[7] found it impossible to resolve quaternary ammonium bases with a double linking between carbon and nitrogen, ($Ph_2C{=}NMePhI$). In the case of the amine oxides, Meisenheimer[8] believes that the double bond between nitrogen and oxygen is semipolar, the oxygen atom figuring both as the fourth positive radical and taking the place of the negative ion of the ammonium salt.

Experimental

Thirty grams of *dl*-1-(α-1-piperidylbenzyl)-2-naphthol[2] was dissolved in 1300 cc. of absolute ethyl acetate on warming to 50°. To this solution, in a 2-liter round-bottomed flask, 22 g. of d-camphorsulfonic acid[9] dissolved in 200 cc. of absolute ethyl acetate was added. Soon after the addition of the d-camphorsulfonic acid solution, small colorless rosets began to form, which, after sixteen hours' standing, were filtered

and washed with hot ethyl acetate; yield, 28.5 g. (Fraction I), After eight more hours the filtrate yielded 7.7 g. of the salt, (Fraction II). The filtrate was evaporated to 850 cc. from which 4 g. of the salt was obtained (Fraction III).

The remaining filtrate was evaporated to dryness under reduced pressure, leaving a residue, somewhat yellow in color, which weighed 9.2 g. (Fraction IV). The total yield in all four fractions was 49.4 g. (theoretical, 51.9 g.).

Fraction I was recrystallized nine times by dissolving in 40 cc. of hot chloroform and then adding twice that volume of ethyl acetate. The degree of resolution and fractionation of the salts was followed by taking the optical rotation of the various fractions. The polarimetric observations were made on a Franz Schmidt and Haensch polarimeter, which was accurate to one hundredth of a degree rotation.

The salt, after the seventh, eighth and ninth recrystallization, had a constant rotation. 0.9385 g. made up to 10 cc. with chloroform at 20° gave $\alpha_D = +0.45°$; $l = 1$; $[\alpha]_D^{28}$ +4.7°. The salt from the ninth recrystallization, levo 1-(α-1-piperidylbenzyl)-2-naphthol-d-camphorsulfonate, melted with decomposition at 184–185° (corr.).

Anal. Calcd. for $C_{32}H_{39}O_5NS$: S, 5.82. Found: S, 5.79%.

Fractions II, III and IV were combined and fractionally recrystallized from a mixture of chloroform and ethyl acetate. The final mother liquor on evaporation gave a hard yellow mass which proved to be the dextro 1-(α-1-piperidylbenzyl)-2-naphthol-*d*-camphorsulfonate.

Preparation of the Free Amines.—Five grams of the levo 1-(α-1-piperidylbenzyl)-2-naphthol-d-camphorsulfonate was suspended in 50 cc. of water and to this suspension 100 cc. of 10% sodium carbonate solution was added. The mixture was poured into a separatory funnel and extracted thrice with 50-cc. portions of benzene. The benzene extracts were combined and dried with anhydrous sodium sulfate. The dried benzene solution was allowed to evaporate spontaneously in a beaker. The yield was 2.5 g. The levo-(α-1-piperidylbenzyl)-2-naphthol was recrystallized twice from a benzene-ligroin mixture, m. p. 201–202° (corr.).

Rotation. 0.2151 g. made up to 10 cc. with benzene at 20° gave $\alpha_D = -4.55$; $l = 1$; $[\alpha]_D^{27}$ −211°. 0.2036 g. made up to 10 cc. with chloroform at 20° gave $\alpha_D = -3.94$; $l = 1$; $[\alpha]_D^{28}$ −193°.

Three grams of the dextro salt was hydrolyzed with dilute sodium carbonate solution in the same manner as for the levo salt. The *d*-1-(α-1-piperdylbenzyl)-2-naphthol obtained was recrystallized twice from a benzene–ligroin mixture. The yield was 1.4 g., m. p. 199–200° (corr.).

Rotation. 0.2148 g. made up to 10 cc. with benzene at 20° gave $\alpha_D = +4.06$; $l = 1$; $[\alpha]_D^{31}$ +189°.

Summary

1-(α-1-Piperidylbenzyl)-2-naphthol has been resolved into its two active forms by means of d-camphorsulfonic acid.

SOME ESTERS OF TRIBROMOMETHYLPHENYLCARBINOL

BY J. W. HOWARD

RECEIVED OCTOBER 11, 1930 PUBLISHED DECEMBER 18, 1930

Introduction

Tribromomethylphenylcarbinol was first prepared by Siegfried,[1] who gives no further experimental details than to state that he used the method of Jocitsch[2] to prepare the analogous chlorine compound. The author[3] has already submitted an improved method for the preparation of trichloromethylphenylcarbinol but now finds that that method must be further modified in order to isolate the analogous bromine compound, on account of its greater instability toward heat.

Siegfried prepared only the acetic ester of this carbinol, using acetyl chloride as the acetylating agent. In the present study acetic anhydride has been used. Corrected melting points of the carbinol and its acetic ester as well as other new data concerning these compounds are also submitted.

In addition, the propionic, butyric and benzoic esters have been prepared and studied.

Experimental Part

Preparation of Tribromomethylphenylcarbinol.—To a mixture of 37 g. of *freshly distilled* benzaldehyde and 130 g. of *dry* bromoform was added with constant stirring 4 g. of powdered potassium hydroxide over a half-hour period. The mixture was allowed to stand for two hours, ether was added and the resultant mixture filtered. The filtrate was distilled until the temperature reached 155° at 680 mm. It was then steam distilled to remove the remainder of the benzaldehyde and small amounts of benzoic acid. The residue was washed with dilute sodium bicarbonate solution, extracted with ether, dried over sodium sulfate and the ether distilled off. The liquid residue crystallized out in one to two days. These crystals were dried on *a* porous plate and recrystallized from 50% acetic acid. Small amounts of crude material can be recovered from the mother liquor by dilution. A yield of 16–18 g. of plate-like crystals melting at 72.5–73.0° was obtained.

Anal. Calcd. for $C_8H_7OBr_3$: Br, 66.81. Found: Br, 66.78.

This compound is only very slightly soluble in water but readily soluble in carbon bisulfide, ethyl alcohol, methyl alcohol, benzene, acetone, ether, chloroform and carbon tetrachloride.

Preparation of the Esters

The acetate and propionate were prepared by heating the carbinol with the corresponding anhydrides at 130–135° for three hours. Both readily formed plate-like crystals on pouring the reaction mixture into water. The acetate was recrystallized from 50% alcohol and the propionate from 75% acetic acid; m. p. of acetate, 133°.

[3] Howard, THIS JOURNAL, 47, 455 (1925).

Anal. Calcd. for $C_{10}H_9O_2Br_3$: Br, 59.81 Found: Br, 59.75.

The melting point of the propionate is 70.5".

Anal. Calcd. for $C_{11}H_{11}O_2Br_3$: Br, 57.79. Found: Br, 57.85.

In the case of the butyrate the use of the anhydride did not give as satisfactory results as butyryl chloride, with which the carbinol was heated at 60–90° for three hours. Even after careful purification and distillation this ester does not solidify on standing for several weeks at room temperature. It is a thick viscous liquid of b. p. 205–207° at 220 mm., d_{20}^{20} 1.779.

Anal. Calcd. for $C_{12}H_{13}O_2Br_3$: Br, 55.90. Found: Br, 55.85.

The benzoate was prepared by treatment with benzoyl chloride according to the usual procedure of the Schotten–Baumann reaction. On recrystallization from 95% alcohol clusters of needles are obtained. It melts at 146°.

Anal. Calcd. for $C_{15}H_{11}O_2Br_3$: Br, 51.81. Found: Br, 51.76.

The average yield of all of these esters was 85%.

All of the esters are insoluble in water and with the exception of the benzoate readily soluble in carbon disulfide, ethyl alcohol, methyl alcohol, benzene, acetone, ether, chloroform and carbon tetrachloride, the benzoate being much less readily soluble in ethyl and methyl alcohols than the others.

Summary

Tribromomethylphenylcarbinol and its acetic, propionic, butyric and benzoic esters have been prepared and studied.

SYNTHESIS OF 1,4-PENTADIENE

BY PAUL N. KOGERMAN

RECEIVED OCTOBER 20, 1930 PUBLISHED DECEMBER 18, 1930

Among various series of unsaturated hydrocarbons the least explored field is that of the 1,4-dienes. According to Beilstein's "Handbook" only a few open-chain 1,4-dienes are known, *i. e.*, hexadiene-1,4, and 4-propylheptadiene-1,4. The first member of the series of diolefins with isolated double bonds has attracted the attention of many chemists. Several investigators have tried to prepare 1,4-pentadiene. Demjanov[2] and Demjanov and Dojarenko[3] on heating pentamethylenediamine nitrate or treating 1,5-di-iodopentane with alcoholic potash obtained among other products a small amount of a substance which on bromination yielded the tetrabromide of 1,4-pentadiene. Thiele[4] and others tried to prepare the hydrocarbon by exhaustive methylation of piperidine but

[1] Beilstein, "Handbuch org. Chem.," 1918, Bd. I, p. 253.

[2] Demjanov, *J. Russ. Phys.-Chem. Soc.*, 26,665 (1894).

[3] Demjanov and Dojarenko, *Ber.*, 40, 2589 1908).

[4] Thiele, *Ann.*, 319, 228 (1901).

obtained its isomer, 1,3-pentadiene. Recently Dojarenko[5] found that on catalytic dehydration of cyclopentanol a small amount of 1,4-pentadiene is formed. All these investigators failed to obtain the pure hydrocarbon. The final stage of the above-mentioned reactions favors molecular rearrangements. It seemed to the author most natural to avoid high temperatures and strong reagents, and in a manner analogous to the preparation of diallyl from allyl bromide[6] to bind vinyl and allyl radicals, using their bromides and magnesium

$$CH_2{=}CHCH_2Br + CH_2{=}CHBr \xrightarrow{Mg} CH_2{=}CHCH_2CH{=}CH_2 + MgBr_2$$

Starting from this point of view the author treated a mixture of vinyl bromide and allyl bromide with magnesium in anhydrous ether; the experiment was successful but the yield of the hydrocarbon was rather low. To increase the yield various modifications of the method were studied. First of all it was attempted to prepare vinylmagnesium bromide, and treat this Grignard compound with allyl bromide. Contrary to expectation, which was based on the researches of Austerweil[7] and Krestinsky,[8] vinyl bromide did not react with magnesium in dry ether under ordinary conditions. Then it was tried *vice versa* to treat ally magnesium bromide with vinyl bromide, using an excess of the latter. The method of Gilman and McGlumphy[9] was used for preparation of allylmagnesium bromide. The Grignard compound was heated in a pressure bottle with three times the theoretical amount of vinyl bromide: the result was negative. One is inclined to assume that allylmagnesium bromide *in statu nascendi* is more active or "activates" vinyl bromide, thus favoring the formation of vinylmagnesium bromide.

Further it was found that the size of the magnesium turnings or particles has some effect on the yield of the hydrocarbon. The best results were obtained with magnesium-copper-alloy,[10] finely ground. Increase in the rate of the reaction also increases the yield of the diolefin. The 1,4-pentadiene obtained by this anomalous Grignard reaction is not pure; after removal of ether with strong hydrochloric acid,[11] the liquid contains a fair amount of vinyl bromide, 1,4-pentadiene and 1,5-hexadiene.

The only way to recover the pure 1,4-pentadiene is via its tetrabromide. The researches of Tissier and Grignard,[12] v. Braun and Sobecki,[13] and

others show that 1,2-dibromides react with magnesium, forming unsaturated hydrocarbons, *i. e.*, regenerating the double bond. The same method was used for regenerating 1,4-pentadiene from its tetrabromide, about 85% of the original hydrocarbon being recovered. The pure 1,4-pentadiene boils at 25.8–26.2°. The yield of the hydrocarbon is about 15% of the theoretical, based on vinyl bromide.

Experimental

Preparation of Vinyl Bromide.—The Swarts[14] method for preparation of vinyl bromide from ethylene bromide and alcoholic potash is not quite satisfactory for preparing larger quantities of vinyl bromide. Therefore the method was improved by introducing the following modifications.

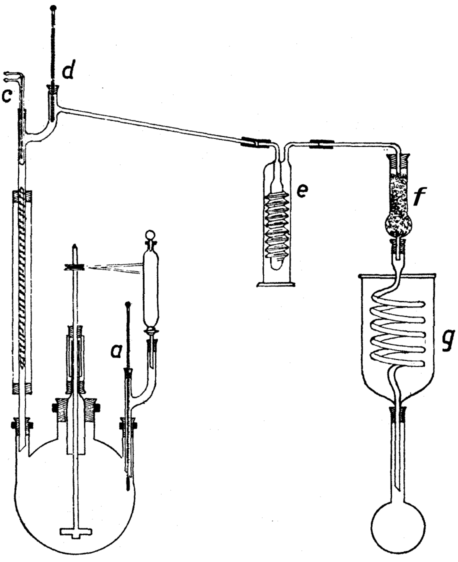

Fig. 1.—Apparatus for preparation of vinyl bromide.

A 1.5-l. flask with three necks is provided with a stirrer (through central neck), with a dropping funnel, and a dephlegmator or Vigreux column, surrounded by a jacket through which water at 17° is circulated (see Fig. 1). The column is connected (in succession) with a wash-bottle, calcium chloride tube and a Staedeler condenser (cooled by means of a freezing mixture). The receiver is also surrounded with freezing mixture. Into the flask is put an alcoholic solution of potassium hydroxide, made from 175 g. of potassium hydroxide, 350 cc. of water and 650 cc. of 96% ethyl alcohol. The solution is stirred and heated on a water-bath up to about 60°. Then 195 g. of ethylene bromide is dropped slowly into the flask. In a few minutes evolution of vinyl bromide begins. By circulating water in the jacket the speed of distillation is regulated so that the temperature of the vapor leaving the column is about 18°. The operation takes about an hour and a half. Then the solution of potassium hydroxide can be removed from the flask by a siphon, the dropping funnel charged with a fresh portion of ethylene bromide and the operation started again. The yield of vinyl bromide from 195 g. of ethylene bromide is 90–100 g. or about 85%. Vinyl bromide obtained by this method is dry and pure; b. p. 16–17°.

Allyl bromide was prepared by the method of Adams;[15] the fraction of b. p. 70–71° was used.

Preparation of 1,4-Pentadiene. (1) Under Atmospheric Pressure.—A 100-cc. round-bottomed pyrex flask is provided with a mercury-sealed stirrer, dropping funnel and Staedeler condenser, surrounded with freezing mixture; 2.65 g. of magnesium, 0.5 g. of iodine and 0.1 mole of ethylene bromide dissolved in about 40 cc. of dry ether is intro-

---

[14] Swarts, *Chem. Centr.*, II, 804 (1901); *Bull. acad. Roy. Belgique,* 383 (1901).

[15] "Organic Syntheses," John Wiley and Sons, Inc., New York, 1921, Vol. I, p. 3.

duced into the flask; 16–17 g. of allyl bromide in about 15 cc. of ether is then slowly dropped into the flask, with stirring of the mixture. In a few minutes the reaction starts. After the reaction ceases the flask is heated for about one hour and cooled. The reaction products are then distilled, using a Widmer column, and two fractions collected: one (i) taken up to the initial decomposition point of the etherates, and (ii) up to 36°. Both fractions are cooled in a freezing mixture, then bromine is slowly added (shaking the flasks) until the color of bromine remains. After bromination the flasks are allowed to stand in a freezing mixture for about two hours. Then the ether is evaporated under reduced pressure, and the contents of the flasks dissolved in hot alcohol. On cooling, crystals (colorless leaflets) of 1,4-pentadiene tetrabromide appear. The ii fraction always contains a certain amount of the tetrabromide of 1,5-hexadiene. The crystals are filtered, dried and weighed. After recrystallization from hot ethyl alcohol, the crystals of 1,4-pentadiene tetrabromide melt at 85.8–86°.

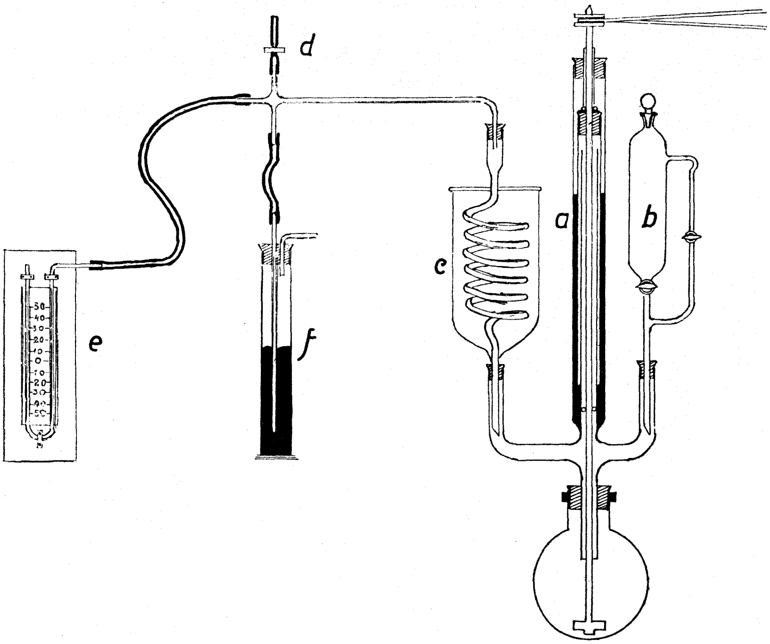

Fig. 2.—Apparatus for preparation of 1,4-pentadiene under pressure.

(2) Under **Pressure.**—When the reaction proceeds violently some vinyl bromide is carried through the condenser uncondensed. To avoid losses the reaction can be carried out in a closed system, under a pressure of 260–270 mm. For this purpose a 100-cc. round-bottomed flask is provided with a rubber stopper through which passes a tube with two side tubes; through the central tube is a mercury-sealed stirrer; the height of the mercury column is about 320 mm. (see Fig. 2a), one side tube is fitted with a dropping funnel, b, the other with Staedeler condenser, c. The body of the funnel is connected with its outlet tube below the stopcock by means of a narrow glass tube. The spiral condenser is connected with a manometer, e, and a mercury seal, f. The height of the mercury column in f is regulated so that the pressure in the apparatus does not exceed 280–290 mm.

For the production of larger quantities of the compound, a 750-cc. round-bottomed flask was used. and the dimensions of other parts of the apparatus were correspondingly larger.

Thirteen and two-tenth grams of magnesium and 0.5 g. of iodine were placed in the flask; from the dropping funnel about 100 cc. of anhydrous ether containing 1 g. of allyl bromide was added. In few minutes the reaction begins. The pinchcock clamp, d, is opened, and air is driven out by the ether vapor. Next 56 g. of vinyl bromide in 100 cc. of anhydrous ether is introduced into the flask, and then 75 g. of allyl bromide in 70 cc. of ether is slowly added in the course of about eighty to ninety minutes. During the reaction the manometer shows about 240–260 mm. pressure; when the pressure rises above that indicated, the flask must be cooled. After the whole portion of allyl bromide has been added the reaction mixture is heated on a water-bath until the pressure begins to fall. The reaction products are distilled, and the distillate is brominated. The yield of crude tetrabromide is about 45 g. or 22% of the theoretical from the vinyl bromide. After recrystallization from hot alcohol, about 25–28 g. of tetrabromide, m. p. 85–86', is obtained.

Anal. Calcd. for $C_5H_8Br_4$: C, 15.47; H, 2.08; Br, 82.47; mol. wt., 387. Found: C, 15.53; H, 1.99; Br, 82.52; mol. wt., 376.

The yield of crystals under various conditions of the experiment is given in Table I.

Tetrabromides of **1,4-Pentadiene.**—When the mother liquor from recrystallization of the solid tetrabromide is diluted with water, an oily liquid is precipitated. As theoretically two isomeric tetrabromides are possible, an attempt was made to isolate the other isomer. About 160 g. of washed and dried heavy liquid was distilled under reduced pressure using a Widmer column as still-head. From the distillate, on cooling, about 60 g. of crystalline pentadiene tetrabromide (m. p. 85–86°) and about 55 *g.* of diallyl tetrabromide were obtained; about 45 g. of the distillate remained liquid. After repeated fractionation crystals again separated from the distillates. Finally, about 10 g. of oily bromide, boiling from 115–123° (1–2 mm.) remained. The figures obtained on the analysis of the liquid did not closely correspond to the composition of pentadiene tetrabromide but were close to the diallyl tetrabromide. Anyhow, the supposed liquid tetrabromide is formed in comparatively small quantities or it might isomerize on distillation.

Regeneration of **1,4-Pentadiene** from *its* Tetrabromide.—Regeneration of the diene was carried out in a flask provided with a stirrer, a dropping funnel and a Staedeler condenser. The condenser jacket was filled with freezing mixture. Between the flask and condenser is placed a T-piece for pushing in the dry tetrabromide (see Fig. 3).

The tetrabromide is put into the side tube, provided with a glass rod. By pushing forward the glass rod the solid tetrabromide is introduced into the condenser tube, wherefrom the ether vapor sweeps it down. This device allows the use of smaller quantities of ether because the solubility of the tetrabromide in ether is rather low, *i. e.*, about 13 g. in 100 cc. In the flask are placed 12.5 g. of magnesium, 0.5 g. of iodine and 3 g. of tetrabromide; then 35 cc. of dry ether is added. The reaction begins immediately and 33 g. of tetrabromide in 250 cc. of dry ether is then slowly added. After the dissolved tetrabromide has been added, 31 *g.* of tetrabromide is gradually pushed in through the T-piece. The reaction takes about two hours, after which the flask is warmed on a water-bath for about thirty minutes. From the reaction mixture the pentadiene and ether are distilled off. The distillate is placed in a separatory funnel, an equal amount of cooled concd. hydrochloric acid is added, and the contents of the funnel are shaken while cooling under the tap. The mixture is allowed to settle, the acid layer is drawn off and the operation is repeated. The ether-free pentadiene is successively washed with water, sodium bicarbonate solution, and again with water, then the liquid diene is dried over calcium chloride. The yield of the products from 145 g. of tetrabromide is 18.5 *g* of 1,4-pentadiene, or about 73% of the theoretical.

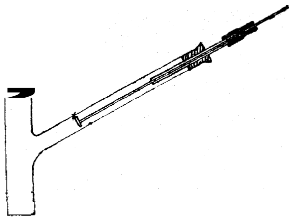

Fig. 3.—T-piece for pushing in solid pentadienetetrabromide.

The total amount of 1,4-pentadiene recovered, as determined by bromination of the distillate is about 85%.

The hydrocarbon was fractionated using a Widmer column as stillhead. A few drops of liquid passed over below 25° and about 70% of the liquid at 25.8–26.2°. The whole boiled below 26.6°. The liquid has a weak characteristic odor.

Properties of **1,4-Pentadiene.**—B. p. 25.8–26.2° at 756 mm.; d_4^{20} 0.6594; n_D^{20} 1.3883; mol. refraction: calcd., 24.26; found, 24.26; mol. wt. (Victor Meyer method): calcd. 68.08; found, 68.66

In conclusion, the author desires to record his thanks to Professor E. P. Kohler for his interest in the work, and to Mr. H. Raudsepp for checking the experiments.

Summary

1. An improved method for preparation of vinyl bromide has been worked out.

2. Two modifications of a new method for the synthesis of 1,4-pentadiene are described.

3. For the first time 1,4-pentadiene has been prepared in pure condition and its properties determined.

4. The bromination products of 1,4-pentadiene were investigated

THE REACTIVITY OF ATOMS AND GROUPS IN ORGANIC COMPOUNDS. XI. THE INFLUENCE OF THE STRUCTURE OF THE SUBSTITUENT ON THE TEMPERATURE OF DECOMPOSITION OF CERTAIN DERIVATIVES OF MALONIC ACID

BY JAMES F. NORRIS AND RALPH C. YOUNG

RECEIVED OCTOBER 21, 1930 PUBLISHED DECEMBER 18, 1930

For a number of years a major problem in this Laboratory has been the study of the influence of the structure of substituents on the lability of the atomic linkings in certain organic compounds. In the earlier work[1] the rates were determined at which such linkings were severed when analogous compounds reacted with a fixed reagent under the same conditions. An interpretation of these results led to conclusions in regard to the effect of the structure of a radical on the lability of certain bonds. In the last communication on this subject[2] a second method of comparing the relative lability of bonds was described. The temperatures at which the C—O bond was broken by heat alone in compounds of the type $(C_6H_5)_3C$-OR were determined. It was shown that these temperatures could be determined in separate experiments within ±2° when the substances were heated under fixed conditions. A comparison of the averages of the values obtained in this way in the case of ten ethers with those obtained from the study of the same bond by means of reaction velocities brought out the striking fact that the two methods gave comparable results. There appears, therefore, to be a relation between the temperature at which a bond is broken by heat and the rate at which it is broken when a chemical reaction involving this bond takes place.

This conclusion appeared to be sufficiently important to warrant further investigation. Malonic acid and its derivatives of the type $RHC(COOH)_2$ decompose smoothly when heated into RH_2CCOOH and CO_2. Several such derivatives were made and the temperatures at which the decomposition began were determined. In the case of these compounds a C—C bond is broken. In the case of the esters previously studied a C—O bond was severed. It was of interest to discover if there was any relationship between the influence of the change in the alkyl radical, R, on the temperatures of pyrolysis in the two series.

In Table I are given the temperatures of decomposition of the derivatives of malonic acid and for comparison the temperatures of decompo-

Isopropyl	90		220		.010

sition of the triphenylmethyl ethers containing the same alkyl radicals. There is also included the velocity constants of the reactions between *p*-nitrobenzoyl chloride and the alcohols containing these radicals.

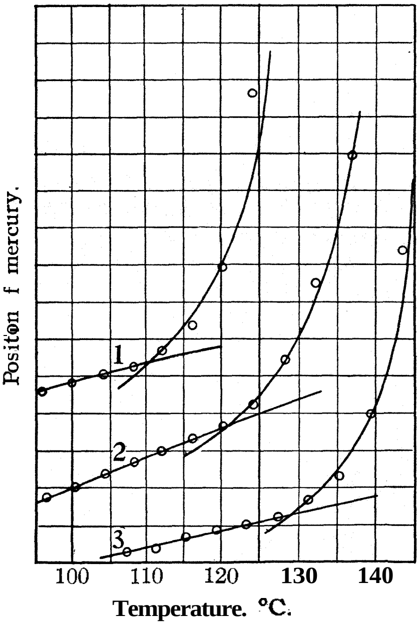

Fig. 1.—Position of mercury above an arbitrary zero for various values of the temperature. Each division = 10 cm. displacement: 1, ethylmalonic acid; 2, methylmalonic acid; 3, malonic acid.

It will be seen from the figures in the table that the temperatures at which decomposition takes place decrease as the radical is changed from methyl to ethyl and to n-propyl, but increase when n-propyl is replaced by n-butyl. This holds true in both series of compounds.

It is also a striking fact that the actual changes of the decomposition temperatures are the same in the two series, within the limits of accuracy of measurement, except in the case of the replacement of the methyl radical by ethyl.

In the two series the temperatures of decomposition fall in the same order as the velocity constants of the reactions between *p*-nitrobenzoyl chloride and the alcohols containing the same alkyl radicals present in the acids and ethers.

The position of the changing substituent relative to the bond severed is the same in the two series of compounds. In both cases the substituent is in combination with an element

(C or O) a second bond of which is severed by heat. This is made clear by writing the formulas of the two classes of compounds as follows, and indicating the bonds which are severed in pyrolysis

$\overset{\text{H}}{\underset{\text{COOH}}{\text{RC}}}\text{—COOH}$ and $\text{RO—C}(C_6H_5)_3$

The interpretation of the results leads to a reasonable conclusion. The change in the nature of R affects the strength of the linking between the radical and the carbon atom in one series and the oxygen atom in the other. These changes affect, in turn, the strength of the bond between these elements and the groups which are removed *as* the result of pyrolysis. The results furnish, thus, experimental evidence of the interrelationship between the affinities of an atom. It was an unexpected fact that the effects on the strength of the bonds of the carbon atom and of the oxygen atom were approximately the same with the same change in radical when measured by the change in temperature necessary to bring about the rupture of the bonds of the two elements.

Other cases of the effect of varying substituents on the temperature at which definite bonds are broken by heat are now being studied to discover if the simple relationships here emphasized are general. Work on certain aliphatic hydrocarbons is well advanced.

Experimental Details

Preparation of the Acids Used.—The derivatives of malonic acid were prepared in the usual way from ethyl malonate. The acids were crystallized from benzene several times until the behavior was constant when melting points were determined.

Method of Determining Decomposition Temperatures.—The method used was similar to that described in the paper on the pyrolysis of certain triphenylmethyl-alkyl ethers.[2] It consisted, in brief, in heating the material in a closed glass tube connected with a horizontal capillary tube containing a drop of mercury, and recording from time to time the position of the mercury on a scale as the temperature was raised at a definite rate. At the decomposition point there was a marked increase in the rate in the change of position of the mercury. One-half gram of malonic acid and equivalent amounts of the other acid were used in the experiments. The temperature of the bath was allowed to rise one degree in approximately forty-five seconds. The observations were plotted and curves drawn through the points recorded.

The accompanying plot indicates the nature of the curves obtained with three of the acids studied. The values of the decomposition temperatures recorded were obtained by plotting all the results accurately on a large scale.

The procedure described above was checked, in the case of malonic acid, by a chemical method. The acid was heated in a tube connected with another containing a solution of barium hydroxide. Air free from carbon dioxide was drawn rapidly through the two tubes, and the acid and the solution were then introduced. The stream of air was continued, and the tube containing the acid was heated at such a rate that the temperature rose about one degree per minute. The temperature observed when the first opalescence appeared in the barium hydroxide was taken as the decomposition temperature. The results obtained in this way in separate experiments agreed with those obtained by the physical method to within ± 1°.

In Table II are given the melting points and decomposition temperatures of the acids as observed by the authors and the previously published values recorded in Beilstein's "Handbuch," The two sets of numbers in the column headed "Temperature of Decomposition Observed by Authors" are the results of independent experiments.

TABLE II

MELTING POINTS AND DECOMPOSITION TEMPERATURES OF DERIVATIVES OF MALONIC ACID

Acid	Melting points (°C.) observed by authors	Melting points (°C.) recorded in Beilstein	Decomp. temp. (°C.) observed by authors		Decomp. temp. (°C.) recorded in Beilstein
Malonic	129–131	130.5 to 135.6	127	129	140-150
Methylmalonic	120–122	125 to 135	120	120	120
Ethylmalonic	110–111.5	111.5	110	110	160
***n*-Propylmalonic**	94–96	96.0	100	98	150
n-Butylmalonic	99.5–101.5	101.5	108	108	150
Isopropylmalonic	85–87	87.0	90	90	120

The melting points were determined in the usual way in capillary tubes. The lack of sharpness in these values was no doubt due to the fact that they lie so close to the temperatures at which decomposition takes place.

The decomposition temperatures recorded in Beilstein's "Handbuch" were determined by observing the behavior of the acids when heated in melting-point tubes. There is no claim for exactness.

Summary

1. The temperatures have been determined at which malonic acid and certain of its alkyl derivatives break down into carbon dioxide and monobasic acids.

2. The influence of the radicals studied on the decomposition temperatures is of the same order of magnitude as that found in the earlier study of the pyrolysis of triphenylmethyl-alkyl ethers; the temperature is lowered in the two series as the radical is changed from methyl to ethyl to *n*-propyl but rises when n-butyl is present. The isopropyl radical derivatives in the two series decompose at lower temperatures than the n-propyl compounds.

3. In both series of compounds the decomposition temperatures fall in the same order, with varying alkyl radicals, as the rates at which alcohols containing the same radicals react with an acyl chloride. There appears to be a relationship between the effect of a radical on the lability of a bond as measured by the temperature of pyrolysis and the rate at which the bond is broken in a chemical reaction.

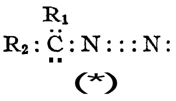
OPTICALLY ACTIVE DIAZO COMPOUNDS. DIAZOCAMPHANE

BY ULRICH HEUBAUM AND WILLIAM ALBERT NOYES

RECEIVED OCTOBER 23, 1930 PUBLISHED DECEMBER 18, 1930

The question whether or not a carbon atom which is attached to a diazo group might cause optical activity has been the subject of a great number of investigations during the last ten years.

On the one hand the results of the investigations of Levene and Mileska[1] in 1921 and of Noyes and Chiles[2] in 1922 imply an asymmetry of a carbon atom which is bound to diazo nitrogen. These investigators prepared the diethyl-a-diazo-succinate in which the only possible asymmetric carbon atom is connected to a diazo group and they found the compound to possess a small optical rotatory power. This fact has recently been confirmed by H. Lindemann[3] and his co-workers. The straight-chain formula established by Angeli and Thiele[4] and modified by Noyes[5] according to the octet theory explains the asymmetry of the carbon atom (A). In this formula the carbon atom represents a center of asymmetry since it is bound to three different substituents and possesses one electric charge.



$R_2:\overset{R_1}{\underset{\cdot\cdot}{\ddot{C}}}:N:::N:$

On the other hand, some qualities of the diazo compounds seem to justify the ring structure rather than the open-chain formula.[6]

This work has been undertaken in order to get further evidence of the behavior of alicyclic diazo compounds. Diazocamphane (B) contains, besides the carbon atom which is connected with the diazo group, the two asymmetric carbon atoms of the camphor. It, therefore, can be expected to exist in four optically active modifications which give two pairs of optical antipodes and two pairs of stereoisomers. The d-camphor consequently furnishes two stereoisomeric diazo compounds and in the same way two stereoisomeric amines or chlorides.[7]

The diazocamphane $C_9H_{16}=C=N_2$ has been prepared in ethereal solu-

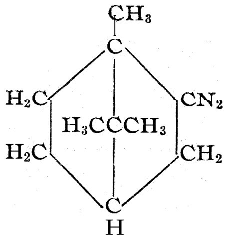
[5] Kendall with Noyes, THIS JOURNAL, 48, 2404 (1926). Staudinger [*Helv. Chim. Acta*, **5**, 75 (1922)], by a study of the addition of phosphines to diazo compounds, also found the open-chain formula to be more probable.

[6] See, for instance, Sidgwick, J. *Chem. Soc.*, 1108 (1929), and Lindemann and Thiele, *Ber.*, 61, 1529 (1928).

[7] Only one of the bornyl chlorides derived from the d-camphor, the dextrorotatory bornyl chloride, has been known until now. Studying the reaction of the diazocamphanes with hydrochloric acid, we have prepared very small amounts of the corresponding stereoisomeric levorotatory form.

tion from the normal and the neo-bornylamines, both of which are formed by the reduction of d-camphor-oxime and represent stereoisomers. The ethereal solution of both of the diazocamphanes is deeply red colored and extremely unstable. Even below 0° the compounds decompose with the evolution of nitrogen and the formation of the inactive polycyclic hydrocarbon tricycene. This reaction proves the old assumption that the diazocamphane is temporarily formed as an intermediate product in the preparation of tricyclene by the oxidation of camphor-hydrazone with mercuric oxide.[8]

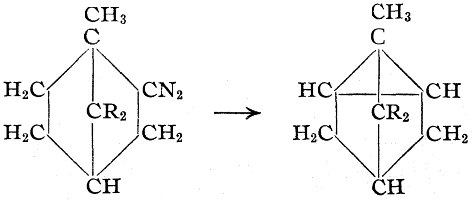


(B)

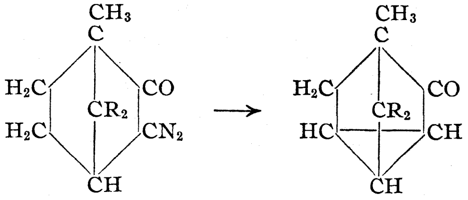
$$C_9H_{16}:C:NNH_2 + HgO \longrightarrow C_9H_{16}:C:N_2 \longrightarrow C_{10}H_{16} + N_2$$

Furthermore, the diazocamphane is very sensitive to hydrogen ions. Even carbon dioxide favors its decomposition.

Tricyclene was found to be the only product of the spontaneous decomposition of the diazocamphane. No nitrogen-containing compounds such as ketazides or bis-hydrazones have been observed. This decomposition is analogous to that of the diazocamphor



Diazocamphane → Tricyclene (α-pericyclocamphane)



Diazocamphor → β-Pericyclocamphanone

When cooled to a temperature of a carbon dioxide–acetone mixture, the compound could be kept without appreciable decomposition for several days.

Attempts to crystallize the diazocamphane from its solution failed because of its instability.

The specific rotations of both of the diazocamphanes are very high, ranging between about +60 and +450°.

---

[8] Friedlander, "Fortschritte der Teerfarbenfabrikation," German Patent 353,933 (1922). Because of the instability of the diazocamphane it is impossible to prepare it by this reaction. Staudinger, Ber., 53,1106 (1920).

For determining the concentration of the diazo solutions, the gasometric method was used. The diazo compound was decomposed by dilute sulfuric acid and the volume of nitrogen evolved was measured. In some cases the two diazo compounds have been compared colorimetrically. The readings of the rotation were taken at about −5°, at which temperature the compound decomposes very slowly. On account of the relatively great inaccuracy of this method in connection with the instability of the diazo compound, the values for the specific rotation vary considerably. The average values of the specific rotation of the diazocamphanes for light of different wave lengths are given in Table I.

Table I

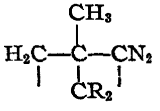
Specific Rotation of Normal Diazocamphane

λ	615	603	592	584	572
$[\alpha]$	179	164	196	350	420
λ	568	557	547	538	530
$[\alpha]$	411	411	339	286	71

Specific Rotation of Neo-diazocamphane

λ	645	635	602	592	585
$[\alpha]$	170	238	279	275	320
λ	578	572	567	558	
$[\alpha]$	455	466	420	398	

The dispersion curve of each of the diazo compounds shows its highest value in the light green part of the spectrum, beginning with a λ of about 5750 Å., and then goes down very rapidly in yellow and blue light. The anomaly of the dispersion curve in this part of the spectrum is caused by an absorption band which is located at about λ5650 Å. (Cotton effect)[9] (Fig. 1) This absorption band is undoubtedly due to the diazo group. It possesses a strong vicinal effect upon the substituents of the one asymmetric carbon atom of the original camphor (C), thus increasing its asymmetry and causing the extremely high rotation.[10] Similar effects have been observed with other alicyclic diazo compounds, e. g., the methyl γ-diazocamphonanate of Noyes and Kendall.[5]



$$\begin{array}{ccccc} & & CH_3 & & \\ & & | & & \\ H_2C & — & C & — & CN_2 \\ | & & | & & | \\ & & CR_2 & & \end{array}$$

(C)

While the study of the single values of the specific rotation did not seem to give satisfactory evidence concerning a difference of the two diazo compounds, a consideration of the whole dispersion curves seemed to be more successful. The curve obtained from the normal compound rises very rapidly toward the green and then shows a rather slow inflection near the maximum. The curve from the neo-compound rises very rapidly, too, but then shows a very strong inflection near the maximum (Fig. 1).

---

[9] Cotton, Ann. *chim. phys.*, [7] 8,347 (1896).

[10] W, Kuhn, Ber.. 63,200 (1930).

The curves plotted from the original observations, as shown in Fig. 2, bring out the differences between the two compounds more clearly. In these curves the inaccuracies of the volumetric determinations of the quantities present are eliminated. Two different solutions were used for each compound. It will be seen that the shapes of the two curves for the normal compound are alike and are different from the shapes of the two curves for the neo compound.

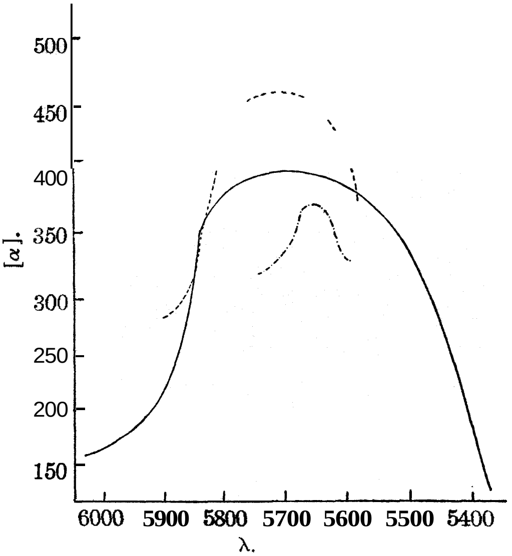


Fig. 1.—Rotatory dispersion of normal and neo-diazocamphane: ———, normal diazocamphane; - - -·- -, neo-diazocamphane; —·—·—·—, absorption curve.

Another evidence showing a difference of the two diazocamphanes was obtained in studying their decomposition products. A rather concentrated ethereal solution of diazocamphane decomposes with ethereal hydrochloric acid forming tricyclene and small amounts of bornyl chloride. The bornyl chloride obtained from the normal diazocamphane was levorotatory, having a specific rotation of $[\alpha]_D$ $-33.2°$ in ether. It thus represents the stereoisomer of the ordinary

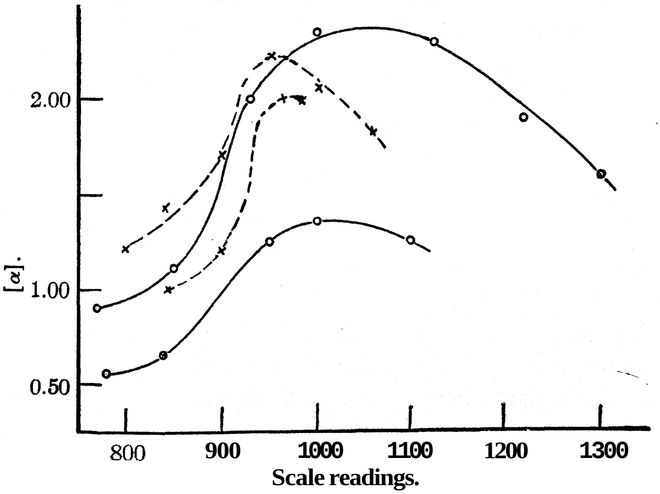

Fig. 2.—Observed rotations of normal and neo-diazocamphane: ———, normal; — — — —, neo.

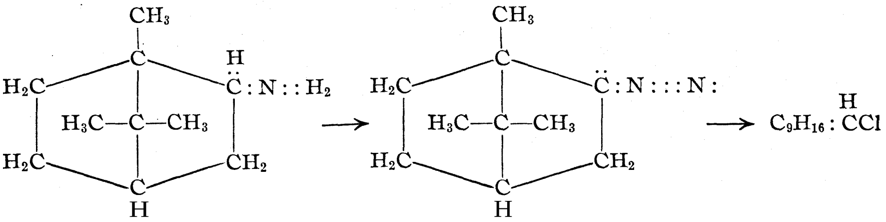
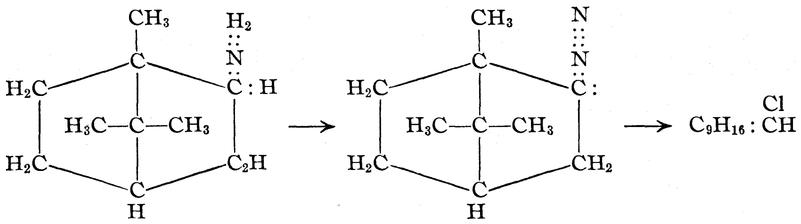
dextrorotatory bornyl chloride. The neo-diazocamphane decomposed under the same conditions with the formation of a very small amount of bornyl chloride, the specific rotation of which we have been unable to determine but it was found to be dextrorotatory.

The fact that the two diazo compounds give different decomposition products and that their dispersion curves have different shapes indicates that their structure must be different. Their behavior might be explained by the following diagrams.

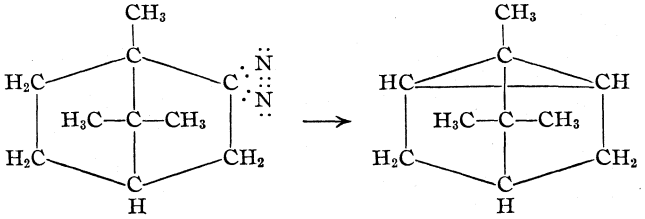


Normal bornylamine ⟶ Normal diazocamphane ⟶ Normal bornyl chloride



Neo-bornylamine ⟶ Neo-diazocamphane ⟶ Neo-bornyl chloride

On the other hand, the formation of tricyclene from both diazo compounds indicates that they may have the same structure, in part. This can be explained by the cyclo form



Cyclo-diazocamphane Tricyclene

The loss of a molecule of nitrogen from this cyclo form would leave a bivalent carbon atom bearing two electrons. This would be followed by the transfer of a hydrogen ion from the CH_2 group to these two electrons and the formation of the bridge across the ring.

The fact that mainly tricyclene and only very little bornyl chloride is formed in each case indicates that the diazocamphane consists mostly of the cyclic form, which is in equilibrium with the chain form.

This idea has recently been suggested by Lindemann,[3] while Sidgwick[6] has advocated the cyclic formula. Further evidence for the existence of optically active chain forms has very recently been secured by Ray[11] through his study of the decomposition of the two methyldiazocamphonanates obtained from the methyl esters of the cis and *trans* aminocamphonanic acids.

Experimental Part

Normal bornylamine, $C_{10}H_{17}NH_2$ and neo-bornylamine are formed by the reduction of camphor-oxime with sodium and amyl alcohol.[12] Normal bornylamine is formed chiefly and was separated from the mixture by fractional crystallization of the chlorides from water. The hydrochloride of the normal amine is much less soluble in water than that of the neo-base. The rotation of 1.36 g. of normal bornylamine hydrochloride in 100 cc. of absolute alcohol was $[\alpha]_D$ +22.6°. The melting point of the free amine was found to be 162.5–163° and its rotation in absolute alcohol $[\alpha]_D$ +45.9°. These values are in close agreement with those obtained by Forster.

Since the bornylamine, being a very strong base, forms a stable nitrite with nitrous acid it is impossible to obtain the diazocamphane by treating the primary amine with N_2O_3. We therefore used the method indicated by v. Pechmann,[13] that of treating the nitroso derivative of an acyl amine with alkali.

N,N′-Dibornylurea, $(C_{10}H_{17}NH)_2CO$, has been obtained by treating an ethereal solution of normal bornylamine cooled to −15° with an equivalent amount of phosgene dissolved in toluene. After evaporating the ether and toluene the residue was purified by recrystallization from aqueous alcohol.[14] The urea sublimes in long needles without melting. In this method the theoretical yield is only 50% since one-half of the amine is converted into the hydrochloride. It can easily be prepared, however, when using diphenylcarbonate, giving a yield of practically 100%.[15]

Mononitroso normal bornylurea has been prepared by passing carefully dried N_2O_3 into the ethereal solution of the urea cooled to −15° until it is colored green and keeping the solution at this temperature for about two hours. The solution is washed first with water and then twice with an ice cold solution of sodium bicarbonate. It is dried by freezing out the water at −80° and filtering off the ice. After evaporating the ether the nitroso compound crystallizes in yellow needles which are quite stable at 0° when kept over phosphorus pentoxide. The compound gives a positive Liebermann test for the nitroso group.

Anal. Subs., 0.3205: N_2, 31.6 cc. (24°, 752 mm.). Calcd. for $C_{10}H_{17}NH{-}CO{\cdot}(NO)NC_{10}H_{17}$: N, 11.63. Found: N, 11.5.

The crystals melt between 73 and 75° with decomposition. The nitroso compound is readily soluble in ether and alcohol. It slowly decomposes at room temperature, changing back into the urea. With sodium hydroxide or sodium methylate the yellow ether solution turns red, forming the diazo compound according to the equation

$$C_{10}H_{17}N(NO)CONHC_{10}H_{17} \xrightarrow{KOH} C_9H_{16}{=}C{=}N_2 + CO_2 + C_{10}H_{17}NH_2$$

This equation shows that only 50% of the amine applied can be converted into the diazo

[14] Neville and Pickard, J. *Chem. Soc.*, 65,687 (1894).

[15] Heubaum, THIS JOURNAL, 52,2149 (1930).

compound, which means a considerable loss of the raw material. Furthermore, the diazo solution is contaminated by bornylamine, which can hardly be separated. We therefore found the urethane derivative of the bornylamine more useful for the preparation of the diazo compound since all of the amine is turned into the diazo compound. The diazo solution obtained in this way does not contain any contaminating by-products

$$C_{10}H_{17}N(NO)COOC_2H_5 \xrightarrow{\text{KOH}} C_9H_{16}{=}C{=}N_2 + CO_2 + C_2H_5OH$$

Normal bornyl urethane has been obtained by the action of an excess of chloroethyl carbonate on normal bornylamine, which was suspended in aqueous potassium hydroxide at 0°. The product was then extracted with ether and purified by recrystallization from aqueous alcohol. All of the amine was thus converted into the urethane. The urethane melted sharply at 93° (Neville and Pickard found 89°)[14] and gave a specific rotation of $[\alpha]_D$ −10.9° in absolute alcohol and $[\alpha]_D$ +3.1° in absolute ether (Neville and Pickard found $[\alpha]_D$ +6.43 in chloroform). The urethane has also most easily been prepared by warming equivalent amounts of the amine and phenylethyl carbonate on the water-bath, only the phenoxy radical being substituted by the amine.[15]

Nitroso normal bornylurethane was obtained in the same way as the nitroso urea. The yellow crystals are more unstable at room temperature than those of the corresponding nitroso urea, turning back into the urethane (m. p. 93"). The compound gives a positive Liebermann test and a specific rotation of $[\alpha]_D$ +11° in ethereal solution. It is very sensitive to hydrogen ions and that is probably why Forster[16] failed to obtain it.

Normal **Diazocamphane.**—The dry solution of the nitroso urethane in ether was cooled to −20° and then a 2% solution of sodium methylate in methyl alcohol was added. The yellow color of the solution slowly changed to red. After standing for thirty minutes at −20° the diazo solution was washed with water to remove the sodium hydroxide and the methyl alcohol and then dried by cooling to −80°. No nitrogen evolution was observed at that temperature. The solution was analyzed by passing a measured volume (5–10 cc.) into a flask which contained dilute sulfuric acid and ether at exactly 0° and which was connected with a eudiometer. The volume of nitrogen evolved was corrected for temperature and the vapor pressures of ether and water; 6.1 cc. of diazo solution gave 7.1 cc. of nitrogen at 23" and 747 mm. This corresponds to a concentration of 0.56%. This solution had a rotation of +2.0° for λ5840 Å. which gives a specific rotation of $[\alpha]_{5840}$ +350°. A Schmidt and Haensch Universal Polarimeter was used and a 1000-watt lamp as a source of light. The light was sent through a spectroscope to obtain light of the wave length desired. On account of the high absorption, especially of the green light, by the diazo compound, exact readings were very difficult to obtain in this part of the spectrum.

Neo-bornylamine.—The separation of the pure neo-bornylamine from the mixture of the two amines was rather difficult and has been carried out in two different ways. One method indicated by Forster[17] consists in converting the amines into the oxamides and recrystallization from ethyl acetate, petroleum ether and absolute alcohol, the neo-bornyl oxamide being much less soluble in those solvents. We obtained a small quantity of the neo-bornyl oxamide in this way. The melting point was 184° and $[\alpha]_D$ −60.1°, both values in close agreement with those obtained by Forster. This method of separation, however, can only be applied to mixtures which contain 60% or more of the neo-amine. Attempts to deal with mixtures containing equal amounts of the two isomers led to the isolation of a compound which melts at 100° (the "normal-oxamide" melts at 140°) and gives a mixture of the two amines on saponification. This compound has

---

[16] Forster, J. *Chem. Soc.*, 85, 1193 (1904).

[17] Forster, *ibid.*, 77, 1152 (1900).

already been described by Forster. The analysis points to the empirical formula of the bornyloxamide. It represents very probably the neo-bornyl-normal-bornyl-oxamide.

Attempts to prepare the diazo compound directly from the oxamide failed since it was impossible to obtain a nitroso derivative of the oxamide.

Since this method of separation is not very satisfactory, we carried out more successfully the method indicated by Pope and Read,[18] using d-oxymethylene-camphor. The d-oxymethylene-camphor was prepared by the method described by Bishop, Claisen and Sinclair[19] and then treated with the corresponding quantity of the mixture of the amines which were dissolved in 50% acetic acid. The normal-bornylamine-oxymethylene-camphor is almost insoluble in petroleum ether and acetone, and remains after extracting the mixture with either one of these solvents. It can be purified by crystallization from alcohol and then gives a specific rotation of $[\alpha]_D$ +380° (Pope and Read found +330°). As much as possible of the normal compound was separated in this way from the mixture. The mother liquors then contained the almost pure neo-compound. After evaporating the mother liquors, the residue was dissolved in alcohol and decomposed with bromine, bornylamine hydrochloride and bromo-oxymethylene-camphor being formed For further purification the amine then was converted into the oxamide.

Neo-bornylurethane.—The pure neo-bornyloxamide thus obtained was saponified with alcoholic potash and the amine converted into the urethane, using chloro-ethyl-carbonate. The neo-bornylurethane melted at 37° and gave a specific rotation of $[\alpha]_D$ −28.0" in absolute alcohol and of $[\alpha]_D$ −31.2" in absolute ether (Neville and Pickard found m. p. 36° and $[\alpha]_D$ −9.6° in benzene).

Nitroso neo-bornylurethane was obtained in the same way as the corresponding normal nitroso compound. Its specific rotation was $[\alpha]_D$ −18.5° in ethereal solution. In other respects it shows the same properties as the normal nitroso compound.

Comparison of Normal and Neo-diazocamphanes.—A solution of neo-diazocamphane in ether which had been obtained in the same way as the normal diazocamphane was compared colorimetrically with a normal diazo solution which had a concentration of 0.34%. The tubes of the colorimeter were cooled with carbon dioxide and acetone. According to the readings the concentration of the normal solution was to the concentration of the neo solution as 21 to 27. The neo solution, therefore, contained 0.44% of diazocamphane, and had a rotation of **a** +2.03°, which for λ5720 Å. gives a specific rotation $[\alpha]_{5720}$ +466°, while the normal solution gave a specific rotation of $[\alpha]_{5720}$ +420° in light of the same wave length.

Exact readings of the rotation in the green and blue light were rather difficult to obtain because of the high absorption in this part of the spectrum. The dispersion curves for the specific rotation of the normal diazo compound as obtained in two different samples show rather high discrepancies, because of the inaccuracy of the gasometric method.

The measurements of the absorption could be carried out only rather roughly since it was impossible to obtain accurate values because of the instability of the compound. At about λ5650 Å., however, an absorption band has been found.

The decomposition of the diazo compounds with ethereal hydrochloric acid has been carried out at −25° and the bornyl chloride separated from the tricyclene by fractional distillation *in vacuo;* 0.2192 g. of the bornyl chloride obtained from the normal diazocamphane dissolved in 5 cc. of absolute ether gave a rotation of **a** −4.2". $[\alpha]_D$, therefore, is −33.2". The amount of the dextrorotatory bornyl chloride prepared

[19] Bishop, Claisen and Sinclair, *Ann.*, 281,328 (1894).

from the neo-diazocamphane was so small that it was impossible to determine its specific rotation.

Summary

1. Diazocamphane has been prepared in ethereal solution from the nitroso urethanes of two stereoisomeric bornylamines with sodium methylate at −20°.

2. Its specific rotation varies between +60 and +450 in different parts of the spectrum.

3. The anomaly of the rotation in the green light is due to an absorption band located at about 5650 Å., caused by the $=CN_2$ group.

4. The shapes of the dispersion curves of the diazo camphanes prepared from the normal- and neo-bornylamine are different, thus indicating a difference in structure of the diazo compounds concerned.

5. Studying the decomposition of the diazocamphanes with hydrochloric acid, a new levorotatory bornyl chloride of $[\alpha]_D$ −33.2° has been prepared from the normal diazocamphane. The neo-diazocamphane gave small amounts of a dextrorotatory bornyl chloride. Both diazo compounds, however, give mainly the same decomposition product, namely, the inactive polycyclic hydrocarbon tricyclene,' which indicates that they have partly the same structure. Their behavior is explained by the following formulas

THE THERMODYNAMIC PROPERTIES OF WEAK ACIDS AND BASES IN SALT SOLUTIONS, AND AN EXACT METHOD OF DETERMINING THEIR DISSOCIATION CONSTANTS[1]

BY HERBERT S. HARNED AND BENTON B. OWEN

RECEIVED JUNE 11, 1930 PUBLISHED DECEMBER 18, 1930

Recently, Harned and Robinson[2] showed that it is possible to determine the hydrogen-ion concentration and activity coefficient of acetic acid in chloride solutions of various kinds and strengths from measurements of the electromotive forces of cells without liquid junctions. To make their calculations, the dissociation constant of acetic acid determined by conductance measurements was employed. In the present study it will be shown that an exact evaluation of the dissociation constant may be obtained from the cell measurements alone. To demonstrate the method, we shall first employ Harned and Robinson's data relating to acetic acid in sodium chloride solutions, and then present some more accurate results on formic acid in sodium chloride solutions. Finally, we shall apply the method to some weak bases by computing the dissociation constants of ammonia and some methylamines from Harned and Robinson's data. These latter will not be so exact as in the case of the acids because of an approximation introduced into the calculation, and because of the special kind of liquid junction used in the cells containing the weak hydroxides.

Since the dissociation constant of a weak electrolyte has usually been determined by the conductance method, or by electrometric methods which involve liquid junction potentials, it is a matter of considerable importance to devise a method which rests entirely upon an exact thermodynamic basis.

Outline of the Method.—Let E represent the electromotive forces of the cells

$$H_2/HAc(M),\ NaCl\ (m)/AgCl/Ag$$

and 0.4644 the electromotive force of the cell

$$H_2/HCl(0.01)/AgCl/Ag$$

Then the electromotive force of the cell

$$H_2/HAc(M),\ NaCl(m)/AgCl/Ag/AgCl/HCl(0.01)/H_2$$

will be given by

$$E - 0.4644 = 0.05915 \log \frac{(0.904)^2\,(0.01)^2}{(\gamma_{HCl})^2\, m_H m}\text{, or}$$

$$16.9062\,E - 3.7636 + \log m + 2 \log \gamma_{HCl} = -\log m_H \qquad (1)$$

---

[1] This paper represents a part of the thesis presented by Benton B. Owen to the Graduate School of Yale University, in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] Harned and Robinson, THIS JOURNAL, 50, 3157 (1928).

if we take the activity coefficient of hydrochloric acid to be 0.904[3] at 0.01 molal concentration. γ_{HCl} is the activity coefficient of hydrochloric acid in the solution containing the undissociated acetic acid molecule at a molal concentration of $(M - m_{\mathrm{H}})$. When M is zero, γ_{HCl} becomes the activity coefficient of hydrochloric acid in pure, aqueous, sodium chloride solutions, and will be denoted $\gamma^{\circ}_{\mathrm{HCl}}$. The values of E for the weak acid–sodium chloride cells, and 0.4644 for the reference cell were obtained under identical experimental conditions, so that the double cell indicated does not include any experimental inconsistencies. It should also be remarked that our final results are independent of the choice of 0.904 as the activity coefficient of 0.01 M HCl. In Equation 1, as first written, the term γ_{HCl} is referred to 0.904 and enters the calculations only in a ratio with this reference value. Thus, at the start, the present method is considerably more advantageous than that employed by Cohn[4] and others in which their choice of this reference value influences the final values by several per cent. From Equation 1 we may write the identity

$$16.9062\,E - 3.7636 + \log m + 2\log \gamma^{\circ}_{\mathrm{HCl}} = -\log m_{\mathrm{H}} - 2\log \frac{\gamma_{\mathrm{HCl}}}{\gamma^{\circ}_{\mathrm{HCl}}} \qquad (2)$$

This is Equation 14a in Harned and Robinson's paper.[2] Since $\gamma^{\circ}_{\mathrm{HCl}}$ and not γ_{HCl} is known in salt solutions, our first step will be to drop the term containing γ_{HCl} in Equation 2, and define an unreal hydrogen-ion concentration, m'_{H}, by means of the equation

$$16.9062\,E - 3.7636 + \log m + 2\log \gamma^{\circ}_{\mathrm{HCl}} = -\log m'_{\mathrm{H}} \qquad (3)$$

m'_{H} would be the true hydrogen-ion concentration if $\gamma^{\circ}_{\mathrm{HCl}}$ was not changed to γ_{HCl} by the variation of the character of the medium caused by the addition of the undissociated molecule of the weak acid, HA. Since the activity coefficient of hydrochloric acid relative to unity at infinite dilution in water is affected considerably by this variation of the medium, the quantity m'_{H} will be designated throughout the following discussion as the "apparent hydrogen-ion concentration," which will serve to differentiate it from the true hydrogen-ion concentration. Later when we come to learn more of the effect of the medium on both m'_{H} and γ_{HCl}, we shall show how the true hydrogen-ion concentration may in all cases be computed.

By subtracting (3) from (2), we obtain

$$\log \frac{m'_{\mathrm{H}}}{m_{\mathrm{H}}} = 2\log \frac{\gamma_{\mathrm{HCl}}}{\gamma^{\circ}_{\mathrm{HCl}}} \qquad (4)$$

which relates the true and apparent hydrogen-ion concentrations. Harned and Robinson estimated approximately the right-hand member of Equation 4 by assuming that the variation of γ_{HCl} with M was the same for

[3] Randall and Young, THIS JOURNAL, 50, 989 (1928).

[4] Cohn, *ibid.*, 50, 696 (1928).

water–acetic acid mixtures as for water–alcohol mixtures. As a part of this investigation it will be shown that this quantity may be determined accurately from the electromotive forces of the acetic acid-sodium chloride cells.

The thermodynamic equation for the dissociation of the acid is

$$K = \frac{\gamma_H \gamma_{Ac} m_H m_{Ac}}{\gamma_{HAc} m_{HAc}} = \gamma_A^2 \frac{m_H^2}{M - m_H} = \gamma_A^2 k \tag{5}$$

This equation is valid when γ_A equals unity at infinite dilution of electrolyte in a given solvent. Thus, k approaches K as the ionic strength becomes zero. Since our first computation yields the apparent hydrogen-ion concentration, m'_H, and not m_H, we must employ another set of quantities defined by

$$K = \frac{\gamma'_H \gamma'_{Ac} m'_H m'_{Ac}}{\gamma'_{HAc} m'_{HAc}} = \gamma'^2_A \frac{m'^2_H}{M - m'_H} = \gamma'^2_A k' \tag{6}$$

The primed quantities in this equation are all apparent values because of their relation with m'_H. Further, k' does not approach K as the ionic strength approaches zero nor does γ'_A approach unity under this condition. Consequently, the limiting value of these functions will be written k° and γ°_A. As a result we may write

$$K = \gamma_A^2 k = \gamma'^2_A k' = \gamma^{\circ 2}_A k^\circ \tag{7}$$

It should be noted here that γ_A corresponds to $\gamma_{(corr.)}$, the corrected activity coefficient, and γ'_A to γ_A in Harned and Robinson's paper.

The Extrapolation of k' to Infinite Dilution of Both Ions and Undissociated Acetic Acid Molecules.—If we take the logarithm of Equation 5, we obtain

$$\log K = 2 \log \gamma_A + \log k \tag{8}$$

For moderate concentrations, the activity coefficient of any uni-univalent electrolyte, referred to unity at infinite dilution in a given solvent, may be expressed as a function of the ionic strength by the semi-empirical equation

$$2 \log \gamma_A = -A \sqrt{\mu} + 2B\mu \tag{9}$$

The constant *A* is equal to unity for aqueous solutions, whence it will suffice for our purpose to combine Equations 8 and 9 to give

$$\log k - \sqrt{\mu} = \log K - 2B\mu \tag{10}$$

Thus, if we plot (log k $- \sqrt{\mu}$) against μ, a straight line should be obtained, and the intercept for $\mu = 0$ will be log K. Several investigators[5] have employed Equation 10 as a basis for similar extrapolations, but, as we have pointed out before, k' and not k is directly measurable. Furthermore, since m'_H and not m_H is used in calculating the ionic strength, the latter must be written μ' and not μ. In salt solutions of weak acids the

[5] Bjerrum and Unmack, *Det. Kgl. Danske Videnskab. Selskab. Math.-fys. Medd.*, 9, 1 (1929); Sihvonen, *Z. Electrochem.*, 36, 165 (1930).

difference between μ' and μ is very small and does not alter the plot appreciably. In practice, therefore $(\log k^{t} - \sqrt{\mu'})$ is plotted against μ', and although this plot is a straight line, the intercept is not log K, but is a quantity which we shall denote log k^{0}. From the definition of k and k', and Equation 7, we may write

$$\log \frac{k'}{k} = 2 \log \frac{\gamma_A}{\gamma'_A} = 2 \log \frac{m'_H}{ma} - \log \frac{M - m'_H}{M - ma} \tag{11}$$

Since for acids of the strength of acetic the last term on the right is less

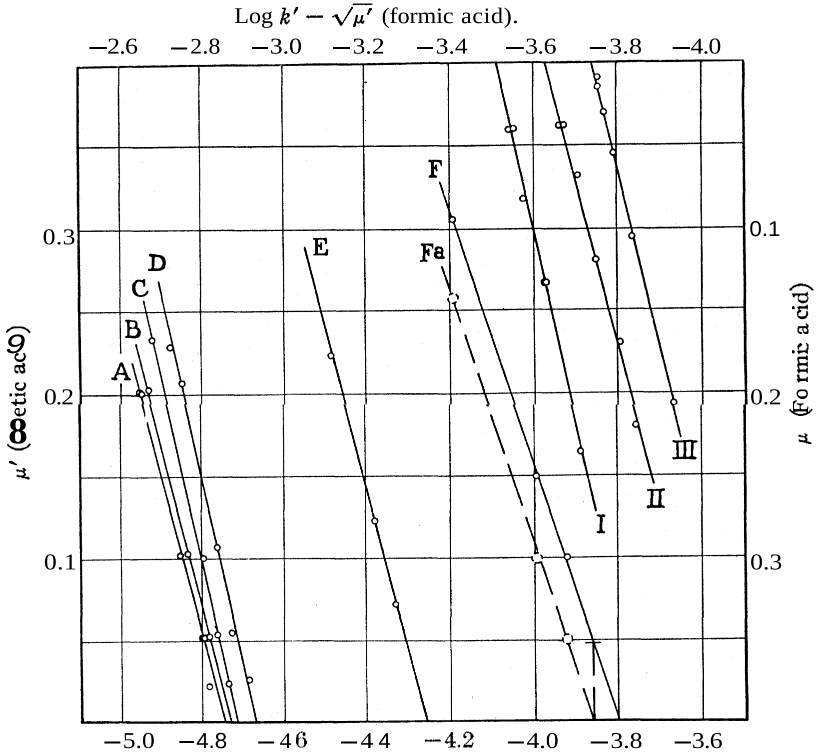

Fig. 1.—Acetic and formic acids in sodium chloride solutions. Molality of acetic acid: A, 0.1; B, 0.2; C, 0.52; D, 1.0; E, 5.41; F, 10.2. Molality of formic acid: I, 2.13; II, 1.0; III, 0.1.

than 0.0008 when M equals 5, it may be neglected. Consequently, rewriting Equation 11 and introducing Equation 4, we obtain

$$\log \frac{k'}{k} = 2 \log \frac{\gamma_A}{\gamma'_A} = 2 \log \frac{m'_H}{m_H} = 4 \log \frac{\gamma_{HCl}}{\gamma^{0}_{HCl}} \tag{12}$$

Further, by combining this equation with (7) and (10), we obtain

$$\log k' - \sqrt{\mu} = \left((\log k^{0} + 2 \log \gamma^{0}_A + 4 \log \frac{\gamma_{HCl}}{\gamma^{0}_{HCl}}\right) - 2B\mu \tag{13}$$

At zero ionic strength, 2 log (γ_A/γ'_A) becomes 2 log $1/\gamma^\circ_A$ by definition, whence by Equation 12

$$2 \log \gamma^\circ_A + 4 \log \frac{\gamma_{HCl}}{\gamma^\circ_{HCl}} = 0, \text{ when } \mu = 0 \tag{14}$$

Consequently, the bracketed member on the right of Equation **13** is log k°.

Since μ' may be written for μ without appreciable error, Equation 13 becomes

$$\log k' - \sqrt{\mu'} = \log k^\circ - 2B\mu' \tag{15}$$

Figure **1** shows the plot of (log $k' - \sqrt{\mu'}$) against μ' for various concentrations of acetic acid in sodium chloride solutions which has been drawn by the use of the data contained in Table I and from which it is obvious that straight lines are obtained.

The first two columns of the table are taken from Harned and Robinson's data. Column 3 contains the values of log $\overset{\circ}{\gamma}_{HCl}$ at the same ionic strength as that obtaining in the acetic acid–sodium chloride cells. These values were obtained from a plot of log $\overset{\circ}{\gamma}_{HCl}$[6] against $\sqrt{\mu}$ of the data given by Harned and Åkerlöf,[7] which have been recalculated to conform with the value 0.904 for 0.01 M hydrochloric acid in pure water. A trial value of $\overset{\circ}{\gamma}_{HCl}$ was used to compute an approximate value of m'_H, which was then employed to compute a more exact value of μ by which a final value of log $\overset{\circ}{\gamma}_{HCl}$ could be read from the plot. Column 4 contains the values of m'_H, calculated by Equation 3, and Columns 5 and 6 the corresponding values of the functions indicated. The quantities in parenthesis are the values of log $k°$ read from the plots in Fig. 1 for infinite dilution of ions. To obtain K it is now necessary to cross-extrapolate these values to infinite dilution of the acetic acid molecules. This can easily be accomplished since we find that $k°$ and K are related by

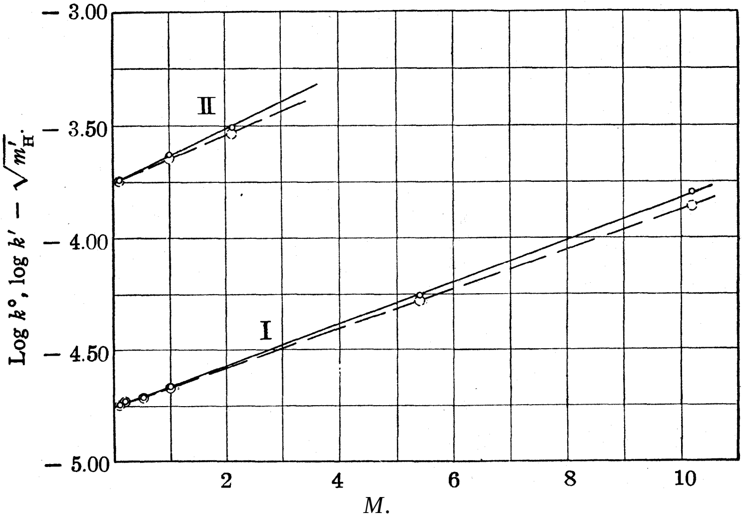

Fig. 2.—Extrapolation for log K. I, Acetic acid; II, formic acid.
——○——, log $k°$; — —○— —, log k' − $\sqrt{m'_H}$.

$$\log \frac{k°}{K} = 2SM \tag{16}$$

where S is an empirical constant which we shall call the medium effect, and M is molal concentration of the acetic acid. Figure 2 contains a plot

---

[6] So long as m_H is of the order of 0.01 molal, or less, the values of the activity Coefficient of hydrochloric acid in salt solutions are practically independent of *r n* and depend only upon μ. Consequently, we have employed the 0.01 hydrochloric acid series throughout. This point was discussed in detail by Harned and Robinson.

[7] Harned and Åkerlöf, *Physik. Z.*, 27, 411 (1926).

of log k° against M. Since a straight line may be drawn through the points, Equation 16 is confirmed. From this plot we find that for acetic acid S equals 0.047 and log K equals –4.758, whence K equals 1.75 X 10^{-5} at 25°.

The Effect of Change of Solvent upon the Quantities under Consideration.—According to Equation 16, we found that log k°/K, the value of log (k'/k) extrapolated to zero ionic strength, varies linearly with the concentration of the weak acid. If *we* ***make*** *the important hypothesis that this effect of the medium due to the undissociated acid maintains at all ionic strengths or is independent of the electrolyte concentrations,* we may combine Equations 12 and 16 and obtain

$$2SM = \log \frac{k^{o}}{K} = 2 \log \frac{1}{\gamma^{\circ}_{A}} = \log \frac{k'}{k} = 2 \log \frac{\gamma_{A}}{\gamma'_{A}} = 2 \log \frac{m'_{H}}{m_{H}} = 4 \log \frac{\gamma_{HCl}}{\gamma^{\circ}_{HCl}} \qquad (17)$$

From the parallel nature of the plots in Fig. 1 and the character of the results obtained by the application of this hypothesis, we regard it as a very close approximation. Upon the basis of this hypothesis, Equation 17 immediately allows the calculation of the true hydrogen-ion concentration and the true activity coefficient of acetic acid in sodium chloride solutions from the data in Table I. It also furnishes an evaluation of γ_{HCl}, the activity coefficient of hydrochloric acid in sodium chloride solutions containing undissociated molecules of acetic acid. Since Equation 17 summarizes the connection between the medium effect and all the thermodynamic quantities under consideration, we shall summarize the approximations involved. Reading from left to right, we shall consider each sign of equality in turn. The first equality is empirical and is justified by Fig. 2. The second is definitional and follows from Equation 7. The third involves the hypothesis that the medium effect is independent of the presence of ions. The fourth and sixth equalities are definitional, and the fifth involves neglecting the small term, log $(M-m'_{H})/$-$(M-m_{H})$, which, however, may be retained, as in Equation 11, if the accuracy of the data would seem to justify this complication.

Properties of the Salt-Free Acetic Acid Solutions, and an Alternate Extrapolation for K.—The dotted line, Fa, in Fig. 1 near that for 10.2 M acetic acid is the plot of (log k' – $\sqrt{\mu'}$) against m, the sodium chloride concentration. If this is assumed to be straight, its intercept is nearly equal to (log k' – $\sqrt{m'_{H}}$) for 10.2 acetic acid in pure water. A more exact value may be obtained from the equation

$$2 \log m'_{H} = R + \sqrt{m'_{H}} + \log (M-m'_{H}) \qquad (18)$$

in which R equals (log k' – $\sqrt{m'_{H}}$). Approximate values of R and m'_{H}-$(= \mu')$ are read from the plot, substituted in the right side of Equation 18 and solved for a more exact value of m'_{H}, which in turn is used to read a more exact value of R from the plot. By repetition of this process until

Equation 18 is satisfied, exact values of R and m'_{H} may be obtained. These are given in Table II together with the true values of m_{H} and log γ_{A} calculated by Equation 17. The noticeable irregularity of these values of log γ_{A} is due to the fact that they represent the difference of two relatively large quantities and include the experimental discrepancy between the experimental points and the straight line in Fig. 2. Figure 2 also contains the plot of (log $k' - \sqrt{m'_{\mathrm{H}}}$) against M, shown as large circles through which a straight line (dashed) extrapolates to log K. This value of K is almost exactly 1.75 X 10^{-5} and thus corresponds very closely to that obtained by means of the log k^{o}, M plot.

Measurements of Cells Containing Formic Acid in Sodium and Potassium Chloride Solutions at 25°.—The electrodes, cells and technique employed in these measurements were the same as described by Harned and Robinson. Table III contains the data. The significance of the various quantities is obvious from the previous discussion of acetic acid. Column 2 gives the observed electromotive force corrected to one atmosphere pressure of hydrogen and divided by 0.05915. All cells which attained equilibrium are included in the table. The electromotive forces of the entire 0.1 M formic acid series in potassium chloride and above 0.025 for m in the sodium chloride solutions are the means of duplicate cells. The average deviation of the individual values from the mean was about 0.04 millivolt for the latter and 0.09 for the former. The data for more concentrated formic acid solutions were obtained with somewhat less care since they were intended only to determine the value of the medium effect.

Figure 1 contains the plot of (log $k^{t} - \sqrt{\mu'}$) against μ', and the extrapolated values of log k° are given in parentheses in Table III, Column 5. The curve for 0.1 M formic acid in sodium chloride solutions, for which the highest accuracy is claimed, gives striking confirmation of the validity of Equation 15 up to $\mu' = 0.2$. The data for 0.1 M formic acid in potassium chloride solutions are not included in Fig. 1 since it extrapolates to the same value of log k° as the corresponding sodium chloride curve,

and diverges too slightly (to the right of Curve III) to be clearly distinguished on the scale used.

The fact that the value of log k° is thus apparently independent of the salt used in the solutions of finite ionic strength is obviously an indication in favor of the assumption leading to Equation 17, but much stress should not be laid upon this point since high accuracy is not claimed for the potassium chloride series, and exact agreement must depend on the values for γ°_{HCl} in sodium and potassium chloride solutions given by Harned and Åkerlöf.

Curve II in Fig. 2 shows the extrapolation for log K for formic acid. The extrapolation represented by Equation 16 is shown by the solid line and leads to the values of 0.0585 and -3.753 for S and log K, respectively. K therefore equals 1.77×10^{-4} at 25°.

The dashed line is based upon values of m'_H equal to 0.004482, 0.01732 and 0.03015 in 0.1, 1 and 2.13 M salt-free formic acid solutions, respectively, and extrapolates to approximately the same value of log K. From the value of S for formic acid and Equation 17, the true values of the hydrogen-ion concentrations and activity coefficients have been calculated from the apparent values, and included in Table III, Columns **6** and 7.

The values for γ_A for the 0.1 M formic acid–sodium chloride series may be expressed by the same type of equation, which holds for a strong electrolyte in similar solutions. Thus, the equation

$$\log \gamma_A = -\frac{0.5\sqrt{\mu}}{1 + 1.175\sqrt{\mu}} + 0.095\,\mu \qquad (19)$$

is valid up to an ionic strength of 3 to within a maximum deviation of 1.75% and an average deviation of 0.85%. Since the dielectric constant of 0.1 M formic acid is not appreciably different from that of water, we have retained the universal constant of 0.5 derived from the Debye and Hückel theory. This calculation shows that by employing the definition of the ionic activity coefficient of a weak electrolyte which Harned has applied to water, and Harned and Robinson to weak acids and bases, we arrive at the conclusion that these quantities may be numerically and theoretically treated by the same methods that were used in the cases of strong electrolytes.

The Dissociation Constants of Some Weak Bases.—By employing the data of Harned and Robinson on the methylamines and ammonia in aqueous sodium chloride solutions, we can determine only one value of k° for each base. In order to calculate the true dissociation constants, K, from k° we have shown that it is necessary to know the values of the medium effects, S, which require additional data for at least two concentrations of base. Even though exact values of S are unknown, our method of extrapolation can be shown to be applicable to solutions of these bases. In Table IV are shown the values of m'_{OH} determined by Harned and Robinson, and the values of μ' and ($\log k' - \sqrt{\mu'}$) calculated therefrom. These latter are plotted in Fig. **3.** Since, on account of the experimental difficulties, the points at high dilution are scattered, it was impossible

lation was accomplished by the use of long curves in such a way that a straight line was approached at dilute ionic strengths. The values of log k° so obtained are included in Table IV in parentheses. The corresponding values of k° are shown in Table V and compared with the accepted values of K calculated from conductivity measurements. Disregarding for the moment the trimethylamine solutions, our values of k° are all slightly higher than those of K, and our experience with the medium effect would lead us to expect this according to Equation 16. In the absence of sufficient data to evaluate S exactly, we have assumed that the value of 0.047 for S, previously found for acetic acid, is applicable to each basic solution and have calculated the corresponding values of K. These are included in Table V and agree satisfactorily with those derived from conductivity data except in the case of trimethylamine. In this case we believe the discrepancy is considerably greater than the experimental error of the measurements, or in the estimation of the medium effect. It should be mentioned that the medium effect must in all probability be intimately connected with the difference between the dielectric constants of water and the weak electrolyte, and since acetic acid and the bases under consideration have dielectric constants of approximately the same magnitude, our assumption of equality of medium effect is logical. Indeed, for the particular concentrations with which we are dealing, an error of 50% in the assumed value of S would only cause an error of 4.3% in K in the cases of the amines, and of 10% for ammonia.

Conclusions and Summary

1. By the use of the extrapolation function. (log k' $- \sqrt{\mu'}$), we have evaluated the dissociation constants of acetic and formic acids from measurements of cells without liquid junction. This method is thermodynamically sound, and employs no extra-thermodynamical postulates. The accuracy of the numerical values obtained depends entirely upon the validity of the empirical extrapolation function used, and the accuracy of the experimental data.

2. By means of Equation 17, the hydrogen-ion concentrations and ionic activity coefficients may be computed in aqueous solutions containing both the weak acid and salts at various concentrations. The logarithm of the activity coefficients of these electrolytes, referred to unity at infinite dilution in water, varies linearly with the weak acid concentration according to the law expressed by Equations 16 and 17. This law is valid at zero

ionic strength and, further, we believe that it is valid, or very nearly so at all salt concentrations. This latter statement may be verified by computing the activity coefficients relative to unity in a given solvent at various concentrations of the undissociated acid molecule. The results thus obtained agree reasonably with what is to be expected according to the Debye and Hückel theory. Since Harned and Robinson considered this matter, we have not considered it in detail in the present investigation.

3. Our value of 1.75×10^{-5} for the dissociation constant of acetic acid agrees closely with 1.785×10^{-5}, recently computed by Davies[8] by applying viscosity corrections to the conductivity data of Kendall.[9] On the other hand, our value of 1.77×10^{-4} for formic acid is considerably lower than 1.87×10^{-4} obtained by Davies with an extrapolation of Auerbach and Zeglin's[10] conductivity data at 18°.

4. Values for the dissociation constants of ammonia, and the mono-, di- and trimethylamines were computed by the same method from Harned and Robinson's data, and compared with those recently compiled.

5. The present investigation, following that of Harned and Robinson, demonstrates how it is possible, from measurements of cells without liquid junction, to evaluate the thermodynamic behaviors of weak acids and bases in salt solutions, and to determine their dissociation constants by a method which is thermodynamically exact.

THE ACID AND BASE CONSTANTS OF GLYCINE FROM CELLS WITHOUT LIQUID JUNCTION[1]

BY HERBERT S. HARNED AND BENTON B. OWEN

RECEIVED JUNE 11, 1930 PUBLISHED DECEMBER 18, 1930

In this study of aqueous solutions of glycine, we shall assume with Bjerrum[2] that the neutral ampholyte molecule in solution exists as "zwitterion," to be designated hereafter "amphion," but our numerical results do not depend upon the validity of this assumption. We further assume complete dissociation of sodium glycinate and glycine hydrochloride in the solutions with which we are concerned, thus

$$ClNH_3CH_2COOH \longrightarrow Cl^- + {}^+NH_3CH_2COOH, \text{ and}$$
$$NH_2CH_2COONa \longrightarrow Na^+ + NH_2CH_2COO^-$$

---

[1] This paper represents part of the dissertation presented by Benton B. Owen to the Graduate School of Yale University, in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] Bjerrum, *Z. physik Chem.*, 104,147 (1923).

or if the sodium glycinate be hydrated

$$HONH_3CH_2COONa \longrightarrow Na^+ + HONH_3CH_2COO^-$$

The amphcation and amphanion being weak electrolytes, their incomplete dissociation may be represented by

$$\begin{aligned} {}^+NH_3CH_2COOH &\rightleftharpoons {}^+NH_3CH_2COO^- + H^+, \text{ and} \\ H_2O + NH_2CH_2COO^- &\rightleftharpoons {}^+NH_3CH_2COO^- + OH^-, \text{ or} \\ HONH_3CH_2COO^- &\rightleftharpoons {}^+NH_3CH_2COO^- + OH^- \end{aligned}$$

For reasons of simplicity we shall hereafter write G^- for the amphanion. $NH_2CH_2COO^-$, Z^* for the amphion, ${}^+NH_3CH_2COO^-$, ZOH^- for the hydrated amphanion, $HONH_3CH_2COO^-$, and ZH^+ for the amphcation, ${}^+NH_2CH_2COOH$ The above equations then become

$$\begin{aligned} ClZH &\longrightarrow Cl^- + ZH^+ && (1) \\ NaG &\longrightarrow Na^+ + G^- && (2) \\ NaZOH &\longrightarrow Na^+ + OH^- && (2a) \end{aligned}$$

and

$$\begin{aligned} ZH^+ &\rightleftharpoons Z^\pm + H^+ && (3) \\ H_2O + G^- &\rightleftharpoons Z^\pm + OH^- && (4) \\ ZOH^- &\rightleftharpoons Z^\pm + OH^-, \text{ and} && (4a) \\ H_2O + G^- &\rightleftharpoons ZOH^- && (5) \end{aligned}$$

The exact thermodynamic equations for the acid and base equilibria in water, in the absence of any effect upon the medium due to the presence of glycine, we represent by

$$K_A = \frac{\gamma_{Z\pm}\ \gamma_{H^+}}{\gamma_{ZH^+}} \frac{m_{Z\pm}\ m_{H^+}}{m_{ZH^+}} = \gamma_A{}^2\, k_A \qquad (6)$$

$$K_B = \frac{\gamma_{Z\pm}\ \gamma_{OH^-}}{\gamma_{G^-}\ a_{H_2O}} \frac{m_{Z\pm}\ m_{OH^-}}{m_{G^-}} = \gamma_B{}^2\, k_B, \text{ or} \qquad (7)$$

$$K_B = \frac{\gamma_{Z\pm}\ \gamma_{OH^-}}{\gamma_{ZOH^-}} \frac{m_{Z\pm}\ OH^-}{m_{ZOH^-}} = \gamma_{Bh}{}^2\, k_{Bh}, \text{ and} \qquad (7a)$$

$$K_h = \frac{\gamma_{ZOH^-}}{\gamma_{G^-}\ a_{H_2O}} \frac{m_{ZOH^-}}{m_{G^-}}. \qquad (8)$$

The "γ's" are the activity coefficients, and the "m's" the molal concentrations of the species denoted by the subscripts. K_h is the equilibrium constant for the hydration of the glycinate ion, and K_A and K_B are the dissociation constants defined by Bjerrum for glycine as acid and base, respectively. k_A, and k_B or k_{Bh}, are the concentration terms in these constants, and γ_A, and γ_B or γ_{Bh}, the corresponding activity coefficients

$$\sqrt{\frac{\gamma_{Z\pm}\ \gamma_{H^+}}{\gamma_{ZH^+}}},\quad \sqrt{\frac{\gamma_{Z\pm}\ \gamma_{OH^-}}{\gamma_{G^-}\ a_{H_2O}}} \quad \text{or} \quad \sqrt{\frac{\gamma_{Z\pm}\ \gamma_{OH^-}}{\gamma_{ZOH^-}}}$$

Now in the measured solutions some neutral glycine is always present in varying amounts. This alters the properties of the medium, the dielectric constants for example,[3] and, therefore, influences the activity coefficients. This "medium effect" has been examined in some detail in a pre-

---

[3] Neutral glycine increases the dielectric constant of water [Fürth, *Ann. Physik,* **70,** 63 (1923)].

vious communication by the authors,[4] and will be referred to later in this paper, so for the present it will only be necessary to state that our measurements yield "apparent" values of the concentrations and activity coefficients defined by the equations

$$K_A = \frac{\gamma'_{Z\pm}\ \gamma'_{H^+}}{\gamma'_{ZH^+}}\ \frac{m'_{Z\pm}\ m'_{H^+}}{m'_{ZH^+}} = \gamma'^2_A k'_A \tag{6'}$$

$$K_B = \frac{\gamma'_{Z\pm}\ \gamma'_{OH^-}}{\gamma'_{G^-}\ a'_{H_2O}}\ \frac{m'_{Z\pm}\ m'_{OH^-}}{m'_{G^-}} = \gamma'^2_B k'_B, \text{ or} \tag{7'}$$

$$K_B = \frac{\gamma'_{Z\pm}\ \gamma'_{OH^-}}{\gamma'_{ZOH^-}}\ \frac{m'_{Z\pm}\ m'_{OH^-}}{m'_{ZOH^-}} = \gamma'^2_{Bh} k'_{Bh}, \text{ and} \tag{7a'}$$

$$K_h = \frac{\gamma'_{ZOH^-}}{\gamma'_{G^-}\ a'_{H_2O}}\ \frac{m'_{ZOH^-}}{m'_{G^-}} \tag{8'}$$

It is important to note that the present investigation does not enable us to differentiate between the hydrated and unhydrated amphanion. We obtain numerical values for a "γ" which may be either γ_B or γ_{Bh}, and a "k" which may be either k_B or k_{Bh}. This is another illustration of the fact that thermodynamics alone does not yield information regarding the nature of the species present or the process taking place. Therefore, for reasons of convenience, we shall employ Equations 6, 7, 6' and 7' and keep the mathematical expressions in formal agreement with those of Bjerrum.

The "medium effect" is a function of the concentration, M, of the weak electrolyte causing a variation in the medium, and its evaluation requires the study of a series of apparent concentrations for several values of M. In this first study of ampholytes by cells without liquid junction, time restricted the measurements to one value of M only, and for this value we selected 0.1. This concentration is high enough to prevent certain experimental difficulties with the electrodes, and small enough to involve only a very small medium effect (probably of the order of 1%). Although we cannot evaluate the small medium effect in this research, we will consistently employ equations which take it into account (primed equations), so that this preliminary paper may serve both as an illustration of the method, and as an exact basis for a more detailed investigation, now under way, concerning the medium effect in glycine solutions.

Experimental Procedure

The cell measurements involved the use of 0.1 molal solutions of glycine hydrochloride, sodium glycinate and sodium hydroxide. Although alkaline solutions of glycine are relatively stable toward boiling, they are rapidly decomposed by oxygen in the presence of finely divided copper.[5] Because of the platinum black on the hydrogen electrodes, it was considered necessary to remove all traces of oxygen from the solutions

---

[4] Harned and Owen, THIS JOURNAL. 52, 6079 (1930).

[5] Traube and Schönewald, Ber., 39, 184 (1906).

during their preparation, and to take every precaution to exclude contact with air during transfer to the cells. An approximately molal solution of sodium hydroxide was prepared by decanting sufficient saturated sodium hydroxide into a flask of thoroughly boiled distilled water, cooled in a stream of hydrogen, and kept thereafter under a pressure of this gas slightly above atmospheric. The solution was standardized against molar hydrochloric acid by means of a 500-cc. weight buret fitted with stopcocks allowing it to be filled and used in an atmosphere of hydrogen only. Next, a six-liter pyrex flask was fitted with a siphon tube bearing a three-way stopcock, an inlet tube with stopcock and a short filling tube bearing a 5-mm. bore stopcock through which the tip of the weight buret could be thrust against a stream of escaping hydrogen. Thirty-five grams of dry ammonia-free glycine was weighed into this flask with sufficient water to make the solution 0.1 molal in sodium glycinate (allowance being made for the water to be added later with the alkali). The glycine solution was boiled and cooled in a stream of pure hydrogen, and kept under a slight pressure of this gas. The boiling was done before the alkali was added to avoid the remote possibility that there might be some decomposition before the last traces of oxygen were removed. Then, by an approximate calibration of the weight buret, the calculated amount of sodium hydroxide solution was delivered into the flask through the large bore stopcock against a brisk counter current of hydrogen. Several weighings were necessary as the last few tenths of a cc. were added, but no air came in contact with the solutions during the manipulations. Since the flask had been tared, the weight of water lost during boiling was calculable, and an equal amount of water, previously boiled and cooled in hydrogen, was admitted through the large stopcock. A similar six-liter flask was fitted up, and in it was prepared an oxygen-free 0.1 molal solution of sodium hydroxide in the manner just described. This solution was to serve as reference solution in one side of the amalgam double cells. Since the same cells and technique are to be employed later with the glycine hydrochloride cells, the 0.1 molal glycine hydrochloride solution was prepared from glycine and molar hydrochloric acid solution in a manner similar to the sodium glycinate solution.

The addition of known amounts of salt to portions of the sodium glycinate solution was carried out in the following manner, and this method also applies *mutatis mutandis* to the glycine hydrochloride solution. Pure dry sodium chloride was weighed into 200-cc. solution flasks fitted with intake and delivery tubes bearing stopcocks. The flasks were then warmed and alternately evacuated and filled with hydrogen to remove the last traces of air, and finally filled with hydrogen. The delivery tube of the flask was then connected to the siphon tube of the sodium glycinate storage flask through a T-tube arranged so that it could be alternately evacuated and filled with hydrogen, thus permitting transfer of solution without the slightest contamination with air. The amount of solution received by the solution flask was then determined by weighing, and the molality of the sodium chloride calculated. The reference solution of 0.1 molal sodium hydroxide was transferred in a similar manner to solution flasks containing no salt.

The amalgam cells employed were of the usual type described by Harned[6] and Åkerlöf[7] except for minor alterations, and a slight reduction in size. In operation each cell contained about 75 cc. of solution, and each bubble tube about 25 cc. Before filling the cells they were fitted with solid rubber stoppers, and connected to the bubble tubes and solution flasks with thick rubber tubing, wired in place. Then the cells, bubble tubes and connections together were alternately exhausted and filled with hydrogen, and finally exhausted, so that when the stopcocks to the solution flasks were opened, the solutions were drawn into cells and bubble tubes containing traces of hydrogen and water vapor only. At this point the cells contained more solution than needed, so the

---

[6] Harned, THIS JOURNAL, 47, 676 (1925).

[7] Åkerlöf, *ibid.*, 48, 1160 (1926).

excess was made to serve the purpose of excluding air while the limbs of the amalgam droppers and hydrogen electrodes were being substituted for the solid rubber stoppers closing the cells. Thus, while this replacement was being quickly made, the pressure of hydrogen from a bubble tube was forcing excess solution out of a cell between the rim and a stopper bearing an electrode, so that the time of simultaneous contact between electrode, air and solution was quite negligible. The amalgam droppers were fitted similarly.

The flow of hydrogen through the cells was begun immediately, and continued at the rate of about three bubbles per second for two or three hours before the flow of amalgam was begun. The droppers contained about 30 cc. of amalgam and required about six minutes to empty. The potentiometer was read thirty seconds after the flow of amalgam was begun, and then two or three times per minute thereafter. In general, the readings increased slightly during the first two or three readings, and then decreased steadily. The difference between the maximum and minimum readings varied roughly in an inverse manner with the salt concentration. Thus, for cells with zero salt concentration, the variation was 0.3 to 0.5 millivolt, while for 2 molal salt the difference was less than 0.1 millivolt.

The Determination of the Dissociation Constant and Activity Coefficient of Glycine as Base.—The electromotive force of the cell

$$H_2/NaOH(0.1)/Na_xHg/NaG(0.1),\ NaCl_{(m)}/H_2 \qquad (I)$$

at 25° is given by

$$E = 0.05915 \log \frac{(0.766)^2\,(0.1)^2\,a_{H_2O}}{(\gamma_{NaOH})^2\,(m + 0.1)\,m_{OH}\,a_{H_2O(0.1)}} \qquad (9)$$

where $a_{H_2O(0.1)}$ is the activity of water in 0.1 M sodium hydroxide, and a_{H_2O} is its activity in the sodium glycinate–chloride solution; 0.766 is the value of the activity coefficient of 0.1 M sodium hydroxide given by Harned and Åkerlöf.[8] It is important to note that our final results are independent of this choice of reference value. We shall let $a_{H_2O(0.1)}$ equal unity, and write Equation 9 as

$$16.9062\,E + 2.2315 + 2 \log \frac{\gamma_{NaOH}}{\sqrt{a_{H_2O}}} + \log p = -\log m_{OH} \qquad (10)$$

by which m_{OH} can be evaluated if we know $\gamma_{NaOH}/\sqrt{a_{H_2O}}$, the activity coefficient of sodium hydroxide in sodium glycinate–chloride solutions. This we do not know, but $\overset{\circ}{\gamma}_{NaOH}/\sqrt{\overset{\circ}{a}_{H_2O}}$, the activity coefficient of sodium hydroxide in sodium chloride solutions has been determined by Harned.[9] Substituting this value in Equation 10 we can calculate an apparent (unreal) hydroxyl-ion concentration defined by

$$16.9062\,E + 2.2315 + 2 \log \frac{\overset{\circ}{\gamma}_{NaOH}}{\sqrt{\overset{\circ}{a}_{H_2O}}} + \log p = -\log m'_{OH} \qquad (10')$$

and anticipated in Equations 6' and 7'. Values[10] of $\overset{\circ}{\gamma}_{NaOH}/\sqrt{\overset{\circ}{a}_{H_2O}}$ were

---

[8] Harned and Åkerlöf, *Physik. Z.*, 27, 411 (1926).

[9] Harned, This Journal, 47, 648 (1925).

[10] So long as m_{OH} is of the order of 0.01 molal or less, the values of the activity coefficient of sodium hydroxide in salt solutions are practically independent of m_{OH} and depend only upon μ. Consequently, we have employed the 0.01 sodium hydroxide series throughout.

recalculated from the data of Harned[9] to conform to the value 0.901, given by Harned and Åkerlöf,[8] for the activity coefficient of 0.01 molal sodium hydroxide in pure water. Table I contains these values at corresponding values of μ read from a plot. The electromotive force, E, is the mean of all the readings made on each cell while the amalgam was flowing, and differs only slightly from the weighted average, using only readings of greatest constancy, or the graphical average from a plot of e. m. f. against time. In the particular case of the cell for which $m = 0$, E is the mean of the "E's" of four such cells, which were 0.09771, 0.09713, 0.09713 and 0.09840. This illustrates the poor agreement at lowest salt concentrations. The values of m'_{OH} were calculated by Equation 10′, of log k'_{B} by the relation $\log k'_{\text{B}} = 2 \log m'_{\text{OH}} - \log (0.1 - m'_{\text{OH}})$ which follows from (7'). The value of log k'_{B} given in parentheses was obtained by extrapolation to infinite dilution of electrolyte, and is therefore log $\overset{\circ}{k}_{\text{B}}$, where $\overset{\circ}{k}_{\text{B}}$ is the apparent basic dissociation constant of glycine. Obviously, $\overset{\circ}{k}_{\text{B}}$ must differ from the real dissociation constant, K_{B}, because its calculation involves extrapolation with a line whose slope is a function of the specific properties of both sodium chloride and sodium glycinate, through the region $\mu = \text{M}$ to $\mu = 0$, in which sodium glycinate alone is present. The same kind of difficulty is encountered in the calculation of activity coefficients of slightly soluble substances by extrapolation of solubility data in salt solutions. K_{B} equals $\overset{\circ}{k}_{\text{B}}$ in the experimentally unrealizable case in which $\text{M} = 0$, or, as we have shown in our previous paper, K_{B} can be evaluated exactly by extrapolation of values of $\overset{\circ}{k}_{\text{B}}$ corresponding to several different values of M. In Fig. 1 (I) are plotted as plain circles the values of log k'_{B} against the ionic strength. The equation of the straight line drawn through the points is

$$\log k_B^\circ - \log k_B' = 2B_B\mu \tag{11}$$

and its intercept corresponds to $k_B^\circ = 5.56 \times 10^{-5}$. To calculate γ_B, the real basic activity coefficient of glycine, we cannot employ Equation 7 directly, because we know neither K_B or k_B. We have, however, demonstrated in our previous paper that $\log k_B'/k_B$ extrapolated to zero ionic

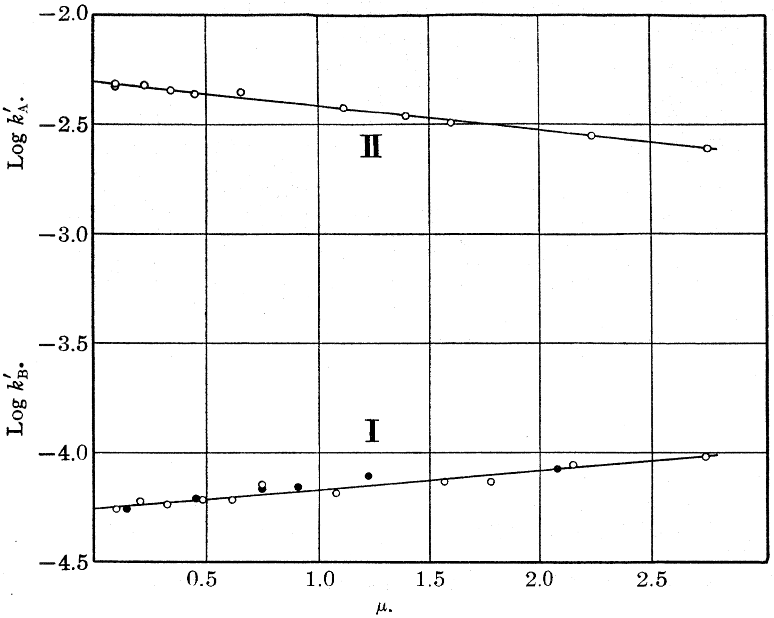

Fig. 1.—Apparent dissociation constants. I, basic; II, acidic

strength becomes $\log k_B^\circ/K_B$, if we are justified in applying to a base this relation discovered for acids. We must also make use again of the hypothesis that this relationship is valid over a considerable range of ionic strengths, so that we may write

$$\log \frac{k_B'}{k_B} = \log \frac{k_B^\circ}{K_B} \tag{12}$$

By combining this with Equation 7, we obtain

$$2 \log \gamma_B = \log k_B^\circ - \log k_B' \tag{13}$$

by which the values given in Table I were calculated. Substituting Equation 11 in 13, we deduce the important relation

$$\log \gamma_B = B_B\mu \tag{14}$$

illustrated by Fig. 2 (I). Indeed this linear variation of $\log \gamma_B$ with μ is to be expected from the nature of γ_B, for, by definition

$$2 \log \gamma_B = \log \gamma_{Z^\pm} + \log \frac{\gamma_{OH^-}}{\gamma_{G^-}} - \log a_{H_2O} \tag{15}$$

Since $Z^{\pm}$ is neutral, the logarithm of its activity coefficient will vary linearly with the salt concentration in dilute or moderately dilute solutions. This is also to be expected for a ratio of ionic activity coefficients of ions of the same valence type. Furthermore, the linear variation of $\log a_{\mathrm{H_2O}}$ will be a close approximation. Hence

$$\left.\begin{aligned} \log \gamma_{Z^{\pm}} &= B_{Z}\,\mu \\ \log \frac{\gamma_{\mathrm{OH}^-}}{\gamma_{\mathrm{G}^-}} &= (B_{\mathrm{OH}} - B_{\mathrm{G}})\mu \\ \log a_{\mathrm{H_2O}} &= B_{\mathrm{H_2O}}\,\mu \end{aligned}\right\} \tag{16}$$

and consequently (14) follows immediately from (15) and (16) by writing $2B_{\mathrm{B}} = B_{Z} + B_{\mathrm{OH}} - B_{\mathrm{G}} - B_{\mathrm{H_2O}}$. These considerations obviously account for the simple linear extrapolation of $\log k'_{\mathrm{B}}$ through Equation **13.**

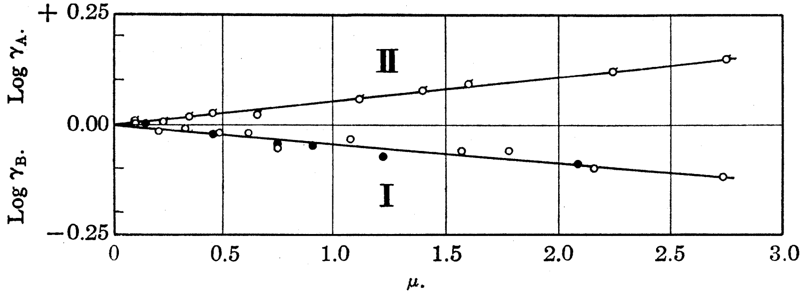

Fig. 2.—Activity coefficient of **glycine.** I, basic; **II,** acidic.

As an important check on the method just outlined, cells in which the silver–silver chloride electrode replaces the amalgam electrode have been employed, and found to give the same numerical results.[11] Since the use of silver–silver chloride single cells in place of amalgam double cells represents a considerable simplification of technique, and a great saving of time, we shall outline the method of calculating our results. It is realized, of course, that the general applicability of the method is limited by the fact that a large number of organic bases have a considerable solvent action upon silver chloride.

If the electromotive force of the reference cell

$$\mathrm{H_2/HCl(0.01)/AgCl/Ag};\ +0.4644 \tag{II}$$

be subtracted from that of the cell

$$\mathrm{H_2/NaG(0.1),\ NaCl(}m\mathrm{)/AgCl/Ag,\ or\ } + \mathrm{E} \tag{III}$$

we obtain the electromotive force, E − 0.4644, of a concentration cell without liquid junction. Thus

$$\mathrm{H_2/NaG(0.1),\ NaCl(}m\mathrm{)/AgCl/Ag/AgCl/HCl(0.01)/H_2} \tag{IV}$$

The equation relating E to the concentrations and activity coefficients is

---

[11] Suggested by work recently conducted in this Laboratory by Dr. E. J. Roberts, [THIS JOURNAL, 52, 3877 (1930)].

$$E - 0.4644 = 0.05915 \log \frac{(0.904)^2\,(0.01)^2}{(\gamma_{HCl})^2\, m_H m} \qquad (17)$$

if the activity coefficient of 0.01 molal hydrochloric acid is taken to be 0.904, as given by Randall and Young.[12] m_H Is the hydrogen-ion concentration in the sodium glycinate solution. This equation permits the calculation of m_H, but since m_{OH} is desired, we must introduce the equilibrium expression for the dissociation of water

$$K_w = \frac{\gamma_{H^+}\,\gamma_{OH^-}}{a_{H_2O}}\, m_H m_{OH} = \gamma_w^2 m_H m_{OH} \qquad (18)$$

Giving K_w the numerical value[13] 1.005 X 10^{-14} and combining (17) and (18), we obtain

$$16.9062\,E - 17.7614 + 2\log\gamma_{HCl} - 2\log\gamma_w + \log m = -\log m_{OH} \qquad (19)$$

Just as in the derivation of Equation (10′), we must introduce known activity coefficients in sodium chloride solutions, in the place of unknown activity coefficients in sodium chloride solutions containing sodium glycinate also. In so doing, we define an apparent hydroxyl-ion concentration, m'_{OH}, thus

$$16.9062\,E - 17.7614 + 2\log\overset{\circ}{\gamma}_H - 2\log\overset{\circ}{\gamma}_w + \log m = -\log m'_{OH} \qquad (19')$$

Table II contains the results of the measurements with silver-silver chloride electrodes. The average electromotive force, E, was measured (Cell III) over a period of at least four hours during which the maximum deviation from the mean did not exceed 0.05 millivolt. The values of log $\overset{\circ}{\gamma}_{HCl}$ were read from a plot of the data of Harned,[8] and the values of log $\overset{\circ}{\gamma}_w$ were obtained from a similar plot of $\overset{\circ}{\gamma}_{HCl}$ and $\overset{\circ}{\gamma}_{NaOH}/\sqrt{\overset{\circ}{a}_w}$, and more recent values of $\overset{\circ}{\gamma}_{NaCl}$ determined by Harned.[14] Column 5 contains the values of m'_{OH} computed by Equation 19'. The values of log k'_B and log γ_B were computed as in the preceding section, and are included in Figs. 1 and 2 as inked-in circles. It is obvious that the same straight

lines will serve to represent both the plain and inked-in circles within the experimental error.

The Determination of the Dissociation Constant and Activity Coefficient of Glycine as Acid.—The type of cell used to evaluate the acid constants of glycine is identical to that used previously in the study of acetic[15] and formic[4] acids, and to Cell III of this research. Thus E, the measured electromotive force, applies to the cell

$$H_2/HZCl(0.1),\ NaCl(m)/AgCl/Ag;\quad E \qquad (V)$$

from which we subtract, as before, the electromotive force of Cell II to obtain the electromotive force of the complete concentration cell without liquid junction, *viz.*

$$H_2/HZCl(0.1),\ NaCl(m)/AgCl/Ag/AgCl/HCl(0.01)/H_2 \qquad (VI)$$

The equilibrium expression for this cell is

$$E - 0.4644 = 0.05915 \log \frac{(0.904)^2\ (0.01)^2}{(\gamma_{HCl})^2(m + 0.1)m_H} \qquad (20)$$

in which the significance of the symbols and numerical values is obvious from the discussion of Cell III. In simplifying this equation we shall simultaneously replace γ_{HCl} by the known function $\overset{\circ}{\gamma}_{HCl}$ and solve for the apparent hydrogen-ion concentration, thus

$$16.9062\,E - 3.7636 + 2 \log \overset{\circ}{\gamma}_{HCl} + \log \mu = -\log m'_H \qquad (20')$$

The experimental values of E are the averages of the readings taken on each cell over a period of at least four hours in which the maximum deviation from the mean was not over 0.08 millivolt. The values of log $\overset{\circ}{\gamma}_{HCl}$ were read from the same plot used for this purpose in Equation 19′, and are shown in Table III along with E, and m'_H calculated therefrom with the

[15] Harned and Robinson, THIS JOURNAL, 50,3158 (1928).

aid of Equation 20'. The values of log k'_A given in the fifth column were calculated by the relation log $k'_A = 2 \log m'_H - \log (0.1 - m'_H)$, and are plotted in Fig. 1 (II). As in the case of the basic system, log k'_A is a linear function of μ, and the equation of the straight line is

$$\log k^{\circ}_A - \log k'_A = 2B_A\mu \tag{21}$$

From similar concentrations to those by which we derived Equation 13, we may obtain the expression

$$2 \log \gamma_A = \log k^{\circ}_A - \log k'_A \tag{22}$$

by which the values of log γ_A shown in Table III were calculated. Combination of Equations 21 and 22 leads to the important relation

$$\log \gamma_A = B_A\mu \tag{23}$$

This linear variation of log γ_A with μ is demonstrated experimentally in Fig. 2 (11), and follows theoretically from the definition of γ_A. Thus, for

$$\log \gamma_A = \log \gamma_{Z\pm} + \log \frac{\gamma_{H^+}}{\gamma_{ZH^+}} \tag{24}$$

we may write

$$\log \gamma_A = B_Z\mu + (B_H - B_{ZH})\mu = B_A\mu \tag{25}$$

because the logarithm of the activity coefficient of a neutral particle and the ratio of two ionic activity coefficients of the same valence type are both linear functions of the ionic strength. The extrapolated value of log k'_A at infinite dilution of electrolyte is log k°_A, and is given in Table III in parentheses. This corresponds to the value 4.92×10^{-3} for k°_A.

Summary

1. Making use of 0.1 molal sodium glycinate and glycine hydrochloride solutions, the apparent dissociation constants of glycine have been measured at 25°. The values obtained are $k^{\circ}_A = 4.92 \times 10^{-3}$ and $k^{\circ}_B = 5.56 \times 10^{-5}$. For purposes of comparison, we may write $k^{\circ}_A = K_A$, and $k^{\circ}_B = K_B$, because, for the dilution we have used, the error introduced by this approximation is negligible compared to the discordance among the various values of K_A and K_B recorded in the literature. Branch and Miyamoto[16] list the results of six independent electrometric studies of glycine besides their own. If we include our results and those of Bjerrum and Unmack,[17] the mean values for the nine determinations are $K_A = 4.26 \times 10^{-3}$ and $K_B = 5.14 \times 10^{-5}$, with average deviations from the means of 10 and 13.6%, respectively. This unsatisfactory agreement in the literature can be traced, in no small part, to uncertainties inherent in the methods used. Among these, liquid junctions and unrecognized medium effects are sources of error that are eliminated in the method we have just described. The elimination of liquid junction has actually been carried out

---

[16] Branch and Miyamoto, THIS JOURNAL, 52, 863 (1930); cf. Kirk and Schmidt, *U. of California Pub. Physiol.*, 7, 57 (1929).

[17] Bjerrum and Unmack, *Det. Kgl. Danske Videnskab, Selskab, Math.-fys. Medd.*, 9, 1 (1929).

in this paper, but the complicated and laborious study of the medium effect of glycine has just been begun experimentally.

2. It has been demonstrated that the use of silver-silver chloride electrodes or amalgam electrodes leads to identical results in the measurements with alkaline glycine solutions.

3. In the absence of any information concerning the medium effect of glycine, we have drawn, by analogy, upon our study of this subject with acetic and formic acids, and have calculated the activity coefficients of the 0.1 molal amphanion and amphcation in sodium chloride solutions. The logarithms of the activity coefficients are linear functions of the ionic strength, which is in accord with theory.

4. By an exact thermodynamic method which eliminates the use of liquid junctions and which takes into account certain medium effects heretofore neglected, we have shown that the acid and base constants of an ampholyte may be evaluated. Further, in the case of glycine, the first steps toward an experimental solution have been made, and preliminary values of the important constants determined.

A MANOMETER FOR THE MEASUREMENT OF SMALL PRESSURE DIFFERENTIALS AT HIGH PRESSURES[1]

BY JAMES H. BOYD, JR.[2]

RECEIVED JULY 12, 1930 PUBLISHED DECEMBER 18, 1930

Introduction

In an investigation of the viscosity of compressed gases by the author a new instrument was developed[3] for the measurement of the small pressure differentials which existed between the two ends of a capillary tube through which flowed compressed gas. It relies on electrical means for determining the pressure differential but requires no calibration and does not demand the use of clean mercury to gain accurate results. This manometer is primarily a laboratory precision instrument though by suitable calibration it may be used as a high pressure flowmeter.

The only other instrument for this use at high pressures described in the literature and known to the author is that used by Wildhagen.[4] It

---

[1] This article is based on a thesis submitted in partial fulfilment of the requirements for the degree of Doctor of Science from the Massachusetts Institute of Technology.

[2] Formerly Research Assistant, Research Laboratory of Applied Chemistry, Massachusetts Institute of Technology. Present address, 3144 Passyunk Ave., Philadelphia, Pa.

[3] J. H. Boyd, Jr., *Phys.* Rev., 35, 1284 (1930).

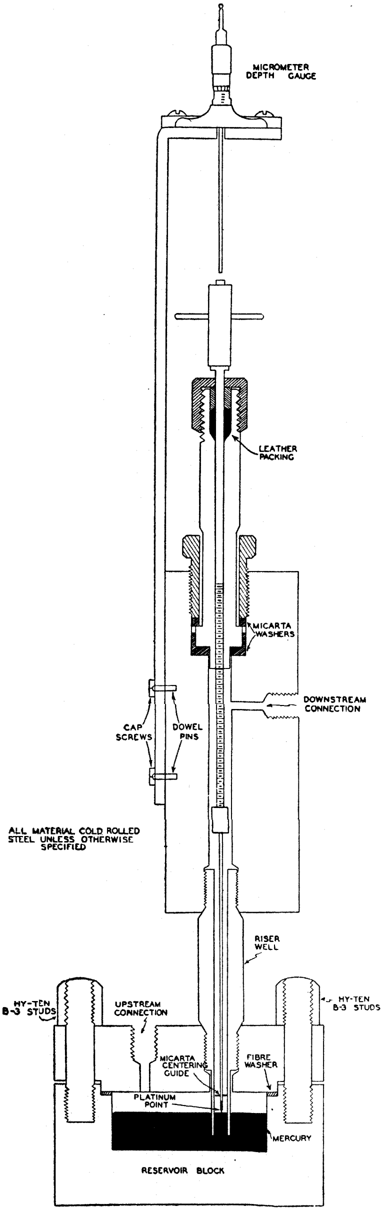
[4] Wildhagen, *Z. angew. Math. Mech.*, 3, 181 (1923).

consisted in principle of a mercury-filled differential steel manometer in one arm of which was a fine platinum resistance wire coaxial with the tube. On applying a pressure differential to the manometer the mercury rose in the arm containing the wire and decreased the electrical resistance of a circuit of which the previously calibrated platinum wire formed the major resistance. In such an instrument errors due to the contamination of the mercury might well prove serious and such fouling is difficult to avoid in practice. Were the mercury contaminated it would adhere to the wire on receding after making an observation and subsequent lesser differential readings would be in error owing to the change in the apparent resistance of the exposed wire.

The New Manometer.—The new differential manometer does not require any calibration and the use of clean mercury is not imperative though ordinary precautions taken to avoid undue contamination are desirable. Essentially, the instrument consists of a mercury reservoir of relatively large diameter (8.9 cm.) beneath whose mercury surface projects the lower end of a riser well of relatively small bore (8 mm.) in which runs a movable screw rod enabling the completion of an electrical circuit through the mercury. The whole is suitably enclosed to permit the use of high pressures. The level of the mercury in the riser well is determined by trial by moving the contact or screw rod so as to make and then break the circuit as indicated by a galvanometer. When this has been done the relative position of the screw rod is determined by measuring the distance to the top of the rod from a fixed reference plane by means of a micrometer depth gage. The difference of such readings when the upstream and downstream pressures are equal and when they are unequal, as is the case for gas flow, is the observed pressure differential. The true differential is obtained on correcting for the drop in level in the reservoir corresponding to the elevation in the riser well, for the buoyant effect of the displaced gas and for the temperature variation of the mercury density. If desired further corrections for the capillarity and compressibility of the mercury may be applied. Calculation showed that pressures up to **3000** lbs. per sq. in. and fluctuations in the room temperature did not affect appreciably the instrument readings.

The construction of the manometer is shown diagrammatically in Fig. 1, which is approximately to scale. A set screw in one of the guide blocks and a stop pin not shown in the drawing allow locking the depth gage in a fixed position. The instrument was designed to give a factor of safety of five based on the ultimate tensile strength of the steel for a working pressure of **5000** lb. per sq. in. at room temperature. The maximum pressure actually used was **3000** lb. per sq. in.

Four auxiliary valves are necessary in the operation of the instrument. Two valves, one in each connection line, permit isolation of the manometer from the rest of the system. A third valve in a by-pass line allows equalization of pressures in the instrument, while the fourth serves as a pressure relief for the mercury reservoir. In addition a mercury trap in the downstream connecting line between the valve and the manometer is desirable to prevent accidental flooding of the rest of the apparatus with mercury.



1.—Diagrammatic sketch of high pressure manometer.

Operation of the Manometer.—The operation of the instrument is quite simple. It is brought under pressure with only the downstream valve open to allow gas to flow down the riser well and under the mercury seal, thus substantially equalizing the pressure in the system. Complete equalization of pressure results on opening the by-pass valve. The zero reading is now made by running the screw rod down until electrical contact with the mercury is made, as shown by the deflection of the galvanometer needle, and then slowly screwing the rod upward until the circuit is just broken. The relative position of the top of the rod on breaking the circuit is determined by measurement with the depth gage from the reference plane. The micrometer gage reads directly to 0.025 mm. (0.001 in.) but the graduations on the barrel permit estimation to 0.0025 mm. (0.0001 in.). The mean of several such readings agreeing within 0.025 mm. (0.001 in.) is taken as the zero reading. This procedure gives very reproducible results. The source of e. m. f. for the circuit is a copper–constantan thermocouple immersed in ice water. The couple is very satisfactory for this purpose as the feeble current so produced minimizes arcing at the mercury surface. After making the zero readings the rod is run up to a greater height than the mercury level anticipated in the ensuing experiment, the by-pass valve is closed and the upstream valve opened. The mercury now rises to its equilibrium position and the observations are again made. In each case the mercury approaches its equilibrium level from below, which tends to introduce a compensation of errors on taking the difference of the two average readings to obtain the apparent pressure differential. The true differential is obtained on applying the corrections previously mentioned. At the conclusion of a series of experiments the pressure in the flowmeter is relieved in order to avoid forcing mercury over into the trap should a leak develop at the rod packing.

Results

The absolute accuracy of the measurement of the pressure differential is not known but in view of the compensation remarked above the error should never exceed the average deviation observed in making a series of zero readings. In Table I a series of consecutive, average zero readings is given which was made over an eight-day period at gage pressures ranging from zero to 3000 lb. per sq. in.

TABLE I

CONSECUTIVE MEAN ZERO DETERMINATIONS, IN INCHES

2.4249	**2.4247**	**2.4265**	**2.4247**
39	**66**	**71**	**45**
82	**62**	**76**	**57**
74	**60**	**73**	**67**
26	**73**	**45**	**43**
57	**59**	**45**	**44**
43	**61**	**51**	**43**

Grand average	**2.4256**
Maximum deviation	**0.0030**
Average deviation	.0011

The tabulated results show the zero reading to be reproducible and indicate that the error in the measurement of a pressure differential does not exceed 0.025 mm. **(0.001** in.). Such accuracy is sufficient for most purposes.

Conclusion

While the instrument described above was satisfactory, certain changes are recommended for future work. The use of a larger riser well will eliminate capillarity effects and also allow the use of **a** larger screw rod whose greater rigidity will make the micarta centering disk unnecessary. In addition the screw rod assembly should be made in two pieces, the lower or contact rod being threaded into the screw rod proper and secured in place by lock nuts. This would necessitate a larger screw rod, which would facilitate packing the rod. Moreover, the bushing through which the rod handle ran and the pin driven into the bushing might well be eliminated.

The author wishes to acknowledge his appreciation of the financial aid granted him by the Research Laboratory of Applied Chemistry and the Committee on Graduate Courses and Scholarships of the Massachusetts Institute of Technology. He also wishes to thank his friends for their many helpful suggestions.

Summary

A manometer has been developed which is capable of measuring by electrical means pressure differentials of an inch of mercury with an accuracy of one part in 1000 at a pressure of 3000 lb. per sq. in. The instrument is direct reading and requires neither calibration nor the use of very clean mercury.

THE THERMAL HYDROGEN–OXYGEN COMBINATION. FORMATION OF HYDROGEN PEROXIDE, AND THE INFLUENCE OF SURFACE NATURE[1]

BY ROBERT N. PEASE[2]

RECEIVED JULY 18, 1930 PUBLISHED DECEMBER 18, 1930

Hydrogen peroxide has not before been reported as a product of the slow reaction between hydrogen and oxygen which takes place in the neighborhood of 550° and 1 atm. Indeed Rowe[3] states that none could be detected by the sensitive titanium sulfate test. This paper reports the results of some flow experiments in which easily detectable quantities were obtained. In addition there are reported some data on the effect of the nature of the reaction tube surface on the hydrogen–oxygen reaction.

The experiments were of the flow type. Compressed hydrogen and oxygen were passed through flowmeters and a drying system to *a* cylindrical reaction tube of pyrex glass to the ends of which were sealed 2-mm. capillaries. The off-gas passed through a weighing tube cooled to $-79°$. The reaction tube was contained in an electrically heated furnace the temperature of which was automatically controlled to about $\pm 2°$. Hydrogen peroxide was determined by washing out the weighing tube and titrating the product with 0.02 normal potassium permanganate in sulfuric acid solution.

---

[1] This paper contains results obtained in an investigation entitled "Catalytic Methods Applied to Petroleum Hydrocarbons" listed as Project No. 7 of American Petroleum Institute Research. Financial assistance in this work has been received from a research fund donated by Mr. John D. Rockefeller. This fund is being administered by the Institute with the cooperation of the Central Petroleum Committee of the National Research Council. Professor Hugh S. Taylor, of Princeton University, is Director of Project No. 7.

The Reaction at Atmospheric Pressure.—The data of Table I refer to experiments in which the reaction tube was approximately 1.7 cm. in diameter and 10 cm. long and had a volume of 20.8 cc. The cleaning of the reaction tube is an important point. In this case the tube was rinsed out twice with hot concd. nitric acid, and then a dozen times with distilled water. The total gas flow was usually 40 cc. per minute at 25° and atmospheric pressure (about 760 mm.). Since the reaction rate is subject to considerable variation, each set of data was bracketed with sets to which it was to be compared. The average of three separate determinations is given in each case. Results are expressed in terms of milligrams of products formed per half-hour, and also as exit-gas concentrations (in 0.01 atm., calculated for 25° and 1 atm. total pressure). In most of the runs the entering gases were saturated with water vapor at 0°, as the behavior of the reaction was somewhat more steady under these conditions. This water was subtracted from the total found in the weighing tube. Complete conversion of 10 cc. per minute of hydrogen in a half hour would yield 220 mg. of water.

In spite of the irregularity of the results, certain conclusions as to the formation of water and hydrogen peroxide may be drawn. It is, first of all, clear that the initial presence of traces of water vapor is not essential. When the heating time is cut to one-third by tripling the gas flow, the off-gas concentration of water vapor is cut to one-tenth while that of the peroxide is not measurably altered. The reaction is clearly auto-accelerated so far as water formation is concerned. The peroxide appears to attain an approximate steady-state concentration. One cannot conclude from these data that hydrogen peroxide is the sole primary product but the results point in that direction.

Experiments on the effect of hydrogen-oxygen ratio show clearly that formation of both products is more rapid with excess of hydrogen. Water formation is again the more affected. A rise of 10° in reaction tube temperature increases the yield of water 2- to 4-fold, and about doubles the peroxide formed over the range studied. The temperature coefficient appears to depend on the $H_2:O_2$ ratio.

These results may be taken to indicate that hydrogen peroxide is a primary product of the hydrogen–oxygen reaction, that water is formed auto-catalytically, and that the reaction is favored by a high ratio of hydrogen to oxygen as well as by high temperature.

There are many other conclusions that might be drawn from these and the quantities of other data on the reaction which we have obtained. Aside from the above, however, the only certainty is that the highly capricious behavior of the reaction mixture in pyrex reaction vessels has made this a most unsatisfactory reaction to deal with. According to Hinshelwood,[4] the reaction in silica vessels is very similar in behavior, glazed porcelain being rather more satisfactory to work with.

The Reaction at Low Pressures.—Hinshelwood[5] has reported the extraordinary fact that hydrogen–oxygen mixtures become unstable and explode within a restricted low-pressure range at temperatures above about 450°. It was of interest to confirm this by a somewhat different method and especially to determine whether the formation of hydrogen peroxide could be detected. Accordingly the flow apparatus was altered to include a three-way stopcock before the reaction tube, a reaction tube about 1 cm. in diameter by 10 cm. long into which the reaction gases passed via a drawn-out capillary, and a vacuum pump and gage for reducing and reading the pressure at the outlet end. With these alterations a number of runs were made. Results are recorded in Table II.

The results are essentially in agreement with those of Hinshelwood as to the existence of an upper pressure limit. There was immediate (but not complete) reaction up to a certain pressure and then a rapid decrease in reaction rate at higher pressures. A significant feature of the results is that no trace of hydrogen peroxide was detectable in the region of rapid action. Nevertheless, at higher pressures with only small amounts of

water being formed, hydrogen peroxide was obtained in easily detectable amounts. In this connection it is to be remembered that the exposure time was shorter in proportion at the lower pressures. The failure of hydrogen peroxide to escape from the reaction tube at the low pressures in the explosion region might be ascribed to the high temperatures attained in the gas. It is not unlikely, however, that the peroxide is itself accountable for the explosivity. A possibility is that a freshly-formed peroxide molecule is subject to dissociation yielding atomic oxygen. If the molecule enters into collision with a normal molecule within a minimum time after formation, it is stabilized. Failing this, it dissociates and produces the chain of results characterizing the explosion. High pressures would favor stabilization, while low pressures would permit of dissociation.

Effects Due to Surface.—Hinshelwood[4,5] has shown that the hydrogen–oxygen reaction is repressed when the reaction vessel is packed with broken wall-material, in the case of porcelain and silica vessels. Data showing that this is also true for pyrex reaction vessels are given in Table III. In addition, the importance of the nature of the surface is brought out by data in this table. When either an empty or a packed reaction tube is rinsed out with a potassium chloride solution, the reaction rate is subject to a marked decrease. Thus, whatever the action of the glass surface may be in suppressing reaction, this action is enhanced by coating the glass with a film of potassium chloride. The special feature of this effect is that it is so marked in the empty tube. Although no direct comparison was made, the rate must be reduced about 2000-fold by the coating.

Without detailing the results, it may be said that treatment with potassium hydroxide solution is about equally as effective as treatment with potassium chloride. In addition, treatments with solutions of aluminum nitrate, barium nitrate, arsenious chloride or phosphoric acid were

TABLE III

HYDROGEN–OXYGEN COMBINATION. EFFECT OF PACKING AND COATING

625		Explos.	10.4	.43
650				.63

all more or less effective. This is in comparison with the same tube when rinsed first with nitric acid and with water. Treatment with a copper nitrate or chromic acid solution caused a marked increase in rate, due no doubt to positive surface catalysis. Yet even in these cases it is significant that no hydrogen peroxide was formed, and that the kinetics were so altered as to suggest that the original reaction had again been suppressed. It may be mentioned that no treatment gave better yields of hydrogen peroxide than the original one with hot concd. nitric acid.

Summary

1. The hydrogen–oxygen combination in pyrex reaction vessels has been studied by the flow method.
2. It has been found that hydrogen peroxide is formed in readily detectable amounts along with water. The former may be the primary reaction product.
3. The reaction mixture becomes unstable at low pressures and reacts explosively, but yields no peroxide under these conditions.
4. Reaction may be partially suppressed by filling the reaction vessel with broken pyrex glass or better by coating its inner surface with any one of a number of substances, among which is potassium chloride.

THE SPECIFIC HEATS OF GASES AT HIGH PRESSURES. II. METHOD AND APPARATUS AT HIGH TEMPERATURES[1]

BY NORMAN W. KRASE AND B. H. MACKEY

RECEIVED AUGUST 11, 1930 PUBLISHED DECEMBER 18, 1930

Introduction

This paper is the second of a series from this Laboratory reporting methods and measurements of the specific heats of gases at high pressures and over a range of temperatures. The first paper[2] described the apparatus developed for use at ordinary temperature and over a range of pressures to 1000 atmospheres. The present one describes a new calorimeter suitable for measurements over the entire range of pressures and up to temperatures of 350° or more. The experimental method is essentially the same as previously described, the new features being concerned entirely with the calorimeter and thermostat. The arrangement of gas storage cylinders, compressor and recirculating system is unchanged. In order to carry the measurements to higher temperatures, an entirely new calorimeter and thermostat were designed and built.

The Thermostat and Calorimeter

Reference to Fig. 1 in the first paper in this series[2] shows the function of the thermostat. This piece of apparatus must be capable of delivering gas at the desired pressure and temperature to the calorimeter at a constant rate of flow. For temperatures used in this work a satisfactory thermostat was built by coiling up about 3.5 meters of 6.5-mm. by 1.5-mm. steel tubing and casting a cylindrical block of copper around the coiled portion. An electric heater was wound on the casting and a Beckmann thermometer placed in a hole drilled in the casting. The temperature was manually controlled by external resistances and could be held to about 0.01°. The gas leaving the thermostat entered the calorimeter through a short, well-insulated tube.

The calorimeter is shown in Fig. 1. The gas, preheated to a temperature usually 5 or 6° below the calorimeter temperature, enters through the horizontal tube shown sectionally at the left.

It passes down through the vertical tube, also shown in section, through the coiled portion, then up through the right-hand tube and out through the horizontal tube shown in full. The coiled portion of the calorimeter tubing is embedded in a copper casting 7.5 cm. long and 6.4 cm. in diameter. This casting also contains an electric heater and a thermometer. By means of the heater the temperature of the calorimeter block is maintained constantly about 5 or 6° above the temperature of the thermostat. During its passage, therefore, the gas takes heat from the calorimeter and its temperature rises. The heat taken up by the gas is continuously supplied by the electric heater, so that the temperature of the calorimeter remains constant. To reduce as much as possible the heat losses by conduction, radiation, etc., the calorimeter is enclosed in a pyrex Dewar flask having an internal diameter of 7 cm. and an internal length of 29 cm. Surrounding

[2] Krase and Mackey, THIS JOURNAL, 52,108 (1930).

the Dewar flask is a heavy, cylindrical copper casting 46 cm. long, 10 cm. inside diameter, and having a wall 15.5 mm. thick. Copper disks close both ends of the cylinder; openings in the upper disk are provided for the necessary electrical leads, the thermometer, and the two steel tubes carrying thermocouple wires shown in the drawing. The other wires and the thermometer and heater are not shown. In order to operate the calorimeter adiabatically, the copper jacket is kept at the same temperature as the calorimeter by means of an electric resistance heater wound around the casting. A thermometer inserted in a hole drilled through the top disk and into the wall of the cylinder indicates the jacket temperature. A thick layer of insulation covers the jacket.

This calorimeter differs from the one previously described particularly because of certain improvements in the method of measuring the temperature rise of the flowing gas and the heat losses by conduction along the steel tubing.

As will be noted in Fig. 1, the wires comprising the couples for reading the rise in temperature of the flowing gas enter at the top ends of steel tubes extending about 13 cm. above the calorimeter cover. This arrangement not only removes the bakelite compression seals from the heated zone but also reduces the temperature gradient along the portion of the tubes through which the gas flows. This latter fact is extremely important in reducing heat conduction losses along the steel tubing. A secondary advantage, also, is the reduction in heat flow along the thermocouple wires as a result of this arrangement. The ends of the coiled calorimeter tubing are connected by "gradient" tubes having a uniform steel cross section for a length of 10 cm. to the gas inlet and outlet tubes. Five copper–constantan thermocouples equally spaced along each of these gradient tubes provide readings of the temperature drop along the tubes and thus data for calculating the heat

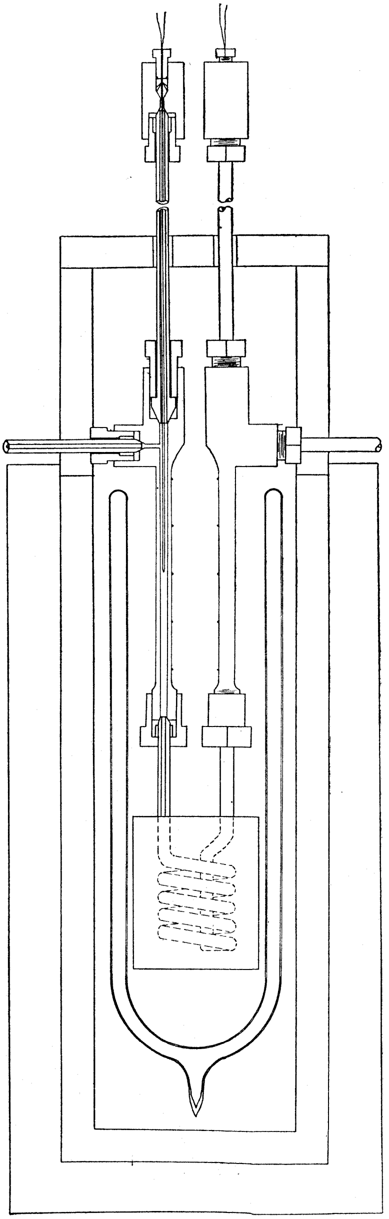

Fig. 1.

flow away from the calorimeter block. The thermojunctions for measuring gas temperature rise are located at the midpoint of the uniform section of the gradient tubes. The thermocouples can be removed from position and calibrated without disturbing the bakelite seals or other connections.

For calorimeter temperatures to 150° Beckmann thermometers are most satisfactory. Since these thermometers are used only to indicate constancy of temperature, the absolute temperature need be known only to about one-tenth of a degree. The settings were checked using liquids of known boiling points as calibration standards.

Experimental Methods

Reference to the first paper is suggested for experimental details. In addition to the measurements described previously it was thought desirable to know the absolute temperature of the gas leaving the calorimeter. The usual experimental routine involved measuring only the gas temperature rise—not its absolute temperature. Since the question of average gas temperature for a given measurement is important for accurate work, a number of experiments were performed designed to measure the exit temperature of the gas. A copper–constantan couple similar to those used in the calorimeter was inserted together with the Beckmann thermometer in the jacket well and the constantan wire connected with that of the couple in the exit tube of the calorimeter. If the exit gas temperature and jacket temperature were the same, the reading of the couples would be zero. The results of a number of such trials showed that the exit gas reached practically the same temperature as the calorimeter within an experimental error of about 0.06". Practically perfect heat transfer was, therefore, accomplished between gas and calorimeter and the temperature of the calorimeter may be taken as the gas temperature for all purposes.

In this work, the rates of gas flow used ranged from 0.7 to 1.5 moles per minute and the results were entirely independent of rate of flow, indicating the absence of systematic errors in measurements. Further refinements in measuring the rate of gas flow involved enclosing the indicating capillary meter and the wet meter as well as the gas humidifier in a compartment whose temperature was thermostatically controlled. Small changes in temperature were sufficient to alter the calibration of the wet meter considerably.

The use of an adiabatic calorimeter at elevated temperatures involves heating the jacket to practically the same temperature as the calorimeter. In the present case this was accomplished by winding a nichrome electrical resistance coil on the copper casting and passing a 110-volt alternating current through it, controlled by an external resistance. It was found that this arrangement generated heat by induction in the copper casting inside the Dewar flask. The effect was very considerably reduced by using a non-inductive winding on the jacket but was not entirely eliminated. Separate measurement of this induced heat was, therefore, necessary at each calorimeter temperature used. The use of direct current for jacket heating was the obvious remedy but this, unfortunately, was not available. The correction was measured by using the same gas flow as during a regular experiment but raising the thermostat temperature so that the gas entered the calorimeter at practically the calorimeter temperature. No heat was supplied to the calorimeter proper except that received by induction from the jacket current. The rise in gas temperature was measured and this subtracted from the observed rise in the regular experiment. The correction measured in this way not only included the induced heat but also any heat change due to a Joule–Thomson effect within the calorimeter.

Table I shows typical results for nitrogen from 30 to 150° at 500 atmospheres pressure. A subsequent paper will give complete data for nitrogen over a range of pressures to 700 atmospheres and temperatures to 150°.

TABLE I

TYPICAL RESULTS FOR NITROGEN

Experiment no.	30	80	108	122
Absolute pressure, atm.	500	500	500	500
Av. calorimeter temp., °C.	30	50	100	150
Gas temp. rise, °C.	6.85	6.84	7.63	6.78
Gas flow, moles/min.	1.412	1.496	1.335	1.383
Heat loss by conduction	0.1	0.15	0.2	0.3
Heat gain by induction	...	0.5	1.4	4.7
Corrected power input	88.2	90.6	85.4	76.5
Molal heat capacity	9.12	8.85	8.39	8.13

Summary

A constant-temperature, adiabatic, flow calorimeter for the measurement of specific heats of gases at high pressures and temperatures has been developed. Typical results for nitrogen together with the methods of measurement and calculation are given.

THE STRENGTH OF ORGANIC BASES IN GLACIAL ACETIC ACID SOLUTION[1]

By Norris F. Hall

Received August 26, 1930 Published December 18, 1930

Although the earlier papers of this series have frequently dealt with the titration of organic amines in glacial acetic acid, the subject has been treated more or less incidentally, and only scattering selections have been made from the available data. In the present paper are summarized the results of a study of a large number of these compounds, and it has been possible to draw certain conclusions of interest to the general theory of acidity. A clear parallelism has been found between the strengths of these bases in acetic acid and in water, and the results are compared with similar results by other workers in three other solvents.

Table I presents an alphabetical list of the bases successfully studied, and the numerals used to identify them on the diagrams.

Table I

List of Bases Studied with Identifying Numerals

Acetamide	11	Formanilide	3b
Acetanilide	5	Guanidine	52f
Acetoxime	19	N-Methylacetanilide	8

Di-n-propylaniline	53a	Urea	13
Ethylaniline	43		

Method of Study.—The bases were all titrated in 0.05 molar solutions with perchloric acid as has been previously described.[2]

The potentials reported are those of cells of a type already pictured[3] and the former convention has been used to define "$P_{\text{H}}^{(\text{HAc})}$." The temperature was 25 ± 2°. Results are reported in this section of the paper for those bases only whose curves showed no marked abnormality such as is caused by rapid reaction with chloranil, the formation of precipitates, or the formation of hemi-perchlorates.

Experimental Results

If the titration data are all plotted on a single diagram (Fig. 1),[4] the assemblage of curves has a considerable resemblance, in spite of differences noted below, to such theoretical plots of the curves of unequally strong acids or bases in water as, for example, the one given by Britton.[5]

Survey of the Titration Curves.—For convenience in discussion, the bases are divisible into three groups. The first group comprises the weakest bases, as far down as No. 11 (acetamide) and includes those whose curves show no appreciable break. The second or intermediate group extends from *p*-nitrodimethylaniline (12) to #-bromo-aniline (31) and includes bases whose curves show both an initial rise and a break at the end of the titration. The remaining (strongest) base curves show no initial rise. The points of division between the groups are of course somewhat arbitrary.

[4] The drawing of the unnumbered curves near the bottom of Fig. 1 is somewhat schematic.

[5] H. T. S. Britton, "Hydrogen Ions," D. Van Nostrand Co., New York, 1929, p. 127, Fig. 36.

Bases of Intermediate Strength.—In the second or intermediate group the curves all run substantially parallel throughout most of their course, as required by the elementary theory of titration, but their e.m.f.

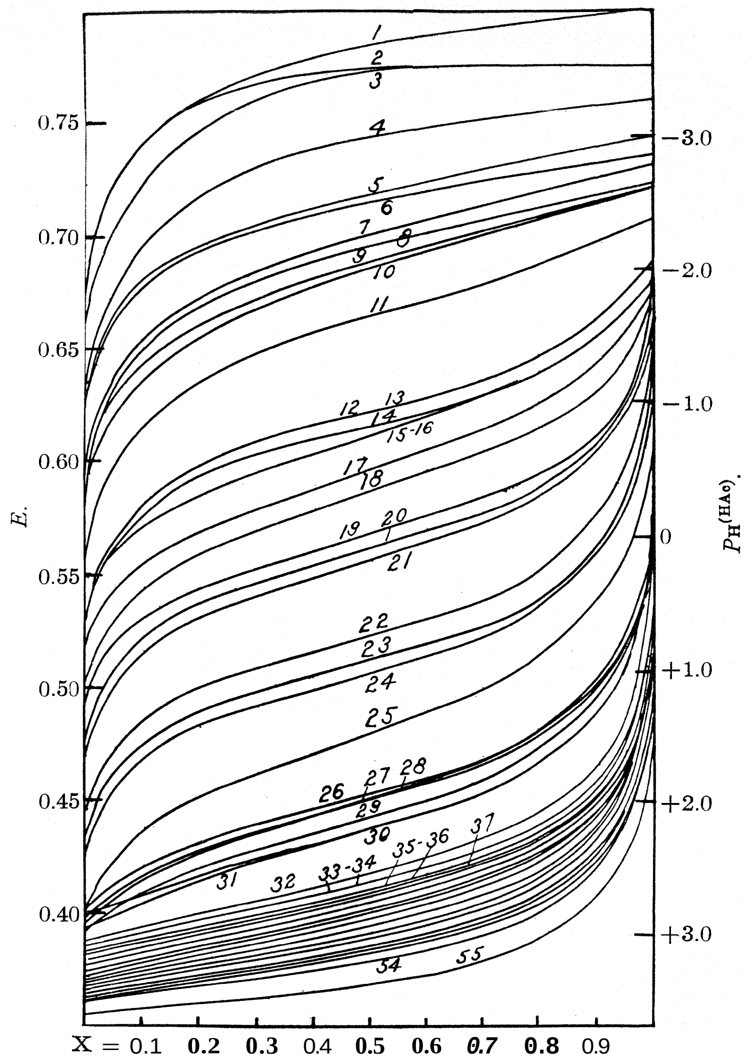

Fig. 1.—Titration curves of 0.05 M bases in glacial acetic acid.

values, as pointed out by Hall and Werner (III), are not even approximately a simple function of log R, (R = $x/(1 - x)$ (x = fraction titrated)), so that the curves appear "too flat" when compared with similar curves obtained in water. It is reasonable to ascribe this anomaly to the change in activity coefficients caused by the increase in ionic strength during titration, and evidence on this point has already been presented by Conant and Werner (IV).

In an attempt to formulate quantitatively the voltage changes during titration, the voltages at round values of x were read from a large plot of Fig. 1 for the middle group of bases. These voltages were converted into $P\text{H}^{(\text{HAc})}$ values by the formula $(0.566-E)/0.0591 = P\text{H}^{(\text{HAc})}$. To these observed $P\text{H}^{(\text{HAc})}$ values were added the values of log R for each point and the resulting \$K^{t} values plotted against $x^{1/2}$. It then appeared that in every case pK' was nearly a linear function of $x^{1/2}$.

As examples, the values of pK' for the first three bases of the group are given in Table II, together with the corresponding values of a + bx''. The average deviation of the two sets of values is also shown.

TABLE II

The formulas used for these three bases are fairly representative of all the others in this group—(with the exception of antipyrine, which shows a much steeper curve)—and it seems desirable in order to save space, not to report the results in full. The constants a and b are mutually adjustable within narrow limits and their theoretical significance is obscure. If pK' is plotted against $\mu^{1/2}$ instead of $x^{1/2}$ the points approximate slightly less closely to a straight line (μ is the concentration of the added acid. μ and x are not strictly proportional because of the appreciable volume of the titrant, nor is the relation between the two always the same because of the use of titrants of more than one concentration). Certain systematic trends in the deviations of the experimental points seem to indicate that functions of $x^{1/2}$ of the type stated are only first approximations to the values of pK'. The reproducibility of the data is insufficient at present to warrant the use of a more complicated approximation formula. Instead of $pK' = a + \text{b}\, x^{1/2}$ or $pK' = a + b'\mu^{1/2}$, it is conceivable that in this concentration range curves of the form $pK' = a'' + b''\mu^{1/2} - \text{b}''cr\mu$ as required by a form of the Debye–Hückel theory might fit the data. If the dielectric constant of pure acetic acid at 25° is 6.17 as obtained by interpolation in the data of Smyth and Rogers,[6] b" should have the value $23.0 and c should be $+1.17$. The constant $10^{-8}r$ is the so-called ion radius and should be positive. Equations of this form with these constants do not fit the data. It is probable that due to the presence of water (up to 0.5%) the dielectric constant of the solvent was higher than 6.17, possibly even as high as 10. And it is further possible that it changed during titration under these conditions, so that a theoretical approach along these lines seems unpromising.

The Strongest Bases.—When a weak base is dissolved in acetic acid it may be assumed that the reaction of salt formation $B + HAc \rightleftharpoons BH^+Ac^-$ is very incomplete, while with a strong base it is virtually complete. When a weak base is titrated the reaction $B + HClO_4$ $BH^+ClO_4^-$ (or $B + H^+(HAc)$ $BH^+ + HAc$) removes the free base and alters the concentration ratio of the cation to the free base remaining with resulting changes in the proton activity since

$$p_{H^{(HAc)}} = pK'^{(HAc)} - \log \frac{a_{BH^+}}{a_B}$$

A strong base is already completely converted into salt when the titration starts, and the only effect of the titration is to substitute a perchlorate for an acetate. The increase in proton activity will depend directly on the removal of acetate since $a_{H^+} \times a_{Ac^-} = \text{const.}$ In this latter case the ionic strength does not change during the titration, and the activity coefficients of the ions remain constant as shown by Hall and Werner's analysis of titration curves of the "strong base" type (III).

Between these two extreme cases, in acetic acid as in water, there exists a group of "transition" bases in which both the free base and its acetate may be assumed to exist together in the solution in appreciable quantities at the start of the titration. These should give curves of intermediate form, and such curves are readily observed in Fig. 1. The lowest curve in the diagram (diethyl-o-toluidine) is clearly anomalous for unknown reasons; dimethyl-o-toluidine (54a) and diethyl-*p*-toluidine (54b) show similar anomalies but to a less extent, and smaller variations are observed for other bases, above and below the "typical" or "average" strong base curve.

The Weakest Bases.—As the base strength diminishes, the tendency to react with even so strong an acid as perchloric acid becomes less and finally disappears, so that a point is finally reached where a solution of the base behaves toward the addition of perchloric acid as though the solvent alone were present (Curve 1, bases 1a, 1b). Bases of progressively diminishing strength give curves which should be the transposed mirror images of the transition and strong base curves at the bottom of the diagram. Because of the relative unreliability of the measurements in this highly acid

---

[6] Smyth and Rogers, THIS JOURNAL, 52, 1824–1830 (1930).

region, it has not been very thoroughly studied and secondary influences evidently distort some of the curves obtained.

Comparison with the Water System.—The basicity constant of a

$$K_{\text{Bas.}} = \frac{1}{a_{\text{H}^+}} \times \frac{c\text{BH}^+}{c\text{B}}$$

given base dissolved in a protogenic[7] solvent HX depends only on the intrinsic strength of the base and on the activity coefficients f_{BH^+} and f_{B}. These latter are primarily influenced by the acidity and basicity constants and the dielectric constant of the solvent, but also exhibit individual variations. If these are not too great, it should be possible to establish a pairwise correspondence between the basicity constants of a series of bases in any non-aqueous solvent and in water. In sufficiently dilute solution in

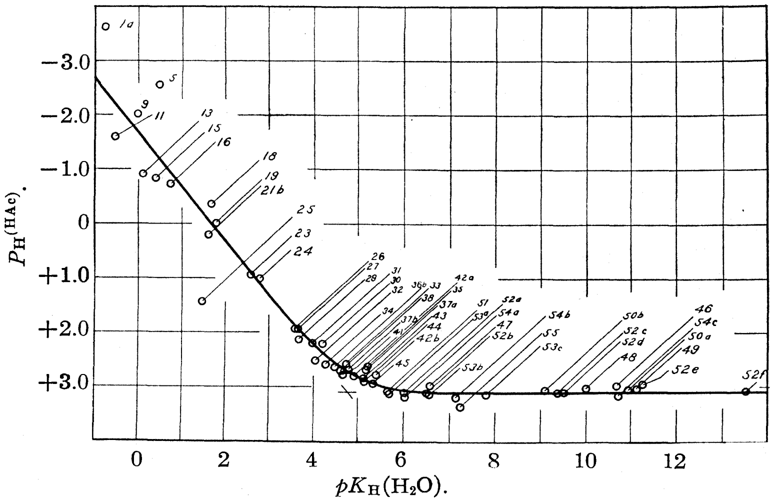

Fig. 2.—Comparative strength of bases in acetic acid and in water.

water $K_{\text{Bas.}}$ for any base is simply the reciprocal of the ordinary hydrolysis constant (*i. e.*, $K_{\text{Bas.}} = K_{\text{B}}/K_{\text{W}}$). In another solvent $\log K_{\text{Bas.}} = P_H + \log R$. In acetic acid $K_{\text{Bas.}}$ is far from constant when the concentration or the value of R is varied, so that it is necessary to choose a particular concentration and value of R, as well as to keep the titrating acid the same in comparing different bases. No satisfactory extrapolation of the values of $K_{\text{Bas.}}$ to infinite dilution has been possible here. The values to be compared with pK_{H} in water are therefore those of $\log K_{\text{Bas.}}^{(\text{HAc})} = P_{\text{H}}^{(\text{HAc})} + \log R$ at $R = 1$, *i. e.*, at the midpoint of titration. This has been done for 52 bases in Fig. **2** for which the necessary data are given in Table V. The abscissa is $\log K_{\text{Bas.}}^{(\text{H}_2\text{O})} = pK_{\text{H}} = \log K_{\text{B}} + pK_{\text{W}}$. The ordinate is the value of $P_{\text{H}}^{(\text{HAc})}$ at the half titration point $= pK'^{(\text{HAc})} = \log K_{\text{Bas.}}^{(\text{HAc})}$

---

[7] Brönsted, *Z. angew. Chem.*, 43, 229–233 (1930).

for each base as read from Fig. 1. The line on the diagram needs further explanation.

If bases at a given concentration in water are titrated with a strong acid, the P_H of the titration midpoints increases with the strength of the base so that it is almost exactly 9 for $pK_B = 5$, 10 for $pK_B = 4$, etc., etc. However, as pK_B diminishes, a point is reached, depending on the concentration of the solution, where the increase in P_H at the midpoint is no longer proportional to the decrease in pK_B. The P_H values now approach a certain maximum which is that shown by a completely ionized base half-titrated under the conditions of the experiment. Thus if the total base is 1 N, the P_H at the midpoint of titration should be 13.7 (neglecting activity coefficients). All bases with K_B above a certain value will show midpoint P_H's experimentally indistinguishable from **13.7.** What this limiting value will be depends on the concentration and the precision of measurement. It is clear that in the case of these strongest bases, the equilibrium

$$B + H_2O \rightleftharpoons BH^+, OH^-$$

is effectively completely displaced to the right even before the titration starts. It is also clear that any solvent capable of releasing a proton to the molecule B should behave in this respect just like water.

$$B + H\,Sol \rightleftharpoons BH^+, \bar{S}ol$$

but that the value of $K_{Bas.}$ at which the maximum P_H is reached should differ with each solvent.

It follows from this discussion that if P_H (midpoint) in any protogenic solvent is plotted against pK_H for a series of bases, the points will lie on a line of slope $= -1$ over a considerable range. At a certain point, depending on the concentration, this line will begin to bend upward and change with an easily calculable curvature into a horizontal line passing through the limiting P_H for the concentration in question. Such a line is the one drawn for acetic acid in Fig. *2*. In this figure the line is drawn as follows: (a) the slope of the left-hand portion is fixed at -1. (b) The curvature of the middle part is determined from the simple theory outlined above. (c) The ordinate of the horizontal part is fixed by the average ordinate of the experimental points for the strongest bases. (d) The three parts of the curve thus restricted are then fitted together so as best to reproduce the experimental points. This semi-empirical method of placing the curve evidently results in a satisfactory fit. One may conclude from Fig. *2* that there is a very definite parallelism between the strengths of the bases in the two solvents but that individual minor departures from exact parallelism are the rule rather than the exception. Both of these conclusions are in accord with previous knowledge of acid strength in solvents other than water.

It must not be forgotten, moreover, that the water values used are averaged from the results of numerous investigators, working at different times and places and by different methods. Under such conditions it is rather surprising that the scattering of the individual points is no greater than it is. Among the very weak bases, measurements are reproducible with difficulty both in water and in acetic acid, so that a greater than normal scattering is there to be expected. (The one unmistakable and significant exception is that of antipyrine (25). This base exhibits no unusual titration behavior in water, but in acetic acid it has a titration curve much steeper than any of the others. It seems possible that this irregularity is due to a reaction with chloranil or to a molecular rearrangement of the base.)

It is interesting to note the value of pK_{H} at which the bases become "strong" in acetic acid. If the two straight portions of the curve are extended, they intersect at a point which has an abscissa $pK_{\mathrm{H}} = 4.75$ (approx.). This is almost exactly the figure representing the strength of acetate ion as a base in water. In other words, it appears from these results that the relative base strength of molecules such as those of the chloroanilines, pyridine, etc., and of the acetate ion remains the same when these substances are transferred from water to acetic acid.

In view of the substantial regularities disclosed by Fig. 2, it is reasonably safe to use it in predicting the strength in water of bases for which no measurements are available. Table III lists those bases which have been successfully titrated in acetic acid but whose constants in water are unknown to me. With each base is given its serial number, its midpoint $pK'^{(\mathrm{HAc})}$ value and its predicted pK_{H} value in water.

TABLE III

DATA FOR BASES

No.	Name	$pK'^{(\mathrm{HAc})}$ obs.	$pK_{\mathrm{H}}^{(\mathrm{H_2O})}$ predicted
1b	4-Nitro-2,6-dichloro-aniline	−3.69	<−1
2	Anisalacetophenone	−3.50	<−1
3a	Diacetylmonoxime	−3.49	<−1
3b	Formanilide	−3.49	<−1
4	s-Dimethyldiphenylurea	−3.00	<−1
6	Tribromo-aniline	−2.52	−0.8
7	N-Propylacetanilide	−2.27	− .6
8	N-Methylacetanilide	−2.17	− .5
10	Phenylurea	−2.01	− .3
12	*p*-Nitrodimethylaniline	−0.92	4 .8
14	Methylurea	− .82	+ .9
17	2,5-Dichloro-aniline	− .51	+1.2
20	2,4-Dichloro-aniline	+ .08	+1.8
21a	3-Nitro-4-chloro-aniline	+ .19	+1.9
22	m-Nitrodimethylaniline	+ .73	+2.4
28	*p*-Nitrodiphenylamine	+1.93	+3.5

Moreover, in the case of certain bases, even though precipitation or other disturbing effects were noted, it is possible from an inspection of the titration curve to predict roughly what the strength in water should be. This has been done for a few additional bases in Table IV.

TABLE IV

PREDICTED STRENGTH OF CERTAIN BASES IN WATER

	pK_H
Acetylphenylhydrazine	$+1.3$
p-Amino-acetophenone	$+2.75$
Benzamide	-1
Carbazole	<-1
Dimethylglyoxime	<-1
p-Nitrosodiethylaniline	$>+5.5$
Pyrrole	$+0.4$

From a few titrations with sulfuric acid one may infer that dianisylcarbinol has a $pK_H < -1$ and hydrobenzamide $> +5.5$.

The following bases, the constants of many of which are at least approximately known in water, could not be titrated satisfactorily in acetic acid under the conditions used for the reason indicated.

Base Insufficiently Soluble.—Alloxantine, dipiperonalacetone, dianisalacetone, tyrosine.

Precipitation Occurred.—Acetone semicarbazone, o-aminobenzoic acid, *p*-aminobenzoic acid, 4-aminodiphenyl, asparagine, benzidine, diphenylanisylcarbinol, dipiperonalacetone, ethylenediamine, glycocoll, hexamethylenetetramine, Michler's ketone, β-naphthylamine, m-nitro-aniline, α-nitroguanidine, β-nitroguanidine, *p*-nitrosodimethylaniline, xanthydrol.

Base Apparently Formed a **Hemi-perchlorate.**—Aminoazobenzene, diazo-amidobenzene, dimethylaminoazobenzene.

Base Reacted with **Chloranil.**—Aniline, hydrazine hydrate, methylphenylnitrosamine, p-nitrophenylhydrazine, phenylhydrazine, piperine, taurine, thiourea.

Titration Curve Had an Irregular Form.—p-Phenylenediamine, *o*-phenylenediamine, quinaldine, thiocarbanilide.

Data Used in Preparing Fig. 2.—In Table V are given in order the identifying numeral of the base, its name, the $P_H^{(HAc)}$ of the titration midpoint as read from a large plot of Fig. 1, the preferred value of pK_H for the base in water at 25° as determined by averaging the values in the next column, the particular values selected from the literature and used in computing the average, and a letter or letters indicating the literature reference from which the value in question was obtained. Figure 2 was drawn with the values in Columns 3 and 4 of Table V as ordinate and abscissa, respectively.

NOTES ON TABLE V

It was necessary to make a complete resurvey of the literature in preparing Table V. In this the well-known compilation of Scudder[8] was of great assistance as were the various large tables of physico-chemical data. All these sources must be used with caution for the following reason. Although most determinations of base strength in water are made by a hydrolytic method which leads directly to the calculation of K_{H} instead of K_{B}, the data are all converted to values of K_{B} in the tables *with the use of a great variety of values for* K_{w}, so that it is nearly always necessary to go to the original paper in order to find out which value of K_{w} was used in the particular computation under review. The advantages of the pK_{H} values used in this paper over the values of K_{B} are obvious. Moreover, as the bases must be compared at a single temperature (here 25°), many of the data in the literature which apply to some other neighboring temperature are useless unless a suitable temperature correction can be applied to them. Mr. Sprinkle in this Laboratory has determined the temperature coefficient of pK_{H} for a number of bases of different strengths, and found the coefficient to increase with the base strength from about $\Delta pK_{\mathrm{H}}/\Delta t = 0.01$ at $pK_{\mathrm{H}} = 4$ to about $\Delta pK_{\mathrm{H}}/\Delta t = 0.02$ at $pK_{\mathrm{H}} = 11$. This work will shortly be published in connection with new determinations of the strength of a variety of bases in water. The coefficients found by Mr. Sprinkle have been used in correcting to 25° those data in the literature which were obtained at temperatures from 15 to 40°, where a determination on a given base at 25" by the same author was lacking.

The values cited do not represent a complete list of the values published up to the present time. The determinations of Veley, aside from being made at low temperatures and by unreliable colorimetric methods, are so discordant with other work as to appear valueless and have not been included. They may be found in Scudder, and in Landolt-Bornstein. The work of Bourgeaud and Dondelinger,[9] while in many cases it agrees with that of others, has been justly criticized by various authors[10] as fundamentally unreliable, and includes a number of values so fantastically incorrect as to make it seem advisable not to include any of it in the averages. The values of Farmer and Warth have also

[10] See, for example, Carothers, THIS JOURNAL, 49,2908–2914 (1927).

been criticized by Flürscheim and are mostly distinctly too low (*i. e.*, pK_H is too low). They have been omitted except in a few cases.

The work of Myrback is peculiar in that every one of his values of pK_H is lower than the most probable value by an amount varying from 0.07 to 0.51 P_H units (average 0.25). The use of a string soaked in concentrated hydrochloric acid as a salt bridge from his saturated calomel electrode to the weakly acid solution he was measuring, as well as a temperature drop of 7° along his salt bridge, may have contributed to these discrepancies His reasons for preferring his own results are not convincing, and I have used them only when other reliable values were lacking.

During the correction of the proof it was found that certain data of Kuhn and Wassermann[10a] had been overlooked in preparing Table V and Fig. 2. The additional values are: for 9, o-nitro-aniline, -0.3, making $pK_H(H_2O) = -0.06$; for 18, p-nitro-aniline, $+1.0$, making $pK_H(H_2O) = +1.6$. The effect of both of these changes would be to bring the corresponding points in Fig. 2 closer to the line, and this would be true to a still greater extent if the values of Farmer and Warth for these bases (-0.32 and $+1.02$) were also included. The revised values would then be -0.13 and -1.4.

Acid Strength in Other Non-aqueous Solvents.—Results somewhat similar to those in the present paper have been reported by other authors for other solvents as follows. Michaelis and Mizutani[11] and Mizutani[12] have shown that in various methanol–water and ethanol–water mixtures the acidity constants of numerous uncharged acids on the one hand and cation acids on the other exhibit roughly equal changes within each class for a given change in composition of the solvent. Goldschmidt and Mathiesen[13] by aminolytic measurements have shown much the same thing in regard to dissociation constants of the two types of acids in absolute methanol, absolute ethanol and certain aqueous mixtures. Brönsted,[14] by a colorimetric method, has determined the relative acidity constants of numerous indicators and uncolored acids in benzene. Acids of the same type are evidently nearly equally affected by transfer from water to benzene, while the strength of cation acids is relatively greatly increased by this transfer.

Materials.—Practically all the bases studied were purchased from the Eastman Kodak Company. A few were obtained from laboratory stock at the Harvard Chemical Laboratory and in this Laboratory and these were specially prepared or purified before use. In most, but not all, cases the Eastman liquids were redistilled and characterized by their boiling points, and the melting points of the solids were determined. Where necessary, special purification processes were used. I am indebted to Professor Tenney L. Davis for certain urea derivatives, and to Dr. Wallace H. Carothers for a number of amines and amides. The other materials were prepared and used as described in the earlier papers.

Acknowledgment.—I should like to express my thanks to Messrs. Tyrrell H. Werner, Marshall R. Sprinkle and Victor A. Reinders for assistance in making many of the measurements and for the communication of certain data (to be published later) on the strength of bases in water.

It is further a great pleasure to acknowledge the aid received from a grant from the Milton Fund of Harvard University covering the purchase of many of the bases studied.

Summary

1. A large number of organic bases have been titrated with perchloric acid in glacial acetic acid solution.

2. It is shown that the relative strengths of the bases in acetic acid and in water are nearly proportional and that. it is possible to determine by titration in acetic acid the "water" strength of certain bases which cannot be studied in water.

3. A large part of the published data on the strength of bases in water has been critically resurveyed and the values "corrected" to 25° where necessary in accordance with new determinations of the temperature coefficient of pK_H for bases of different strengths.

A STUDY OF THE DENSITY, SURFACE TENSION AND ADSORPTION IN THE WATER–AMMONIA SYSTEM AT 20°[1]

BY H. H. KING, J. LOWE HALL AND GLEN C. WARE

RECEIVED AUGUST 30, 1930 PUBLISHED DECEMBER 18, 1930

In view of the fact that liquid ammonia behaves as an ionizing medium for electrolytes it was thought that the determination of its behavior as a polar liquid toward adsorbed substances containing polar groups would be of interest. As a preliminary step this investigation is concerned with the surface tension of water–ammonia mixtures as compared with the theoretical values for ideal mixtures obtained by Whatmough's rule.[2] The resemblance of these two liquids as a solvent can be thus quite satisfactorily indicated. Incidentally some indication of the extent to which ammonia is associated in the liquid state may be observed.

Surface tension in liquid ammonia has been investigated by Berthoud[3] but the range of his work was not extensive. Rice[4] recently has made

determinations upon solutions up to a concentration of 14 moles per liter. Apparently Rice's method lacked certain refinements, particularly precautions relating to distillation from the capillary surface, thorough mixing and density determinations.

It was necessary to develop a method for determining the density of solutions, for no data upon the density of ammonia–water mixtures at 20° could be found in the literature for concentrations above 50% ammonia.

Experimental Procedure

The capillary height method was used to determine the surface tension. The apparatus, a modification of the Richards and Coombs type, was constructed of a heavy grade pyrex tubing (Fig. **1-A**). The cylindrical bowl, *35* mm. in diameter, was used to provide a surface of such size that its center portion would provide a flat surface. A capillary side arm was attached to the bowl below and to the stem above with a gooseneck at its juncture with the stem. This design permitted thorough irrigation of the capillary at will and yet prevented the liquid which drained down from the walls after agitation of the contents from draining into the capillary.

The bowl was banded by three rings etched into the glass. These served only as a guide when filling the tube so that the quantity of liquid introduced could be approximated quickly and controlled. The portion of the tube above the juncture of the side-arm to the stem was designed to serve as a pycnometer. The barrel and the small tube attached were of such size that the volume of the pycnometer measured from the upper end down to the upper end of the graduated scale in the stem was about equal to the volume of the bowl and side-arm up to the middle ring of the bowl. This provided an apparatus easily handled in which the density and surface tension of a given solution could be determined without the necessity of transferring it to other apparatus or even unsealing the tube. Errors in transference of solutions or escape of gaseous substances were entirely eliminated.

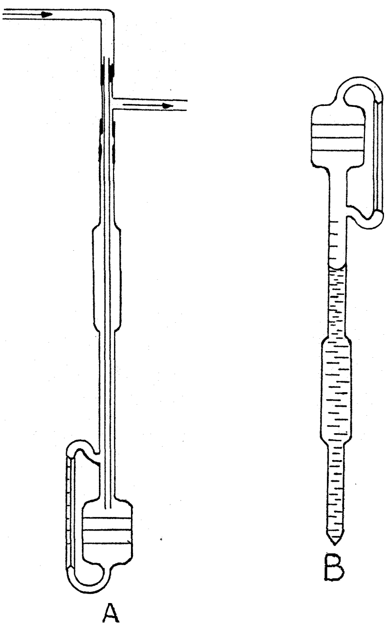

Fig. **1**.—**A**, Showing method of introducing ammonia vapor into apparatus where it is condensed; B, showing method of measuring volume of vapor phase in density determination. The total volume is determined subsequently.

Gaseous ammonia was condensed into the tube by carbon dioxide snow. Figure **1** shows how the apparatus was connected to fill the tube. The gas was led first to a drying train consisting of freshly ignited aluminum oxide. **A** T-tube with rubber connections through which protruded a small bore tube which reached down into the top part of the bowl was used to introduce the gas into the tube.

Last in the train of apparatus was a mercury trap which served to control and increase pressure and condensation. The tubes were dried, weighed and then filled with sulfuric acid-dichromate cleaning solution and allowed to stand until the next fill.

They were then thoroughly rinsed with surface tension water and dried only when to be filled with pure ammonia.

When sufficient ammonia was condensed, the delivery tube was partly removed from the apparatus until the rim of the tube was softened in the flame; then the delivery tube was held just above the opening until the apparatus was sealed. In this manner air was excluded while the tube was being sealed. In measurements where density determinations were to be made, the tip, or sealed-off piece, was retained to be included in further weighings. Capillary height readings were taken with a William Gaertner calibrated traveling microscope.

Densities for solutions above 50% ammonia at 20° were determined by weighing the tube before and after filling and measuring the volume of the pycnometer on the calibrated volume scale, the tube being in the inverted position shown in Fig. 1-B while volume readings were taken. The water sample was weighed in, ammonia was introduced, and the tube was sealed off and weighed. After reading the capillary height the tube was inverted and the volume of the vapor was read on the calibrated scale on the stem of the pycnometer. The volume of the liquid was determined by difference after the total volume of the tube had been measured. The tube was opened by heating at the tip with a needle flame after the pressure had been greatly reduced in carbon dioxide snow. When the tubes were opened a small pin-hole was blown through the tip The sharp edges were melted back, and the minute bulb raised with the pin-hole was shrunk back to its former shape. Thus the volume of the tube was not altered,

Meniscus volume corrections were made by means of the Bashforth and Adams data in the "International Critical Tables," Vol. I, p. 73. Corrections for air buoyancy were made on all weighings.

Obviously the vapor, especially at high pressures, would contain enough ammonia to affect the calculated value of the density. The tables of Wilson[5] were used to give the total vapor pressure of ammonia–water mixtures and the composition of the vapor phase corresponding to each solution composition studied. The density of the vapor present was assumed to be directly proportional to the pressure and the mean molecular weight of the vapor.

$$D = D_a \cdot \frac{P}{P_a} \cdot \frac{M}{M_a}$$

in which D_a, P_a and M_a refer, respectively, to the density, pressure and molecular weight of the vapor above pure ammonia and D, P and M refer, respectively, to the density, pressure and mean molecular weight of the vapor above the solution. Since the vapor over the solutions whose densities were determined in no case contained greater than a few tenths of 1% of water vapor, no objectionable error was introduced by omitting the second proportionality factor from density calculations. The density of saturated ammonia vapor at 20° was taken as 0.007474 from the Landolt–Börnstein Tables. However, in the data for pure liquid ammonia the vapor and liquid densities were taken from the Bureau of Standards Circular No. 142, Tables of Thermodynamic Properties of Ammonia.

Sufficient density determinations were made to determine the curve

---

[5] T. A. Wilson, *Univ. Illinois, Eng. Exptl. Sta. Bull.* No. **146 (1925).**

plotted in Fig. 2. These were plotted on sufficiently large scale to be read to the fourth significant figure.

Apparatus.—All pieces of apparatus were carefully calibrated. The diameters of the capillaries were carefully determined by measuring the length of a weighed pellet of mercury at successive positions in the capillary. An additional check was made with the purest obtainable thiophene-free benzene.

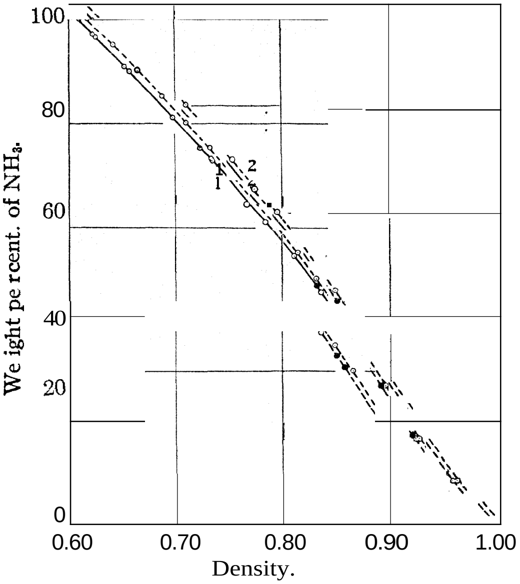

Fig. 2.—1, Densities of water–ammonia mixtures at 20°. Solid line covers range of experimental determinations. Solid circles are determinations by Mittasch, Kuss and Schlueter. Lower points from "International Critical Tables." 2, Densities at 15° for comparison taken from "International Critical Tables."

The formula used for calculating surface tension was

$$\gamma = \frac{r\,(h + r/3)\,(d - D)g}{2}$$

in which r is the radius of the capillary, h the capillary height, d the density of the liquid, and D the density of the vapor.

Discussion of Results

The surface tension of liquid ammonia as determined in this work agrees closely with Berthoud's[3] value at 11.1° if his data are calculated by the corrected capillary height formula as given above. Measurements at 0° were made in a transparent Dewar tube.

In the range of 0–20° the molecular weight of liquid ammonia was calculated by the differential method of Ramsay and Shields.[6] The value of K was found to be 1.662, indicating an apparent molecular weight of 24.5, or approximately 3/2 NH_3. Such a condition must indicate an equilibrium mixture of two or more molecular components, as possibly $(NH_3)_2$ (60%) $\rightleftarrows$ $2NH_3$ (40%). The surface tension–temperature data in Table II when plotted appear to lie in a nearly straight line, indicating a temperature coefficient of 0.220 dyne per degree centigrade.

The determined densities of solutions above 50% NH_3 are tabulated in Table I and plotted in Fig. 2 along with data from Mittasch, Kuss and Schlueter,[7] and with data from the "International Critical Tables."

10.0	.03625	22.029	.61985	24.25
20.0[a]	....	....	.60360	22.03

[a] Average of twelve determinations ranging from 21.94 to 22.09.

The data from all three sources agree very well. The density curve at 15° was included in broken lines for the purpose of comparison. The solid line portion of the lower curve in Fig. 2 represents the values determined experimentally. The accuracy is indicated from the fact that the density curve joins closely with the points obtained by Mittasch, Kuss and Schlueter[7] and that the curve follows closely the character of the 15° density curve. The eight density determinations on pure ammonia, averaging 0.61026 (range 0.6100–0.6107) compared with the Bureau of Standards value of 0.61029, is additional evidence to show the accuracy and dependability of the method used in this work.

The surface tension values found in Table I were calculated from experimental data, the densities being taken from the curve. All surface tension determinations were made under conditions such that the percentage composition of the solution could be determined even though the volume were not such as to make a density determination possible.

Rice[4] has made surface tension determinations of solutions of ammonia in water up to a concentration of 14.08 moles per liter. His values throughout were lower than those obtained in this work with a greater difference at lower concentrations. Since Rice determined density by transferring solutions to a pycnometer and reading the concentration from density–concentration tables, disagreement of results is to be expected. Rice ascribed fluctuations in capillary height to the action of ammonia on glass; they could equally as well be ascribed to a state of unequilibrium because of difficulty in obtaining thorough mixing in the system, also to the fact that the apparatus was not enclosed in a thermostat.

The pyrex glass apparatus used in this work gave no cause for any suspicion as to its reaction with ammonia. When the system had been given time to come to temperature equilibrium, the contents had been thoroughly mixed, and the capillary had been irrigated several times, the capillary height became constant within a moderate period of time necessary for the draining of the walls of the apparatus.

The observed surface tension values were compared with theoretical values obtained by Whatmough's[2] modification of the Volkmann rule

$$\gamma = (V_1\gamma_1 + V_2\gamma_2)R$$

in which V_1 and V_2 are the volume fractions of the components, γ_1 and γ_2 are the surface tensions of the pure components, and R is the ratio of the calculated to the observed density. The values are shown graphically in Fig. 3. It is to be observed that the theoretical and observed surface tensions are in good agreement except in the middle region, where a divergence of less than six dynes occurs. It is of interest to note that the vapor pressure of the system goes through a marked depression from the normal in this region, thereby conforming to Worley's rule[8] of perfectly miscible liquids. Worley shows for a number of mixtures that abnormalities of surface tension tend to move contrariwise to abnormalities in vapor pressure.

---

[8] Worley, *J. Chem. Soc.*, 105, 273 (1914).

It is evident from the surface tension and thermodynamic standpoint that the system does not deviate radically from what is to be expected of a perfect mixture. No doubt the formation of ammonium hydroxide contributes to such deviation, but no attempt is made to take it into account. Consequently it is to be expected that liquid ammonia would behave as a polar liquid similar to water, and that orientation of substances on the surface of liquid ammonia would be quite similar to their orientation on water surfaces. The surface tensions of solutions of ammonium salts of aliphatic acids in liquid ammonia are being investigated at present in this Laboratory with the intention of determining the surface adsorption.

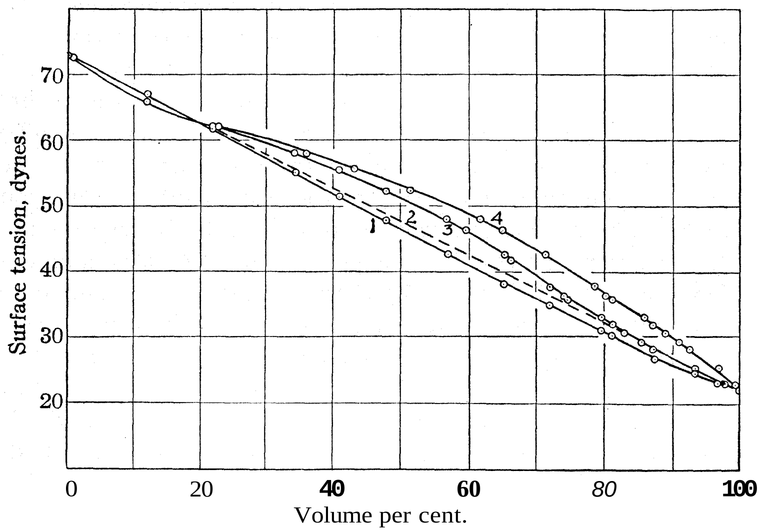

Fig. 3.—Theory of admixtures applied to surface tension of ammonia–water mixtures. 1, Surface tensions calculated by Whatmough's rule; 2, theoretical values for a perfect mixture; 3, observed values for volume per cent., $V_a/V_a + V_w$; 4, observed values for volume per cent., $V_a/V_{sol.}$.

Deviation of the ammonia–water system from the rule of admixtures might be due to adsorption of one or the other component in the surface. Assuming such to be the case, and assuming that deviation of the slope of the surface tension–log activity curve from the normal curve derived from the rule of admixtures would indicate the adsorption when used in the Gibbs equation

$$\mu = -\frac{1}{RT}\left(\frac{\mathrm{d}\ \gamma(\text{obs.})}{\mathrm{d}\ln a} - \frac{\mathrm{d}\ \gamma(\text{theor.})}{\mathrm{d}\ln a}\right)$$

such values have been assembled in Table I. They consist of from 1 to 5% of the normal surface concentration. It is of interest to note that it changes sign in the region of 50% ammonia, being negatively adsorbed in dilute solutions and positively adsorbed in the upper range of concentration.

The activities of ammonia in the mixtures were calculated by the approximate method of Lewis and Randall,[9] taking the activity equal to the concentration in pure liquid ammonia.

Summary

1. The surface tension of liquid ammonia at 0, 10 and 20°, and its temperature coefficient were determined.
2. By the differential method of Ramsay and Shields the molecular weight of liquid ammonia is found to be 24.5.
3. Surface tension and density of water–ammonia mixtures from 50–100% NH_3 at 20° are given for the first time.
4. A method is shown whereby the surface tension and density of a solution may be determined in the same sealed tube without removing the contents.
5. Surface tensions of water–ammonia mixtures follow closely values to be expected from the rule of admixtures except in the middle region, where a divergence of less than six dynes occurs.
6. Assuming divergence to be due to adsorption, it is shown that adsorption of ammonia in the surface is small, amounting from one to five per cent, of the normal surface concentration.

THE QUANTITATIVE PRECIPITATION OF SULFIDES IN BUFFERED SOLUTIONS.[1] I. COBALT SULFIDE

BY MALCOLM M. HARING AND MARTIN LEATHERMAN

RECEIVED SEPTEMBER 4, 1930 PUBLISHED DECEMBER 18, 1930

Introduction

The separation of metals by means of sulfide precipitation in acid or basic solution has long been practiced. However, the regulation of the degree of acidity and the conditions under which a thoroughly satisfactory precipitate may be obtained have not been the subject of much careful study. Fales and Ware[2] carefully investigated the conditions under which zinc sulfide might be precipitated quantitatively, but practically nothing else is available. Such a study on cobalt sulfide seemed desirable because the methods for the determination of this element are neither so numerous nor

[9] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., Inc., New York, 1923.

[1] Part of a thesis submitted by Martin Leatherman in partial fulfilment of the requirements for the degree of Doctor of Philosophy in the Graduate School of the University of Maryland.

[2] Fales and Ware, THIS JOURNAL, 41,487 (1919).

satisfactory as might be wished, and because solid cobalt sulfide behaves so peculiarly when treated with acids.

Review of Literature.—Fresenius[3] and Landrum[4] both discuss the precipitation of cobalt sulfide by ammonium sulfide, but neither takes up acidity control. Both convert the sulfide to oxide and reduce the latter with hydrogen for the final weighing. Low[5] describes a method whereby cobalt sulfide is precipitated, together with nickel sulfide and traces of zinc sulfide, in a solution buffered with ammonium acetate. The cobalt and nickel mixed are weighed as oxides. No details are given as to the PH maintained, the character of the precipitate, etc.

Theoretical.—The physical character of a precipitate is conditioned, among other factors, upon the rate of formation. The latter is largely governed by the ionic concentrations concerned. Since the concentration of sulfide ion is dependent upon the hydrogen-ion concentration, the use of a buffer to control the acidity in sulfide precipitations is very desirable.

Apparatus.—The weights used were carefully calibrated. The measurements of **PH** were made using a Hildebrand type bubbling electrode. A small electric resistance furnace equipped with a silica tube was used for the roasting and reduction. Porcelain boats were used to hold the cobalt sulfide.

Materials.—The hydrogen, made by the action of zinc on 30% sulfuric acid, was purified by passage through alkaline pyrogallate, alkaline permanganate and distilled water.

The hydrogen sulfide was passed through absorbent cotton to filter out spray and then through two bottles of distilled water.

All materials were of "reagent" quality. Blanks were run on the acetic acid and ammonium acetate, and a constant weight of 0.2 mg. subtracted from all determinations to allow for the non-volatile impurities. Stock solutions of these reagents were made up in sufficient volume to permit the same solutions to be used throughout the work.

The water had a specific conductance of 2×10^{-6} mhos.

Metallic cobalt was used as the raw material in all experiments. It was purified from a good grade of $CoCl_2 \cdot 6H_2O$ by the chloropentamminecobaltic chloride method described in Biltz–Hall and Blanchard.[6] The chloride from the purification process was precipitated as sulfide, roasted and reduced with hydrogen to produce the metal in a very suitable form. No trace of nickel was detected by the dimethylgloxime method, or of iron by addition of ammonia. It had been hoped that the purified hexahydrate

might be weighed out directly, but it is sufficiently efflorescent to make its use inadvisable. The anhydrous form is easily made but cannot be weighed out with certainty without the most extreme precautions[7]

Discussion of Experiments

About 0.2 g. of metallic cobalt was found to be a suitable quantity for these experiments. This amount was weighed out into *a* 250 cc. beaker and dissolved in **5** cc. of concentrated hydrochloric acid. The solution was evaporated to dryness on an asbestos-covered hot-plate until all the chloride showed the bright blue color of the anhydrous salt and there was no odor of hydrochloric acid; *25* cc. of 0.4 N ammonium acetate, 40 cc. of water and sufficient 6.8 N acetic acid to produce the desired acidity were added and the ***PH*** measurement made.

Ammonium acetate was chosen as the salt of the buffer mixture used for the following reasons. Moist cobalt sulfide is readily oxidized by oxygen from the air. Hence washing with pure water will yield low results due to loss of soluble sulfate. Washing with hydrogen sulfide water is likewise inadvisable due to the tendency shown by many sulfides to peptize under such conditions. Therefore, for good results, non-volatile materials except cobalt salts should be absent at this point. Ammonium acetate is completely volatile and maintains the acidity desired and hence is eminently suitable for the purpose; 25 cc. of 0.4 *N* solution was found to provide an ample margin of safety in nullifying the effect of the acid liberated.

PH measurements could not be made with the hydrogen electrode on the mother liquor after precipitation since hydrogen sulfide poisons the electrode. The effect of the liberated acid was ascertained indirectly. Varying amounts of 6.8 N acetic acid were added to 25 cc. of 0.4 N ammonium acetate and the whole made up to 65 cc. The ***PH*** was determined, 38.6 cc. of 0.1 N hydrochloric acid was added and the ***PH*** redetermined. This quantity of hydrochloric acid is equivalent to that liberated when *0.25* g. of cobalt is precipitated as sulfide. At the ***PH*** finally selected **(3.93)** the decrease in acidity caused by precipitation was found to be *0.28* PH units. Since but 0.2 g. of cobalt was used in analysis, the decrease would be even smaller than this.

The initial ***PH*** having been determined, the solution was transferred back to the Erlenmeyer flask. The beaker and electrode washings had by this time increased the volume to about **95** cc. Hydrogen sulfide was then passed through the flask, *but not through the solution,* for about five minutes, after which the exit was closed and the pressure allowed to rise to the maximum produced by the Kipp generator. This was maintained throughout the period of precipitation. Preliminary experiments had revealed that cobalt sulfide is powerfully adsorbed by glass and that this

---

[7] **Baxter** and **Coffin,** THIS JOURNAL, **28, 1580 (1906).**

adsorption is prevented by using a hot solution, by washing down the walls of the flask just before admitting hydrogen sulfide, and by having no agitation during the first few minutes of precipitation. Accordingly the solution was heated just to boiling prior to precipitation, the flask walls were immediately washed down and there was no agitation for at least the first five minutes of precipitation. Heating likewise increased the speed of precipitation and made the precipitate more compact. Giving the contents of the flask a gentle swirling motion after the earlier stages of precipitation also served to speed up this operation. The precipitation period was always continued until the contents of the flask were at room temperature (forty-five minutes to one hour). For the very low P_H values, precipitation was continued overnight. The precipitate always settled quickly, leaving a crystal clear mother liquor. At the higher P_H values precipitation was very rapid and the precipitate flocculent and very bulky. The speed of precipitation diminished with diminishing P_H, and the precipitate was very compact, forming an exceedingly thin layer in the bottom of the flask.

Filtration was carried out as expeditiously as possible. A rapid filtering, "ashless," fluted filter paper of 9 cm. diameter was used. The bulk of the precipitate and mother liquor was poured through this filter. Then the filtrate was used to wash out of the flask and onto a 3 cm. filter the remaining precipitate. In this way no liquid was poured over the precipitate after it had dried to the least extent. As stated previously, non-volatile materials should be absent at this point so that washing will be unnecessary. If this is impracticable, washing may be carried out by using as wash water a buffer solution of the same P_H as that used in precipitation, previously saturated with hydrogen sulfide and cobalt sulfide. The filtrate was always tested for cobalt by means of Vogel's test.[8] This test was found to be sensitive to 0.01 mg. of Co^{++} per 10 cc. of solution. By this means it was proved that each precipitation had been made as complete as possible under the conditions.

The procedure of Fales and Ware[2] could not be followed from this point because sulfuric acid, even when hot and concentrated, appeared to have little effect on the cobalt sulfide. Therefore instead of weighing as the sulfate it was decided to roast and reduce to the metallic state.

The filter papers and precipitate were dried at 100°, then burned in a porcelain crucible until carbon was removed. The residue was transferred to the porcelain boat, roasted at a dull red heat for half an hour, then reduced in hydrogen at 1000° for twelve to fifteen minutes, cooled in hydrogen and weighed as metal. It was found that a reduction temperature even as high as 800° was insufficient to destroy completely pyrophoric cobalt. The results of this study are displayed in Table I and Fig. 1.

As will be noted, precipitation was complete, within 0.5%, at a PH of about 3.6. No appreciable increase in error was noted at high PH values

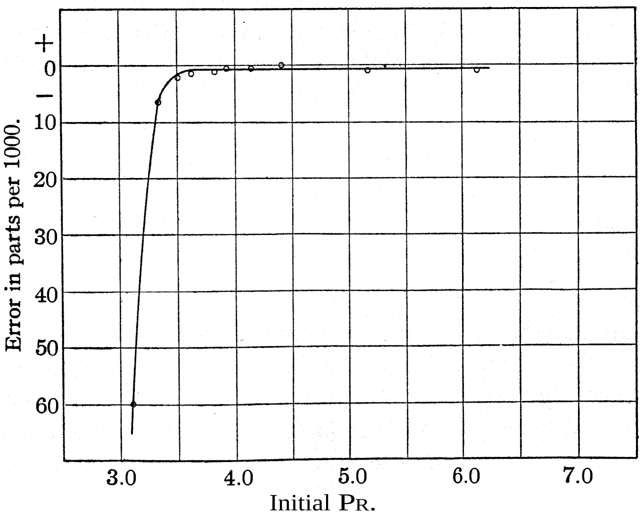

Fig. 1.—Relation between completeness of precipitation and initial acidity.

such as was found by Fales and Ware[2] with zinc sulfide. As already stated, the **PH** value selected for the quantitative precipitation of cobalt sulfide should be as low as is consistant with complete and fairly rapid precipitation. At *P*H **3.93** these conditions were met. The precipitation is complete in less than one hour and the precipitate compact and granular so that only a very small filter is needed. The **PH** values recorded in Table I are the initial values, *i.* e., before precipitation. The slight variations in PH observed between duplicates is doubtless due to the fact that there was a small loss of hydrogen chloride when the chloride solution was evaporated to dryness, To test out the method, six more determinations were made at this PH with results as recorded in Table II.

It was thought that nickel and cobalt might be determined simultaneously by this method. If so, nickel could be determined separately in the metallic product by the dimethylglyoxime method and cobalt by difference. Investigation showed that nickel sulfide is precipitated practically completely at the same PH as cobalt sulfide. However, the much more highly pyrophoric nature of nickel prevented the obtaining of accurate results. This investigation is to be pursued further.

A few determinations were made to investigate the effect of concentration and the influence of ammonium salts. Although the results cannot be considered conclusive, large quantities of ammonium salts and a low concentration of cobalt ion appear to diminish somewhat the precision of the method.

Summary of the Method

Prepare an aqueous solution containing about 0.2 g. of cobalt preferably as chloride. Free acid should be absent. Add 25 cc. of 0.4 N ammonium acetate, 4.5 cc. of 6.8 N acetic acid and 70 cc. of water. Heat to boiling in a 300-cc. Erlenmeyer flask, remove from flame, wash down and saturate with hydrogen sulfide under slight pressure until the solution has reached room temperature (forty-five minutes suffices). Do not agitate for at least five minutes at the start Afterward swirl around occasionally. Pour most of the mother liquor and precipitate through a

9-cm. fluted ashless filter paper. Use the filtrate to wash out the flask and pour this and any remaining precipitate through a 3-cm. fluted ashless filter. Do not wash unless non-volatile materials are present. In this case wash with a buffer solution made up as above saturated with hydrogen sulfide and cobalt sulfide. Dry the filters in the larger funnel at 100°, fold and transfer over white glazed paper to a small porcelain crucible. Burn off filter paper by heating strongly on a quartz plate. Transfer to a weighed porcelain boat, wiping out crucible and funnel with a shred of filter paper and place in furnace. Draw air slowly through the combustion tube and start the furnace. Roast for one-half hour after the tube glows dull red. Remove tube from furnace, without cooling the latter and allow to cool for three minutes. Pass hydrogen through slowly for several minutes and replace in furnace. Heat to 1000° for fifteen minutes and remove from furnace, the hydrogen being allowed to flow until the tube is quite cold. Weigh boat and metallic cobalt.

Summary

1. A precise method has been developed for the precipitation of cobalt as sulfide and its subsequent determination as the metal.

2. The precipitation of cobalt sulfide as a function of the acidity has been studied.

THE QUANTITATIVE PRECIPITATION OF SULFIDES IN BUFFERED SOLUTIONS. II. NICKEL SULFIDE[1]

By Malcolm M. Haring and Benton B. Westfall

Received September 4, 1930 Published December 18, 1930

The quantitative precipitation of metallic sulfides as a function of the acidity of the solution has been studied systematically only in the case of zinc sulfide[2] and of cobalt sulfide.[3]

Introduction.—The latter research revealed that nickel sulfide precipitates almost completely at about the optimum P_H for cobalt sulfide. It was found also that metallic nickel, produced by the reduction of the oxide with hydrogen, was so pyrophoric as to make it difficult or impossible to weigh it in that form. The purpose of this research was to investigate more fully these two points.

[3] Haring and Leatherman, *ibid.*, 52, 5135 (1930).

Review of the Literature.—Fresenius[4] discusses the precipitation of nickel sulfide by ammonium sulfide in solutions buffered with ammonia plus ammonium chloride or with ammonium acetate plus acetic acid. Gooch[5] gives directions for precipitation with hydrogen sulfide in the presence of an ammonium acetate–acetic acid buffer. Baubigny[6] describes the estimation of nickel in nickel sulfate by the sulfide method; Cormimboef[7] describes the precipitation of nickel sulfide in solutions "acidified sufficiently." He stresses the method of washing the precipitate. The nickel sulfide is finally roasted to the oxide.

Apparatus, Materials and Method.—The theoretical aspects of this study are the same as those discussed in the first paper of this series on CoS.[3] Likewise the apparatus, materials and general procedure remain for the most part unchanged. Platinum Gooch crucibles were used as containers for the nickel sulfide and nickel oxide instead of the porcelain boats. Silica Gooches were also found satisfactory although more fragile. These crucibles were small enough to fit snugly into the end of the silica tube so that when air was drawn through it was obliged to go through the asbestos mat. A LaMotte color comparator block with brom cresol green color standards was used in the determination of the final PH after precipitation.

The asbestos used in the Gooch crucibles was a good grade of acid-washed material prepared for this purpose. It was chipped fine, reboiled with hydrochloric acid and washed until chlorine free.

The source of the nickel was the complex ammine salt, $Ni(NH_3)_4SO_4 \cdot 6H_2O$, chosen chiefly because a large quantity of pure material was available. This had been prepared as follows. A saturated solution of recrystallized nickel sulfate hexahydrate was made in the cold. It was acidified with sulfuric acid and iron nails added to replace any copper present. Ammonium hydroxide was then added until a small amount of nickel hydroxide precipitated, and it was then aerated for about one week to remove any iron present by double displacement. The solution stood for about two weeks, being agitated occasionally, after which it was filtered. Concentrated ammonium hydroxide was then added until all the nickel hydroxide dissolved, and this mixture was allowed to stand for three days. The solution was filtered and the nickel ammine precipitated with 95% alcohol, washed with ammonium hydroxide, a mixture of equal portions of ammonium hydroxide and alcohol, alcohol, and last with ether.

A 5-g. sample, when neutralized with sulfuric acid, boiled with an excess of nitric acid and then boiled with an excess of ammonium hydroxide, gave no residue of ferric hydroxide on being filtered. A sample tested with Vogel's reagent (amyl alcohol and ether plus ammonium thiocyanate) gave no test for iron or cobalt. This is capable of detecting 0.01 mg. of cobalt per 10 cc. and the thiocyanate test for ferric iron is even more sensitive.

This salt was analyzed electrolytically (Treadwell–Hall)[8] and found to contain 22.67% of nickel. The theoretical composition gives 22.6651%.

Description of Experiments

The efficiency of the buffer was first investigated by adding different amounts of acetic acid to a given amount of the solution containing approximately 0.2 g. of nickel as $Ni(NH_3)_4SO_4 \cdot 6H_2O$. Usually there was no ammonium acetate added as there would be approximately the equivalent of 34 cc. of 0.4 *N* ammonium acetate formed by the reaction of the acid with the salt. Acetic acid was added in excess to give the desired ***P*H**, and the ***P*H** taken, after dilution to constant volume (90 cc.), with the hydrogen electrode. The precipitation was carried out as described later, and the ***P*H** taken on the filtrate with the indicator brom cresol green. The decrease in PH during precipitation at ***P*H** 4.4 (the optimum value) was found to be 0.16 unit.

About 0.89 g. of the nickel ammine was taken for the analysis. This contained 0.2 g. of nickel, which previous experience had shown to be a sample of the most desirable size. The samples were weighed out on a watch glass and then rinsed into a 300-cc. Erlenmeyer flask. Sufficient acid was added to neutralize the ammonia and to give the desired ***P*H**. The contents of the flask were diluted to 65 cc. and the ***P*H** determined electrometrically. The volume of the solution after rinsing the electrodes was 90 cc.

Precipitation was carried out as described by Haring and Leatherman[3] except that the solution before precipitation was heated to 90°, ***not*** to ***boiling***, and the walls of the flask were not washed down. Also, just before the end of precipitation, the temperature was raised to 60°. This modification proved helpful in reducing the annoying adsorption of the nickel sulfide on the glass.

A portion of the filtrate was taken and the ***P*H** determined colorimetrically, using the comparison method. The hydrogen sulfide was boiled off the remainder and the solution tested for nickel with dimethylglyoxime.[9] When 80 cc. of the hydrogen sulfide containing filtrate was taken, as was usually the case, and evaporated to 40 cc., there was nearly always a faint pink color developed momentarily, indicating that even at the most favorable ***P*H** there was not quite complete precipitation. The test with dimethylglyoxime would indicate the presence of one part in four hundred thousand, or 0.0001 g. of nickel in the filtrate, which checks with the determination as the sulfide.

The amount of adsorption seems much more a function of the glass surface used, rather than anything else. If the glass is strained, local adsorption takes place on the strained area, whereas it may not on the rest of the surface. Of eight flasks used, two were found which gave almost no adsorption under any *P*H values used, while others gave, particularly at the upper limit, adsorption so marked that nothing short of aqua regia would remove the sulfide from the walls of the container.

An entirely new technique was developed for the operations of filtration and roasting. These were both carried out in a platinum Gooch crucible. The mat was prepared in the usual manner, but the drying was carried out at 1000°. At this temperature it was found necessary to repeat the operation of washing and drying three times in order to reach constant weight. During filtration it was found essential to keep the Gooch full of liquid at all times. Washing was unnecessary since no non-volatile materials were present. It was found impossible to destroy completely the pyrophoric character of reduced nickel, even at 1000°. For this reason the nickel was

weighed as nickel oxide, roasting being carried out at 1000° so as to insure decomposition of any nickel sulfate. The results of this study are displayed in Table I and Fig. 1.

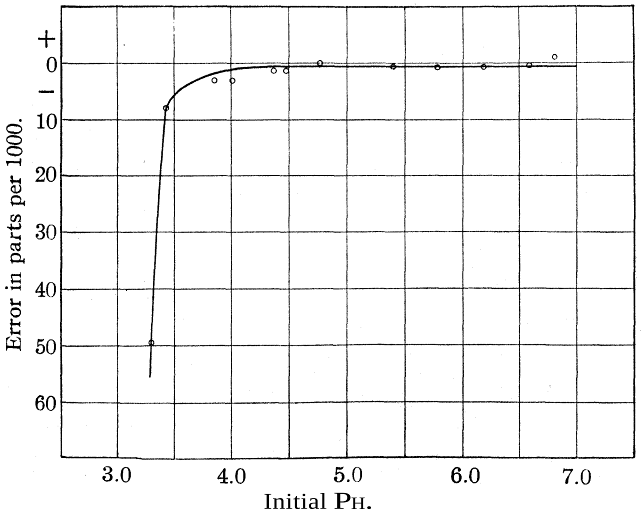

Fig. 1.—Relation between completeness of precipitation **and** initial **acidity.**

As will be evident, even at P_H 7 there is no diminution in precision. The curve reveals that the optimum P_H for nickel sulfide precipitation, *i. e.*, the lowest P_H consistent with complete precipitation and reasonable time for the same, is 4.4.

Summary of the Method

A definite quantity of the material is weighed so as to give approximately 0.2000 g. of nickel. This is dissolved in 10–15 cc. of water, the P_H is adjusted to 4.4 (the desired value) by adding 34 cc. of 0.4 *N* ammonium acetate and 2.8 cc. of 6.8 N acetic acid. The solution is then made up to a volume of approximately 90 cc. This is heated in the Erlenmeyer flask to about 90° (not to boiling). It is then connected with a source of hydrogen sulfide and the air expelled by the gas. After about five minutes the flask is rotated vigorously to aid precipitation by stirring. After precipitation the temperature is raised to 60° by heating on a water-bath. During this time it is connected to the generator. Precipitation is complete in slightly less than an hour. The solution is filtered from the precipitate by suction, using a Gooch crucible. It is very necessary that the crucible be kept full of liquid until this is complete, *i. e.*, until all the liquid and precipitate have been added. The crucible is then placed in the cold furnace and heated to 1000°, while a good current of air is drawn through, after which the crucible is cooled and weighed.

To test the method a sample of recrystallized nickel sulfate hexahydrate was analyzed for nickel content and the following results obtained.

TABLE II

RESULTS OF ANALYSES

Taken, g.	Found, g.	Initial P_H	Final P_H	Acid added, cc.	Error in parts/1000

Summary

1. A precise method has been developed for the precipitation of nickel as sulfide and its subsequent determination as the oxide.

2. The precipitation of nickel sulfide has been studied as a function of P_H.

3. Adsorption of metallic sulfides on glass surfaces appears to vary markedly with the state of strain of the glass.

THERMOLUMINESCENCE IN GLASSES WHICH CONTAIN TWO ACTIVATORS

By Byron E. Cohn and William D. Harkins

Received September 15, 1930 Published December 18, 1930

Introduction

It is generally accepted that the property of luminescence may be conferred upon a solid substance by the addition of certain materials which are termed activators. The variation of luminescence with the concentration of a single activator has been studied by many workers.[1] Mathematical developments of the relation between the intensity of fluorescence and the concentration of an activator in solid solutions have been made by Brüninghaus[2] and Merritt.[3] The luminescence produced by two activators in a solid material, each acting in the presence of the other, is the subject with which this paper is concerned.

Method of Making Samples and Determination of Thermoluminescence.—The material chosen as the solid solvent was a zinc borate glass. In previous experiments[4] it had been found that a similar material could be reproduced exactly, and that activators could be uniformly dispersed within this medium. Manganese and cerium were selected as the activators because the glasses which contain them are only slightly colored, within the range of concentrations to be studied. The individual glasses were prepared as follows. To 16.5 g. of glass mixture were added the computed quantities of c. p. manganous carbonate and cerous oxalate. The glass mixture contained c. p. boric acid and zinc oxide in the ratio of six parts by weight of the former to five of the latter. These had been thoroughly mixed in a quartz pebble tube mill. The mixture for the given sample, containing the manganese and cerium salts, was placed in a covered platinum crucible and heated in a gas muffle until the molten material was entirely clear and free from bubbles. The glass was then poured into a graphite mold previously heated to 400°. The glass cast and its mold were immediately placed within an electric furnace at 400° after which the glass was allowed to cool to room temperature within the furnace. The glass was then ground and polished on the two faces until the thickness was ap-

proximately 2.7 mm. and the small plate was cut into squares 6 mm. on a side.

The thermoluminescence of the glasses was next determined. Before each determination the samples were heated to 300° and allowed to cool to room temperature within an electric furnace to drive off any luminescence. The samples were exposed to a quartz mercury arc to excite the thermoluminescence. The glasses were exposed for ten minutes at a distance of 20 cm. from a "Lab-Arc," the latter being operated on alternating current at sixty cycle frequency and with a current of 1.50 amperes. The glasses were removed to a dark room and allowed to remain for eight hours before measurement. This precaution was taken to remove the error due to the decay of luminescence within the glass, which is quite rapid immediately after excitation. The intensity of thermoluminescence at 100° was measured by a polarization photometer with a radioactive source as the standard of intensity of the type described by Nyswander and Lind.[5] The method of measurement is described by Nyswander and Cohn.[6]

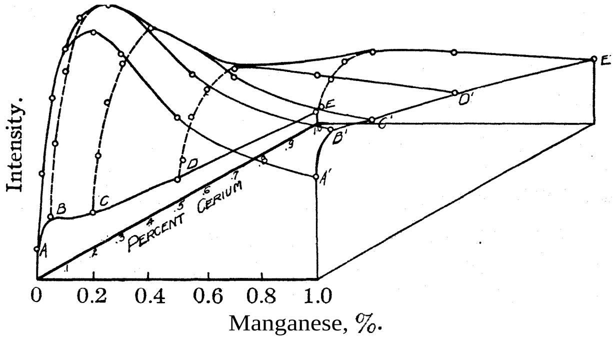

Fig. 1.—Diagram of the surface which represents the intensities of thermoluminescence of zinc borate glasses which contain both manganese and cerium, when a mercury arc is the source of excitation.

Results of Luminescence Measurements.—The intensities of thermoluminescence of a large number of samples which contain both manganese and cerium were obtained. As the intensity of the luminescence depends both upon the concentration of the cerium and that of the manganese, the intensities of luminescence when graphed form a surface. The form of surface in this case is suggested by Fig. 1. In this projection diagram the observed intensities are plotted as ordinates above the plane of concentrations. Curve A to A' represents the intensity of thermoluminescence in samples which contain 0% of cerium and varying quantities of manganese from 0 to 1%. In a like manner Curve B to B' gives the intensity in samples which

[5] Nyswander and Lind, *J. Optical Soc. Am.*, **13**, 651 (1926).

[6] Nyswander and Cohn, *ibid.*, **20**, 131 (1930).

contain 0.05% cerium and varying amounts of manganese and similarly for the remaining curves. A better representation of the actual shape of the surface which gives the luminescence is obtained from the photograph of a model, as shown in Fig. 2. In this photograph the interval between two adjacent black lines represents 0.2% change in the concentration. The zero coordinate is at the corner of the base hidden from view. It will be noted that the glass itself, though made from c. p. materials, is slightly thermoluminescent.

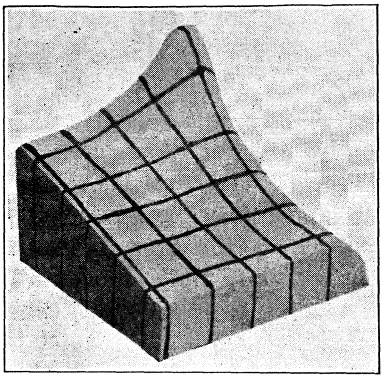

Fig. 2.—Photograph of a model of the surface indicated by Fig. 1.

Figure **3** shows the change in the intensity of the thermoluminescence of the glasses with the concentration of cerium when the concentration of the manganese is held constant. The curves represent the amounts of manganese as follows: A, 0; B, 0.02; C, 0.05; D, 0.1; E, 0.2; F, 0.5, and G, 1.0% cerium.

Figure 4 is similar to Fig. **3** except that in this set of curves the concentrations of cerium are constant for each curve. Curve **A** represents the change of the intensity of thermoluminescence with the concentration of manganese when 0% of cerium is present. The amounts of manganese are: Curve B, 0.05; C, 0.1; D, 0.2; E, 0.5, and F, 1.0%.

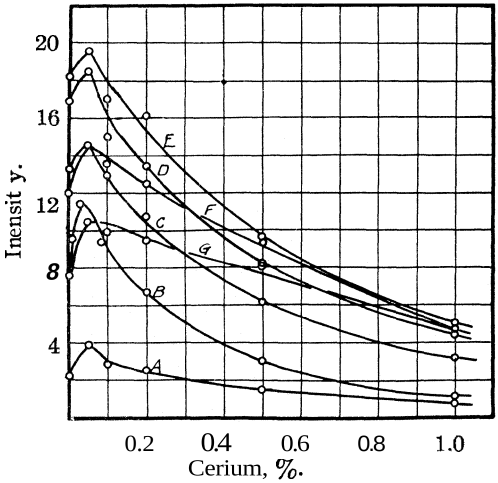

Fig. 3.—The intensity of thermoluminescence of zinc borate glasses which contain both cerium and manganese. The concentration of manganese is constant for each curve.

In Fig. 5 the intensity of thermoluminescence for glasses, each of which contains 0.02% manganese, is plotted as the ordinate and the cerium concentration of the individual glasses as the abscissa. This curve is typical of the curves for glasses which contain both manganese and cerium. It has been separated from the remaining curves of Fig. **3** for the purpose of indicating the damping action of the second activator, cerium, upon the manganese. If there were no such effect the intensity of the luminescence would approach the dotted line of the figure since the percentage of manganese remains constant; instead it falls below as indicated. The damping seems to be the same phenomenon observed qualitatively in the fluorescence of solids by Nichols and Howes[7] and discussed by them under the heading of the dominance and suppression of activators,

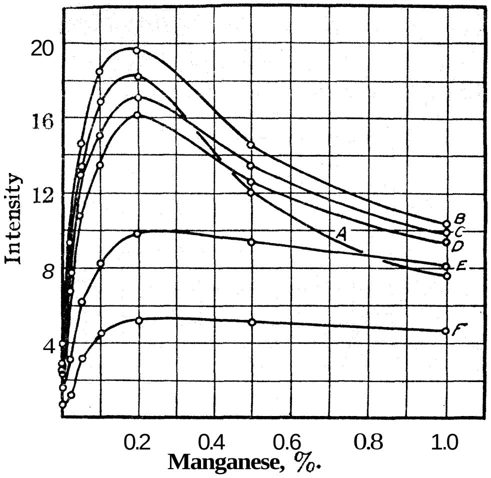

Fig. 4.—**The intensity of thermoluminescence of zinc borate glasses which contain both cerium and manganese. The concentration of cerium is constant for each curve.**

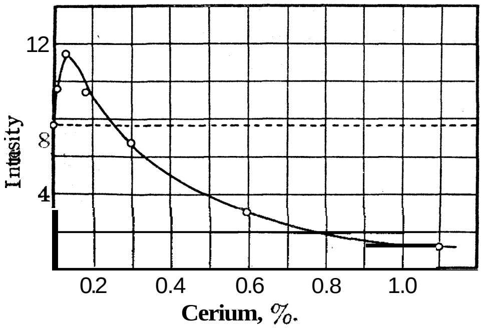

Fig. 5.—The intensity of thermoluminescence of zinc borate glasses which contain 0.02% of manganese together with cerium.

The effect of the cerium upon the luminescence of the manganese may be discussed from another viewpoint. A quantity, which will be termed the damping coefficient, will be defined as the ratio of the decrease in the intensity of thermoluminescence to the initial luminescence, when the decrease is caused by the addition of a fixed amount of the second activator. That is

$$\text{Damping coefficient} = \frac{I_1 - I_2}{I_1}$$

where I_1 is the intensity of thermoluminescence in a sample which contains manganese at a concentration A; I_2 is the intensity of thermoluminescence in a sample which contains manganese at a concentration A and cerium of concentration B. When such values are computed from the data and the damping coefficient is plotted as ordinate against the concentration of manganese (A) as abscissa, Fig. 6 is obtained. In this figure Curve A represents the damping coefficient for 1.0; B, 0.5; C, 0.2; D, 0.1; and E, 0.05%. When the damping coefficient is negative the cerium acts to increase the luminescence and therefore is an activator. It would appear from this figure that the same concentration of cerium may act either to damp the luminescence or to increase it. The effect of the cerium depends upon the concentration of the manganese. For ex-

---

[7] **Nichols and Howes,** *J. Optical Soc. Am.*, 13, 573 (1926).

ample, from Curve C it is seen that 0.2% of cerium decreases the luminescence in all glasses which contain less than approximately 0.4% manganese, but acts as an activator in glasses which contain more than 0.4% of manganese. If the accuracy of the data permit the extrapolation, it would seem that the addition of 1% cerium, which decreases the luminescence of a 0.02% manganese glass to less than one-fifth its initial value, would slightly increase the luminescence in a sample which contains 2% manganese.

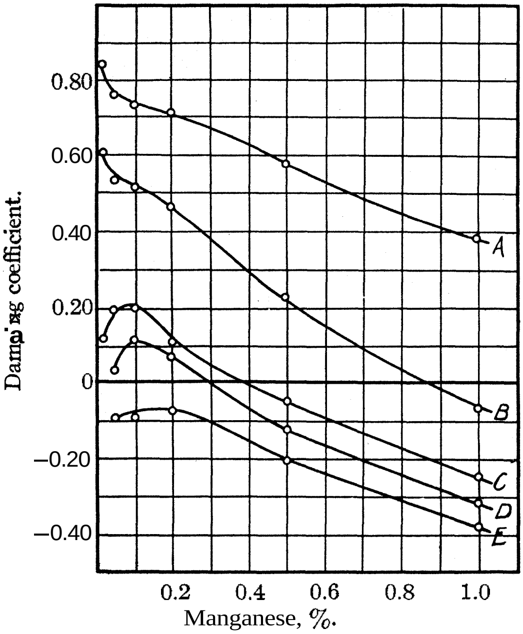

Fig. 6.—The damping coefficient as a function of the concentration of manganese in zinc borate glasses. The concentration of cerium is constant for each curve.

The Emission Spectrum of Thermoluminescence.—So far in this paper only the relative intensities of the thermoluminescent light have been discussed. Due to the low intensity of the emitted light it has not been found possible to obtain accurate spectrometric data on the thermoluminescence. However, by the use of a transmission grating, with a glowing square of zinc borate glass which contained manganese and acted as its own slit, the thermoluminescence emission was found to be a band which extends through the red, yellow and green portions of the visible spectrum. The infrared spectrum was not examined.

As the process of thermoluminescence in glasses when excited by light may be divided into the three steps: (a) the absorption of light energy, (b) the storage of the absorbed energy and (c) the emission of the stored energy, it was decided to study the absorption spectra of thermoluminescent glasses to secure more information concerning the process.

Absorption Spectra of Glasses which Exhibit Thermoluminescence.—Absorption spectra of the glasses were obtained by the use of a quartz Hilger spectrophotometer with a sector disk. The source of continuous ultraviolet light was a high frequency spark under water. The light source was constructed from the design given by Snyder.[8] From the settings on

---

[8] Snyder, This Journal, 49, 2510 (1927).

the sector disk the values of the absorption coefficient K could be computed from the equation

$$\frac{I_0}{I} = e^{K\alpha d}$$

In this work I_0 is the intensity through the glass without any solute, I the transmitted intensity through glass which contains α grams of solute per 100 g. of glass and d is the thickness of the sample in centimeters. From the match point, equal density position on the spectrogram, the wave length which corresponds to K could be determined.

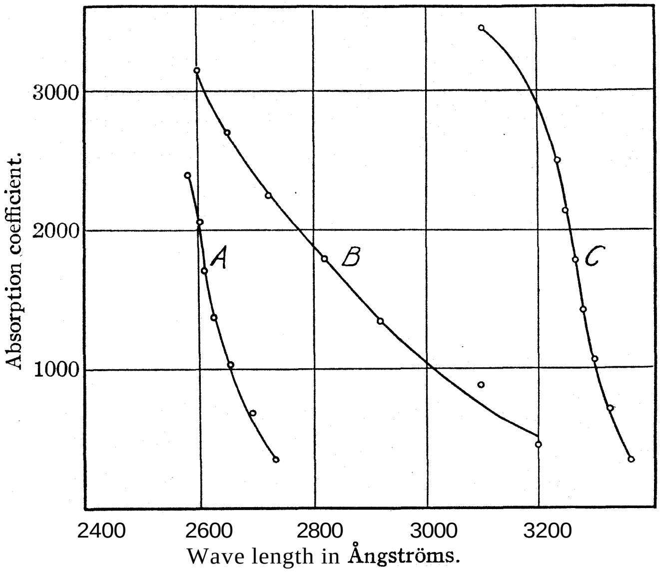

Fig. 7.—The values of the absorption coefficient K as dependent upon wave length: for zinc borate glasses which contain: Curve A, manganese; B, thorium; C, cerium.

When the values of K are plotted against the corresponding wave lengths, curves of the type shown in Fig. 7 are obtained. In this figure Curve A represents values of K obtained from a zinc borate glass which contains 0.5% manganese; B, 0.4% thorium; C, 0.5% cerium. High values of K indicate a high absorption for a given thickness and concentration. If it be assumed that these values relate to the spectral region from which the energy of thermoluminescence is absorbed, some interesting facts are indicated by the curves of Fig. 7. In the first place, absorption by these materials in glasses seems to give an absorption band only one end of which can be observed for the zinc borate glass, although a thickness of 0.27 cm. of this glass without any solute transmits well to 2500 Å., with a transmission limit close to 2400 Å. Secondly, it may be noted that for the same solvent, different light sources would show a different relative intensity of thermoluminescence for various solutes. For example, with sunlight as the source of energy, glasses which contain cerium may be expected to show a much higher intensity, relative to those which contain manganese, than when a quartz mercury arc is used as the source of excitation.

In the preceding paragraph the curves of Fig. 7 have been interpreted on the basis of the assumption that the values for K relate to the general spectral region which furnishes the energy of thermoluminescence. That this assumption has some justification is indicated by the following data. When zinc borate glass which contains 0.44% cerium was exposed to a carbon arc it was found that if the intensity of the emitted light from a square exposed directly to the source is considered to be 100, the thermoluminescent intensity from a square exposed beneath a 2.6-mm. thickness of the same glass is 3. From these values it follows that I_0/I for the exciting light which causes thermoluminescence is 33.3 and K is 3065. For this value of K in cerium glass, Curve C indicates that the mean wave length of the excitation light is 3185 Å. When the plate which gives the absorption for glass which contains 0.5% cerium is examined it is found that the absorption limit as recorded by the photographic plate varies from 3200 Å. for a ten-second exposure to 3140 Å. for a 250-second exposure. The value of 3185 A. lies within this range and seems to give some justification to the provisional assumption that the absorption boundary for which K has been calculated is the region in which the absorbed light furnishes the energy from which the energy of thermoluminescence is derived. It is hoped that this assumption can be tested with monochromatic light, but it is difficult to obtain a sufficiently high intensity.

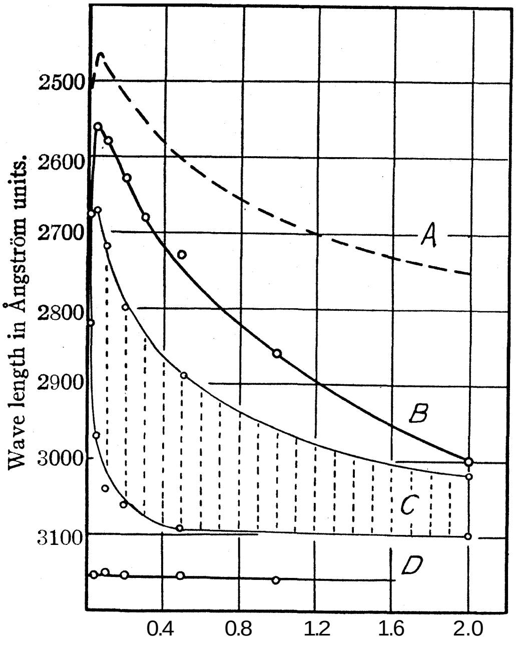

Fig. 8.—Curves B, C and D show wave lengths for which log I_0/I is equal to 0.2. Curve A represents the transmission limit for the glasses shown in curves B, C and D. Curve B represents glasses which contain zero; C, 0.02%; D, 0.05 % of cerium.

The wave lengths for which the value of log I_0/I is equal to 0.2 are shown in Curve B of Fig. 8 for zinc borate glasses which contain varying concentrations of manganese and no cerium. These are the wave lengths for which the transmission is approximately 63% of that which the glasses would have were no manganese present. If 0.02% cerium is present in addition to the manganese, the match points are definite but extend over the range indicated by the area of Curves C. With 0.05% cerium the manganese has little effect on the position of the wave lengths for which the ratio log I_0/I equals 0.2, as is exhibited by Curve D. With a sixteen-second exposure for all of the glasses, shown in Curves B, C and D, the short wave length limit of transmission obtained from the end of the spectrum on the photographic plate corresponds closely to the dotted line of Curve A. This indicates that the absorption limit of these glasses is determined by the manganese, but that the cerium determines the absorption unless the absorption is small. The form of Curve B and of Curve A, which represents the absorption limit, is unexpected.

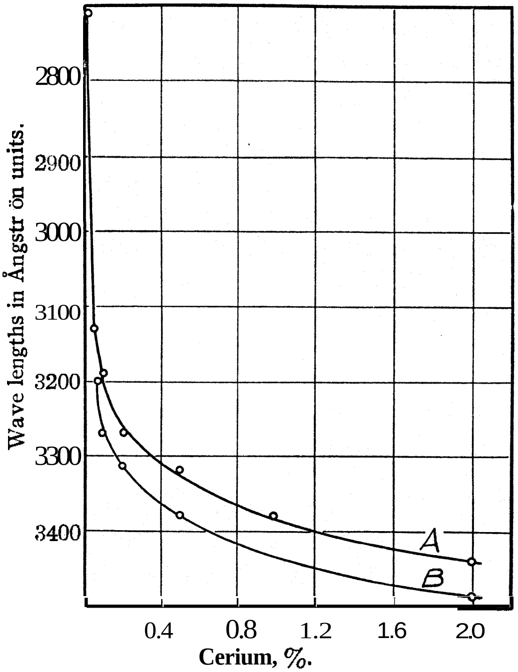

Fig. 9.—Curves which give wave lengths for which log I_0/I is equal to 0.2; Curve A represents values with zero; B, 0.02 % of manganese.

It is of particular interest since thermoluminescence is most marked in zinc borate glasses with slight concentrations of manganese and in the region affected by the anomalous absorption. Curve A of Fig. 9 gives the wave lengths for which the value of log I_0/I is equal to 0.2 for zinc borate glasses which contain varying concentrations of cerium and no manganese. If 0.02% of manganese is present in addition to the cerium, Curve B is obtained. These curves do not exhibit the anomalous behavior of the curves which represent glasses which contain manganese.

Summary

1. The thermoluminescence of glasses which contain two activators has been measured.

2. The effects of one activator upon the second are not additive. For

example, the thermoluminescence of a zinc borate glass which contains *a* small amount of manganese is increased by small amounts of cerium, but decreased by larger amounts. A definite amount of cerium may either increase or decrease the thermoluminescence, since the effect is dependent upon the amount of manganese present.

3. The emission spectrum for zinc borate glass which contains manganese has been found to be a band.

4. Single ended absorption bands have been found in the ultraviolet spectra with zinc borate glasses which contain manganese, cerium or thorium as the solute.

5. Intensity measurements of the thermoluminescence have been used to indicate that it is probably from near the edge of these bands that the energy for thermoluminescence is drawn.

6. From the positions of the absorption bands the conclusion is drawn that the relative thermoluminescent intensities of two materials in the same solvent changes with a change of the source of excitation.

7. Absorption curves which show the effect of cerium upon glasses which contain manganese and vice versa have been obtained.

8. An anomalous absorption has been found for zinc borate glasses which contain manganese.

STUDIES ON HETEROPOLY ACIDS OF GERMANIUM. I. GERMANOMOLYBDIC ACID[1]

BY CHARLES G. GROSSCUP

RECEIVED SEPTEMBER 18, 1930 PUBLISHED DECEMBER 18, 1930

In the list of elements known to form heteropoly acids with molybdenum, tungsten and vanadium, one notices the absence of three members of the fourth periodic group. These elements, carbon, germanium and hafnium are missing from an otherwise complete series of the type $H_8[X(Mo_2O_7)_6]$ aq. where X may be silicon,[2] titanium,[3] zirconium,[3] thorium,[4] tin[6] and lead.6 Possibly this may be supplemented by hafnium, which, it is conceivable, was present in the preparations of zirconomolybdates, since this element was not recognized at the time of the investigations and has since

---

been proved to be present in specimens of supposedly pure zirconium compounds to the extent of as much as 5%. Other elements exhibiting tetravalency such as manganese,[7] platinum[6] and cerium[8] may also be included here. The elements grouped about germanium in the periodic system, especially boron, phosphorus and arsenic, are known to play the role of central atom in similar compounds, *e.* g., the familiar ammonium phosphomolybdate, $(NH_4)_3H_4[P(Mo_2O_7)_6]$ aq.

The similarities in chemical behavior of germanium to arsenic and silicon were largely responsible for the present endeavor to prepare a heteropoly acid which would be the germanium analog of silico-duodecimomolybdic acid, $H_8[Si(Mo_2O_7)_6]\cdot 28H_2O$. That germanium would enter into such "poly acid" formation was a logical conclusion and is supported by the results of this paper. A knowledge of "complexes" is important from an analytical standpoint, since the identity of the constituents of certain compounds and mixtures may be so masked that the elements escape detection in the usual procedures and the analyst is confronted with unusual reactions. It is through a study of the formation and properties of these compounds that the unexpected behavior of certain elements in the presence of molybdic, tungstic and vanadic acids is to be anticipated and means taken to insure their detection.

Experimental

Materials.—The germanium dioxide was prepared from zinc residues which were kindly furnished by Professor J. H. Müller. It was of the highest purity and entirely free from arsenic. The molybdenum trioxide was Baker's "Special," free from arsenic and phosphorus. Lead, calcium, magnesium and ammonium salts, sodium hydroxide, hydrobromic acid and sulfuric acid (special arsenic free) were Baker chemicals. Reagent quality ether was distilled over sodium. Guanidine carbonate was obtained from the Eastman Kodak Co. Laboratory distilled water was redistilled for preparation work. Ammonium hydroxide was redistilled in pyrex vessels and used immediately.

Preparation of the Free Acid.—Five grams of germanic oxide was dissolved in 200 ml. of water containing 7 g. of sodium hydroxide and the solution brought to boiling, whereupon 70 g. of molybdic oxide was slowly added with stirring. Rapid solution of the molybdic oxide took place until about half the amount had been added. Almost complete precipitation occurred at this point, followed by re-solution with continued addition of the molybdic oxide. An intense yellow color developed after this midpoint of reaction. Gentle boiling was continued for five minutes, the solution filtered and allowed to cool. The method of extraction was that of Drechsel;[9] several hundred ml. of ether was added, followed by an excess of cold 9 *N* sulfuric acid. An intermediate turbidity disappeared when sufficient acid had been added. Heavy yellow oily drops separated and settled, forming the third layer common to such extractions. This lower layer—an ether solution of the "complex acid"—was removed and evaporated at 40°. After powdering, the residue was dissolved in a small volume of water and the extraction with ether and sulfuric acid repeated. The ether was removed as before, the residue

[8] Barbieri, *Atti accad. Lincei*, **23i**, **5**, 805 (1914).

[9] Drechsel, *Ber.*, **20**, 1452 (1887).

dissolved in water, the solution filtered and then allowed to crystallize at room temperature (18–28°). The major portion of mother liquor was removed by filtration and the crystals dried as rapidly as possible by pressing between filter paper, after which they were kept in tightly stoppered weighing bottles or weighed out at once for analysis. In spite of the high solubility, the solutions crystallized well. Three separate batches of the acid were prepared.

Preparation of the Guanidine Salt.—To an aqueous solution of the acid was added a concentrated solution of guanidine carbonate, the mixture warmed and filtered. The residue was boiled with water until solution was nearly complete, then filtered and cooled. The shining greenish-yellow crystals were removed and dried at 105°. On standing for several days the filtrate deposited white crusts containing germanium and molybdenum.

Properties.—The free acid crystallizes in yellow transparent octahedra, readily efflorescing. The melting point is approximately 65". Induration, with loss of color and transparency, invariably resulted from attempts to preserve crystals imperfectly freed of mother liquor. Such changes took place in a few days and the substance produced, in sharp contrast to the parent compound, was but sparingly soluble in water. Well-dried specimens on the other hand have been kept ten weeks, suffering no apparent deterioration and differing from fresh samples only in a slightly lower water content Analogous to the behavior of the corresponding silicon compound, pale yellow, difficultly soluble compounds are obtained with silver, thallous, mercurous, cesium, rubidium and guanidine salts and with alkaloids.

Analysis.—Calibrated weights were used and all gravimetric determinations were brought to constant weight (±0.05 mg.).

A. **Water.**—Samples were dried in an oven at 105° for "water of hydration." Total loss on ignition was determined by heating at 400° in a resistance furnace. The residues were yellow when hot and pale blue when cold.

B. Germanium and Molybdenum.—A number of separations were tried but only one yielded duplicable results. The procedure finally adopted was a distillation from 9 *N* hydrobromic acid. The free acid or ignition residue was placed in a 200-ml. round-bottomed flask, to which was attached by a ground joint a 25-cm. neck with side arm. A meter length of glass tubing dipping under water in an Erlenmeyer flask served as a condenser and receiver for the germanium tetrabromide; 25 ml. of hydrobromic acid (sp. gr. 1.30) containing a small amount of bromine was added to the flask and the mixture slowly distilled. If less than two hours were consumed in this operation, a little molybdenum usually appeared in the distillate as evidenced by the brown color of the sulfide. The distillation was continued until the volume of the solution remaining in the flask was about **3** ml.; an additional 25 ml. of hydrobromic acid was introduced and the distillation repeated. The distillate was made 6 N in acid by adding concentrated sulfuric acid and the germanium precipitated as sulfide by saturating the hydrogen sulfide. The germanium sulfide was filtered on a Konig crucible and, after washing with 6 N sulfuric acid saturated with hydrogen sulfide, was converted to oxide by nitric acid in the usual manner. The brown solution remaining in the distilling bulb was washed into a small sillimanite crucible, ten drops of concentrated sulfuric acid added and this mixture evaporated to dryness in an air-bath. The residue was gently ignited to expel sulfur trioxide and weighed as molybdic oxide.

C. The guanidine salt was analyzed for nitrogen by the Dumas method.

Discussion

Three physical constants of the compound under investigation suggested a formula similar to silicomolybdic acid, $H_8[Si(Mo_2O_7)_6]$ aq. They are:

(1) the isomorphism of the free acids; (2) the yellow color, which is usually associated with "poly acids" containing Mo_2O_7 groups; **(3)** the melting point, which is comparable with the values for the silico acid, 45°, and the titano acid, 60°.

The theoretical composition of $H_8[Ge(Mo_2O_7)_6]$ aq., according as the amount of "aq." is 24, 25, 26 and 28 moles, respectively, is given in Table I.

TABLE I

THEORETICAL COMPOSITIONS

	24 aq.	25 aq.	26 aq.	28 aq.
Ignition loss	21.58	22.18	22.77	23.92
GeO_2	4.48	4 44	4.41	4 34
MoO_3	73.94	73.38	72.82	71 74
	100.00	100 00	100.00	100.00
"aq."	18.48	19.02	19.72	21.58
Molecular weight	2336.6	2354 6	2372 6	2408 6

The tendency of the crystals to effloresce made it difficult to obtain samples of exactly the same composition, although the deviation and variance of results is not great, *as* is evident from the analyses.

TABLE II

"AQ." AND IGNITION LOSSES

No.	Sample, g.	Loss at 105°, %	Ignition loss, %
1	0.46224	19.26	22.41
2	.37547	19.10	22.65
3	.20490		22.20
4	.17245		22.31
5	.17857		22.19
6	.59183		22.47
7	45747		22.62
8	.57261		22.32
9	.38234		21.77
10	.30670	18.70	21.88
11	.31427		22.15
12	.25630		22 08
13	.18382		22.08
14	.11287		21.18
15	.14546		21.22
16	.13040		21.20

Samples 1–5 from Preparation **A**; samples 6–10 from Preparation B; samples 10–16 from Preparation *C*; samples 14, 15, 16 were kept for ten weeks before analysis.

It will be seen that the ignition losses predicate an "aq." content of 24–26 moles and that the values for loss at 105° are in proportionate agreement. The molecular formula for silicomolybdic acid is accepted as $H_8[Si(Mo_2O_7)_6]\cdot 28H_2O$ but the analysis of the germanium compound failed to reveal a water content of the same magnitude. Five of the above samples were analyzed by the hydrobromic method and gave the following values.

TABLE III

ANALYSIS OF THE FREE ACIDS

No.	2	6	12	8	9
Wt. of sample, g.	0.37547	0.59183	0.25630	0.57261	0.38234
MoO_3 found, g.	.27177	.43085	.18761	.42087	.28217
MoO_3, %	72.38	72.80	73.20	73.50	73.80
GeO_2 found, g.	0.01633	0.02604	0.01164	0.02548	0.01759
GeO_2, %	4.35	4.40	4.54	4.45	4.60
Ignition loss, g.	22.65	22.47	22.08	22.32	21.77
Total	99.38	99.67	99.82	100.27	100.17
Ratio $GeO_2:MoO_3$	1:12.07	1:12.01	1:11.72	1:12.00	1:11.65
Ratio GeO_2 $MoO_3:H_2O$	1:30.10	1:29.68	1:28.92	1:29.25	1:28.22

Since vapor pressure measurements were not made, the existence of lower hydrates is not postulated. By efflorescence, however, it is conceivable that samples could have compositions agreeing with those selected in Table I.

Because of the simplicity of procedure we may use the ignition loss as a standard in the critical examination of results. Comparing, for example, Analyses 2 and 6, we see that lower ignition loss in No. 6 is compensated for by a higher metallic oxide content and, by reference to Table I, that the values for ignition loss, MoO_3 and GeO_2, agree proportionately within the limits of experimental error.

North and Beal[10] made use of a titration with sodium hydroxide as a means of analysis for silicomolybdic acid. Scroggie[2] repeated the work, using chlor phenol red as indicator. The complete decomposition of the germanium compound by alkalies may be expressed by the equation

$$GeO_2 \cdot 12MoO_3 \text{ aq.} + 24\,NaOH = GeO_2 \text{ aq.} + 12\,Na_2MoO_4 + \text{aq.}$$

if the germanic acid is not attacked under the conditions of the experiment. A sample, No. 13, after ignition was titrated with 0.2920 N sodium hydroxide and chlor phenol red. The water content, 22.08%, corresponds closely with that of $H_8[Ge(Mo_2O_7)_6] \cdot 25H_2O$, with a molecular weight of 2355. On this basis the titration required 23.93 moles of sodium hydroxide per mole of acid. Calculated from the weight of ignited oxides the value is 23.95. Another sample, No. 17, wt. 0.15717 g., was weighed out at the same time as samples No. 6 and No. 7, the water content of which gave a mean value of 22.54%, approximately equivalent to $H_8[Ge(Mo_2O_7)_6] \cdot 26H_2O$. Assuming then a molecular weight of 2373, the titration showed a consumption of 23.80 moles of the base.

That progressive decomposition with the intermediate formation of "unsaturated" compounds—those with lower MoO_3 content—took place was indicated by the fact that upon the addition of a drop of the base the basic color of the indicator persisted several minutes and then gradually

---

[10] North and Beal, *J. Am. Pharm. Assn.*, 13,889 (1924).

faded. The titration was necessarily extended over a period of several hours before a permanent "end-point" was reached.

The analysis of the guanidine salt gave 7.97% nitrogen. The theoretical value for the tetrabasic salt, $(CN_3H_5)_4H_8[Ge(Mo_2O_7)_6]$ is 7.84%.

The product resulting from the deterioration of the undried crystals was washed with hot water, air dried and analyzed.

Table IV

Analysis of White Insoluble Compound

Water at 105°, %	0.00
Ignition loss, %	11.20
MoO_3, %	86.50

Lack of material prevented a further study. Disruption of the original molecule apparently took place and a portion of the germanium was removed in the washing operation.

While the deviations from theoretical values are at times large, yet the results indicate the existence of a heteropoly acid of germanium and molybdenum with the formula $GeO_2 \cdot 12MoO_3 \cdot aq.$, which may be written, after the fashion of the Miolati system of constitution, as $H_8[Ge(Mo_2O_7)_6]aq.$, a member of the series $H_{12-n}[X_n(Mo_2O_7)_6]aq.$ The coefficient for the "aq." has an apparent maximum of 26. The seriousness of the deviations is somewhat mitigated if one considers that ammonium phosphomolybdate, used since the time of Berzelius in analytical procedures, is, because of somewhat indefinite composition, still unsuited for gravimetric work.

In accordance with the present system of nomenclature the new compound may be called 12-germanomolybdic acid or germano-duodecimo-molybdic acid.

The ease of formation of germanomolybdic acid and its salts makes the compound susceptible to qualitative and perhaps quantitative application for the detection and determination of germanium. To this purpose, germanium sulfide—the usual form in which the element is isolated—can be converted into the oxide and this boiled with a small volume of water and some molybdic oxide. The presence of the germanomolybdic acid thus produced may be confirmed by color or precipitation reactions. A yellow color is easily seen when 0.00183 g. of the free acid (corresponding to approximately 0.000082 g. of germanic oxide) is dissolved in 5 ml. of water. This may prove of particular value since no colorimetric determination of germanium has been reported.

Summary

1. The preparation and properties of a heteropoly acid of germanium and molybdenum of the type $H_8[Ge(Mo_2O_7)_6]$ aq. is outlined.

2. The use of the new acid and its salts for the colorimetric determination of germanium is suggested.

NITROGEN COMPOUNDS OF GERMANIUM. I. THE PREPARATION AND PROPERTIES OF GERMANIC NITRIDE

BY WARREN C. JOHNSON

RECEIVED OCTOBER 2, 1930 PUBLISHED DECEMBER 18, 1930

According to the literature silicon[1] combines directly with nitrogen, when heated at 1300 to 1450°, to form the normal nitride, Si_3N_4. A similar reaction takes place when this element is heated in an atmosphere of ammonia at high temperatures. Analogous reactions in the case of germanium, tin and lead are lacking.

Carbonic anammonide, $(C_3N_4)_x$, has been obtained[2] as a highly polymerized, orange powder by heating mercuric thiocyanate. Pauly[3] has reported $(C_3N_2)_x$, carbonous nitride or anammonide, as being obtained by the thermal decomposition of tetra-iodo-imidazole. This has since been shown[4] in all probability to be a mixture of carbon and paracyanogen, $(C_2N_2)_x$. Bergstrom[6] prepared stannous imide, SnNH, by reacting potassium ammono stannite, SnNK, with a solution of ammonium bromide in liquid ammonia. The imide was deammonated by heating in a vacuum at 340°. The reaction resulted in the formation of stannous anammonide or nitride, Sn_3N_2. This nitride is the only definite one known of the fourth outer group elements exhibiting a valence of two. Carbonic nitride and silicic nitride are the only representatives of these elements functioning with a valence of four.

Recently Schwarz and Schenk[6] studied the ammonolysis of germanium tetrachloride in liquid ammonia solution. Their results indicate that the hexammonate described by Thomas and Pugh[7] may not exist in liquid ammonia. Schwarz and Schenk allowed germanium tetrachloride to ammonolyze, separated the ammonium chloride and found a definite combination in the imide, $Ge(NH)_2$. At 150° the imide was found to lose ammonia with the formation of the germanam, Ge_2N_3H. This latter

combination was found to be stable at 300° but at higher temperatures to decompose, with loss of ammonia, to the nitride, Ge_3N_4. Their evidence for the formation of the nitride is based entirely upon the changes in weight resulting from the decomposition of the germanam and of the imide; no analyses are reported to substantiate the existence of germanic nitride. In the case of the decomposition of the imide the ammonia liberated was determined. Since these changes in weight are very small, especially when minute quantities of the substances are used, it is difficult to state the purity of the nitride without analytical data on the germanium and nitrogen content. However, it is the belief of the writer that Schwarz and Schenk have prepared germanic nitride.

Before the work of these investigators appeared, Kraus and E. G. Johnson[8] studied the ammonolysis of germanium tetrachloride. Their results are in agreement with those of Schwarz and Schenk in the formation of the imide and the germanam, and definitely substantiate the existence of the nitride.

The following described investigation confirms the results of the above-mentioned workers in that germanic nitride is prepared by the action of ammonia gas on metallic germanium at elevated temperatures. Some of the physical and chemical properties of the nitride are also determined.

Experimental

Source of Material.—The germanium was obtained as germanous sulfide from germanite ore according to the procedure described by Kraus and Johnson.[9] The sulfide was oxidized with nitric acid to germanic oxide, which was then reduced with hydrogen at 600° to the gray germanium powder. For purification, the metal was heated in a stream of chlorine gas at 250' to form germanium tetrachloride, the chloride was hydrolyzed to the oxide, and finally the oxide was again reduced with hydrogen to germanium. This procedure gave germanium in a finely divided state and of fairly high purity.[10]

Anhydrous ammonia of commerce was siphoned from its container into a small steel cylinder containing several small pieces of sodium, which served to remove the water completely. During the course of a reaction the ammonia was allowed to escape from this cylinder as a gas.

Preparation of Germanic Nitride

(a) The Action of Ammonia on Germanium.—A weighed amount of the powdered germanium, obtained from the reduction of germanic oxide, was placed in a weighed alundum boat in a vitreosil tube. The tube extended horizontally through an electric

---

Kraus and E. G. Johnson, Brown University, private communication.

Kraus and Johnson, Paper given at the Swampscott Meeting of the American Chemical Society, September, 1928.

[10] It has been shown by Dennis, Tressler and Hance, THIS JOURNAL, 45, 2034–5 (1923), that small amounts of germanium dioxide may be reduced quantitatively with hydrogen, but when several grams of the oxide are used, the reduction does not appear to be complete. This fact accounts for the low yields of germanic nitride obtained in the following described experiments.

furnace the temperature of which was measured with a thermocouple. A fairly rapid stream of ammonia gas was allowed to pass over the germanium at different temperatures. A slow reaction was observed at 650"; at 700° the formation of nitride appeared to be quite rapid, only three hours being required to convert 1 g. of germanium to the nitride. The samples of germanium were heated in an atmosphere of ammonia until no increase in weight of the boat was observed to indicate the continued formation of nitride. The nitride appeared as a light brown powder.

The following data show the formation of germanic nitride.

Ge, g.	Ge_3N_4 (obtained), g.	Ge_3N_4 (calcd.), g.
0.4603	0.5756	0.5787
4.2852	5.3718	5.3878

When ammonia was passed over germanium at temperatures in the neighborhood of 850" and above, no nitride was formed. Since, as was found in later experiments, the nitride is readily reduced with hydrogen at elevated temperatures, the absence of its formation at 850° is readily accounted for by the high concentration of hydrogen present in the gas mixture due to the dissociation of ammonia.

(b) The Action of Ammonia on Germanic Oxide.—Ammonia was found to react slowly with germanic oxide at 700° and much more rapidly at 750°. The ammonia served to reduce the oxide to germanium, which in turn reacted with additional ammonia as described above. The probable course of the reaction is

$$3GeO_2 + 4NH_3 = Ge_3N_4 + 6H_2O$$

The formation of the nitride in this reaction was indicated by the light brown color and the following changes in weight.

GeO_2, g.	Ge_3N_4 (obtained), g.	Ge_3N_4 (calcd.), g
0.4808	0.4188	0.4195
4.1299	3.6074	3.6039

The Reduction of Germanic Nitride. The Determination of Germanium and Nitrogen.—Preliminary experiments showed that the usual methods for the determination of nitrogen were not highly satisfactory. Concentrated sulfuric acid and also a mixture of this acid with concentrated nitric acid reacted slowly with the nitride even on boiling. Several days were required to dissolve a small amount of the nitride when this procedure was followed. A concentrated solution of sodium hydroxide, even when boiled, did not liberate ammonia and appeared to have no effect on the nitride. It was found, however, that, when the nitride was heated at a temperature as low as 600° in a stream of hydrogen gas, reduction took place readily to metallic germanium and ammonia. At 700° the reduction process was found to be extremely rapid. The reaction evidently proceeds as follows

$$6H_2 + Ge_3N_4 = 3Ge + 4NH_3$$

Likewise, the reaction to the left expresses the process for the formation of the nitride from germanium and ammonia.

In collecting the ammonia resulting from the reduction of the nitride, the gas stream was allowed to pass through two wash bottles containing a known amount of standard hydrochloric acid solution. The strength of the acid was 0.1032 N. When the reduction was completed, the solutions were titrated back with standard sodium hydroxide solution and the amount of acid used to combine with the ammonia was calculated accordingly. The residue remaining in the boat after complete reduction of the nitride was germanium in the elementary state.

Quantitative results were obtained in this procedure when a rapid stream of hydrogen was used so that the ammonia would be rapidly swept out of the hot regions of the furnace. A slow gas stream permitted the ammonia to dissociate into nitrogen and hydrogen and low results were obtained.

The results of the reduction are given in Table I. In the first column is given the weight of germanic nitride reduced, in the second and third columns, the weight of germanium found in the boat after complete reduction and the theoretical amount, respectively; in the fourth, the volume of standard acid solution used to neutralize the ammonia collected; and in the fifth and sixth columns, the amount of nitrogen as calculated from the titration and the theoretical amount, respectively.

TABLE I

ANALYSIS OF GERMANIC NITRIDE FOR GERMANIUM AND NITROGEN

Ge_3N_4, g.	*Ge* (found), *g.*	*Ge* (calcd.), g.	HCl, cc.	N_2 (found), g.	N_2 (calcd.), *g.*
0.5000	0.3989	0.3977	70.17	0.1020	0.1023
.6586	.5270	.5238	91.14	.1318	.1348
.5732	.4553	.4559	82.65	.1195	.1173

The Oxidation of Germanic Nitride.—Germanic nitride was found to be exceedingly stable toward the usual oxidizing agents. Even a mixture of fuming nitric and fuming sulfuric acids caused only a slow oxidation on boiling. When the compound was heated in air at the temperature of the Méker burner, oxidation took place with difficulty. Pure oxygen gas was found to oxidize the nitride at 850–900°; on the other hand, the reaction proceeded slowly at 800°. White germanic oxide was formed in this reaction; the condition of the nitrogen was not determined but, without doubt, it was eliminated as elementary nitrogen.

Anal. Subs., 0.5766, 0.9777. Calcd. GeO_2: 0.6607, 1.1203. Found: 0.6593, 1.1180.

The Chlorination of Germanic Nitride.—Germanic nitride, 0.4321 g., was weighed in an alundum boat which was introduced into a vitreosil tube. A slow stream of chlorine gas, emitted from a tank and dried with concentrated sulfuric acid, was allowed to pass over the nitride at different temperatures. The temperature was controlled as previously described. The first heating was carried out at 400–450° for a period of two hours; only 2.3 mg, loss in weight resulted. When the temperature was increased to 600° for four hours, more than one-third of the material was found to have left the boat. The color of the remaining material was brown, but of a little lighter shade than that of the original sample. The heating was continued for several hours at temperatures ranging from 500–575° but no indication of reaction was found; however, at 600–700°, the reaction proceeded rapidly, as all but 50 mg. of the original sample of the nitride disappeared from the boat during a four-hour heating. The color of the remaining nitride was still a light brown. It was found possible, on further heating at the last-named temperature, completely to remove the nitride from the boat by the reaction with chlorine gas. Germanium tetrachloride was observed as one of the products of the reaction. The following equation expresses the probable course of the reaction

$$Ge_3N_4 + 6Cl_2 = 3GeCl_4 + 2N_2$$

Color.—Schwarz and Schenk state that germanic nitride is white when pure. In the decomposition of their germanam they obtained a brown colored nitride, but they attribute the color to the presence of finely divided germanium. In view of the above-described experiment on the chlorination of the nitride, it is impossible to ascribe the color to any appreciable amount of metallic germanium. Germanium is well known to react with chlorine readily at temperatures as low as 100°.

In the above, the brown color persisted after the nitride had been heated for many hours in chlorine at temperatures ranging from 400–700°. If any germanium were present with the nitride, one would expect it to be quickly removed as germanium tetrachloride, which is thermally stable at the temperatures of the experiments. Since the brown color did appear to vary in intensity in the different preparations and since the chlorine rendered them lighter in color, undoubtedly a small amount of germanium was present. This amount is accounted for in the first loss in weight recorded in the chlorination experiment, namely, 2.3 mg., but no loss resulted when the same material was later heated at 500–575°. On the other hand, the persistence of the color throughout the entire reaction either means that the nitride is normally a light brown or that another constituent is present, possibly germanium or a lower nitride, which is so finely dispersed throughout the mass of the material as to render its separation difficult.

The presence of an appreciable amount of germanous nitride[11] with the germanic nitride is not substantiated by experiments. This nitride is quite volatile and would be removed from the germanic nitride at the temperatures required for the preparation of the latter.

It may also be suggested that the color is due to the polymerization of the germanic nitride molecule.

The Dissociation of Germanic Nitride.—The decomposition of the nitride at 900–1000° resulted in the production of germanium and nitrogen. (A small amount of material, black to brown in color, appeared on the walls of the tube. This is thought to be germanous nitride.)[12] The results obtained by Schwarz and Schenk at the high temperatures are confirmed in this experiment. It should be stated, however, that in our experiments the nitrogen was removed rapidly by means of a Hyvac pump while the dissociation proceeded.

When the nitride was decomposed in a closed system at lower temperatures, 600–700°, a considerable amount of material collected on the walls of the tube in the cooler regions. The pressure developed by the nitrogen was measured at different intervals over a period of several weeks and was found to increase gradually. There was no indication of any equilibrium values. If dissociation at this temperature produces nitrogen and germanium, there must necessarily result some germanous nitride, which would volatilize and collect on the walls of the tube. It will be necessary to study the dissociation of germanic nitride under dif-

---

[11] Germanous nitride, Ge_3N_2, has been prepared in this Laboratory by Mr. J. R. Hart. It is formed readily when metallic germanium is heated in nitrogen at 800–950°. Thin layers of this nitride appear brown in color while the substance in a compact form appears black. It is readily volatile at a temperature as low as 650°. The results concerning its preparation and properties will appear in a forthcoming publication.

[12] Observations by Mr. J. R. Hart.

ferent conditions, and, if possible, to obtain equilibrium values before any definite statement may be made concerning the mechanism of the process.

Other Properties.—Germanic nitride resembles the corresponding compound of silicon in its remarkable stability. It is not affected by air at ordinary temperatures. It is insoluble in water and all the common inorganic solvents. It is not attacked by water at 100°. A boiling solution of sodium hydroxide does not liberate nitrogen as ammonia from the nitride. Strong acids appear to affect it slightly.

Summary

Germanic nitride has been prepared by reacting metallic germanium with ammonia gas at 700°. Germanic oxide may be used in place of germanium in this reaction.

The nitride is readily reduced by hydrogen at 700° to germanium and ammonia. This process serves as a method of analysis for the germanium and nitrogen.

The oxidation of the nitride to germanic oxide by means of oxygen at 850° proceeds rapidly. Chlorine gas reacts with germanic nitride at high temperatures.

The color, dissociation and other properties are discussed.

A SPECTROSCOPIC STUDY OF THE DECOMPOSITION AND SYNTHESIS OF ORGANIC COMPOUNDS BY ELECTRICAL DISCHARGES. I. THE ELECTRODELESS DISCHARGE

BY WILLIAM D. HARKINS AND DAVID M. GANS

RECEIVED OCTOBER 10, 1930 PUBLISHED DECEMBER 18, 1930

1. Introduction

While the effects of electrical discharges upon organic gases and vapors have been investigated extensively, little has been known concerning the mechanism of their action. Thus the final condensation products have been studied, but there has been practically no knowledge of the decomposition products formed initially in the discharge.

In certain respects the conditions in low voltage discharges resemble those in flames, although the velocities of the free electrons are commonly greater in the former. In flames produced by the combustion of organic hydrogen compounds in oxygen, molecules of water, of hydroxyl (OH), of carbon (C_2) and of carbon monoxide, are present. These molecules also exist in electrical discharges which pass through organic vapors, provided these contain the elements oxygen and hydrogen as constituents. In flames an excess of oxygen converts the carbon partly into carbon dioxide. In electrical discharges in pure organic vapors such an excess of oxygen is not present, so that practically no carbon dioxide is formed, and oxygen and carbon are combined almost entirely as carbon monoxide. Carbon is present as molecules of C_2, of CH, and as carbon atoms and singly charged positive carbon ions (C^+), while hydrogen is found also as atoms (H).

Such atoms, ions and molecules are obviously extremely active, and unite rapidly to form very complex organic liquids or solids. For example, Lind and Glockler[1] found that silent, semi-corona and corona discharges effect the condensation, with a liberation of hydrogen and some methane, of the lower saturated hydrocarbons and of ethylene. With the ozonizer type of discharge, the products are almost entirely liquid, whereas the corona type of discharge yields as much resinous solid as liquid product. Similarly, Lind and Bardwell[2] found that a-radiation causes the condensation of the lower saturated hydrocarbons with elimination of hydrogen and methane and the formation of higher saturated and unsaturated hydrocarbons, which may be gaseous, liquid or solid. Carbon monoxide gives carbon, carbon dioxide and a solid, presumably a suboxide of carbon. With unsaturated compounds, Lind, Bardwell and Perry[3] obtained solid polymers from acetylene, cyanogen and hydrogen cyanide under the influence of a-particles, and a colorless liquid condensate from ethylene upon elimination of one-sixth of its content of hydrogen.

The effect of canal rays was studied as early as 1906 by Kinoshita,[3a] who worked with several gases, including acetylene, and obtained characteristic line and band spectra. More recently, Kohlschiitter and Frumkin[3b] investigated the decomposition of hydrocarbons by canal rays.

The electrodeless discharge, as the writers have reported,[4] is a convenient means of effecting the polymerization or condensation of organic compounds. Thus, when benzene vapor at a pressure of 0.1 mm. (relatively low compared to the pressures used by Lind and his co-workers) is subjected to the electrodeless discharge, a greenish-white, ring-like glow appears, concentric with and adjacent to the coil of wire which supports the discharge. This glow immediately spreads through the entire flask, and is extinguished in a red flash, since the benzene is converted into a solid, so that the pressure falls too low to carry the discharge. If, how-

ever, benzene vapor is continuously admitted at the proper pressure, the discharge persists as a brilliant white ball, arid a brown solid deposits on the walls of the vessel. The formula of this product is (CH),. The spectrum from the discharge shows that the benzene is first decomposed into neutral hydrogen (H) and carbon (C) atoms, into singly charged carbon ions (C^+), and into molecules of carbon (C_2) and monohydrocarbon (CH).[5]

Other organic substances form similar compounds and give related spectra. If oxygen is present in the substances, molecules of water, of hydroxyl (OH) and of carbon monoxide are formed as intermediate products, as has already been stated. If nitrogen, but not oxygen, is present, cyanogen (CN), nitrogen (N_2), singly charged N_2^+ ions and imine (NH) molecules are formed.

In general, these atoms, molecules and ions react with each other very rapidly, almost instantaneously, to form products of higher molecular weight. For example, benzene is decomposed and the fragments unite to form a reddish-brown solid almost as rapidly as the benzene vapor can flow into the flask at the proper reduced pressure. One exception is the product water, which is relatively inactive and does not seem to unite to any very great extent with the other materials produced by the decompositions.

2. Apparatus and Procedure

The apparatus used in these experiments is shown in Fig. 1. Here F is a 1-liter pyrex flask which contains the vapor studied. Over the mouth of the flask, a quartz window Q is attached with de Khotinsky cement. The tube E, sealed to the neck of the flask, acts as a trap for any solid product which may be thrown against the window, and, when necessary, as a liquid-air trap. Around the flask, in the plane passing through the

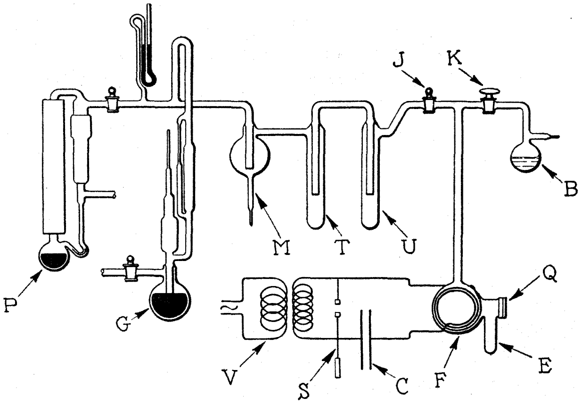

Fig. 1.

---

[5] This is confirmed by Austin, This journal, 52, 3026 *(1930).*

window, is tightly wound a vertical coil of six turns of insulated, heavy copper wire. In addition to this coil, the high-frequency circuit consists of a 1 kv. a. Thordarson transformer V which supplies 25,000 volts, a spark gap S capable of adjustment by a screw and made of cylindrical zinc electrodes 1.7 cm. in diameter, and a 0.02 microfarad condenser C of 14 squares of sheet metal immersed in transformer oil between plates of double-strength window glass in a metal container. The frequency of the circuit, as determined with a radio receiver, was about 1100 kilocycles per second.

Vapor is admitted to the flask F from the supply bulb B. Mercury vapor from the diffusion pump P, which is backed up by a Cenco Hyvac pump, is kept from the flask by the liquid-air trap T, while the liquid-air trap U prevents the substance in the bulb from getting into the pumps. The special McLeod gage G is capable of measuring pressures up to several millimeters of mercury.

The compound to be studied, properly purified and dried, is distilled into the bulb B, which is then sealed, except for the outlet through stopcock K. After the air is pumped out of the bulb, stopcock K is closed and the apparatus is completely evacuated. Stopcock J is now closed permanently, the electrodeless discharge is started and vapor is admitted to the flask F through stopcock K. The vapor, as it enters the vessel, is decomposed with emission of light and formation of the products already mentioned.

The discharge is very sensitive to pressure changes and operates at low pressures. With a very volatile liquid, the stopcock K must therefore be opened only very slightly, and it is sometimes necessary to surround the bulb B with a properly chosen cooling agent. The vapor pressure of a relatively non-volatile solid or liquid may not be high enough at room temperatures to support the discharge, in which case that part of the apparatus which lies to the right of stopcock J is enclosed in a box which contains an electrical heater capable of maintaining the contents of the box at 60° or more. When the pressure in the flask F is correctly controlled, the decomposition can be continued without interruption for several hours. Should the compound form products whose vapor pressure is too high at ordinary temperatures, the side-arm E is surrounded with liquid air. The discharge causes a considerable evolution of heat, which is dissipated by the use of a fan.

The light which passes out through the window Q is focused on the slit of a spectrograph. In this work a Hilger E1 quartz spectrograph and a Steinheil GH glass spectrograph were used. A small plane silver mirror, placed when desired at an angle of 45° just in front of the quartz window, throws the spectrum of an ion arc on each plate, for comparison. For work in the visible region, panchromatic plates were used. The deposition of a firmly adhering film of product necessitated a change of window after each exposure, which lasted from one-half to two hours.

3. Purification of Compounds

The compounds studied were benzene, acetylene, naphthalene, n-heptane, aniline, nitrobenzene, phenol and chlorobenzene. Acetylene was prepared[6] by dropping ethylene dibromide into 30% alcoholic potash at its boiling point. To remove vinyl bromide the gases evolved were passed through a series of two coil condensers, through which ice-water was circulated. The acetylene was collected over water, passed over phosphorus pentoxide and repeatedly through a trap surrounded by carbon dioxide snow to remove water and any remaining vinyl bromide. The acetylene was finally isolated in the bulb B over liquid air. C. P. naphthalene was used. With the other compounds, the middle fractions obtained by distillation of the C. P. reagents were dried over sodium,

---

[6] This procedure was suggested to us as the best method for preparing pure acetylene by Prof. M. S. Kharasch.

phosphorus pentoxide, or anhydrous sodium sulfate, and distilled into the bulb B under reduced pressure.

4. Effects of the Electrical Discharge

(a) Benzene.—-With benzene, no liquid air was required around the side tube E. In half an hour several thousand liters of vapor were admitted continuously to the discharge vessel, and decomposed, yet not enough permanent gas accumulated in the flask to extinguish the discharge, despite its sensitivity to pressure changes. This is evidence that the fragments produced by decomposition reunite completely to form the reddish-brown solid observed. Analysis of the product gave $(C_{1.00}H_{1.00})_n$ as its average composition. It was insoluble in ordinary solvents, although a continuous extraction with xylene in a Soxhlet apparatus for three weeks yielded a brown solution which left a small amount of gummy, viscous liquid on evaporation of most of the solvent. On further heating the product charred before the xylene was completely removed. No fraction could be pumped off from the solid in *vacuo,* although it was heated above **100°** and liquid air was used as the condensing medium. A sample of the solid gained **1.0%** in weight after being exposed to the atmosphere for twenty days, and 2.5% after sixty-six days, through absorption of oxygen, adsorption of water vapor, or both.

Benzene vapor at a pressure of **0.25 mm.** of mercury could be decomposed by the discharge only when the spark gap was increased to 6 mm. At lower pressures, not so long a spark gap was required. Thus, at a pressure of **0.14** mm., a spark gap of **3** mm. sufficed, while at 0.03 mm. pressure, a spark length of 1.5 mm. effected decomposition. At a pressure of about **0.1 mm.,** approximately **1.2** g. of solid was produced per hour.

These data are summarized in Table I. The first column gives the color of the initial ring discharge, greenish-white in the case of benzene. In the second column is the color of the brilliant glow within the flask when decomposition is in progress. This glow completely fills the flask at intermediate pressures, but shows a non-luminous core at higher pressures. It was this glow, white for benzene, which was photographed. The next column of Table I gives the color of the product. The solid formed on the walls, and peeled off as a powder, as thin flakes or as thick scales, depending on the substance decomposed. The physical form of the product is listed in the fourth column. That part of the solid which did not peel off clung tenaciously to the glass, but could be cleaned away by filling the flask with water, which seemed to get between the glass and the film with great ease. **A** fresh, dry flask was used for each substance. In the last column is given the approximate rate of formation of the product in grams per hour at an intermediate pressure. Data for all the substances studied are presented in Table I.

TABLE I

Substance	Color of discharge Ring	Glow	Color of product	Form of product	Rate of formation of product, *g.* per hour
Benzene	Greenish-white	White	Medium brown	Powder and small scales	1.2
Acetylene	Bluish-white	White	Medium brown	Powder and small scales	1.3
Naphthalene	Violet-white	White	Very dark brown	Thick scales	1.2
n-Heptane	Bluish-white	Reddish-white	Yellow brown	Very thin scales	0.00
Aniline	Violet-white	Bluish-white with red spots	Medium brown	Powder and scales	0.9
Nitrobenzene	Bluish-white	White	Dark brown	Thick scales	0.7
Phenol	Violet-white	White with red spots and greenish-blue center	Medium brown	Powder and scales	0.4
Chlorobenzene	Greenish-white	Greenish-white with red at center	Black	Powder and thick scales	0.4

Photographs of the decomposition spectrum for benzene are shown in Figs. 2 and 3. The fainter portions, easily visible in the original plates, are here indiscernible, because of repeated reproduction. The spectrum taken with the Steinheil instrument, Fig. 2, extends from 6600 to 3800 Å., and that taken with the Hilger spectrograph in the first position, Fig. 3a, from 6600 to 3300 Å. Spectrograms were also secured with the Hilger instrument in the second position, which carried the work down to 2400 Å. in the ultraviolet.

The decomposition spectrum of benzene showed all five groups of Swan bands very prominently. The other C_2 bands, discovered by Deslandres and D'Azambuja[7] and analyzed and discussed by Dieke[8] and by Johnson[9] were also present, though faintly, at λ4102, λ4068, λ4041, λ3852, λ3826, λ3607, λ3593, λ3588, λ3400 and λ3398. The CH bands at λ4300 and λ3900 were both prominent, and the first five lines of the Balmer series of hydrogen, H_α to H,, were very apparent. The line spectrum of C^+ and the line due to C at λ2478 were also present. The relative intensities are tabulated in Table II, which lists similar data for all of the compounds investigated.

When the decomposition was carried out at the lowest possible pressures, the nature of the spectrum was changed. The glow itself became

[a] C_2 bands other than Swan bands.

1, Very weak; 2, weak; 3, average; 4, intense; 5, very intense.

much redder and weaker and what bands appeared were very feeble in intensity. The Balmer series for hydrogen became relatively more prominent, and, despite the precautions taken to keep mercury vapor out of the discharge vessel, there appeared an intense line spectrum of mercury corresponding to that excited by the spark, rather than the arc.

The spectrum thus indicated the intermediate existence of C^+ ions, C and H atoms and CH and C_2 molecules during the decomposition of the benzene.

(b) Acetylene.—The product obtained with acetylene resembled that for benzene. To cool the side tube E was not necessary. The spectrum was the same as for benzene. The details are given in Tables I and II.

(c) Naphthalene.—Naphthalene produced a very dark brown product, which flaked off the glass in thick scales. No liquid air was required around tube E. The initial electromagnetic ring discharge did not show as great a tendency as with benzene to spread through the flask to give decomposition. The decomposition spectrum differed from that for benzene in its lower intensity for the same time of exposure.

(d) *n*-Heptane.—*n*-Heptane reacts differently from the unsaturated hydrocarbons. Although an amber-colored solid was formed on the walls, the quantity was very slight. When the discharge vessel was filled with n-heptane vapor at the proper pressure and stopcock K was closed, the pressure on decomposition seemed to rise slightly, rather than to fall. If fresh vapor was admitted to the flask, the discharge was extinguished because of the increase in pressure. Nor was the passage of the discharge made possible when the side tube E was immersed in liquid air, if vapor was continuously admitted to the flask. No liquid products were visible. The gaseous products could not be condensed with liquid air. The spectrum consisted of the Balmer series, which was very prominent, of the CH bands, which were faint, and of the C line at λ2478. In addition, an intense mercury spectrum was present, as it was for benzene when decomposed at the lowest pressures.

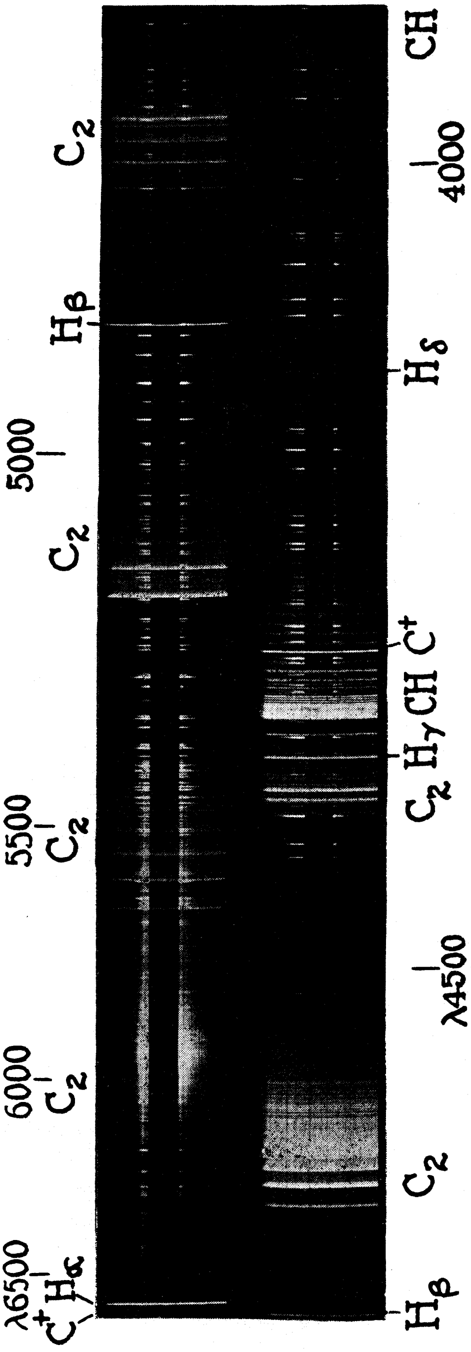

Fig. 2.—Spectrum obtained when benzene is decomposed in the electrodeless discharge. Taken with a Steinheil GH glass spectrograph. The spectrum of the iron arc is also shown.

(e) Aniline.—With aniline, it was necessary to immerse the side tube E in liquid air in order to keep the pressure low enough for the discharge to pass. The product had a strong odor of bivalent carbon compounds, which made difficult the detection by smell of ammonia and the lower amines, but neutral litmus paper, when inserted into a freshly opened flask F, rapidly turned blue.

In the spectrum, the violet cyanogen bands were prominent, from Group II at λ4532 to Group V at λ3590. The β-bands of NH, at λ3360 and λ3370, were visible. The second positive group of N_2 appeared at λ3577, λ3371 and λ3159, and the first negative group, due to N_2^+, showed at λ3914. The spectrum characteristic of benzene was also present, although subdued. The spectrogram obtained for aniline with the Hilger spectrograph in its first position is reproduced in Fig. 3b, next to that for benzene.

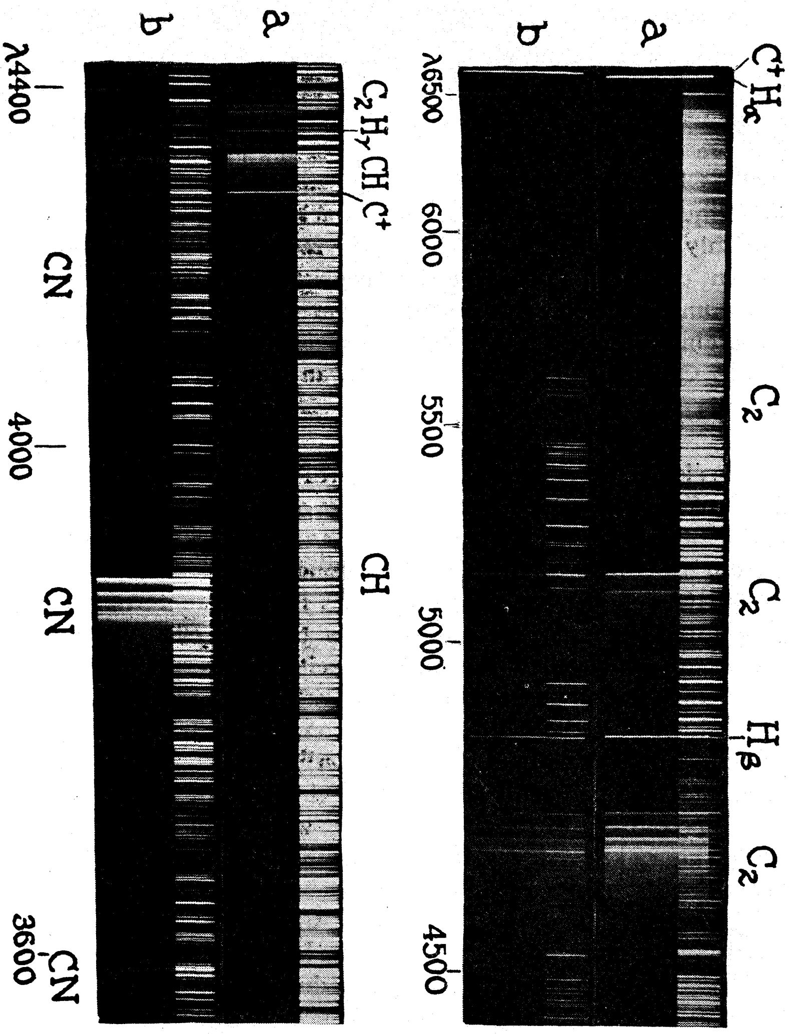

Fig. 3.—(a) Spectrum given by benzene when decomposed in the electrodeless discharge. Taken with a Hilger El quartz spectrograph. The narrow spectrum is that of the iron arc. (b) Spectrum obtained with aniline, showing cyanogen bands not found with benzene.

(f) Nitrobenzene.—For continuous decomposition, nitrobenzene required liquid air at E. The product did not have the strong odor of the solid from aniline, and was dark and coarse, although *a* slight deposit that formed at the neck of the tube E was much lighter in color, a characteristic that was observed also with other compounds. Moist neutral litmus paper was not affected when it was held in a flask F opened just after the end of an exposure. The spectrum was in general like that for aniline, but showed also the OH band at λ3064 and the CO bands at λ2974 and λ2832, as for phenol. A search for NO bands was made down to λ2200, but none was found after a two-hour exposure.

(g) Phenol.—To condense the water vapor which phenol forms on decomposition, liquid air was kept around the tube E. In addition to the typical benzene decomposition spectrum, phenol showed the water vapor band, for which the carrier is OH, at λ3064, and, faintly, the third positive group of carbon, due to CO, at λ2974 and λ2832.

(h) **Chlorobenzene.**—With chlorobenzene, also, the tube E was cooled with liquid air. The product was black, and neutral litmus thrust into a freshly opened flask quickly turned red, indicating the presence of hydrogen chloride. The spectrum consisted almost entirely of the line spectrum of chlorine, as excited by the spark, but the first three lines of the Balmer series for hydrogen were present. Also, some of the lines due to C^+ and C and part of the Swan bands were very faintly visible.

4. Discussion

The electronic energy utilized in breaking up the molecules is in part given off as radiation, and the energy of this radiation gives some idea of the range of the electronic energy and velocity involved. This range is from 1.8 to 5 volts, which corresponds to velocities from 8×10^7 to 1.3×10^8 cm. per sec. and to energies from 41 to 115 kg. cal. per mole. Undoubtedly electron velocities below this are effective in breaking up the organic molecules, but such velocities correspond to the infra red spectrum, which has not been investigated. According to Hittorf[10] and J. J. Thomson[11] the electrodeless discharge is due to electromagnetic induction, but Townsend and Donaldson[12] consider it to be caused by the electrostatic potential. MacKinnon[13] has shown that Thomson's work has been confined to the ring discharge, which is electromagnetic in origin, while the relatively weaker glow discharge investigated by Townsend and Donaldson is electrostatic. In the present work both types of discharge existed, but the decomposition always started as a ring discharge.

It may be assumed that the decomposition of the organic vapors into simpler molecules, atoms and ions is due to free electrons. These gain velocity, due to the field, between impacts. The higher the pressure of the gas, the smaller the mean free path of these electrons, and the more rapidly must the electrons gain velocity in order to attain any definite final velocity at the time of impact with a molecule. For this reason

---

[10] Hittorf, *Wied. Ann.*, 52, 473 (1884).

[11] J. J. Thomson, *Phil. Mag.*, [7] **4**, 1128 (1927); [5] 32, 321, 445 (1891).

[12] Townsend and Donaldson, *ibid.*, [7] 5, 178 (1928).

[13] MacKinnon, *ibid.*, [7] **8**, 605 (1929).

it is necessary to increase the voltage on the coil as the pressure of the gas increases, if the discharge is to continue to pass. Since there are great differences in the individual electron mean free paths as well as differences between the electrostatic and the electromagnetic fields, the individual electrons attain very different velocities before impact. If the velocities are in general too small, the discharge will not pass through the gas, since not enough ions and free electrons are produced.

It is not the intention of the preceding paragraph to indicate that the effects of ions, produced by electron bombardment, in causing ionization and dissociation by collisions of the second kind are negligible. There may be, in addition, some dissociations produced by collisions of the first kind, other than those due to electrons.

The writers wish to thank the National Research Council for a grant which has enabled them to secure a Steinheil GH glass spectrograph for use in this and other spectroscopic work.

5. Summary

1. In the electrodeless discharge organic vapors are commonly decomposed into simpler molecules, atoms, ions and electrons. For example, benzene is rapidly decomposed into molecules of monohydrocarbon (CH) and of carbon (C_2), into atoms of carbon (C) and of hydrogen (H), and into singly charged positive ions of carbon (C^+). Phenol gives all of these products and molecules of hydroxyl (OH), of water (H_2O) and of carbon monoxide (CO) in addition. Aniline gives the same decomposition products as benzene, and also single molecules of cyanogen (CN), of imine (NH), of nitrogen (N_2) and singly charged molecular nitrogen ions (N_2^+). Acetylene and naphthalene give the same products as benzene.

2. The intermediate decomposition products listed in (1) are extremely active and unite very rapidly to form brown or black solids which are insoluble in water and organic liquids, and which doubtless have high molecular weights.

3. n-Heptane, unlike the unsaturated hydrocarbons, gives very little solid in the type of apparatus here employed. During the decomposition of this saturated compound there exists much atomic hydrogen (H), relatively few molecules of monohydrocarbon (CH) and some neutral atoms of carbon (C).

The investigation of the molecular weight of egg albumin in salt-containing solutions to be reported in this paper is a continuation of the ultracentrifugal study of egg albumin described in 1926.[3] The experimental data were obtained in 1927, but certain points arose which were difficult to explain and which were thought to be due either to experimental error or to abnormalities in the behavior of the protein. The data were therefore set aside to await confirmation.

Although the sedimentation-equilibrium method had given very concordant results and had indicated that egg albumin was composed entirely of molecules 34,500 in weight the diffusion constant from the sedimentation-velocity runs, even in electrolyte-free solution, was only about six-tenths of the required value calculated from the molecular weight and the sedimentation velocity and was fairly irregular from run to run. On the other hand, the specific sedimentation velocity gave reasonable values throughout.

At first it was thought that a slight temperature inequality was present leading to a small convection current which made the diffusion constant appear smaller than it actually was but had no marked effect on the sedimentation velocity.[4] However, a more detailed study of other abnormal cases that have since appeared suggests that the egg albumin centrifugings were not in error and that the material had not undergone harmful decomposition. In a recent paper on Bence-Jones[5] protein a discussion has been given of these abnormalities in the diffusion constant. Since then more examples of abnormal diffusion have been met with. For many of the proteins thus far studied, the values of molecular weights obtained from the sedimentation-equilibrium and the sedimentation-velocity methods have agreed within the experimental error. This fact signifies that the molar frictional coefficient active in free diffusion is often the same as that effective in sedimentation—especially at the isoelectric point. However, hemo-

cyanin[6] and cuprammonium cellulose[7] have shown abnormalities due to hindered diffusion in the more concentrated solutions, the first on account of its large size and the second probably because of its thread-like nature. This hindrance to diffusion caused by the too close proximity of the molecules in the more concentrated solutions disappears in sufficiently dilute systems. The same explanation does not suffice for egg albumin, Bence-Jones protein and some other proteins because the molecules are small! compared with hemocyanin and regular compared with cuprammonium cellulose. Further consideration must be given to this problem before it will be possible to state with certainty what the cause is of the abnormally small diffusion of the proteins with small molecules.

On the other hand, the sedimentation velocity behaved normally for egg albumin and gave consistent results under conditions which have been found to produce normal behavior in other proteins: (1) sufficiently salt-free, stable solutions as prepared by electrodialysis; (2) well-buffered solutions in the neighborhood of the isoelectric point; **(3)** solutions containing buffering or neutral salts in quantity insufficient to cause "salting-out." Therefore only determinations of the sedimentation constant will be used to characterize the egg albumin in different ionic environments, but it is well to mention in passing that the value found for the diffusion constant of egg albumin at 30° is roughly 0.065 sq. cm./day or 0.076 $\times 10^{-5}$ sq. cm./sec., which is of the same order as Herzog's value? 0.087 $\times 10^{-5}$ sq. cm./sec. when the latter is adjusted to the same temperature, 30°.

Experimental

The egg albumin used in the experiments was crystallized according to the method of Sørensen,[9] and dialyzed for fifteen days in flowing distilled water at 0°, saturated with toluene. The material was further purified previous to the experiments by electrodialysis at a current density of *0.3* ma./sq. cm., bringing down the conductivity of a 1% solution to *1.3* X 10^{-5} mhos at 18°. The solutions were brought to the desired concentration and salt content or PH immediately before starting the centrifuge runs. In the neighborhood of the isoelectric point the partial specific volume was taken as *0.754* at 30° except in sodium chloride solutions, where $V = 0.749$.[10] The reason for this depressing action is not clear Sodium chloride would be expected to show a dehydration effect but it is not evident that such an effect would produce the observed depression of the value of the partial specific volume.

Table I shows that the partial specific volume does not vary over an appreciable PH range, in fact not until we reach strongly acid solutions.

All of the experiments were carried out in the high-speed oil-turbine type

TABLE I

VARIATION OF PARTIAL SPECIFIC VOLUME IN DIFFERENT SOLVENTS AT 30°

Solvent	P_{H} of soln.	Partial sp. vol
0.102 *N* HCl	1.16	0.759
0.010 N HCl	2.44	..
Acetate buffer 0.025 N with respect to sodium	3.6	.755[a]
0.02 *N* acetate buffer	4.7	.754
1.0% NaCl solution	4.75	.749
Electrolyte-free	4.67	.754[a]
Acetate buffer 0.025 *N* with respect to sodium	5.4	.754[a]
0.017 M primary–secondary phosphate buffer	7.3	.749

[a] These values are adjusted to 30° from a temperature of 19.2°.

of ultracentrifuge[11] with the exception of the one sedimentation-equilibrium experiment. As shown in previous communications the molecular weight is determined from the sedimentation equilibrium [3,12] by the relation

$$M = \frac{2\,RT \ln (c_2/c_1)}{(1 - V\rho)\,\omega^2\,(x_2 + x_1)(x_2 - x_1)} \qquad (1)$$

and from the sedimentation velocity[10,13] by the expression*

$$M = \frac{RT\,s}{(1 - V\rho)D} \qquad (2)$$

R is the gas constant, T the absolute temperature, V the partial specific volume of the solute, ρ the density of the solvent, ω the angular velocity, c_2 and c_1 the concentrations at the distances x_2 and x_1 from the center of rotation, D the diffusion constant and $s = (\mathrm{d}x/\mathrm{d}t)\ (1/\omega^2 x)$, the specific sedimentation velocity or sedimentation constant.

Since, however, the diffusion constant for egg albumin is abnormal, Equation 2 is not valid as it stands, and the results will be left in terms of s, the sedimentation constant, which will be shown later to be equal to the value calculated from the molecular weight determined by sedimentation-equilibrium measurements.

The solutions were subjected to a centrifugal force approximately 100,000 times that of gravity. Exposure time was from twenty to forty seconds and the usual time of centrifuging was three to four hours. Pictures of the sedimenting system were taken every half hour. The length of column of solution used was from 13 to 15 mm. and the thickness 2 mm. All values refer to 1% egg albumin at 30°. The absorption band of egg albumin in the short ultraviolet region of the spectrum was employed in making the concentration determination in the centrifuge by isolating the wave length range 290–240 mμ from the mercury arc by means of gaseous chlorine and bromine filters. Imperial Process plates were used on account of their

thin, uniform emulsion and were developed with Eclipse metol-hydroquinone developer.

Figure 1 gives a reproduction of the photographic record of the centrifuging of an acetate buffer solution of 1.0% egg albumin at a PH of 4.7. This experiment was performed at 30° and at a speed of 41,900 r. p. m. corresponding to a centrifugal force of nearly 100,000 times that of gravity. The first exposure to the left shows the condition of the solution at the start of the run, and succeeding exposures show it after one-half, one hour, etc., up to three and one-half hours of centrifuging.

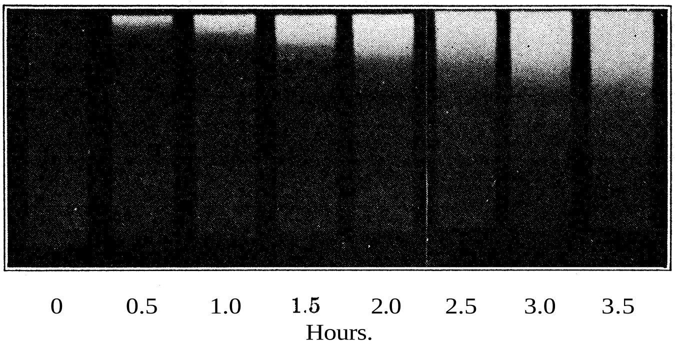

Fig. 1.—Sedimentation of egg albumin at 4.7 PH.

Table II contains typical data describing a centrifuge run. It refers to a 1.0% solution of egg albumin 0.0102 N with respect to hydrochloric acid and gives results from one of the three plates used in calculating the s-value for this solution.

TABLE II

SPECIFIC SEDIMENTATION VELOCITY OF EGG ALBUMIN IN 0.01 N HYDROCHLORIC ACID

Egg albumin concn., 1 g. per 100 cc.; HCl concn., 0.0102 N; PH of solution, 2.44; T, 303.1°K; length of column, 1.39 cm.; thickness of column, 0.20 cm.; Imperial Process plates; short ultraviolet illumination (290–240 mμ region isolated from the mercury arc by gaseous chlorine and bromine filters); exposure time, 20 sec.; Eclipse metol-hydroquinone developer, 2 min.

Time interval, hr.	Δx, cm.	$x_{\text{med.}}$, cm.	Speed, r. p. m.	Centrifugal force $\omega^2 x$	Sp. sedimentation velocity, $s_{30°}$ cm./sec.
0.5–1.0	0.044	4.625	41,880	8.90×10^7	2.81×10^{-13}
1.0–1.5	.048	4.671	41,780	8.94	2.98
1.5–2.0	.044	4.717	41,650	8.98	2.69
2.0–2.5	.046	4.762	41,380	8.94	2.81
2.5–3.0	.048	4.809	41,370	9.03	2.89
3.0–4.0	.102	4.884	41,280	9.13	3.03
				Mean s =	2.87×10^{-13}

Table III gives the values for the sedimentation constant obtained in the isoelectric region of the protein. In common with the findings on the majority of the proteins thus far studied, the addition of salts or buffer solutions of the same P_H as the isoelectric point of the protein does not affect the molecular condition of the protein, as evidenced by the constancy of the sedimentation velocity. Furthermore, the mean value obtained for the sedimentation constant, 4.06 × 10^{-13} cm./sec., is nearly the same as the s-value for Bence-Jones protein.[14] Reduced to the same temperature, 20°, the sedimentation constant of egg albumin is 3.25 × 10^{-13} cm./sec., while that for Bence-Jones protein is 3.55 × 10^{-13} cm./sec.

TABLE III

SEDIMENTATION VELOCITY OF ISOELECTRIC AND OF SALT-FREE EGG ALBUMIN

Solvent	P_H of soln.	Speed, r. p. m.	Mean centrifugal force	Sp. sedimentation velocity, $s_{20°}$ in cm./sec.
Water	4.67	41,800	9.61 × 10^7	4.03 × 10^{-13}
Water	4.67	41,430	9.04	3.94
0.02 *N* acetate buffer	4.70	41,370	9.63	4.07
0.017 *N* acetate buffer	4.70	41,900	9.16	4.12
0.7% NaCl	4.73	41,290	9.12	4.15
			Mean s =	4.06 × 10^{-13}

By the sedimentation-equilibrium method both proteins have been found to possess a molecular weight of approximately 34,500. Using the s- and M-values determined, respectively, by the sedimentation-velocity method and by the sedimentation-equilibrium, we may determine whether these proteins consist of spherical molecules.[5] The molar frictional constant calculated from the sedimentation velocity was found to agree closely with that calculated for a substance of molecular weight 35,000 and possessing spherical molecules of the same specific volume as the two proteins. As mentioned in the article cited, the radius of the egg abumin molecule is 2.17 mμ as compared with 2.18 mμ for Bence-Jones protein.

In a recent paper on the osmotic pressure of egg albumin, Marrack and Hewitt[15] determined the molecular weight of egg albumin to be 43,000 in salt solutions as compared with the present determination of 34,500 both in salt-containing and in salt-free solution. Unpublished data tend to support their consideration that a small amount of impurity in constant amount might be formed in salt-containing solutions on standing. This small amount of material is perhaps the first step in the slight precipitation of denatured egg albumin that always occurs on standing. An electrodialyzed, salt-free solution of egg albumin is relatively stable. In the high-speed type of ultracentrifuge the whole experiment is completed in three or four hours after the addition of the salt or buffer, so there is much less chance for the formation of the approximately 5% of aggregated material required to give the average value of 43,000 found by the osmotic method that requires from one to two days to reach equilibrium. Under

[15] Marrack and Hewitt, *Biochem. J.*, 23, 1082 (1929).

conditions comparable to the osmotic method, however (*e. g.*, in the sedimentation-equilibrium method at ordinary temperatures, which requires two days of centrifuging), a change in the egg albumin frequently occurs, causing an increase in light absorption and the appearance of a small amount of aggregated material at room temperature.

As the isoelectric region is left, the sedimentation velocity seems to be decreased slightly more than the experimental error would account for.

TABLE IV

DEPRESSING EFFECT ON THE SEDIMENTATION CONSTANT IN ACID AND ALKALINE EGG ALBUMIN

Solvent	PH of solution	Sp. sediment. velocity s in cm./sec.	s/s_0
0.34 *N* acetate buffer	3.53	3.59×10^{-13}	0.89
0.017 M double phosphate buffer	7.4	3.57×10^{-13}	.885

Table IV shows the possible slight depressing effect occurring in an egg albumin solution buffered at a PH of 3.53 with 0.34 N acetate buffer and in a solution buffered at a PH of 7.4 with 0.017 M primary-secondary phosphate buffer. The normal sedimentation velocity, s_0, has been reduced by nearly the same ratio, respectively, 0.89 and 0.885, in each case.

Table V gives evidence from the sedimentation equilibrum of 3.59 PH egg albumin in 0.2 *N* acetate buffer, that the possible slight depression of the s-value in moderately acid egg albumin is not due to a slight Donnan effect since the buffer concentration is actually lower for the sedimentation-equilibrium run than for the sedimentation-velocity run. The value for the molecular weight is normal; therefore, it follows that the depression of the s-value did not arise from an electrical effect produced by a partial separation of charges in the centrifuge.

TABLE V

Repression of Donnan Effect.—If we add acid or alkali to a salt-free protein and subject the solution to a high centrifugal force, a partial separation is produced of the large protein ion from the small inorganic ions of opposite sign. An electrical potential acting in opposition to the centrifugal potential is thereby set up similar in character to the Donnan membrane potential. In the simplest case—no foreign ions present—which we very likely approximate for unbuffered solutions, the effect of the electrical potential is to reduce the true value of the molecular weight by the factor[16] $(n + 1)$ or

$$M = \frac{(n+1)RT\,s}{(1-V\rho)\,D}$$

where n is the mean valence of the protein ion. Thus it is possible to gain some information about the mean valence of a protein by first centrifuging in unbuffered acid or alkaline solution and then centrifuging another sample to which has been added sufficient electrolyte to repress the electrical potential to a negligible value. The latter determination is made chiefly for the purpose of showing that no actual change has occurred in the molecular weight at the given P_H value.

In order to give some idea of the action of the Donnan effect on the diffusion constant as well as on the sedimentation constant, the values of D as well as those of *s* are given in Table VI. It is evident that the electrical effect produced by the separation of the ions has a much greater effect on the diffusion constant than it has on the sedimentation constant. The values of D given in the table should be considered only apparent as mentioned earlier, but they at least illustrate the action of the Donnan effect. No attempt has been made to calculate the valence of the protein ion from the changes produced in the D and the s-values by the free acid or alkali because relatively minute quantities of decomposition products largely repress the true Donnan effect. For the 0.01 N HCl solution, the amount of free acid present amounts to approximately 36% of that added, thus

TABLE VI

REPRESSION OF DONNAN EFFECT

Expt.	Solvent	P_H of solution	Apparent diffusion constant, $D_{30°}$, sq. cm. /day	Sedimentation constant, $s_{30°}$ cm./sec.
1	0.001 N HCl	3.94	0.111	3.19×10^{-13}
2	0.34 N acetate buffer	3.53	.061	3.59[a]
3	0.01 N HCl	2.44	.103	2.86
4	0.01 *N* HCl + 0.7% NaCl	2.68	.069	4.01
5	0.001 N NaOH	5.13	.144	2.85

accounting for the extremely small change from 0.001 *N* HCl solutions to 0.01 N HCl solutions. The apparently greater effect in alkaline solution is in line with the higher asmotic pressure found by Loeb[17] on the alkaline side of the isoelectric point as compared with that on the acid side.

Figure 2 represents the variation of the sedimentation constant with *Ph* for unbuffered solutions compared with the variation in osmotic pressure over the same range found by Loeb.[17] The agreement of maxima and minima is fairly good. On the acid side of the isoelectric point the maximum osmotic pressure occurs at a *Ph* of 3.4. It probably agrees within experimental error with the minimum sedimentation constant which occurs at a *Ph* of 3.0 approximately; the minimum osmotic pressure in the isoelectric region appears to be at a slightly higher *Ph* than the maximum sedimentation constant, which occurs at a *Ph* of 4.65, corresponding closely to Tiselius' value of 4.6 from cataphoresis measurements. The significance of the rapid increase of the sedimentation constant below a Ph of 2 will be explained further on. It should also be noticed that both the s-values and the osmotic pressures experience a greater change on the alkaline side than on the acid side.

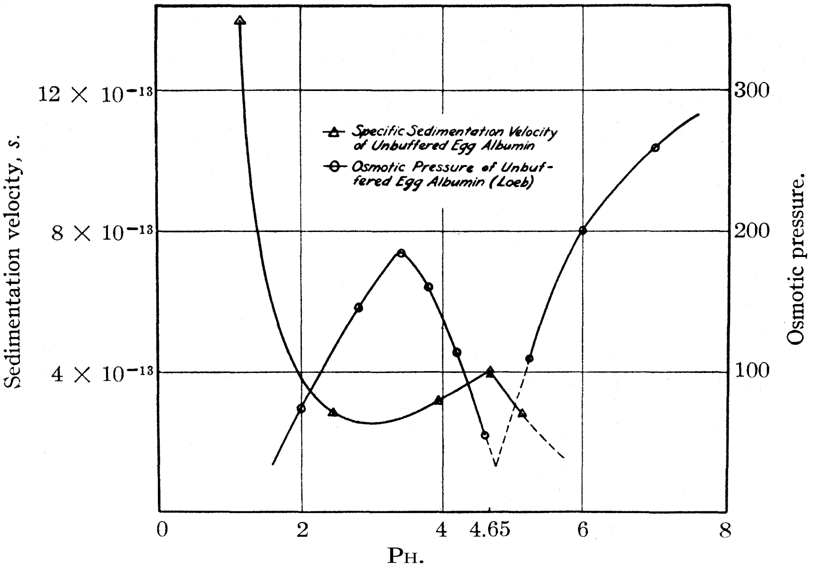

Fig. 2:—Dontian effect on sedimentation velocity of egg albumin.

Figure **3** shows the variation of the sedimentation constant with *Ph* for buffered and unbuffered solutions of egg albumin. The s-value for buffered solutions as drawn appears to be nearly constant over a considerable

---

[17] J. Loeb, "Proteins and the Theory of Colloidal Behavior," McGraw-Hill Book Co., New York, 1st ed., 1922, p. 75, Fig. 18 and p. 118, Fig. 39.

range but may decrease slightly (possibly owing to hydration if this decrease is subsequently verified) on the acid side of the isoelectric point, return to the normal value found for the isoelectric region at a *P_H* of about 2.4 and then join the upward arm of the unbuffered curve at some point; that is, denaturation may be taking place to an increasing extent from a PH of 2.5 down.

Acid-Denaturation.—When the egg albumin is made still more acid, 0.102 N HCl solution, PH 1.16, it is evident (Fig. 3) that a profound change occurs. In a solution of 0.1 N HCl the protein grows more and more viscous on standing and the opalescence increases as well. A 4.0% solution of egg albumin sets in a few hours to a stiff gel. In a 1.0% solution the viscosity at 30° increases from 0.00853 to 0.01057 in eleven hours. The solution centrifuged was considered to have an age of three hours or a viscosity of 0.00908 at 30°.

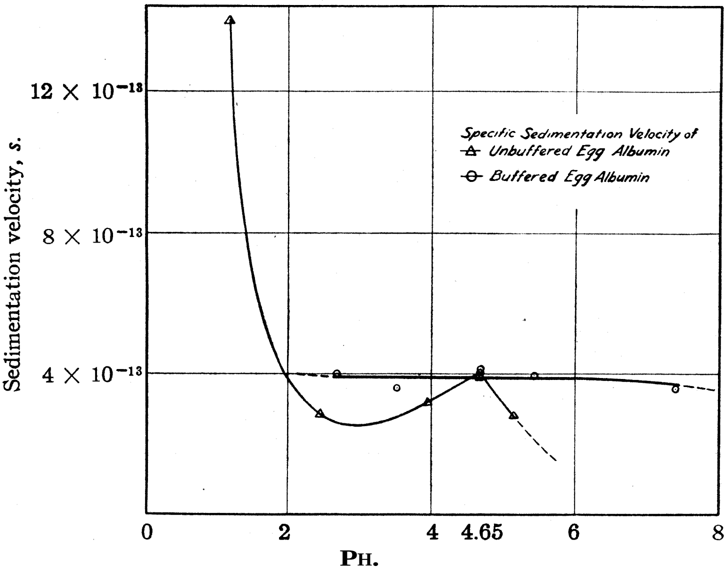

Fig. 3.—Repression of Donnan effect on sedimentation velocity of egg albumin by addition of salts.

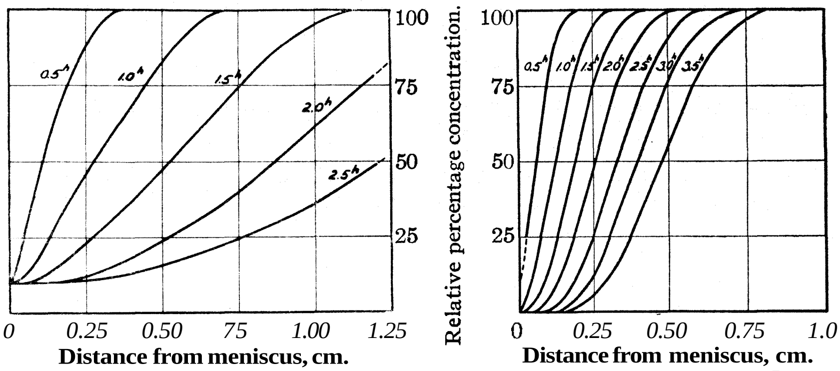
The extreme difference in character of the concentration curves for the egg albumin in 0.1 N HCl solution from those obtained for egg albumin in isoelectric buffer is shown in Fig. 4. The time interval between successive curves was half an hour in each case and the experimental conditions were practically the same for the two solutions. There was some increase in light absorption in the highly acid protein and about 10% of uncentrifugible material was present. The rapid sedimentation indicates a rather large increase in size of the effective particle, yielding a rough s-value of 14.0 ×

10^{-13} cm./sec. as compared with the normal value of 4.0×10^{-13} for a molecular weight of **34,500.** The protein has evidently been denatured by the strong acid and has aggregated to gel clumps. Any Donnan effect may be neglected on account of the large excess of hydrochloric acid present. Diffusion should also be small enough to be neglected after incipient gelling has set in because of the increase in size of the effective particle, the increase in the gross and the structural viscosity and the relative inaccuracy of the calculations on a changing system.



1% Egg albumin in $0.1N$ HCl P_H 1.16.

1% Egg albumin in 4.7 P_H acetate buffer.

Fig. 4.—Sedimentation curves of acid-denatured and isoelectric egg albumin.

The distribution curve calculated for the run is given in Fig. 5 for the exposures taken after **60, 90, 120** and **150** minutes of centrifuging. The gradual shift of the points obtained from the successive exposures in the direction of larger radii indicates that the system was changing throughout the whole period. Another possible source of error in the calculation of the distribution curve lies in the assumption of a constant light absorption over the range of sizes of particles present. The distribution curve corresponding to thirty minutes of centrifuging is dotted in to indicate that it is far from correct since the limit of the smaller particles comes at such a small radius. It is probable that diffusion was still playing some part at this stage of the gelling and thus that the system was changing the most rapidly during the first hour. The number of molecules per particle is also plotted to give an idea of the range of "molecules" present in the gel clumps formed of the denatured egg albumin.

Thus we see that egg albumin is moderately stable until fairly high acidities and alkalinities are reached and exhibits a strong Donnan effect in the intermediate acidity and alkalinity range if the ionization of the protein is allowed to exert its maximum effect in unbuffered solutions.

A careful investigation of the behavior of egg albumin in the region of high acidities should throw much light on the acid-denaturation of proteins and on gelling phenomena. Similarly, a study of the conditions at high alkalinities will prove of interest because no information has been gained by osmotic methods in this region on account of the action of strong alkali on the membranes.

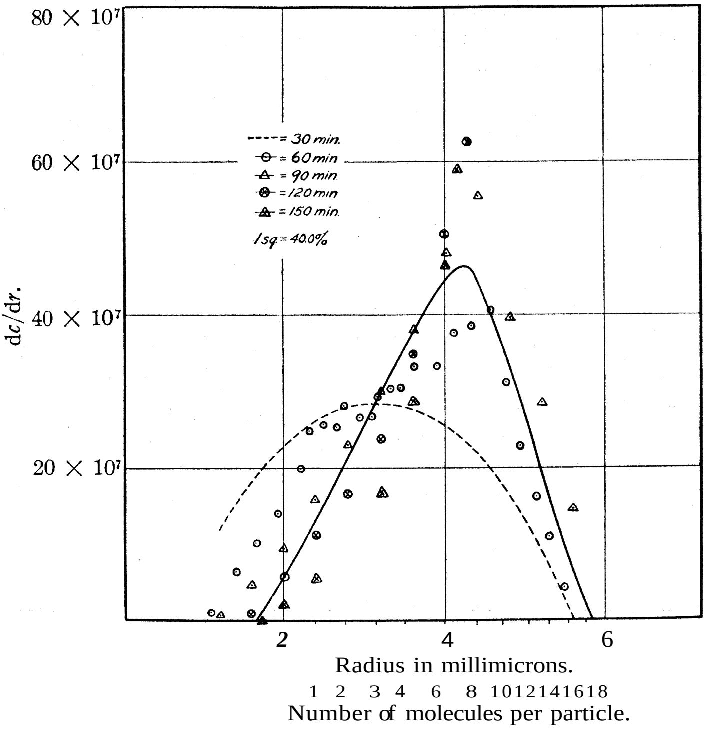


Fig. 5.—Distribution curve for egg albumin in 0.1N HCl

The expenses connected with these experiments have been defrayed by grants from the Nobel Fund of Chemistry and from the foundation "Therese och Johan Anderssons Minne."

Summary

1. Crystallized, electrodialyzed egg albumin has a sedimentation constant of 4.06 X 10^{-13} cm./sec. at 30° but the diffusion constant is abnormal, approximately six-tenths of the required value on the basis of the sedimentation constant and the molecular weight.

2. The molecule is spherical and has a radius of 2.17 mμ; it is practically identical in size and mass with that of Bence-Jones protein, although entirely different in chemical composition.

3. The depression of the sedimentation constant arising from the Donnan effect in unbuffered solutions on either side of the isoelectric point of

egg albumin has been investigated; the maximum depression occurs in the neighborhood of 3.0 **PH.**

4. At a PH of 1.16 in 0.1 *N* hydrochloric acid, egg albumin is completely denatured and gradually forms a gel showing a distribution curve of gel clumps; the mean size corresponds to about seven molecules per particle after three hours.

THE PH-STABILITY REGION OF EGG ALBUMIN

BY BERTIL SJÖGREN AND THE SVEDBERG

RECEIVED JULY 5, 1930 PUBLISHED DECEMBER 18, 1930

An ultracentrifugal study of the molecular weight of egg albumin in electrolyte-free condition near its isoelectric point was carried out by Svedberg and Nichols in 1926.[1] This protein when properly purified was found to be homogeneous with regard to molecular weight. The value arrived at, 34,500 ± 1000, is in good agreement with the result of Sørensen's osmotic measurements, *viz.*, 34,000.[2] In 1927 Nichols made a series of determinations of the molecular weight and the sedimentation constant of egg albumin in the presence of electrolytes within the **PH** region 1.2–7.4.[3] His measurements showed that egg albumin is probably stable from PH 3 to 7. The value of the sedimentation constant arrived at was 4.06 X 10^{-13} at 30°, which corresponds to 3.31 X 10^{-13} at 20°. In acid solution (*P*H 1.16) this protein was found to be completely denatured, gradually forming a gel and showing a distribution curve of gel clumps, the mean size of which corresponded to about seven molecules per particle after three hours.

Since the time when Nichols' determinations were carried out, the ultracentrifugal technique has been further developed and it was, therefore, considered of importance to supplement his measurements by a new and more detailed study of the behavior of egg albumin within a wider PH range.

Preparation of Material and Light Absorption

The egg albumin was prepared according to Sorensen's method[2] with some slight modifications. The material was crystallized three times, the isoelectric state of the crystallizing liquid being checked directly by means of **PH** determinations. The crystals were dissolved in water, dialyzed in the ice box against water and finally electrodialyzed; concentration of stock solution 5.25%. At the time when the determinations were made the material was about three months old.

[3] J. B. Nichols, THIS JOURNAL, 52, 5176 (1930).

Some measurements were also carried out on a similar material which had been kept in the ice box for sixteen months.

The former material did not show any decomposition when submitted to the ultracentrifugal analysis, whereas the latter substance was found to be decomposed to a considerable extent.

The light absorption of solutions of egg albumin at three different hydrogen-ion concentrations was measured by means of the Judd-Lewis spectrophotometer as described in previous communications. The thickness of layer was 2.0 cm. in all measurements and the protein concentration 0.10% at *P*H 2.2 and 5.5 but 0.05% at *P*H 11.2. In Table I the position of the maximum and the minimum of absorption and the values of the extinction coefficients for the maximum and the minimum are recorded. Fig. 1 gives the absorption curves.

TABLE I

LIGHT ABSORPTION OF SOLUTIONS OF EGG ALBUMIN

	M	Solvent	*M*	PH of soln.	Wave length of max. mμ	Wave length of min. mμ	ϵ/c at max.	ϵ/c at min.
HCl	0.007	KCl	0.093	2.2	279	253	8.5	5.0
KH_2PO_4	.095	Na_2HPO_4	.005	6.5	280	255	5.7	2.7
Na_2HPO_4	.026	NaOH	.014	11.2	280	254	10.8	5.6

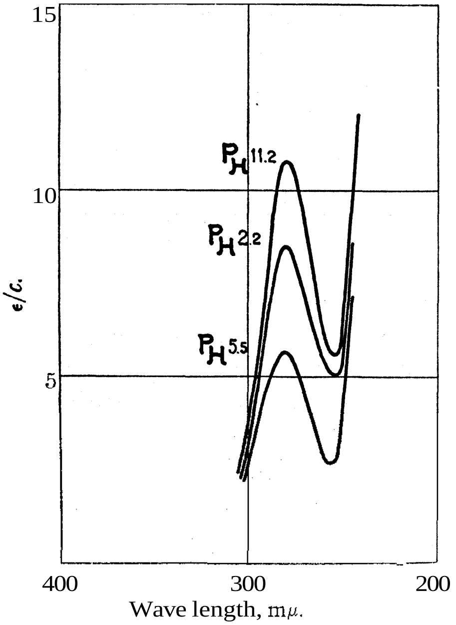

Fig. 1.

As seen from the table the position of the maximum and the minimum does not change with *P*H. The value of the extinction coefficient, however, is much higher in the acid and alkaline solutions than in the solution of *P*H 5.5. The ultracentrifugal analysis described below gives the result that at *P*H values lower than 4 and higher than 9 some of the egg albumin molecules are broken up into a non centrifugible substance. The increase in light absorption is probably due to the presence of this decomposition product.

Determination of the *P*H-Stability Region.—A number of sedimentation velocity runs were made in the oil-turbine ultracentrifuge as described in previous communications. The speed was 40,000–45,000 r. p. m., the temperature in the solution 20–23° and the time of centrifuging three to five hours, The solutions studied were brought to the desired ***PH*** immediately before starting the run. In Table II and Fig. 2 the results are summarized.

TABLE II

EGG ALBUMIN, SEDIMENTATION VELOCITY MEASUREMENTS

[a] 1% in NaCl

The sedimentation constant is independent of PH within the range **3** to **11** with a mean value of **3.54** × 10^{-13} at 20°, which is slightly higher **than** the value **3.31** × 10^{-13} calculated from Nichols' determination at 30°. Downward from a ***PH*** of ***4*** and upward from **a** *PH* of 9 the egg albumin

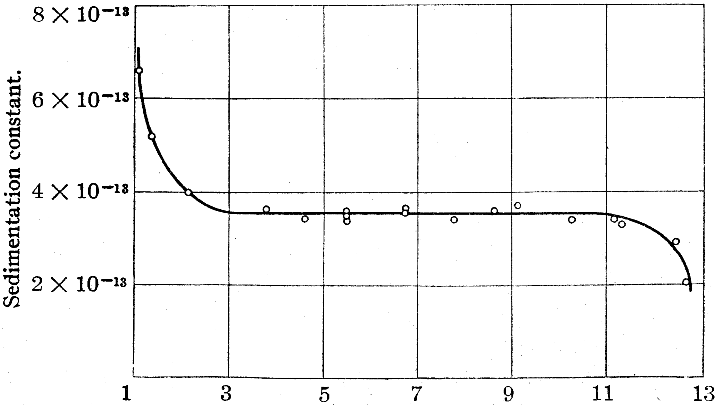

Fig. 2.

molecules begin to dissociate into low-molecular decomposition products. The stability region is, therefore, somewhat smaller than the range within which normal molecules still exist. At high acidities the sedimentation rises rapidly owing to the formation of condensation products as already observed by Nichols. At high alkalinities the sedimentation drops, indicating the breaking up of the protein molecule.

In order to ascertain whether the centrifugible part of the material was homogeneous with regard to molecular weight at the ends of the *P*H-stability range, two sedimentation equilibrium runs were made at *P*H 4.0 and 9.2. In Table III the result is recorded.

TABLE III

EGG ALBUMIN, SEDIMENTATION EQUILIBRIUM MEASUREMENTS

Solvent	*P*H of soln.	Molecular weight
0.016 M in HAc .004 M in NaAc	4.0	33,800, no drift in the values with distance from center of rotation
.032 M in Na_2HPO^4 .001 M in NaOH 1% in NaCl	9.2	34,600, no drift

A sedimentation equilibrium run performed by Nichols at a *P*H of 3.59 gave the value 33,700 for the molecular weight and likewise no drift with distance from center of rotation. It is obvious, therefore, that the centrifugible material is quite homogeneous at the ends of the stability region.

The homogeneity of a sample of egg albumin which had been kept in electrolyte-free solution with toluene as a preservative for sixteen months in the ice box was tested at a *P*H of 5.5 in a sedimentation velocity run and a sedimentation equilibrium run.. The sedimentation constant had increased to about 4×10^{-13} cm./sec. The molecular weight showed strong drift with distance from the center of rotation, the values ranging from 18,100 to 52,000. From these measurements it follows that egg albumin undergoes decomposition and aggregation with time. The same material when new had given a sedimentation constant of 3.4×10^{-13} cm./sec. (O. Lamm).

Discussion of Results

It is of interest to compare the ultracentrifugal behavior of egg albumin with that of Bence-Jones protein using the new value for the sedimentation constant recorded above. As already pointed out by the present authors in a previous communication,[4] egg albumin and Bence-Jones protein are closely related with regard to molecular weight, sedimentation constant s, molar frictional constant f and molecular radius r, the said constants being identical within the limits of experimental error. In Table IV the values of these constants are recorded, the new s-value for egg albumin being used for the calculation; f_s denotes the value of the molar frictional constant to be expected for a spherical molecule of the same density.

[4] T. Svedberg and B. Sjogrcn, THIS JOURNAL, 51, 3594 (1929).

TABLE IV

MOLECULAR CONSTANTS FOR EGG ALBUMIN AND BENCE-JONES PROTEIN (20°)

Protein	Mol wt.	$s \times 10^{13}$	$f \times 10^{16}$	$f_s \times 10^{-16}$	r, mμ
Egg albumin	**34,500**	**3.54**	**2.47**	**2 47**	**2.17**
Bence-Jones protein	**35,000**	**3 55**	**2.48**	**2 49**	**2.13**

The coincidences borne out by Table IV are even closer than could be expected when taking into account the probable experimental errors of the data. The PH-stability regions of egg albumin and Bence-Jones protein are similar but show some distinct differences. Egg albumin has a somewhat wider stability range than Bence-Jones protein, the stability extending further into the acid as well as into the alkaline regions. The acid decomposition of Bence-Jones protein consists in the splitting-up of some of the molecules into a non-centrifugible substance, leaving some molecules intact, while the decomposition of egg albumin in acid solution is accompanied by the formation of a highly aggregated and rapidly sedimenting substance. In electrochemical respect egg albumin and Bence-Jones protein are quite different, the former having its isoelectric point at PH 4.6 and the latter at 5.2 according to recent determinations by A. Tiselius. The two proteins, although not separable by centrifuging, may easily be separated by means of cataphoresis.

The expenses connected with these experiments have been defrayed by a grant from the foundation "Therese och Johan Anderssons Minne."

Summary

1. The ultracentrifugal methods have been applied to the study of the PH-stability region of egg albumin.

2. In the PH-range 4–9 the protein is stable and homogeneous with regard to molecular weight. The mean value 34,200 is in good agreement with the previous determination by Svedberg and Nichols, *viz.*, 34,500.

3. Below PH 4 and above 9 some of the molecules are split up into a non-centrifugible substance. The sedimentation constant of the centrifugible material is independent of PH within the range 3–11 with a mean value of 3.54×10^{-13} at 20°. The molar frictional constant is 2.47×10^{16} at 20°, which value is identical with the molar frictional constant calculated for a spherical molecule of the same molecular mass and density. The egg albumin molecule, therefore, is spherical and has a radius of 2.17 mμ.

4. At PH values lower than 3, the sedimentation increases, indicating the formation of aggregates of denatured protein; at PH values higher than 9 the sedimentation decreases, indicating the breaking up of the whole material. Both the acid and the alkaline decomposition is accompanied by an increase in the light absorption.

5. A comparison of egg albumin and Bence-Jones protein using the new value of the sedimentation constant for egg albumin shows a still closer

agreement than was formerly found for the molecular constants of these proteins.

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

THE HYDROGENATION OF ACETOACETIC ESTER AND CERTAIN OF ITS DERIVATIVES OVER NICKEL

BY HOMER ADKINS, RALPH CONNOR AND HOWARD CRAMER

RECEIVED JULY 28, 1930 PUBLISHED DECEMBER 18, 1930

The hydrogenation of acetoacetic ester in the liquid phase with a nickel catalyst has apparently not previously been investigated although Sabatier and Mailhe[1] obtained ethyl butyrate, acetone, isopropyl alcohol, propionic and dehydroacetic acids in a vapor phase reduction over nickel. The methods used in the present investigation were essentially the same as those previously described.[2]

Acetoacetic ester absorbed one mole equivalent of hydrogen when reduced over a nickel catalyst. There were produced small quantities of alcohol and dehydroacetic acid, two parts of ethyl β-hydroxybutyrate and one part of a derivative of this ester, ethyl β-(β'-hydroxybutyryloxy)-butyrate, $CH_3CHOHCH_2CO_2CH(CH_3)CH_2COOC_2H_5$. The ratio of the mono-ester (I) to the di-ester (II) when the reduction was carried out in various solvents is as indicated: no solvent 67% I, 33% II; in ethanol 100% I; in diethyl ether 68% I, 32% II; in methylcyclohexane 68% I, 32% II; in ethyl β-hydroxybutyrate 69% I, 31% II; in *tert.*-butyl alcohol 83% I, 17% 11; in *n*-butanol 66% I and 34% n-butyl β-hydroxybutyrate, b. p. 96–97 (13 mm.). Ethyl a-methylacetoacetate upon reduction gave a mono- and di-ester (ethyl α-methyl-β-(α'-methyl-β'-hydroxybutyryloxy)-butyrate), in the ratio of approximately two parts by weight of the latter to five parts of ethyl α-methyl-β-hydroxybutyrate. However, the dialkyl substituted derivatives of acetoacetic ester, ethyl α,α-dimethylacetoacetate and ethyl a-methyl-a-ethylacetoacetate, gave quantitative reduction to the corresponding α,α-dialkyl-β-hydroxybutyric ester. The formation of the di-esters may be avoided by the use of ethanol, for a quantitative yield of ethyl α-methyl-β-hydroxybutyrate was obtained by reducing ethyl a-methylacetoacetate in that solvent.

The salient facts seem to be: (1) the two beta ketonic esters capable of enolization upon hydrogenation in the absence of a solvent or in the presence of the ethyl-β-hydroxybutyrate or of ether or methylcyclohexane gave large amounts of di-esters along with the simple hydroxy ester.

---

[1] Sabatier and Mailhe, Bull. *soc. chim.*, [4] 3,232 (1908).

[2] Adkins and Cramer, THIS JOURNAL, 52,4349 (1930).

(2) The amount of the di-ester was less if tertiary butyl alcohol was used as a solvent and was negligible in the product from the hydrogenations carried on in ethyl or n-butyl alcohols. **(3)** The two keto esters incapable of enolization were hydrogenated quantitatively even without a solvent to the corresponding simple hydroxy esters.

The effect of the alcohols in decreasing the yield of di-ester was not due to the alcoholysis of the di-ester after it was formed, for the alcoholysis of the di-ester was very difficult and did not occur under the conditions in which the alcohols were effective. For example, ethyl β-(β′-hydroxybutyryloxy)-butyrate did not undergo alcoholysis with ethanol upon being heated for three hours at 150° in the reduction apparatus. Only 40% of it was converted to ethyl β-hydroxybutyrate after six and one-half hours at 190°. The resistance of this ester to alcoholysis is further shown by the fact that there was no alcoholysis of the di-ester after it had been refluxed with an ethanol solution of sodium ethoxide for two and one-half hours.

The effectiveness of the alcohols in inhibiting the formation of the di-ester is understandable upon the hypothesis of Arndt and Nachtwey[3] with regard to the formation of dehydroacetic acid from acetoacetic ester. They suggested that two reactions are involved. The first of these was supposed to be reversible since removal of ethyl alcohol permitted the formation **of** dehydroacetic acid, while the second was supposed to be an irreversible reaction, since boiling alcohol did not convert dehydroacetic acid into acetoacetic ester. (It will be shown later that the latter is also a reversible reaction.) These authors suggest that the mechanism of the formation of dehydroacetic acid may be as shown in Reactions I and II

$$CH_3C(O)CH_2COOEt + HOC(CH_3){=}CHCOOEt \rightleftharpoons CH_3C(O)CH_2C(O)OC(CH_3){=}CHCOOEt + EtOH \quad (I)$$

$$CH_3C(O)CH_2C(O)OC(CH_3){=}CHCOOEt \longrightarrow CH_3C(O)\underline{CHC(O)OC(CH_3){=}CHC}{=}O + EtOH \quad (II)$$

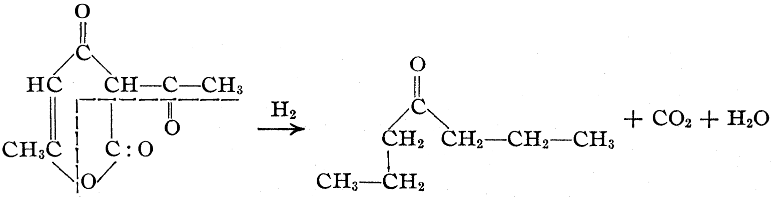
The formation of ethyl β-(β′-hydroxybutyryloxy)-butyrate in the reduction of acetoacetic ester substantiates the mechanism postulated by Arndt and Nachtwey, since it is the reduction product of the intermediate indicated in the formation of dehydroacetic acid from acetoacetic ester. The presence of ethanol would shift the first reaction to the right and thus greatly decrease the amount of $CH_3C(O)CH_2C(O)OC(CH_3){=}CH\text{-}COOEt$ and consequently of the di-ester formed from it by hydrogenation. n-Butanol would behave similarly since there is little difference among the primary alcohols in the concentration at equilibrium in similar reactions such *as* ester and acetal formation. Tertiary butyl alcohol would be expected to be much less effective in shifting the equilibrium toward the left since it is so little active in ester and acetal formation.

[3] **Arndt and** Nachtwey, ***Ber.,*** 57B, 1489 **(1924).**

The rate of reduction of acetoacetic ester in methylcyclohexane or ether was three times as great as in the absence of a solvent; in fact pure acetoacetic ester reduced much more slowly at 150° than it did in the presence of these solvents at 125°. The rate of reduction of an alcoholic solution of the ester was intermediate between that of the pure ester and that in a methylclohexane solution.

The formation of 1 or 2% of dehydroacetic acid in the reduction of acetoacetic ester and the possible relationship of the di-ester obtained to an intermediate in the formation of dehydroacetic acid led to an investigation of the hydrogenation of the latter compound. Dehydroacetic acid was not readily reduced, as from two to five applications of catalyst were necessary in each run before the maximum absorption of hydrogen was obtained. The temperature of reduction was 185–190° and the pressures were from 108 to 325 atmospheres, the reduction going approximately four times as rapidly at the highest as at the lowest pressure.[4] At pressures of about 130 atmospheres three moles of hydrogen per mole of dehydroacetic acid were absorbed, but at a pressure of about 325 atmospheres, five moles of hydrogen were taken up. Methylcyclohexane was used as a solvent for the reduction. It was found that when ethanol was used as a solvent, no reduction occurred, but heating with or without nickel at 190° for two hours gave 70% conversion of dehydroacetic acid to ethyl acetoacetate, the remainder of the acid being recovered unchanged.

The chief product obtained in the hydrogenation of dehydroacetic acid was heptanone-4, the yield being 40 to 45% under the optimum conditions. The formation of this ketone must involve the removal of oxygen and decarboxylation as well as hydrogenation, e. g.



The water formed in the removal of the oxygen would hydrolyze dehydroacetic acid[6] and the products under reducing conditions would presumably give acetone, acetic acid and isopropyl and ethyl alcohols. These alcohols would in turn bring about the formation of acetoacetic ester through the alcoholysis of dehydroacetic acid. These compounds except acetic acid were all found among the reduction products of dehydroacetic acid.

---

[4] Adkins, Cramer and Connor, unpublished work

[5] Collie, J. Chem. *Soc.*, **59**, 179 (1891).

It is noteworthy that in the hydrogenation of dehydroacetic acid in methylcyclohexane and in the attempted hydrogenation in ethanol, there were formed compounds (acetone, heptanone-4 and acetoacetic ester) which are readily hydrogenated under the conditions of temperature and pressure at which they were formed. This is not due to the action of dehydroacetic acid, for acetoacetic ester in a mixture of it with dehydroacetic acid was readily hydrogenated but the acetoacetic ester produced by the dehydrogenation of the dehydroacetic acid was not reduced. This was indicated by the hydrogen absorption and by the evidence for acetoacetic ester in the reaction product.

Experimental Part

A summary of typical results obtained in the reduction of acetoacetic ester and some of its derivatives is given below. There is given in

TABLE I

REDUCTION OF VARIOUS DERIVATIVES OF ACETOACETIC ESTER

order, the name and amount in moles of the compound reduced, the moles of hydrogen absorbed, the weight and number of the catalyst according to our records, the volume and name of solvent when one was used, the temperature, pressure and time for reduction after reaching the designated temperature, the name and yield of product(s). The yields marked "A" are those actually obtained while in those marked "B" allowance is made for the mechanical losses in handling the materials during reduction and filtration, and in "C" for mechanical losses and for the amount of the starting material recovered unchanged.

The product from 50 g. of acetoacetic ester after separation of the nickel catalyst in a typical experiment weighed 45 g. It gave no coloration with a ferric chloride solution and upon fractionation through a 20-cm. Widmer column gave two main fractions: 28 g. 77–79" (15 mm.) and 13 g. 154–156° (15 mm.). The remainder (4 g.) distilled below, between and above these fractions. The part distilling below the two main fractions was identified as ethanol through the formation of its 3,5-dinitrobenzoate. The part distilling above the two main fractions contained dehydroacetic acid, m. p. 110°. The fraction boiling at 77–79° (15 mm.) was ethyl β-hydroxyethylbutyrate. The fraction boiling at 154–156° (15 mm.) was identified as ethyl β-(β′-hydroxybutyryloxy)-butyrate on the basis of the following experimental findings. Upon saponification ethanol, identified as the 3,5-dinitrobenzoate, was formed. The acid so produced was a white rancid-smelling solid melting at 72° and boiling at 184° (740 mm.). It rapidly reduced cold alkaline permanganate solution, showed a neutral equivalent of 87, and gave a dibromide melting at 85–86.5°. Crotonic acid melts at 72°, has a neutral equivalent of 86 and its dibromide melts at 87°. The ester showed a saponification number of 109.5 and 110.3, d_{25}^{25} 1.0678, n_{D}^{25} 1.4360, and a molecular refraction of 53.36 ($\mathrm{MR'_D}$). The calculated saponification number for the di-ester is 109 and the $\mathrm{MR'_D}$ 53.39.

Anal. Calcd. for $C_{10}H_{18}O_5$: C, 55.05; H, 8.25. Found: C, 54.97; 54.70; H, 8.30, 8.33.

The ester showed no alcoholysis when 15 g. was boiled for two and one-half hours in 50 ml. of ethanol containing 6.8 g. of sodium ethoxide, nor when it was heated with ethanol alone for three hours at 150° under a pressure of 130 atmospheres of hydrogen. However, 40% of it was converted to ethyl β-hydroxybutyrate in six hours at 190°. Butyl β-hydroxybutyrate was identified on the basis of the facts that it showed a saponification value of 157 and 160 (theoretical 160) and gave n-butanol, identified as the dinitrobenzoate, upon saponification.

The fractionation of the products from the reduction of ethyl a-methylacetoacetate showed 1.4% ethanol, 70.5% ethyl α-methyl-β-hydroxybutyrate, b. p. 85–87° (22 mm.), 26% ethyl α-methyl-β-(α′-methyl-β′-hydroxybutyryloxy)-butyrate, b. p. 155–158° (17 mm.), and 1.4% residue. The ethyl α-methyl-β-(α′-methyl-β′-hydroxybutyryloxy)-butyrate was characterized by a saponification number of 124.4 and 124.1 (calcd. 123), d_{25}^{25} 1.0332, n_{D}^{25} 1.4393, $\mathrm{MR'_D}$ 62.65 (calcd. 62.59).

Anal. Calcd. for $C_{12}H_{22}O_5$: C, 58.53; H, 8.94. Found: C, 58.29, 58.49; H, 8.94, 8.81. The acid corresponding to this ester has been prepared previously.[6]

Dehydroacetic Acid.—In the runs made at 130 atmospheres three main fractions, besides the solvent, were obtained upon distilling the reduction product of dehydroacetic acid. The first of these comprised 23% of the recovered material and contained ethyl

---

[6] Wislicenus, *Ber.*, 8, 1036 (1875); Rohrbeck, Ann., 188,229 (1877); *cf.* Skau and Saxton, THIS JOURNAL, 52, 335 (1930).

alcohol, acetone and water. The second was heptanone-4, b. p. 144–146° (735 mm.), and comprised 17.3% of the material recovered, while the third fraction was acetoacetic ester, b. p. 178" (735 mm.), and amounted to 29.8%. When the latter fraction was collected over a four degree range, 174–178° (735 mm.), enough butyric acid was present after hydrolysis to obtain as derivatiyes, the anilide and the *p*-bromo-anilide. The 30% of the material not included here represents the transition material between fractions, and about 7.6% of unreduced material.

The fractionation of the products from the hydrogenation of dehydroacetic acid at 325 atmospheres gave amounts of compound boiling below 140° similar to those obtained in the hydrogenation at lower pressures but there was approximately two and one-half times as much heptanone-4 as under those conditions. There was less than half as much material boiling above the range of heptanone-4 with no evidence of the presence of acetoacetic ester. Unquestionably ethyl β-hydroxybutyrate and probably ethyl β-(β′-hydroxybutyryloxy)-butyrate were present in the high fractions but the total amount (3 g.) was too small and impure to obtain crystalline derivatives.

The presence of ethanol and of acetone among the reduction products of dehydroacetic acid was demonstrated through the formation of the 3,5-dinitrobenzoate of the former and the dibenzal derivative of the latter. Heptanone-4 was characterized by its boiling point 145–146° and the melting point of its semicarbazone (133–134") and the melting point (133–134°) of a mixture of this semicarbazone with some known semicarbazone of this ketone. It was further characterized by reduction over nickel at 175° and 160 atmospheres to heptanol-4, b. p. 152–154 (740 mm.), which gave a 3.5-dinitrobenzoate melting at 64° and an a-naphthylurethan melting at 79–80".

Anal. Calcd. for $C_{18}H_{32}NO_2$: C, 75.52; H, 8.39. Found: C, 75.68, 75.58; H, 8.34, 8.25.

The fraction, b. p. 170–174° (740 mm.), was characterized as acetoacetic ester by its boiling range and its coloration with ferric chloride solution, by the formation of acetone and ethanol through alkaline hydrolysis. The fraction gave a vigorous reaction with phenylhydrazine but the reaction product was an oil which could not be purified.

Dehydroacetic acid was prepared as by Arndt and Nachtwey.[7] Three hundred grams of acetoacetic ester in a 500-ml, flask was heated so that the vapors reaching the top of a 60-cm. Vigreux column had a temperature of 78–85". After 40 g. of ethanol had distilled, 34.4 g. of dehydroacetic acid separated out on cooling the contents of the reaction flask. Fifteen grams of ethanol was then distilled out and 29.5 g. of dehydroacetic acid obtained; further heating gave successively 8.3 g. of ethanol, 14.5 g. of the acid and 10 g. of ethanol and 17.5 g. of the acid. The total yield from 300 g. of the ester was 96 g. or 50% of the theoretical yield. Much lower yields were obtained when attempts were made to distil out all the ethanol without the removal of the dehydroacetic acid from time to time as indicated. The product had a melting point of 98–103°, and 109–110" after recrystallization from ethanol and water. The product used for reduction was not so purified.

Summary

Ethyl acetoacetate readily took up one molecular equivalent of hydrogen over a nickel catalyst at temperatures from 100 to 150°. If the hydrogenation was carried out in an ethanol solution, ethyl β-hydroxybutyrate was formed practically quantitatively. In the absence of a solvent or in ether or methylcyclohexane, there was formed along with two parts of ethyl β-hydroxybutyrate, one part of a derivative of it,

---

[7] Arndt and Nachtwey, Ber., 57B, 1487 (1924).

ethyl β-(β'-hydroxybutyryloxy)-butyrate. This ester despite the fact that it is the ester of a secondary alcohol did not undergo alcoholysis at the temperature used for the reduction of acetoacetic ester or in a boiling alcoholic solution of sodium ethoxide. It did undergo alcoholysis at 190° in the presence of a nickel catalyst. This complex ester appears to be formed through the reduction of two molecules of acetoacetic ester with the elimination of one molecule of ethanol. This condensation product was postulated by Arndt and Nachtwey as an intermediate in the formation of dehydroacetic acid from acetoacetic acid, so that the results here reported support their hypothesis. The methyl derivative of acetoacetic ester on reduction behaved similarly to the unsubstituted ester. The α,α-dimethyl and the a-methyl-a-ethylacetoacetic ester reduced smoothly to the corresponding simple hydroxy ester either with or without a solvent since there is no possibility of the formation of a complex ester analogous to that formed from the 8-ketonic esters capable of enolization.

Dehydroacetic acid appears to give heptanone-4 as the chief product in hydrogenation over nickel. The use of hydrogen pressure in excess of 300 atmospheres appears not only very greatly to accelerate the rate of hydrogenation but to favor the formation of heptanone-4 with a decrease in the products formed through the hydrolysis and alcoholysis of the dehydroacetic acid. Dehydroacetic acid has been found to undergo a smooth alcoholysis to acetoacetic ester at 190°.

THE STRUCTURE OF PARA-DIMETHYLAMINOBENZOIN[1]

BY SANFORD S. JENKINS[2] WITH LUCIUS A. BIGELOW AND JOHANNES S. BUCK

RECEIVED JULY 30, 1930 PUBLISHED DECEMBER 18, 1930

In the preceding paper, dealing with the reduction of *p*-dimethylaminobenzil,[3] it was found that the corresponding benzoin, on treatment with tin and hydrochloric acid in alcohol solution, yielded two isomeric desoxy derivatives, designated as *a*- and β-forms, the structures of which were established. This fact made it seem possible that the benzoin itself might be a mixture of *a*- and @-modifications, which, at least theoretically, would be expected to exist.

Accordingly, efforts were made to separate the apparently pure benzoin (m. p. 163–164°) into isomeric components by ordinary methods. For

---

[1] This paper is in part constructed from portions of a thesis presented by Sanford S. Jenkins in partial fulfilment of the requirements for the degree of Doctor of Philosophy in the Graduate School of Arts and Sciences, Duke University.

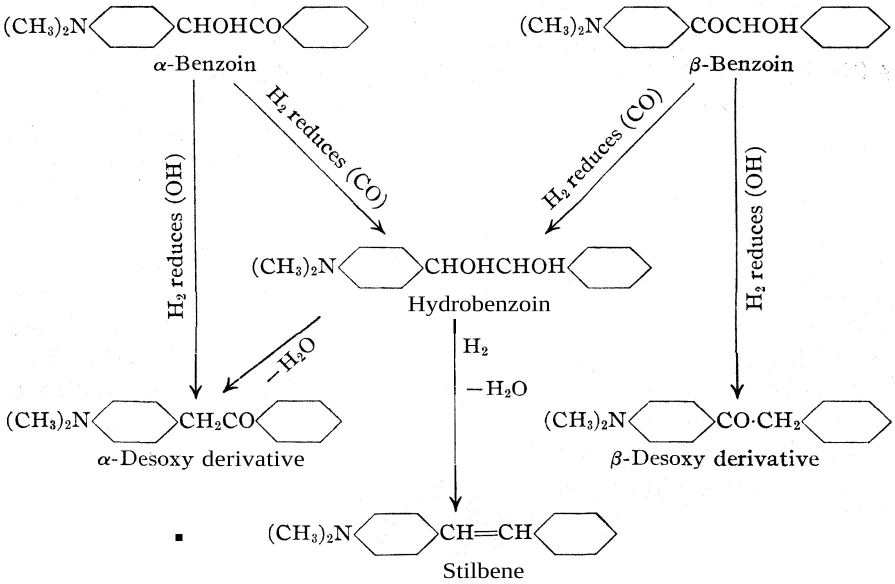
instance, the material was repeatedly fractionally crystallized, both from glacial acetic acid and from alcohol, but, while the melting points of the different fractions varied slightly, when samples of these were mixed with the pure substance, there was no depression. Also, pure *p*-dimethylaminobenzil was reduced catalytically to the benzoin in the Adams apparatus, employing different solvents, in the hope of obtaining isomers, but in every case mixed melting points of the products with an authentic sample of the benzoin showed no depression.

H. Staudinger,[4] who first prepared *p*-dimethylaminobenzoin by condensing *p*-dimethylaminobenzaldehyde with benzaldehyde in the presence of potassium cyanide, states unequivocally that the product (m. p. 163–164°) can be but a single substance having the constitution expressed by the formula *p*-$(CH_3)_2NC_6H_4CHOHCOC_6H_5$, which we designate as the a-form. Certain experimental data, which form the basis for considerable speculation, are advanced in support of this assertion.

In spite of the fact that the present writers were not able to separate the benzoin into a- and β-components, they were led to doubt the validity of the conclusion reached by the earlier investigator on the basis of the following considerations.

As shown in the preceding paper, already cited, the reduction of the benzoin with tin and hydrochloric acid yields both the a- and β-desoxy derivatives, but the dehydration of the hydrobenzoin with a mixture



THE POSSIBLE REDUCTION PRODUCTS OF α- AND β-*p*-DIMETHYLAMINOBENZOIN

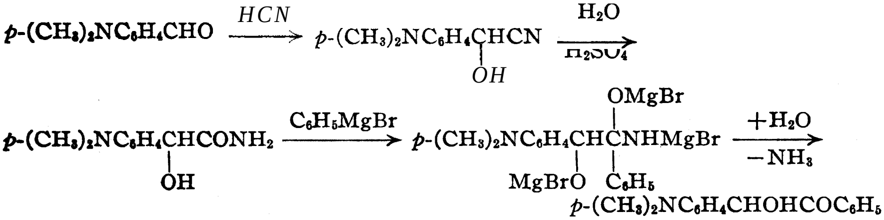
---

[4] Staudinger, *Ber*, 46, 3530, 3535 (1913).

of acetic and hydrochloric acids gives only the a-isomer. Furthermore, the action of tin and hydrochloric acid on the hydrobenzoin produces only the corresponding stilbene. From this it follows, upon theoretical considerations, that the a-form of the benzoin cannot, upon reduction, yield both desoxy compounds, whereas the β-modification, or a mixture of the two, can do so. The reasons for these statements may be made clear by reference to the diagram.

Thus, it did not seem possible that "ordinary" *p*-dimethylaminobenzoin, prepared according to Staudinger, which does yield two desoxy compounds upon reduction, could consist solely of the a-modification.

The writers, therefore, decided to attempt the synthesis of the a- and β-benzoins, by means of such methods as would establish definitely the structures of these substances. Accordingly, *p*-dimethylaminobenzaldehyde was treated with anhydrous hydrocyanic acid, and the resulting cyanohydrin hydrolyzed to form *p*-dimethylaminomandelamide, as described by Sachs.[5] The procedure was considerably modified, however, and is given in detail further on. The amide was then condensed with phenylmagnesium bromide according to the general method of McKenzie and Wren,[6] with the formation of the desired a-p-dimethylaminobenzoin of undoubted structure. The reactions may be expressed as follows:



$$p\text{-}(CH_3)_2NC_6H_4CHO \xrightarrow{HCN} p\text{-}(CH_3)_2NC_6H_4\underset{\underset{OH}{|}}{C}HCN \xrightarrow[H_2SO_4]{H_2O}$$

$$p\text{-}(CH_3)_2NC_6H_4\underset{\underset{OH}{|}}{C}HCONH_2 \xrightarrow{C_6H_5MgBr} p\text{-}(CH_3)_2NC_6H_4\underset{\underset{MgBrO}{|}}{C}H\overset{\overset{OMgBr}{|}}{\underset{\underset{C_6H_5}{|}}{C}}NHMgBr \xrightarrow[-NH_3]{+H_2O}$$

$$p\text{-}(CH_3)_2NC_6H_4CHOHCOC_6H_5$$

a-p-Dimethylaminobenzoin

The product, after crystallization from alcohol, melted at 159–160° (corr.). It gave on analysis the correct values for carbon, hydrogen and nitrogen and it had the molecular weight indicated by the formula. Upon oxidation with Fehling's solution, it formed the known benzil, and, when reduced with tin and hydrochloric acid in alcohol solution, it yielded only the a-desoxy derivative, not a trace of the β-isomer being formed. This was to be expected from the theoretical considerations already outlined.

When the new benzoin was mixed with the corresponding substance, prepared according to Staudinger, the melting point was depressed 15–18°, indicating clearly that the two compounds are different. These facts appear to prove with certainty that *p*-dimethylaminobenzoin prepared by the potassium cyanide condensation method is not the α-isomer.

It remained to be ascertained, however, whether the so-called "ordi-

---

[5] Sachs and Lewin, *Ber.*. 35,3571 (1902).

[6] McKenzie and Wren, J. *Chem. Soc.*, 93,311 (1908).

nary" benzoin was the pure β-isomer, or a mixture of the two forms which was uncommonly difficult to separate. Either possibility accorded with the known facts at this time. Having had success with the method outlined above in the synthesis of the a-derivative, the writers decided to prepare the @-benzoin by an analogous procedure. Mandelamide was therefore synthesized, as described by McKenzie and Wren, in their paper already cited, and condensed with p-dimethylaminophenylmagnesium bromide. The Grignard reagent was prepared by refluxing *p*-bromodimethylaniline with magnesium, activated with a little ethyl bromide. The reaction was sluggish, however, and the yield not very favorable. The condensation took place in a manner similar to that already illustrated, and must lead to the β-benzoin.

The product, after crystallization from alcohol, melted at 163–164°. It also gave, on analysis, the correct values for carbon, hydrogen and nitrogen. On oxidation, it formed the benzil, and on reduction with tin and hydrochloric acid in alcohol solution it yielded both the α- and @-desoxy derivatives. When it was mixed with the a-benzoin, the melting point was sharply depressed, but when the corresponding substance, prepared according to Staudinger, was added, no change in the melting point was observed.

It therefore seems certain that p-dimethylaminobenzoin prepared by the potassium cyanide condensation method is a single substance, consisting of the β- and not the a-isomer, and having the structure *p*-$(CH_3)_2NC_6H_4COCHOHC_6H_5$.

It appears to the writers that the only conclusion which it is possible to draw from the facts here reported is that in this instance the assertion of the earlier investigator cannot be sustained.

Experimental

_p_-Dimethylaminobenzaldehyde Cyanohydrin.—The method finally adopted for the preparation of this substance was a modification of that described by Sachs and already cited. It was not found possible, however, to obtain results, using liquid hydrogen cyanide synthesized according to Wade and Panting' until it was noticed that a trace of calcium chloride, which was carried into the apparatus by chance, catalyzed the reaction. This fact, together with the observations that hydrocyanic acid of German manufacture containing calcium chloride as a drying reagent, produced results, while purified calcium chloride did not, made it evident that the actual catalyst was calcium oxide, contained in the commercial chloride. In the presence of a trace of the oxide. the reaction took place without the slightest difficulty. The detailed procedure consisted in placing 10 g. of p-dimethylaminobenzaldehyde and about 0.2 g. of calcium oxide in a thick-walled bottle of 400-cc. capacity, cooled in a freezing mixture. Ten cc. of anhydrous hydrogen cyanide was then distilled into the bottle, which was tightly corked and heated to 40–45° in a water-bath until the reaction mixture had solidified, requiring about thirty-five minutes. The excess hydrogen cyanide was removed by

---

[7] Wade and Panting, J. *Chem. Soc.*, 73,256 (1898).

suction and the solid residue dissolved in 50 cc. of warm chloroform. Finally, ligroin (b. p. 60–70") was added until precipitation appeared to be complete. The white solid cyanohydrin was filtered off and dried. It weighed 7 g., which is 59% of the theoretical, melted at 110–113° and was sufficiently pure for use in the subsequent work.

p-**Dimethylaminomandelamide.**—This compound was also prepared by Sachs, but the details given are rather meager. The writers proceeded as follows. Four grams of the cyanohydrin was dissolved in approximately 10 cc. of sulfuric acid (sp. gr. 1.84) and the mixture allowed to stand for about fifteen minutes. After this it was poured slowly, with constant shaking, into a slush of ice and water. Then the solution was carefully neutralized with ammonia (sp. gr. 0.90). During these operations care was taken that the temperature at no time rose above 15". Just before the neutral point was reached a brown amorphous precipitate was formed, which was filtered off and discarded. The resulting neutral mixture was allowed to stand in the ice box overnight, when the amide crystallized out A further quantity was obtained on evaporating the mother liquor. The product weighed 2 g. (45% of the theoretical), and after two crystallizations from water melted at 184–186° (uncorr.). The yields obtained in different runs varied considerably.

α-*p*-**Dimethylaminobenzoin.**—A mixture of 30 g. of bromobenzene, 5.5 g. of magnesium turnings and 50 cc. of anhydrous ether was refluxed until most of the metal had dissolved. Then 2.5 g. of finely powdered *p*-dimethylaminomandelamide was added, in small portions, over a period of fifteen minutes. After each addition of the amide, a vigorous reaction occurred, which was allowed to subside before the next portion was added. After heating on the water-bath for twelve hours the solution was poured into 200 g. of crushed ice containing 30 g. of concd. sulfuric acid. The ether was removed, and the aqueous layer extracted with two 100-cc. portions of ether. The extracts were discarded. The acid solution was then neutralized with ammonia and the yellow precipitate which formed was separated, dissolved in 50 cc. of alcohol and filtered hot. On cooling, a mass of yellow needles separated which weighed 1.5 g. (45%) and melted at 152–153°. After three recrystallizations from alcohol, the product melted at 159–160" (corr.). When this was mixed with a sample of the benzoin prepared according to Staudinger, the melting point was depressed 12–18".

Anal. Calcd. for $C_{16}H_{17}NO_2$: C, 75.29; H, 6.67; N, 5.49; mol. wt. 255. Found: C, 75.19; H, 7.02; N (Kjeldahl), 5.58, 5.29; mol. wt. (in benzene), 258.

Oxidation of α-*p*-**Dimethylaminobenzoin.**—About 0.10 g. of the benzoin dissolved in 10 cc. of alcohol was heated on the water-bath with concentrated Fehling's solution for one hour, after which the cuprous oxide was filtered off and the mixture diluted with 50 cc. of water. On standing a yellow crystalline precipitate formed, which was removed by filtration and recrystallized from 60% alcohol. The product melted at 115–116° and a mixed melting point taken with known *p*-dimethylaminobenzil showed no depression.

Reduction of α-*p*-**Dimethylaminobenzoin.**—The reduction was carried out by treating 1.0 g. of the benzoin with 1.0 g. of mossy tin, 5 cc. of hydrochloric acid (sp. gr. 1.19), 0.10 g. of copper sulfate pentahydrate and 20 cc. of alcohol. The solution was refluxed for five hours, filtered hot and diluted with 30 cc. of water. After standing overnight, no precipitate whatever had formed, indicating the absence of the β-desoxy derivative, which is relatively insoluble in dilute acid mixtures. The solution was then made alkaline with ammonia and filtered, after which the yellow precipitate was extracted with 100 cc. of boiling alcohol. The extract was evaporated to a volume of about 25 cc. and allowed to stand.

The product which separated consisted of long white prisms which weighed 0.70 g. (74%) and melted at 127–128°. When it was mixed with known α-*p*-dimethylaminodesoxybenzoin, no depression in the melting point was observed.

An exactly parallel reduction of p-dimethylaminobenzoin prepared according to Staudinger, yielded 0.30 g. of the a-desoxy compound and 0.47 g. of the β-desoxy derivative. In this case the total yield was 0.77 g., which is 82% of the theoretical quantity.

β-*p*-Dimethylaminobenzoin.—A mixture of 30 g. of p-bromodimethylaniline, 3.1 g. of magnesium turnings and 75 cc. of absolute ether was refluxed for forty-eight hours. To start the reaction, about 12 drops of ethyl bromide was added in two portions. After the heating, 1.5 g. of finely powdered mandelamide, prepared according to McKenzie and Wren,[8] was added in small portions, over a period of ten minutes. A vigorous reaction ensued after each addition. The solution was then refluxed for fifteen hours more. and poured into 200 g. of crushed ice which contained 20 g. of sulfuric acid (sp. gr. 1.84). The clear yellow aqueous layer was extracted six times with 50-cc. portions of ether and, in this case, the aqueous layer was discarded. The ether was removed by distillation and the solid residue, after one crystallization from a small amount of alcohol, weighed 0.7 g. (25%) and melted at 159–161°. After two further recrystallizations from alcohol the product formed stout yellow needles melting at 161–162° (corr.). When a sample of this was mixed with the benzoin prepared according to Staudinger, the melting point was not depressed.

Anal. Calcd. for $C_{16}H_{17}NO_2$: C, 75.29; H, 6.67; N, 5.49. Found: C, 75.43; H, 7.04; N (Kjeldahl), 5.28, 5.39.

Oxidation of **β-*p*-Dimethylaminobenzoin.**—The reaction was performed by heating 0.12 g. of the benzoin, dissolved in 15 cc. of alcohol, with Fehling's solution. The mixture was heated on the water-bath for three-fourths of an hour and the reagent added in small portions until no further action occurred. The cuprous oxide was filtered off, the solution diluted with 50 cc. of water and the precipitate which formed on standing filtered and recrystallized from 15 cc. of 60% alcohol. The product formed yellow prisms melting at 116–117°, and weighing 0.072 g., which is 60% of the theoretical. When it was mixed with a sample of known *p*-dimethylaminobenzil, the melting point was not depressed.

Reduction of **β-*p*-Dimethylaminobenzoin.**—The reduction was carried out in a manner similar to that described for the case of the a-isomer. After the reaction was complete, the mixture was allowed to stand in the cold and the β-desoxy derivative separated. It weighed 0.20 g. and on crystallization from alcohol formed plates melting at 163–164°. The mother liquors from the reduction mixture were worked up as already described, and yielded 0.50 g. of the a-desoxybenzoin. After this had been purified in the usual way, it melted at 127–128°. The combined yields of the α- and p-isomers amounted to 0.70 g., which is 74% of the theoretical amount. When samples of these were mixed with known α- and β-*p*-dimethylaminodesoxybenzoin, respectively, the melting points were not depressed.

Reduction of ***p*-Dimethylaminohydrobenzoin.**—In order to show that no p-desoxybenzoin results from the reduction of the hydro derivative even with tin and hydrochloric acid in alcohol solution, the following experiment was carried out: 2.55 g. of "ordinary" p-dimethylaminobenzoin was dissolved in 50 cc. of absolute alcohol and reduced to the hydro compound in the Adams apparatus, in the presence of 0.1 g. of platinum oxide. The method is essentially identical with those described in the preceding paper, already cited. The catalyst was filtered off, and, without isolating the product, 3 g. of tin, 10 cc. of hydrochloric acid (sp. gr. 1.19) and a crystal of copper sulfate pentahydrate were added to the solution, which was refluxed for six hours. The unchanged tin was filtered off, and 90 cc. of water added. On standing, no precipitate appeared, so the mixture was neutralized with sodium carbonate, and the resulting product filtered, washed and extracted with alcohol. On cooling, the extract deposited colorless scales weighing 1.9 g. and melting at 147–148". When these were mixed with known *p*-dimethylamino-

---

stilbene, the melting point was not depressed, thus determining the identity of the product. The yield was 85%.

Summary

1. α- and β-*p*-Dimethylaminobenzoin have been synthesized by the Grignard method, leaving no reasonable doubt as to their structures.

2. The reduction products of these isomers have been studied and correlated with the corresponding substances produced by reducing p-dimethylaminobenzoin as prepared by condensing the corresponding aldehydes in the presence of potassium cyanide.

3. *p*-Dimethylaminobenzoin, as prepared by the condensation method, is shown to be the 8-isomer, and not the a-derivative, as was hitherto supposed. It has the structure *p*-$(CH_3)_2NC_6H_4COCHOHC_6H_5$.

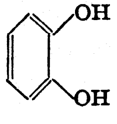
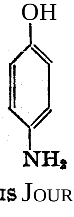
AN INDIRECT METHOD OF STUDYING THE OXIDATION–REDUCTION POTENTLALS OF UNSTABLE SYSTEMS, INCLUDING THOSE FROM THE PHENOLS AND AMINES

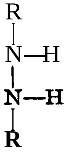
BY LOURS F. FIESER

RECEIVED AUGUST 2, 1930 PUBLISHED DECEMBER 18, 1930

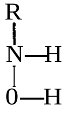
With certain unstable oxidation–reduction systems it has been found possible to measure the potentials with a reasonable degree of accuracy even though decomposition of the oxidant occurs so rapidly that the half-life period is less than one minute.[1] A limit was reached, however, in the application of the method in its present form. Such substances as amphi-naphthoquinone and o-quinone-di-imine decompose so very rapidly that no adequate measurements could be made. The number of such failures of the direct method, to be sure, is comparatively small. In over two hundred cases the simultaneous removal by oxidation of two hydrogen atoms from hydroxyl or amino groups which are ortho or para or adjacent to one another, or which bear some similar relationship, gives rise to a fairly stable oxidant and the system formed by the two components is electromotively active and its potential can be determined by one means or another which involves the direct observation of that potential. The following substances thus belong to what may be termed the "hydroquinone type."



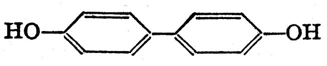




$R-NH-NH-R$



$R-NH-OH$



---

[1] Fieser, THIS JOURNAL, 52, 4915 (1930).

On the other hand, there is a second type of compound, to which the monatomic phenols and amines belong, the partial oxidation of which produces an oxidation–reduction system with which a high degree of instability is the rule rather than the exception, for the oxidant is a free radical. Thanks to the brilliant investigations of Wieland, of Pummerer, and of Goldschmidt, the existence of these radicals and the nature of the systems of which they are components is not a question for speculation but one of proof. Since the existence of the diphenyl nitrogen radical was established by Wieland,[2] several bivalent nitrogen radicals[3] and aroxyls[4] have been isolated. Some of these have been obtained by the direct oxidation of the corresponding amine or phenol, and it has been proved in a highly ingenious manner that the primary oxidation product of aniline is a radical containing bivalent nitrogen.[5] With few exceptions the radicals are highly unstable, but the information concerning the nature of their decompositions is very complete. The nitrogen radicals generally polymerize to hydrazines; the aroxyl radical either polymerizes to a peroxide or isomerizes to a keto-methyl radical, which may enter into various subsequent reactions. Careful studies of these reactions have led the workers in this field to conclude that the primary step in the oxidation in neutral medium of all phenols or amines consists in the removal of one hydrogen atom from oxygen or nitrogen.

With respect to the mechanism, then, there is no difference between the oxidation of the monatomic substances and that of the compound of the hydroquinone type. The oxidation products differ to the extent that those of the first class are usually much less stable than those of the second type, but the difference is hardly a significant one, for exceedingly unstable quinones have been described, as well as very stable radicals.

The property most characteristic of the quinones, the azo and similar compounds, is that they respond almost instantly to reduction at a low temperature and in dilute solution. The reverse reaction takes place with equal ease, and it may be said that the hydroquinone–quinone system is an unusually mobile one. No less mobile is the system 9-chloro-10-phenanthrol (I)–9-chloro-10-phenanthroxyl (II).[6]

Possibly because the blocking of the positions ortho and para to the oxygen atom prevents a wandering of the free valence to carbon, and because the high molecular weight retards the velocity of association, the radical,

I II III

II, is far more stable than the average and in this and other respects it is strikingly similar to the quinones. It does slowly polymerize at ordinary temperatures to the peroxide, III, but Goldschmidt was able to isolate the substance and to characterize it very completely. Outstanding among its properties is the great ease of reduction; the oxidation of I to II may be reversed quantitatively with such reagents as hydrazobenzene, hydroquinone and phenylhydrazine. So great, indeed, is the velocity of reduction of some of the bivalent nitrogen radicals that Goldschmidt and Bader were able to effect a quantitative determination of the radical by titration at $-80°$ with hydrazobenzene solution.[7]

All of the evidence thus shows that there is no essential difference between the systems produced on partial oxidation of compounds of the hydroquinone and of the phenol type, even though the ultimate fate of the oxidant is usually different. It is reasonable to infer that, since the one is electromotively active, the other would share this property, and preliminary experiments with 9-chloro-10-phenanthroxyl have shown that this is the case.' It may even be possible to measure the potentials of such systems, but whether or not a few substances of special structure may be capable of study in this way, it does not seem at all likely that any direct measurements will be possible with compounds such as phenol and aniline. Consequently, we believe that it is worth while to develop an indirect method of study which is entirely general in application, if limited in accuracy.

The Theory of the Method

The general method may be called that of potentiometric indicators and it was originated by Conant.[8] It consists in measuring the potential of a solution of some stable oxidation–reduction system, usually an inorganic one, and then adding a sample of, say, a phenol. If the potential of the solution is so low that the phenol is incapable of becoming oxidized by the oxidant of the system which is being used for reference,

---

[7] Goldschmidt and Bader, *Ann.*, 473, 137 (1929).

[8] (a) Conant and Lutz, THIS JOURNAL, 45, 1047 (1923); (h) *ibid.*, 46, 1254 (1924); *(c) ibid.*, 49, 1083 (1927); (d) Conant and Pratt, *ibid.*, 48, 2468 (1926); *(e) ibid.*, 48, 3178 (1926); (f) *ibid.*, 48, 3220 (1926); (g) Conant, Aston and Tongberg, *ibid.*, 52, 407 (1930); (h) Conant, *Chemical Reviews*, **3**, 1 (1926).

no change in the potential of the system will occur; but if the phenol becomes oxidized, it will obviously consume some of the oxidant, and the potential will change and thus indicate that a reaction has proceeded. The experiment can, of course, be made quantitative, so that the decrease in the potential of the inorganic, or "reference system" as we shall call it, indicates the amount of phenol which is oxidized in a given period of time. Now the potential begins to fall at once, but it does not rapidly reach a constant level, as in the interaction of two stable oxidation–reduction systems, but continues to fall at a measurable rate. The reason for this is that the reaction between the two reversible systems, say, those from a-naphthol and potassium ferricyanide (1)

$$\text{ROH} + \text{K}_3\text{Fe(CN)}_6 \rightleftharpoons \text{RO}— + \text{K}_3\text{HFe(CN)}_6 \qquad (1)$$

$$\text{RO}— \longrightarrow \text{Decomposition products} \qquad (2)$$

cannot come to a point of equilibrium because the oxidant of the organic system is unstable and changes over more or less rapidly into other substances according to (2). The destruction of the radical by (2) allows more of it to be formed by (1), and the potential, which is determined by the relative concentrations of the ferri- and ferrocyanides, continues to decrease. The rate at which the potential of the solution decreases is a measure of the rate of Reaction 2, for the first reaction is much more rapid; for practical purposes it may be regarded as instantaneous.

Now Conant has presented evidence in support of the altogether reasonable theoretical conception that the velocity of Reaction *2* is dependent upon the equilibrium constant of Reaction 1. The concentration of the radical available at any instant for Reaction 2 is determined by the extent to which Reaction 1 has proceeded to the right. In other words, the first reaction (rapid) feeds the second (slow). Since the equilibrium constant of Reaction 1 may be expressed in terms of the normal oxidation–reduction potentials and concentrations of the two interacting systems, there is obviously a relationship between the velocity of the decomposition reaction, the potential of the solution, and the normal potential of the arol–aroxyl system. It is desirable to evaluate the last-named quantity, but unfortunately there is one other unknown and undeterminable quantity: the velocity of the un-fed decomposition reaction. For each radical there must be an intrinsic rate of decomposition; the rate which can be measured by the above method is proportional both to this intrinsic rate and to the equilibrium constant of Reaction 1.

If this equilibrium constant is represented in terms of the normal potential of the ferri–ferrocyanidesystem, E_0(Fe), and of the unstable organic system, E_0, the situation may be summed up by means of the equation

$$\textbf{(1)}\quad \text{Observed velocity} = \text{Constant X } \frac{[\text{ROH}][\text{K}_3\text{Fe(CN)}_6]10^{\left(\frac{E_0(\text{Fe}) - E_o}{0.0591}\right)}}{[\text{K}_3\text{H(CN)}_6]}$$

This shows that the velocity of oxidation will be increased by the substitution of another reference system of normal potential greater than E_0(Fe). It is also clear that there are two unknowns, E_0 and the constant which defines the true rate of decomposition of the oxidant.

In order to gain some idea of the potential of the unstable organic system, Conant prepared a series of solutions containing various reference systems so chosen that there was a progression in the potentials of these solutions. A quantity of a given phenol was added to each solution and the potential was followed. Below a certain potential no reaction occurred, above that the potential dropped at a rate which increased as the potential of the solution was increased. By measuring the rates of the reactions and applying certain approximate equations, Conant was able to estimate the potential at which 20–30% of the phenol would be oxidized in the course of thirty minutes; this value he termed the "apparent oxidation potential." The value is dependent upon two factors: the normal oxidation–reduction potential of the phenol–phenoxyl system and the intrinsic rate of decomposition of the phenoxyl radical.

A separation of these two factors is not easily accomplished, but until this is done there can be no adequate means of estimating, even approximately, the true potentials of the unstable systems. To illustrate the point we may quote the example of two substances of the hydroquinone type which form unstable systems on partial oxidation, and for which the potentials, as well as the true velocities of decomposition of the oxidants, have been measured by direct means. The potentials of the systems from *p*-methylaminophenol and from *p*-benzylaminophenol are very nearly identical at PH 3.5 and yet the velocity constant is about seven times as great in the second case as it is in the first.' If the "apparent oxidation potentials" were determined for these substances it would be found, on comparing the action of *p*-methylaminophenol and of *p*-benzylaminophenol on identical solutions of a given reference system, that the drop in potential occurred much more rapidly with the benzyl than with the methyl derivative, and a lower value for the "apparent oxidation potential" would be assigned to this than to the methyl derivative. The "apparent oxidation potentials" would thus indicate a difference between the two systems when there is no appreciable difference in the actual normal potentials.

Thus, even as a means of indicating the relative (true) potentials of a series of closely related compounds, the "apparent oxidation potential" is unreliable. It reflects not only all of the characteristics peculiar to the rate of decomposition of each oxidant, but also the very marked influences on reaction velocities of changes in temperature and environment.

If the facts were otherwise and if the velocity of the reaction were the same for all members of a given series of substances, then Conant's "apparent oxidation potentials" would give an accurate measure of the relative normal potentials of the various systems. Ordinarily, however, the velocities differ considerably. Now it will be observed that the velocity of the reaction is, in part, dependent upon the potential of the reference system and this can be adjusted to progressively lower values and the reaction can thus be made progressively slower and finally brought practically to a stop. Under these conditions the velocities of reaction for a series of compounds all approach the limiting value of zero and hence they are all very nearly the same at some point representing a small percentage of oxidation in a brief period of time. It follows from these considerations that, while the rate factor may influence greatly the "potential at which 20–30% oxidation occurs in thirty minutes," it should have a slight, possibly an inappreciable, effect on the potential at which the velocity becomes vanishingly small.

Critical Oxidation Potentials

We have thus sought to develop a method of determining the potential at which the velocity of the reaction between a given oxidizable substance and a suitable reference system reaches some limiting, small value. We believe that a means of accomplishing this end has been found and that, although the method is of a purely empirical character, it answers to certain reliable tests which may be applied. The method will be described in detail in the Experimental Part; it may be explained here briefly by quoting some experiments with a-naphthol in a neutral 37% alcoholic solution at 25°. The alcohol was included to increase the solvent power; neutral buffer salts were used in order to avoid dissociation phenomena. The potentials given all refer to the difference in potential between the oxidation–reduction electrode and a hydrogen electrode in the same solvent.

The potential of the molybdicyanide–molybdocyanide system may be varied from about 1.0 v. to 1.2 v., but at any potential in this range α-naphthol becomes oxidized with great rapidity. Using the ferri–ferrocyanide system, a rapid oxidation is observed at a potential of 0.870 v., but no reaction can be detected in a reasonable length of time at a potential of 0.770 v. After thus limiting the range to be studied more carefully, a series of solutions of ferri- and ferrocyanides is prepared in such a way that their potentials lie in this range and differ by about 5–10 mv. The total concentration of the cyanides is kept exactly the same, but the ratio of oxidant to reductant is varied. Each solution is brought to thermal and electrochemical equilibrium and the potential is carefully determined. A sample of a-naphthol is then added, the amount taken being just equivalent to the potassium ferricyanide present in each experiment, and the potential is followed for five minutes. At the potentials 0.780 v. and 0.790 v. no oxidation occurs, but at 0.800 v. and above a drop in potential is noted and this becomes progressively greater as the potentials of the solutions increase. There is thus a potential range of 0.790–0.800 v. above which oxidation occurs, below which the extent of the reaction is so limited that no reaction at all can be detected with the apparatus employed. It may be noted that the period of observation may be extended to about thirty minutes and still the reaction fails to become detectable at 0.780 v.

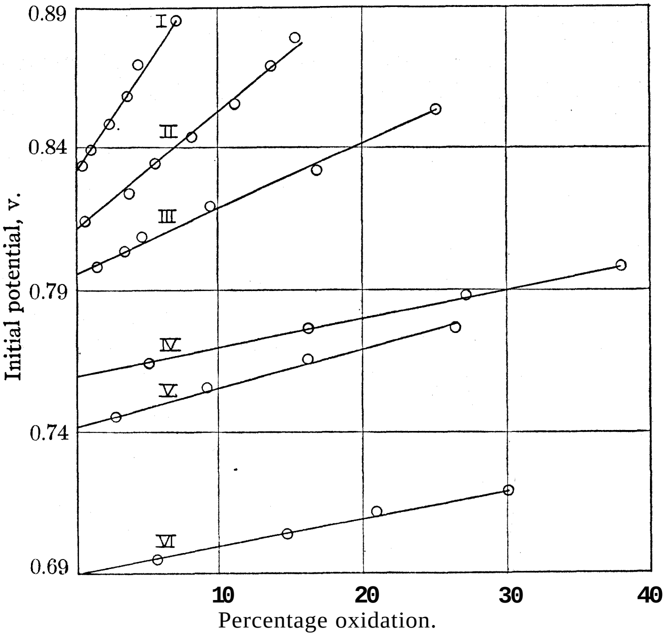

Fig. 1.—The determination of critical oxidation potentials: I, eugenol; II, 2,3-dihydroxy-naphthalene; III, α-naphthol; IV, pyrogallol dimethyl ether; V, catechol; VI, 2,6-dihydroxynaphthalene. Reference systems for I–V, ferro- and ferricyanides; for VI, *p*-hydroxydiphenylamine–N-phenylquinone-imine.

A narrowing of the potential range which thus appears to be critical may be accomplished as follows. The drop in the potential is an indication of the amount of ferricyanide which has entered into reaction and, hence, of the amount of α-naphthol which has been oxidized. One can calculate the percentage oxidation from the equation

$$\text{Percentage oxidation} = 100([\text{Oxid.}]_i - [\text{Oxid.}]_t)/[\text{Oxid.}]_t \qquad (2)$$

where $[\text{Oxid.}]_i$ is the concentration of ferricyanide at the start of the experiment and $[\text{Oxid.}]_t$ is that at time, *t*. These quantities are calculated from the normal potential of the ferri–ferrocyanide system and the potentials at the beginning and end of the experiment, by means of the usual electrode equation. Results of the following nature are obtained (Table I).

Table I

The Oxidation of α-Naphthol

Potential, E(v.)	0.7915	0.7985	0.8040	0.8087	0.8190	0.8321	0.8535
ΔE (mv.)	.0	.9	2.2	3.2	7.3	18.1	38.8
Oxidation, %	.0	1.5	3.4	4.6	9.4	16.8	25.0

While the drop in potential is not directly proportional to the initial potential of the solution, the relationship between the potential and the percentage oxidation is unmistakably linear. These results are represented by Curve III, Fig. 1, and Figs. 1 and 2 give similar graphs for several other compounds. Included in the list are phenols, primary and secondary amines, and compounds of the hydroquinone type (catechol and 2,6-dihydroxy-naphthalene). Two inorganic and one organic reference systems are represented. It is clear that the relationship noted holds good in each case. In fact with over seventy compounds studied it appears to be quite generally true that when equimolecular quantities of the oxidizable substance and the oxidant of a reference system are allowed to interact over a brief period of time, the percentage oxidation is a linear function of the initial potential of the solution.

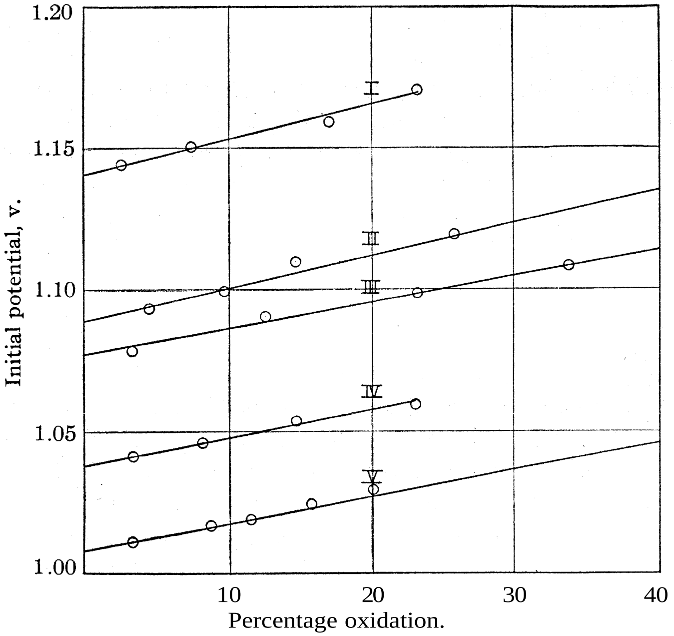

Fig. 2.—The determination of critical oxidation potentials: I, 2-nitro-1-naphthol; II, phenol; III, p-toluidine; IV, p,p'-dihydroxydiphenylmethane; V, diphenylamine. Reference system: cyanides of molybdenum.

We have not been able to solve the complicated problem of deriving this relationship from theoretical principles, but the relationship does exist and use may be made of it in the following way. On extrapolation of the percentage oxidation—potential curve, a potential is obtained which corresponds, on the curve, to the point of "zero oxidation." It really does not correspond to the point at which there is absolutely no reaction but rather to the potential at which the oxidation ceases to be detectable in a short period of time with the particular instruments employed. If these instruments were refined this "zero-oxidation" potential would be shifted to somewhat lower values. Theoretically there is no potential at which the reaction completely comes to a stop. What this extrapolation value does represent is thus the potential at which, with *a* particular technique and apparatus, the rate of the reaction becomes so small as to be just detectable. We shall call this the critical oxidation potential and designate it by the symbol E_c. If it is a reasonably reproducible constant with which to characterize a series of substances, it is evident that this critical oxidation potential meets precisely the requirements defined above, for it is a constant determined both by the potential-factor and the rate-factor, but for which, since the rate is made very small, the rate-factor must be exceedingly small.

The accuracy with which the critical oxidation potential can be determined may be judged from the following results. Two series of experiments with a-naphthol both gave the value **0.796** v. When the concentrations of all of the reactants were halved, the value obtained was **0.799** v. In a further series another reference system having a different normal potential was employed; with the complex cyanides of tungsten the E_c value found was **0.798** v. The percentage oxidation–potential curve in this case had a slightly different slope. It is probable that catalysts would also change the slope of the curve without changing the point of origin.

The only limitation discovered in the application of this method is that there are not enough suitable reference systems to cover the entire range of potential. The potentials of the systems which we have used are represented in Fig. **3.** The most satisfactory results are obtainable when the potential desired can be secured without resorting to either very high or very low values for the ratio of oxidant to reductant. It will be seen that this can be done in the lower potential zone, for the curves for four systems overlap each other. There is a range, however, between the systems from tungsten and molybdenum which cannot be covered. The upper and lower limits of the usefulness of these systems are indicated on the graph; critical oxidation potentials falling between **0.91** v. and **1.01** v. cannot be determined until other systems of suitable potential are discovered.

The slopes of the potential–oxidation curves vary over wide limits, indicating quite different reaction velocities. This difference probably is not entirely due to the nature of the unstable substances produced on oxidation, for there is a general disposition for the curves to become steeper as the relative amount of the oxidant of the reference system is increased. Thus Curves I–V of Fig. 1 all refer to experiments in which the complex cyanides of iron were employed, and the ratio of ferri- to ferrocyanide varied from values of about 4–5 for Curve I, to 0.1–0.3 for Curve V. The slopes of the curves seem to reflect this variation.

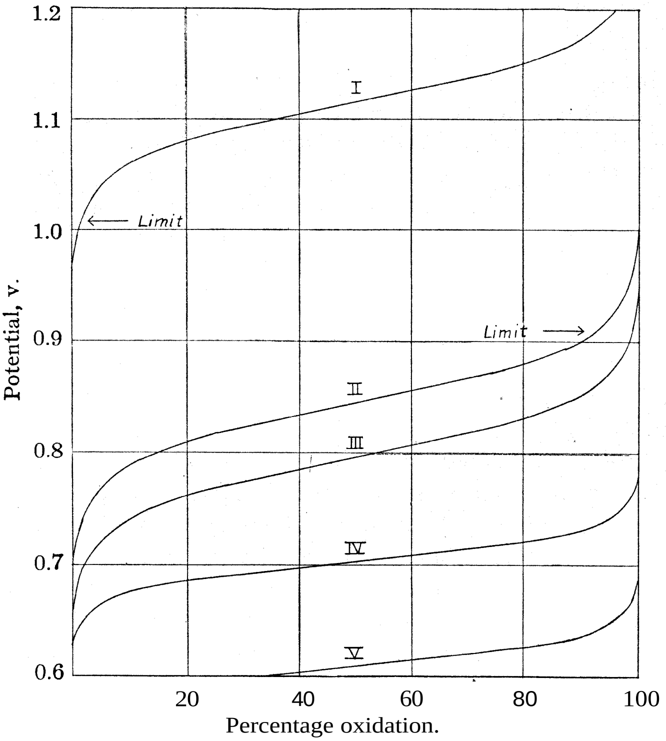

Fig. 3.—The potentials of the reference systems: systems. named as reductant, I, potassium molybdocyanide; II, potassium tungstocyanide; III, potassium ferrocyanide; IV, *p*-hydroxydiphenylamine; V, 2,4-diaminodiphenylamine.

Tests of the Reliability of the New Constant.—According to the reasoning developed above, the critical potentials which have been determined should bear some definite relationship to the normal oxidation–reduction potentials of the unstable systems to which they refer. For a group of similar substances the critical potentials would be expected to lie at some approximately constant distance below the normal potential. We have been fortunate enough to find a few systems for which both of these potentials may be determined, and the results are summarized in Table II. The determinations were all made in a neutral phosphate buffer solution containing 37% of alcohol. The potentials are those measured against a hydrogen electrode in the same solvent. The compounds listed are all of the hydroquinone type (two hydrogens involved).

TABLE II

THE RELATIONSHIP BETWEEN THE NORMAL OXIDATION–REDUCTION POTENTIAL (E_0) AND THE CRITICAL OXIDATION POTENTIAL (E_c)

System, named as reductant	$E_0{}^1$, v.	E_c, v.	Difference, v.
p,p'-Dihydroxydiphenyl	0.954	0.882	0.072
p,p'-Dihydroxystilbene	.854	.786	.068
p-Phenylenediamine	.783	.710	.073
p-Aminophenol	.733	.673	.060
		Av.	.068

Although these results are not very extensive, they do indicate a constant difference between the two potentials. The variation in the difference is no greater than the uncertainty in the experimental results. The decomposition of two of the oxidants here concerned is a monomolecular reaction; with the other two it is a catalytic second-order reaction. The half-life periods vary from sixty seconds to 234 seconds.[1] When these great differences are considered, it seems quite clear that the rate-factor has been reduced to a minimum in the new term which has been called the critical oxidation potential.

Where direct determinations of normal potentials have not yet been possible it appears admissible to estimate approximate values from the critical potential values and the average difference found up to the present time for similar systems, that is, for systems of the same oxidizing equivalence. Table III gives values calculated in this manner for all of the compounds of the hydroquinone type which have been studied.[9] The normal potential for o-benzoquinone has been measured[10] in alcoholic hydrochloric acid solution by a method which very probably yields low results; the value found was 0.784 v.

TABLE III

NORMAL POTENTIALS (CALCD.) AT 25° IN NEUTRAL ALCOHOLIC SOLUTION

System, named as oxidant	E_0, v.
o-Benzoquinone	0.810
Amphi-naphthoquinone	.758
Nitro-p-benzoquinone	.765
3-Hydroxy-1,2-benzoquinone	.677
Isatin	.813
Quinone from aesculetin	.827

---

[9] A more accurate estimate would be obtained by taking the mean of the critical oxidation potential of the reductant and the critical reduction potential of the oxidant if the latter quantity could be evaluated.

[10] Conant and Fieser, THIS JOURNAL, 46, 1858 (1924).

Another test of the soundness of considering the critical oxidation potential as a potential-factor from which the rate-factor has been very nearly separated is in determining the effect of temperature. One valuable feature of this test is that it may be applied to each compound individually, rather than to a series. The few measurenients which we have made at 40° are not as accurate as those at 25°, but they will serve to show the order of magnitude of the effect of this variable. The results are described in the Experimental Part and summarized in Table IV. A 15° increase in the temperature has relatively little effect on the critical oxidation potential; this quantity decreases by from 3 to 21 mv. The direction of the change and its magnitude are entirely comparable with the change in the normal oxidation–reduction potentials of the quinones.[11]

TABLE IV

THE EFFECT OF TEMPERATURE

Compound	Critical oxidation potential, E_c, v. 25°	40°	Difference
4-Nitro-1-naphthol	...	1 123	...
2-Nitro-1-naphthol	1 141	1 120	-0 021
2,4,6-Trichlorophenol	1 103	1 097	006
1-Naphthol-2-carboxylic acid	1 065	1 062	003
Hydroquinone monomethyl ether	0 848	0 833	.015
2,3-Dihydroxynaphthalene	812	809	003
a-Naphthol	797	784	013
Phloroglucinol	799	791	008
p,p'-Dihydroxystilbene	786	.773	.017
1,3-Dihydroxynaphthalene	754	744	010

The effect of a temperature change is thus that normal to true potentials. Where a rate-factor is involved as in Conant's "apparent oxidation potentials," it has been found[S] that a 37° increase in temperature causes a decrease in the "potential" of as much as 150–400 mv.

One other standard by which the critical potential may be judged is that of the consistency of the results, and we shall now attempt to determine whether the figures obtained reveal any regularities and form a consistent pattern.

The Relationship between Critical Oxidation Potentials **and** Structure.—The values found for the critical oxidation potentials at 25° are recorded in Table XIII of the Experimental Part. From these figures tables have been constructed which will simplify the comparisons. The first of these, Table V, shows the effect produced on the critical potential of phenol and of α-naphthol of substituting various groups in the ortho, para or meta position to the hydroxyl group. The influence of a given group is very nearly the same for ortho or para substitution, that of a meta group is in the same direction but only 16–18% as great, and this is true whether the potential is increased or decreased.

---

[11] Conant and Fieser, THIS JOURNAL, 44,2480 (1922).

TABLE V

A COMPARISON OR ISOMERIDES

Substituent	Substance	Effect of substituent on E_c of substance Ortho	Para	Meta
Methyl	Phenol	−0.049	−0.050	−0.009
Phenyl	Phenol	.041	.043	...
Methoxyl	Phenol	.221	.241	.037
Nitro	a-Naphthol	.336	.339	...

Table VI gives a comparison of the oxidation of the hydroxyl and the amino group when attached to an aromatic nucleus. It is seen that the amines become oxidized only at a higher potential than that required for the corresponding phenols. The difference is so nearly constant that one could make a fairly accurate estimate of the potential of an amine from a knowledge of the potential of a phenol of similar structure.

TABLE VI

A COMPARISON OF PHENOLS AND AMINES

Amines	E_c, v.	Phenols	E_c, v.	Difference
Aniline	1.135	Phenol	1.089	0.046
p-Toluidine	1.077	*p*-Cresol	1.039	.038
p-Anisidine	0.892	*p*-Methoxyphenol	0.848	.044
p-Naphthylamine	1.064	8-Naphthol	1.017	.047

In constructing Table VII, which summarizes the data on the influence of substituent groups, we have regarded ortho and para substitution to be identical, and we have considered and combined the results in the phenol and in the amine series. The figure representing the effect of the nitro group should be accepted with some reservation. A comparison of a substituted with an unsubstituted compound, in this case 2-nitro-1-naphthol with α-naphthol, is only valid when the hydroxyl group is un-ionized in each case. It is not unlikely that the nitro derivative is ionized to some extent in the buffer solution employed; hence the observed difference which we have attributed to the nitro group represents only the order of magnitude of the true effect.

TABLE VII

THE EFFECT (v.) ON THE CRITICAL OXIDATION POTENTIAL OF ORTHO OR PARA SUBSTITUENTS

Group	Effect	Group	Effect
$—NO_2$	0.344	$—CH_2CH{=}CH_2$	−0.037
—COOH	.268	$—CH_2COOH$	− .038
—CHO	.212	$—C_6H_5$	− .042
$—SO_3H$	.084	$—CH_3$	− .052
—Cl	.005	$—OC_6H_5$	− .059
$—CH_2OH$	− .037	$—OCH_3$	− .235
$—CH_2C_6H_5$	− .037	$—N(CH_3)_2$	− .371

In general, unsaturated groups increase the potential, saturated ones decrease it; the nitro group has the greatest positive effect, the modified hydroxyl and amino groups the greatest effect in the negative direction. Ortho–para directing groups usually weaken the bond holding the hydrogen atom to oxygen or nitrogen, meta directing groups have the opposite effect.

When the few results for polysubstituted substances are 'considered, it is found that the influence of a given group increases as the number of such groups in the molecule is increased. The effect of a meta hydroxy group may be estimated in two ways: phenol may be compared with resorcinol; α-naphthol may be compared with 1,3-dihydroxynaphthalene. The differences found in E_c are 0.046 v. and 0.043 v., respectively. A comparison of resorcinol with phloroglucinol, on the other hand, indicates that the introduction of one more meta hydroxyl group lowers the potential 0.244 v. Other substituents usually behave in the same fashion. We do not yet know how to account for this increased effect with increasing substitution, but the same thing was observed among the oxidation–reduction potentials of substituted phenanthrenequinones.[12]

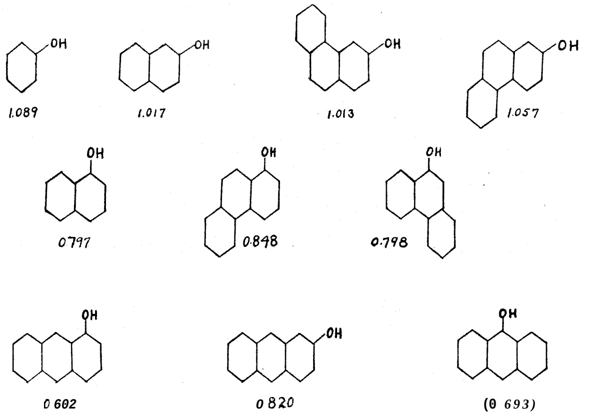

Fig. 4.—Critical oxidation potentials of phenols.

The next comparison is of the phenols derived from the various aromatic hydrocarbons, and the data are recorded in Fig. 4. According to the potentials, the substances fall into definite groups. The four phenols at the top differ relatively little in potential; they are structurally similar in that the oxidizable group is either in the unreactive 8-position to a second benzene ring, or else no such ring is present. This may be called the β-naphthol type. The second group consists of **α-naphthol, 1-phenanthrol** and 9-phenanthrol, and their potentials are all nearly 0.2 v. lower than those of the compounds of the β-naphthol type. In each of these three substances the hydroxyl group is adjacent to a benzene ring, which

---

[12] Fieser, This Journal, 51, 3101 (1929).

is thus in a position to exert an activating influence. In these two series the nature of the hydrocarbon skeleton appears to be of little consequence and the dominating influence is that which may be exerted by an adjacent aromatic nucleus.

In the last line are to be found results for three anthracene derivations. On account of the uncertainty introduced by its extensive ketonization, the value for anthranol is not reliable. The figures for α- and β-anthrol clearly show that neither compound fits into the a- or β-naphthol series. It will be observed, however, that each is lower in potential than the corresponding naphthalene derivative by almost exactly the same amount, 0.195 v. for the a-derivative and 0.197 v. for β-anthrol. The difference between the *a*- and β-positions of anthracene is thus the normal one, but in this case the hydrocarbon structure appears to have a specific activating influence which is quite appreciable. This influence may be related to the other unique properties of anthracene.

Another interesting comparison is that given in Table VIII, which gives the potentials for a few secondary amines which result from the replacement of one of the amino hydrogen atoms of aniline by various groups. Alkyl groups cause a rather slight lowering of the potential, indicating that they tend to weaken the nitrogen–hydrogen linkage; the unsaturated phenyl group has an effect which is similar but greater, while the presence of a carbon–nitrogen double bond adjacent to the oxidizable group appears to produce a very marked change in the potential. In view of this fact, it appears odd that the azo group of diazoaminobenzene has such a moderate influence.

TABLE VIII

THE EFFECT OF N-SUBSTITUTION ON THE CRITICAL OXIDATION POTENTIAL OF ANILINE

Subst.	$C_6H_5N{=}N—$	$C_6H_5CH_2—$	$CH_3—$	$C_2H_5—$	$C_6H_5—$	$C_6H_5CH{=}N—$
Effect, v.	−0.077	−0.078	−0.082	−0.097	−0.127	−0.344

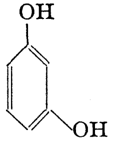
Some Theoretical Speculations

It is evident that, on the whole, the critical oxidation potentials of a large number of substances reveal many regularities and reasonable relationships; the constant responds just as well to this criterion of reliability as it does to specific experimental tests. We thus feel confident that this new constant gives a dependable, if approximate, indication of the relative normal potentials of the compounds concerned and that it may be taken as a true measure of the tendency of a given substance to become oxidized. Because of this demonstrated reliability, we shall now venture to present a few deductions of a somewhat speculative nature.

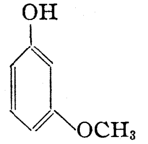
1. The Possibility of Quinone Formation.—The property of forming a quinone on oxidation is not shared by all dihydroxyl derivatives of the aromatic hydrocarbons, and it is important to determine the requirements

for this type of reaction and the limitations. Whether or not 2,3-dihydroxynaphthalene possesses this property is a question which has received considerable attention and one to which some of the present results may be applied, for the ability of a substance to yield a quinone, azo compound or similar oxidant, rather than a univalent radical, appears to be reflected in the potential.

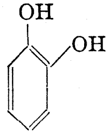
With resorcinol (IV) the formation of a quinone is impossible and the relation of the potential to that of phenol gives a measure of the effect of one meta hydroxyl group. The potential of the monomethyl ether, V, gives a measure of the influence of a meta methoxyl, and it will be observed that the effect is practically the same for these two groups. Turning to the ortho derivatives, catechol (VI) would be expected to have a potential very close to that of guaiacol (VII) if the oxidation involved a single hydrogen atom and the formation of a univalent radical. The observed potential, however, is very much below that of guaiacol, and the obvious reason for this is that the oxidation of catechol is different and results in the formation of a quinone. Even the transitory existence of the most unstable of quinones should affect the potential in this way.



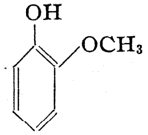
E_c = 1.043 v.
IV



E_c = 1.052 v.
V

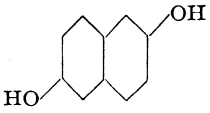


E_c = 0.742 v.
VI

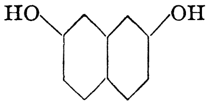


E_c = 0.868 v.
VII

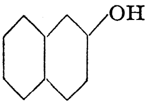
A further example of the manner of applying this criterion of quinone formation is the case of the oxidation of 2,6-dihydroxynaphthalene (VIII). If this substance is to be imagined as a 8-naphthol derivative which will become oxidized at a single hydroxyl group, we need a means of predicting the effect on this oxidation of the hydroxyl in the second nucleus. A comparison of 2,7-dihydroxynaphthalene (IX) with 8-naphthol (X) indicates that this effect ordinarily is practically negligible. The potential of VIII, however, is not at all close to that of 8-naphthol, but far below it. This may be interpreted as the result of the formation on oxidation of the highly unstable *amphi*-naphthoquinone.



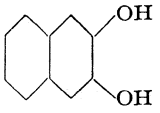
E_c = 0.690 v.
VIII



E_c = 1.007 v.
IX



E_c = 1.017 v.
X

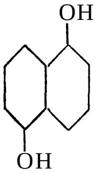


E_c = 0.812 v.
XI

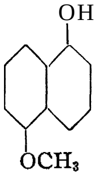
The possible existence of "2,3-naphthoquinone" may now be considered. The oxidation potential of 2,3-dihydroxynaphthalene (XI) is only 0.205 v.

below that of β-naphthol (X). It has been shown that the effect of a hydroxyl group is about the same as that of a methoxyl, where the oxidation is of the univalent type, and it is known that the effect on the potential of phenol of an ortho-methoxyl group is 0.221 v. The value is so close to the difference between X and XI that a completely adequate conception of the potential of XI is given by the assumption that the oxidation is of the univalent type, that it is simply an ortho substituted naphthol which cannot form a quinone.

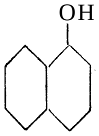
The opposite decision is reached in the case of 1,5-dihydroxy-naphthalene (XII). A comparison of the ether, XIII, with a-naphthol (XIV) indicates that a methoxyl in the 5-position, and hence by inference a hydroxyl in that position, has little effect upon the potential for the oxidation at the single hydroxyl group in the 1-position. Since the potential of 1,5-dihydroxynaphthalene is 0.124 v. below that of a-naphthol, it must be concluded that the oxidation is not similar to that of α-naphthol and that a quinone is formed, however brief its existence.



E_0 = 0.673 v.
XII

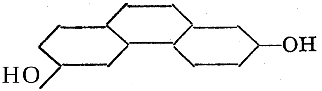


E_0 = 0.792 v.
XIII

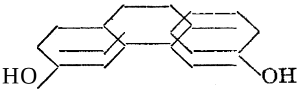


E_0 = 0.797 v.
XIV

In the phenanthrene series it is found that an hydroxyl group in one terminal ring has little influence on the potential of oxidation at an hydroxyl in the other terminal nucleus. The 2,6-dihydroxy derivative (XV) is to be regarded as a substituted 3-phenanthrol, and its potential is practically identical with that of this compound. On the other hand, the potential of the 3,6-derivative (XVI) is well below that for its isomer and this suggests that the quinone, XVII, is the primary oxidation product. Preliminary qualitative tests with 3,6-dihydroxyphenanthrene have failed to reveal any indication of the formation of a quinone,[13] but this problem will now bear closer study.



E_0 = 1.010 v.
XV



E_0 = 0.832

XVII

2. The Nature of the Compounds of the Hydroquinone Type.—Some comparison of the systems involving one and those involving two hydrogens in the oxidation process has been made above in a qualitative way,

---

[13] Fieser, THIS JOURNAL, 51, 2480 (1929).

but when a closer relationship between the two types is desired, the critical oxidation potentials do not furnish an adequate basis for comparison. This can only be obtained through a knowledge of the normal potentials and the free energies of the oxidation.

It has been shown that for a few substances of the hydroquinone type it is possible to relate the critical potential (E_c) to the normal potential (E_0) experimentally. On the average, the former is 0.068 v. below the latter. From the electrode equation, which must apply to E_c as well as to any potential of the system, one may write

$$E_c - E_0 = -0.068 = 0.02957 \log [\text{Oxid.}]/[\text{Red.}] \quad (3)$$

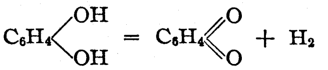
A calculation from this equation shows that the potential represented by E_c corresponds to a point at which 0.5 part of the oxidant is in equilibrium with 99.5 parts of the reductant; in other words, we have determined in *E*, the potential at which 0.5% of the reductant becomes oxidized in five minutes. Though the amount is quite small, it appears that this represents quite closely the extent of the reaction in each case.

The difference, $E_c - E_0$, was determined for systems with which two hydrogens are removed on oxidation, hence the difference would not be the same where a monatomic phenol or amine is concerned. In the latter case the equation becomes

$$E_c - E_0 = 0.05915 \log [\text{Oxid.}]/[\text{Red.}] \quad (4)$$

The experiments, however, establish that the reaction proceeds to the extent of 0.5% in five minutes. We have shown that the variation in the rate of the reaction is insignificant when the rate is so very small and we are thus justified in assuming that the extent of oxidation would be very nearly the same for all similar systems. Since there is an abundance of evidence to show that the hydroquinone–quinone and arol–aroxyl systems are entirely similar, we may assume 0.5% reaction for the latter system and thus calculate from Equation 4 that the difference between E_c and E_0 is 0.136 v. We regard this value, which gives a means of estimating the normal potentials for the systems containing radicals, *as* uncertain only to the extent that it is an approximation which may be subject to some revision as more data accumulate.

Having a method of estimating approximate values for the normal potentials, the free energy changes in the oxidations can be calculated. Thus for phenol the critical potential is 1.089 v., hence the normal potential for the phenol–phenoxyl system is 1.089 + 0.136 = 1.225 v. The normal potential for the quinone–hydroquinone system is 0.715 v. The free energy changes are as follows



$$C_6H_4{<}^{OH}_{OH} = C_6H_4{<}^{O}_{O} + H_2$$

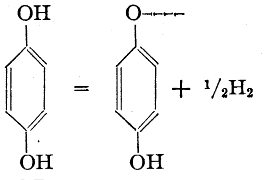
AF = 33.0 Cal.

$$C_6H_5OH = C_6H_5O\text{---} + {}^1/_2H_2$$

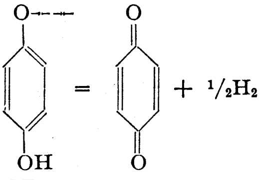
AF = 28.3 Cal.

Not much more energy is required for the removal of two hydrogens from hydroquinone than for the oxidation of the single hydrogen of phenol.

One interesting application of these calculated free energy changes is to the question of the possibility of carrying out the step-wise oxidation of hydroquinone. Estimates of the free energy changes for the removal of each hydrogen atom may be made in the following way. Considering the first step in the reaction, hydroquinone may be regarded as a substituted phenol which is converted into a univalent radical. The hypothetical critical potential for this oxidation would be close to that of its monomethyl ether (E_c = 0.848 v.), and one can estimate from the known relationship between hydroxy and methoxy compounds (resorcinol and its ether) that the value would be 0.839 v. The normal potential would be 0.136 v. greater, or 0.975 v., and the increase in free energy 22.5 Cal. For the complete oxidation of hydroquinone to quinone the energy change is 33.0 Cal. The difference between these quantities gives the free energy change in the second step of the process. We may thus write



AF = 22.5 Cal.



AF = 10.5 Cal.

This shows that considerably less energy is required for the removal of the second hydrogen atom than for the first. If the energy level in a given oxidation experiment is great enough to produce the radical, it will be more than sufficient to complete the oxidation. The free radical is thermodynamically unstable except when it is present at very low concentrations. If it were possible to prepare it by some other method, it would disproportionate to give quinone and hydroquinone. The situation may be expressed in terms of the equilibrium constants of the two reactions (3×10^{-17} and 2×10^{-8}), and it may be shown that the concentration of the radical in a solution containing 0.1 M each of quinone and hydroquinone is 4×10^{-6}.

By following similar processes of reasoning we have estimated the corresponding free energy changes for other substances which yield quinones, and the figures are given in Table IX.

TABLE IX

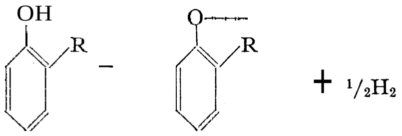
CALCULATED FREE ENERGY CHANGES IN THE OXIDATION OF HYDROQUINONES

	AF, Cal.	
Reductant	First hydrogen	Second hydrogen
Hydroquinone	22.5	10.5
Catechol	23.0	14.4
2,6-Dihydroxynaphthalene	26.4	8.6
p,p'-Dihydroxydiphenyl	27.0	17.0

Invariably the energy required to complete the oxidation of the radical is very much less than that required to produce it. This not only serves to explain why radicals or their reaction products (other than quinones) have never been observed in the oxidation of this type of compound, but it also gives a new insight into the nature of these substances. When one hydrogen atom has been separated from the hydroxylic oxygen atom, the free valence on this oxygen transmits to an ortho or para hydroxyl or amine group a reactivity, a mobility, which it did not before possess.

3. The Effect of Substituents on the **Normal** Potentials of the **Quinones.**—Throughout the entire investigation of the subject named it has been a perplexing problem to decide whether the observed shifting in the normal potential of an oxidation–reduction system as the result of the introduction of a substituent group, or of other structural change, is to be regarded as connected with the structural change in the oxidant or in the reductant. Thus the normal potential of the quinone-hydroquinone system is lowered 0.121 v. by the introduction of a methoxyl group;[14] but there has been no way of telling whether this pronounced change results from the fact that the methoxyl group weakens the oxygen–hydrogen bond of the hydroxyl groups of hydroquinone, or if it is because of an effect of this group on the unsaturated system of quinone, causing the molecule to have a diminished tendency to add hydrogen in the 1,6-positions. Possibly both factors are of importance. On account of the great contrast in the structure of the oxidant and reductant, oxidation cannot be visualized as the exact reverse of reduction. This is, however, true of the oxidation of a phenol to a free radical, for each substance retains the truly aromatic structure and it is immaterial whether one considers the activation of the functional hydrogen atom of the reductant or the affinity of the univalent oxygen atom of the oxidant for hydrogen.

One may compare guaiacol with phenol and thus obtain a difference in the free energy changes which represents the effect of the methoxyl group



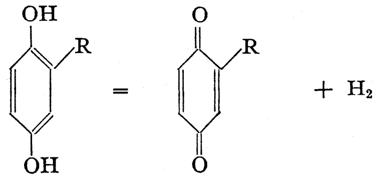
$-\Delta F$ (Cal.) $\begin{cases} R = H: & 28.3 \\ R = OCH_3: & 23.2 \end{cases}$

Difference = 5.1

The effect of the methoxyl group in guaiacol, which is thus determined, must be very nearly the same as the effect of that group on the hydroxyl group ortho to it in methoxyhydroquinone. The influence of the substituent on the second hydroxyl group cannot be very great, because this group is in the meta position and groups which are meta to each other have very little effect on one another. A comparison of the hydroquinone system with the methoxy-substituted system gives the following results

---

[14] The value for the normal potential of methoxyquinone (0.594 v.) was **kindly** supplied by Dr. J. B. Conant.



$$-\Delta F\ (\text{Cal.}) \begin{cases} R = H: & 33.0 \\ R = OCH_3: & 27.4 \end{cases}$$

Difference = 5.6

The effect of substitution is hardly any greater than that found above for guaiacol, and this means that almost the entire change brought about by introducing this group is to be attributed to the influence of that group on the character of the hydroquinone, and that the change produced in the quinone molecule is relatively insignificant.

The inference which the present results suggest, namely, that the normal potential of a quinone–hydroquinone system is influenced much more by the change produced in the reductant as the result of substitution than by the corresponding change in the oxidant, is an important one and one which will be investigated further.

While the effect of simple substitution now appears traceable largely to the character of the hydroquinone in question, there can be no doubt that the influence of some structural changes must be attributed to the nature of the quinone in question. Thus, for example, the pronounced difference in the normal potentials of the quinone–hydroquinone and the o-benzoquinone–catechol systems results from a difference inherent in the two quinones and not in their reduction products, for there is good evidence that ortho and para substitution produce the same effect on the oxidation potential of a phenol.

4. The Relationship between Various Oxidizable Substances.—With the information supplied by the present study of phenols and amines, we are in a position to understand somewhat better the relationship between the various types of compounds which yield more or less stable oxidation products by the loss of two hydrogen atoms.

Since a given primary amine is oxidized only at a potential higher than that required for the oxidation of the corresponding phenol, we may conclude that the hydrogen is the more firmly bound in the primary amino group. This gives a rational explanation of the fact that the normal potential of the hydroquinone–quinone system is progressively increased by the substitution of amino and imino groups for the hydroxyl and ke-

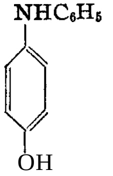
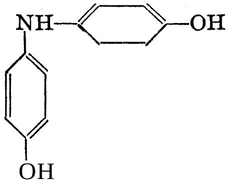
XIX



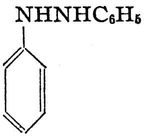
E_0 = 0.703 v.
XX



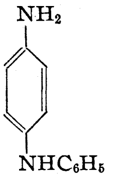
E_0 = 0.656 v.
XXI

tone groups, respectively (Compare XVIII and XIX).[1] That diphenylamine is lower in potential than aniline accounts for the relationship between XIX and XX. The structural difference between XX and XXI is that the latter substance has one additional para hydroxyl group. Since such a group has been found to impart a considerable mobility to a hydroxylic or amino hydrogen, the shifting of the potential of the system of which XXI is the reductant to a lower level is easily understood. Thus the systems from the quinones, the quinone-imines and di-imines, the quinone-anils, the indophenols and indamines are all closely related to one another and in a qualitative way their relative potentials are now understood.

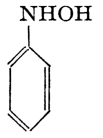
On considering the structures of hydrazobenzene and phenylhydroxylamine, which form systems with azobenzene and nitrosobenzene, respectively, one is impressed by the relationship of these substances to *p*-aminodiphenylamine and to *p*-aminophenol. The first two compounds



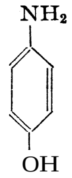
E_0 = 0.420 v.[15]
XXII



E_0 = 0.751 v.
XXIII



E_0 = 0.562 v.
XXIV



E_0 = 0.727 v.
XXV

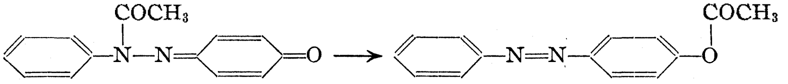
are amines in which there is, adjacent to the amino group, a group which appears to impart a considerable reactivity to the amino hydrogen. Once this hydrogen has been removed by oxidation, the resulting free valence in turn aids in the immediate oxidation of the group which caused the activation. The other two substances, XXIII and XXV, are exactly similar except that their activating group which eventually becomes oxidized is across the benzene ring from the first group, rather than adjacent to it. One may roughly estimate how the activating effect of a group would compare when it is in these two situations by considering the critical potentials of aniline (1.135 v.), N-methylaniline (1.053 v.) and *p*-toluidine (1.077 v.). Attaching the methyl group to nitrogen, and substituting it in the para position, both cause a lowering in the potential but the effect of N-substitution is the greater of the two. Consequently it is understandable that the potentials for hydrazobenzene and phenyl hydroxylamine are lower than those for their isomers.

5. A Possible Reason for Certain Molecular Rearrangements.—The comparisons which have just been made suggest an interesting relationship in the field of the molecular rearrangements. This can be made

---

[15] This value is estimated from the potentials for 3,3′-diaminoazobenzene (0.4095 v.) and azobenzene-4,4′-disulfonate (0.424 v.). Compare: Biilmann and Blom, *J. Chem. Soc.*, 125, 1719 (1924); Conant and Pratt, Ref. 8d.

clear by the following statements. Under certain conditions N-methylaniline (E, = 1.053 v.) can be caused to rearrange into *p*-toluidine (E_c = 1.077 v.); phenylhydroxylamine (E_0 = 0.562 v.) yields p-aminophenol (E_0 = 0.733 v.); the hydrazobenzenes (hydrazobenzene, E_0 = 0.420 v.) rearrange either to benzidines (benzidine, E_0 = 0.921 v.[16]), or semidines (p-aminodiphenylamine, E_0 = 0.751 v.). In each case the rearrangement involves the formation of a less oxidizable isomer, a substance of higher potential. The converse of this proposition appears equally true as, for example, in the case of the rearrangement of acetylquinonephenylhydrazone, XXVI, into acetoxy-azobenzene, XXVII. From the known potentials for quinone-imines and for azo compounds it is quite safe to assume that the azo compound has the lower reduction potential, so that the change represented here is from one reducible substance to an isomer which is less reducible. This reaction constitutes one of the few exceptions to Latimer's theory of molecular rearrangements,[17] and yet it falls into line with the other reactions noted. It has been shown that a given reducible substance tends to tautomerize, if this is possible, into a less reducible form, a form of lower reduction potential.[18] There is a suggestion in the present observations that a given reducible (or oxidizable) substance possesses a tendency to rearrange, where possible, into an isomeric form which is less reducible (or oxidizable).



XXVI XXVII

Experimental Part

Buffer Solution.—The solvent employed in all of the experiments was 0.038 M in potassium dihydrogen phosphate and 0.067 M in disodium hydrogen phosphate, and contained approximately 37% of alcohol. It was prepared by diluting 534 cc. of a solution 0.07 M in potassium dihydrogen phosphate and 0.105 M in disodium hydrogen phosphate to a volume of 1 liter with 95% alcohol. When diluted with water instead of alcohol, the solution had a P_H value of 7.04. The alcoholic solution contains about the maximum quantity of salts, and crystallization is likely to occur if it is allowed to stand for any length of time at a temperature below 25°.

Potassium Molybdocyanide, $K_4Mo(CN)_8 \cdot 2H_2O$.—After carrying out several preparations of this material according to the method outlined by Rosenheim,[19] the following procedure was adopted as being rapid and reliable.

One hundred grams of molybdic acid (85% MoO_3) and 210 cc. of concentrated hydrochloric acid were added to a solution of 210 g. of sodium thiocyanate in 1.2 liters of water and the mixture was boiled under the reflux condenser for three hours. The deep red solution of the basic molybdenum-IV-thiocyanate was filtered by suction and

60 cc. of pyridine was added slowly to the well-stirred solution. A dark red oil was thus precipitated, and toward the end of the addition a light yellow solid began to separate. On thorough cooling in an ice-bath the red oil solidified (dry weight, 148 g.). Without drying the product or breaking up the lumps the pyridine compound was stirred into a solution of 300 g. of potassium cyanide in 500 cc. of water. Noxious gases were evolved and the material rapidly dissolved to give a solution which was first green and then yellow-brown, The mixture was heated on the steam-bath and stirred for one-half hour, filtered from a certain amount of black material, and evaporated on the water-bath until a large crop of amber-colored crystals had separated. After cooling, the material was collected and washed with a small amount of potassium chloride solution. The crystals collected in this way were usually contaminated with a considerable amount of black material, but the latter is not soluble in water and is easily removed. The crude product was dissolved in warm water, the solution was treated with animal charcoal, filtered, and to it there was added one to two volumes of alcohol. The potassium molybdocyanide soon separated in the form of golden-yellow crystals of great purity; yield, 100 g. Further evaporations of the cyanide mother liquor yielded, after two or three recrystallizations, 9 g. more of the pure product.

Potassium Molybdicyanide Solution, $K_3Mo(CN)_8$.—Oxidation to the pentavalent cyanide was carried out according to Olsson.[20] A solution of 4.4 g. of potassium molybdocyanide in 20 cc. of water and 10 cc. of 6 N sulfuric acid was titrated with a 10% solution of potassium permanganate until a pink color indicated complete oxidation. Fifty cc. of 10% silver nitrate solution was then added to precipitate the molybdicyanide in the form of the fine, brown-red silver salt. This was collected on a Biichner funnel washed with water, suspended in 50–100 cc. of water, and treated with 50 cc. of 10% potassium chloride solution. By shaking the mixture vigorously in a stoppered flask the silver salt was soon decomposed. The solution was filtered by suction from the silver chloride, clarified with animal charcoal and diluted to a volume of 250 cc. As the pentavalent molybdenum compounds are sensitive to light, the above operations were carried out in the dark-room.

The strength of the molybdicyanide solution was determined by electrometric titration with potassium ferrocyanide, and it was found to vary from 0.032 to 0.034 M. The solution was diluted to 0.030 M and stored in the dark. The fresh solution always contained a small amount of molybdocyanide, as revealed by the titration curve, and when exposed to the light of the laboratory the concentration of molybdicyanide decreased at the rate of about 0.2% per hour.

Potassium Ferricyanide and Ferrocyanide Solution.—These solutions were prepared by dissolving 0.03 mole of the salt in 200 cc of water and diluting to 1 liter with the alcoholic buffer solution. The solutions decompose slowly and should be rejected after the second day.

Procedure for the Determination of Critical Oxidation Potentials.—The five reversible oxidation–reduction systems which were employed as reference systems are listed in Table X. Since the potentials of the complex cyanides vary considerably with dilution, it was essential to determine the normal potential under conditions comparable with those of the oxidation tests. For this purpose 20 cc. of the 0.03 M potassium ferrocyanide solution was added to 200 cc. of the buffer solution and titrated electrometrically with 0.03 M molybdicyanide solution, giving a curve from which the normal potential could be calculated. The potential of

TABLE X

NORMAL POTENTIALS OF THE REFERENCE SYSTEMS

0.0016 N solution of oxidant and reductant in neutral alcoholic phosphate solution

System, named as reductant	Abbreviation	E_0 25°	E_0 40°
Potassium molybdocyanide	Mo	1.1160	1.111
Potassium tungstocyanide	W	0.8450	0.833
Potassium ferrocyanide	Fe	.7965	.786
p-Hydroxydiphenylamine	A	.7030	..
2,4-Diaminodiphenylamine	B	.6090	..

the oxidation–reduction half-cell was measured against a hydrogen electrode immersed in some of the same solvent, and the value found when [Oxid.] = [Red.] is that reported as the normal potential. In the case of potassium tungstocyanide, a solution of 0.0006 M of the salt in 20 cc. of water was added to 200 cc. of the buffer solution and titrated with potassium molybdicyanide, while 0.0003 M of each of the organic compounds was dissolved in 220 cc. of the solution and titrated with the same reagent. The potential of the molybdicyanide–molybdocyanide solution was determined by titration of the oxidant with ferrocyanide solution and correcting the titration curve for a small amount of the reductant which was invariably present.

The molybdenum system reaches a constant potential with great rapidity while such constancy is reached relatively slowly in the case of *p*-hydroxydiphenylamine and, when the proportion of the reductant is small, with the complex cyanides of iron. Solutions of 2,4-diaminodiphenylamine should be protected from the air, for the rate of oxidation is sufficient to cause trouble.

The potentials recorded in the table are all subject to a slight inaccuracy owing to the fact that it was necessary to prepare the 0.03 M complex cyanide solutions either with water (Mo, W) or with a mixture of water and buffer solution (Fe), rather than with the latter solution alone.

In performing the oxidation tests the solutions were prepared in exactly the same manner, and with the same amounts and concentrations, as in these determinations of the normal potentials, but the titration was discontinued when the desired potential had been reached. The relationship between the potential of the system and the ratio of oxidant to reductant is conveniently expressed in the form of a large graph showing the potential plotted against Equivalents of oxidant $\times 10^5$. When completely oxidized, each solution contains 6×10^{-4} equivalent of the oxidant, and the curves may be constructed from the normal potentials given and the theoretical equations. Having titrated a solution to the potential desired, the number of equivalents of oxidant present was found by reference to the chart and the equivalent amount of the substance to be studied was dissolved in 30 cc. of the buffer solution. While releasing the stop watch, this solution was poured through a funnel into the oxidation–reduction vessel (three seconds required for the addition) and the potential was recorded after one minute and after five minutes. When a progressive drop in potential occurred, the extent of the reaction after five minutes was determined from the potential at that time and the chart.

It was usually necessary to apply a correction to the potentials actually noted after adding the sample under investigation. In most cases it was observed that at potentials well below that at which oxidation quite evidently occurred, the potential dropped almost immediately about 1 mv. and then remained constant indefinitely. Such a drop in potential can hardly be indicative of an oxidation, for such a reaction is not instantaneous and proceeds at a regular rate. As will be shown later, the potential is decreased to a certain extent as the result of diluting the solution of the reference system by the addition of the sample, but this does not account for the entire effect. It is probable that a further factor is the change in the activities of the oxidant and reductant produced by the organic material added. A correction for the effect was applied in the following manner. With each substance studied experiments were carried out at such a potential that this small change in potential during the first minute to a constant value could be observed, that is, at a potential 5–10 mv. below that fixed for E_c. This change in potential was then subtracted from the initial potential of the solution in each of **the** other experiments with the compound in question, for the same drop, which is not due to oxidation, must occur in each case. In calculating the percentage oxidation these corrected potentials were employed. The correction was greatest with the molybdenum system, amounting usually to about 2 mv., and it was scarcely perceptible with the organic systems.

The Use of Various Reference Systems and the Effect of Changing the Concentrations.—The procedure may be illustrated by quoting in full the measurements with a-naphthol at 25°. In Series I, Table XI, the first two experiments show that the potential of the ferri–ferrocyanide system falls 1 mv. on adding one equivalent of α-naphthol and then remains constant. In the next experiment the potential might be expected to fall 1 mv. whether or not a reaction occurs; the corrected initial potential is thus 0.7985 v. But the potential falls progressively, hence .a reaction occurs at this potential level. From the corrected initial potential and the potential at the five-minute interval it was calculated that 1.5% of a-naphthol was oxidized during this period of time. On plotting the corrected initial potentials against the percentage oxidation for the entire series, a value of 0.796 v. was found for the critical oxidation potential. It should be noted that the second and third experiments **fix** this value as between 0.7930 v. and 0.7990 v. and that the remaining experiments serve merely to give a means of interpolating accurately be-

	E_c = 0.799 v.				

tween these figures. The second series of experiments is that referred to in the first part of this paper. In connection with Series III it may be pointed out that the normal potential of the tungsten system differs considerably from that of iron, which means that the amount of oxidant present at a given potential was less than half that used in Series I. In spite of this difference, the percentage oxidation at a given potential was only slightly greater and very nearly the same result was obtained for E_c. Series IV shows that halving the concentrations of both the oxidant and the a-naphthol does not materially alter the value for E_c or the percentage oxidation at a given potential,

In deciding upon a time interval at which to compose the extent of oxidation at different potentials it was felt that, aside from the theoretical considerations which have been mentioned earlier, this interval should be fairly short in order to avoid secondary oxidations and in order that the potential of the reference system should not fall so far as to diminish greatly the initial driving force of the reaction. Comparison of the results for the one-minute and the five-minute intervals showed that the latter were much more consistent and regular, and this period of time was thus adopted for all of the experiments at 25°.

The Effect of Varying the Ratio of Oxidant to Substance Oxidized.—In each of the experiments just described the amount of a-naphthol taken was that equivalent to the oxidant of the reference system. Since there is no theoretical reason for preferring this particular ratio, experiments were undertaken to determine the effect of varying the ratio indicated. Table XII summarizes the critical oxidation potentials found for six compounds under different conditions of concentration. Each figure represents the results of extrapolating a curve constructed from the results of five or six experiments similar to those described above. The total amount of the reference system was kept the same (0.0006 mole), and the amount of the sample was varied in each series in the proportions shown in the Table. Though the results are not recorded in detail, it may be said that it was invariably found that as the proportion of the sample to the oxidant was increased, the percentage oxidation at a given potential above the critical potential became progressively less. That is, a greater percentage of the sample was oxidized in five minutes when the total amount of substance was small than when a large excess was present.

TABLE XII

CRITICAL OXIDATION POTENTIALS (25°)

Compound	Reference system	E_c (v.) when equiv. ratio of oxidant to sample was 1:05	1:1	1:2	1:3	1:4
Aniline	Mo	1.137	1.135	1.121	1.116	...
p-Toluidine	Mo	1.080	1.077	1.063	1.059	...
p-Cresol	Mo	...	1.038	1.023	...	1.021
β-Naphthol	Mo	...	1.016	1.006	...	...
Aesculetin	Fe	...	0.766	0.759	...	...
Catechol	Fe	...	.754	.742	0.739	...

The results show that E_c decreases as the relative amount of phenol or amine is increased. This is in accord with the prediction from the electrode potential equation. The greatest difference seems to occur between the results for the 1:1 and the 1:2 ratios, though the difference appears to be fairly constant (av., 12 mv.) for all six compounds and to be independent of the nature or the potential of the reference system. The results in themselves furnish no basis for preferring any particular set of conditions for carrying out a large number of determinations, and considerations of a practical nature governed the choice. Several of the compounds which it seemed desirable to study are so sparingly soluble in the buffer solution employed that it would not be possible to adopt the concentrations called for by the higher ratios. Thus in all subsequent evaluations of critical potentials the 1:1 ratio was adopted.

General Application of the Method.—On the basis of the orienting experiments which have been described, the following general procedure was adopted as being that most suitable for a wide survey of oxidizable substances. A solution of 0.0006 equivalent of the completely oxidized or reduced form of the reference system in 220 cc. of the alcoholic buffer solution (or in a mixture of 200 cc. of this solution and 20 cc. of water) was titrated to the potential desired with a suitable reagent. The substance to be studied in amount equivalent to the oxidant present, and dissolved in 30 cc. of buffer solution, was added, the percentage oxidation at five minutes was determined and the critical potential found in the usual way.

In studying ortho or para dihydroxy or diamino compounds, and substances of similar structure, it was assumed that the primary oxidation is of the 2-hydrogen type. Thus for each mole of a complex metal cyanide one-half mole was taken of catechol, pyrogallol, *p*-phenylenediamine, 1,5- and 2,6-dihydroxynaphthalene, *p,p'*-dihydroxystilbene, *p*-hydroxyphenylglycine and similar substances. The percentage oxidation in these cases was calculated on the basis of the assumption made.

A complete record of the experiments will not be given, but rather a summary of the significant results. In Table XIII, under the symbol E, there is given for each compound the initial potentials of the reference system, corrected for the drop observed when no progressive reaction occurred, and the corresponding percentages of oxidation observed in five minutes ("% Oxid."). The correction applied ("Corr.") and the critical oxidation potential, E_c, follow these figures. In the one or two cases in which it was not possible to determine the magnitude of the correction term, this was estimated from the behavior of similar compounds under similar conditions.

Though experiments quoted above indicate that about the same amount of α-naphthol is oxidized at a given potential by either potassium ferricyanide or potassium tungsticyanide, there is little assurance that this would be true in every case, and thus it was considered advisable to use a single reference system in determining the potential for each substance studied. The nature of the reference system employed is indicated in the heading of each small table, using the abbreviations listed in Table X.

The majority of the compounds studied are simple substances which are easily obtainable in a state of purity. Many of them, purchased from the firms of Kahlbaum, Schuchardt and Eastman, required no further purification. A few of the compounds have been described in recent publications of the author, others were supplied by the E. I. du Pont de Nemours & Company, while some were prepared according to known methods. In each case the sample was purified until it corresponded to the literature description of the pure material, and it does not appear necessary to record the physical constants. While the present method of determining oxidation potentials makes some use of the velocity of oxidation, it is very improbable that catalysts would appreciably influence the results. It is conceivable that one sample of a phenol might contain a catalyst which would accelerate the oxidation and that the slope of the percentage oxidation–potential curve would be different from that obtained with the pure compound, but the extrapolations to the point of zero oxidation should give very nearly the same results in each case.

While no special effort was made to exclude all traces of catalytically active impurities, it was absolutely essential to free the sample of more easily oxidizable substances. Thus preliminary experiments with commercial samples of the monomethyl ethers of the dihydroxybenzenes gave irregular results which were very probably due to the presence of a small amount of unmethylated material. When this was removed by extracting the ethereal solution of the substance with water, and then distilling and crystallizing the product, no irregularity was noted.

Measurements at 40°.—At the beginning of this research we hoped to provide for the study of even very sparingly soluble substances, and with this end in view the early procedure called for a relatively small volume (100 cc.) of buffer solution as solvent for the reference system (in 20 cc.), while the sample was dissolved in 130 cc. of the buffer.

A temperature of 40° was chosen in order to further increase the amount of material which could be accommodated. It was observed, however, that the potential of the molybdenum system often dropped as much as 15 mv. even when no progressive reaction occurred, and blank determinations soon showed that the drop in potential is largely the result of dilution. The potential of the molybdenum system was found to become less positive by about 12 mv. when the volume was increased from 120 cc. to 250 cc., and the change was independent of the ratio of oxidant to reductant. Since the ratio of the concentrations of the two components of the system is not influenced by dilution, the observed change in potential must be the result of a change in the ratio of their activities, and the direction of the effect is such as to indicate that the activity coefficient of the reductant increases more rapidly with dilution than that of the oxidant. The same was true of the ferri–ferrocyanide system, though the effect was less pronounced. The decrease in potential on dilution ranged from 1.5 mv. to 7.5 mv. as the ratio of oxidant to reductant varied from $^1/_9$ to 9.

When determinations of critical oxidation potentials were carried out it was found that the rapid decrease in potential to a constant value, which was observed at a region well below that at which a progressive reaction occurred, was always somewhat greater than that attributable solely to dilution. The components of the system thus appear to be affected by the oxidizable substance even when no oxidation occurs. While no means of eliminating this effect was found, the effect of dilution was reduced to a minimum in the determinations which have been described above. The original procedure was thus soon abandoned, for the large correction term which had to be applied to the initial potentials rendered the results subject to an unnecessary source of error. The few determinations which had been made before the method was modified have been summarized in Table IV of the Theoretical Part.

It should be stated that when working at 40° the velocity of oxidation is much greater than at the lower temperature. Consequently the time interval over which the fall in potential of the reference system was observed was made shorter, namely one minute instead of five minutes. The reference systems used were those of iron, molybdenum and tungsten, and their potentials at 40° are recorded in Table X.

Normal Oxidation–Reduction Potentials of Stable Systems.—In the course of this survey of oxidizable substances a constant watch was kept for electromotively active oxidation–reduction systems of sufficient stability to permit direct potentiometric study. Such a system may reveal itself in the determination of the critical oxidation potential by causing a very rapid drop in potential to a constant value. A few such cases were discovered, and it was found that the reductant could be titrated in the ordinary way with molybdicyanide. Sharp, reproducible potentials were established in the mixtures of the oxidant and reductant and there was no drift in potential which would indicate a destruction of the oxidant. A summary of the results for this group of substances is given in Table XIV, and two more compounds of this type have been listed in Table X. The figures represent the averages of several closely agreeing determinations. The solutions of the amines (0.0003 mole in 220 cc.)

TABLE XIV

NORMAL POTENTIALS (25°) IN NEUTRAL ALCOHOLIC SOLUTION

System, named as reductant	E_0, v.
p-Aminodiphenylamine	0.751
Hydroquinone	.715
p-Hydroxyphenyl-β-naphthylamine	.701
p-Methyl-*p*′-hydroxydiphenylamine	.684
p,*p*′-Dihydroxy-diphenylamine	.656
2,4-Diamino-4′-hydroxydiphenylamine	.568
β-Phenylhydroxylamine	.562

were prepared from freshly crystallized or distilled material and kept in an atmosphere of nitrogen. In the case of *p*-methyl-*p*′-hydroxydiphenylamine it was necessary to reduce catalytically a small amount of the oxidant which was found to be present.

The potential of the quinone–hydroquinone system was determined by the use of quinhydrone. The potential of such a solution is initially 5–10 mv. above the normal potential. Within one to two minutes it falls to a point where it remains constant for about six minutes, and then it falls off at the rate of about seven mv. per hour. The reading during the period of constancy is reproducible on various electrodes and with different preparations, and this point was taken as the normal potential. On titration of hydroquinone with potassium molybdicyanide, the electrode equilibrium is established slowly and the results are not satisfactory.

β-Phenylhydroxylamine behaved in a very curious manner. The potential of a fresh solution was about 20 mv. higher than the normal potential of the nitrosobenzene–β-phenylhydroxylamine system, whereas one would expect the solution containing none of the oxidant to have a potential considerably below the point of half-oxidation. The initial potential was not constant, but fell off fairly rapidly as the solution was stirred and treated with a steady stream of nitrogen, and in about an hour a fairly constant level had been reached which was 47 mv. below the normal potential. A titration commenced after this or a longer period of time gave perfectly normal results, though electrode equilibrium was somewhat slow. After each addition of molybdicyanide the potential reached a constant value (from below) only after about three minutes. On the other hand, when the titration was commenced ten minutes after preparing the solution, that is, before the low, constant level had been reached, the same amount of oxidizing agent was consumed, but the curve was flat, as though some oxidant were present at the outset, and the value found for E_0 was about 10 mv. too high.

Summary

The unstable systems formed by phenols or amines and the free radicals formed as their immediate oxidation products have been characterized

by a new term called the critical oxidation potential. This is the potential of some oxidizing solution which will cause a certain small amount of the amine or phenol to become oxidized in five minutes when equivalent amounts of the sample and of the oxidizing agent are employed. This value, which may be determined with reasonable accuracy, represents the potential at which the velocity of oxidation becomes vanishingly small, and hence the result is influenced by the reaction rate to an extent which is insignificant. This has been demonstrated experimentally, for the critical oxidation potential bears a definite relationship to the normal potential, and it is influenced no more by temperature changes than is the latter quantity.

The critical oxidation potentials of over seventy compounds have been determined and many relationships, conclusions and deductions have been pointed out in discussing the results.

SOME ERRORS IN ANALYTICAL BROMINATION. THERMAL CLEAVAGE OF HYDROGEN BROMIDE FROM BROMINATED SUBSTANCES. A NEW PROCEDURE FOR DETERMINATION OF ORGANIC UNSATURATION[1]

BY H. M. BUCKWALTER AND E. C. WAGNER

RECEIVED AUGUST 20, 1930 PUBLISHED DECEMBER 18, 1930

I. Introduction

Halogenation methods for the determination of organic unsaturation are in general referable to three types, based upon the nature of the agent and the medium: (1) iodine–halide methods, such as those of Hübl, Wijs and Hanus, conducted in non-aqueous solvents;[2] (2) bromination in non-aqueous solvent, especially carbon tetrachloride, the best-known method being that of Schweitzer–Lungwitz–McIlhiney;[3] (3) the bromide–bromate method, conducted in the presence of water, and due to Koppeschaar.[4]

The last method has been applied to determine unsaturation,[5] but is most useful in the analysis of phenols and aromatic amines.[6]

A useful classification of the non-aqueous methods differentiates those which permit determination of only the total halogen consumed and those which attempt its distribution into halogen used in addition and that used in substitution. Methods of the first kind (Hübl, Wijs, Hanus) employ what are probably less severe halogenating agents, especially iodine halides, and short periods of halogenation when possible, with exclusion of light, to minimize substitution. They are satisfactory only when complete addition, without substitution, can be effected under these conditions,' and may not be applicable to compounds whose unsaturation is for any reason less accessible to halogenation.[8] In methods of the second type the extent of substitution is determined by the device of titrating the hydrogen bromide of substitution.[9]

The sample, in an iodine flask, is treated with a measured excess of a standard solution of bromine (or iodine chloride or bromide) in carbon tetrachloride. After a suitable interval (thirty minutes to eighteen hours) potassium iodide solution is introduced, and the liberated iodine, equivalent to the excess halogen, is titrated with thiosulfate. Potassium iodate solution is then introduced, and the liberated iodine, equivalent to the hydrogen bromide of substitution, is titrated. The total halogen consumed. less twice that represented by the second titration, is that taken up by addition.

The only really satisfactory solvent appears to be carbon tetrachloride, in which halogenation is irreversible,[10] and which when properly purified is neutral and not attacked by the dissolved halogen.[11] The greater effectiveness of iodine halide in carbon tetrachloride solution (method of Marshall[2]), compared with that of the solution in acetic acid, was shown by Boeseken and Gelber.[8] Bromine in carbon tetrachloride appears to be equally vigorous. The fact that the increased saturating power of

[10] In dissociating solvents, including acetic acid, Boeseken and Gelber (Ref. 8) found addition of iodine chloride to be reversible, especially in the neighborhood of negative groups.

[11] Bromine dissolved in chloroform, ethylene bromide or in acetylene tetrabromide generates hydrogen bromide so rapidly that such a reagent cannot be used satisfactorily as a standard solution.

these reagents is accompanied by an increased ability to cause substitution appears to be not a drawback, since the extent of the substitution can be determined.

Both addition and substitution of halogen are influenced, and in ways not always known or predictable, by a variety of factors, including not only time, temperature and quantity and concentration of halogen, but also identity of solvent, condition in which halogen is present, proximity (to the unsaturated condition) of strongly polar radicals or other structural influences, and presence of substances which may operate catalytically. Addition of bromine to unsaturated acids in carbon tetrachloride, according to Williams and James,[12] is catalyzed by traces of hydrogen bromide or water. Davis[13] found light, low temperature and moisture to favor addition of bromine to olefins in carbon tetrachloride. Addition of bromine is retarded by proximity of negative groups,[14] though this influence is not always consistently shown.[15] Difficulty may also be encountered in halogenation of conjugate systems whose saturation is only partial.

Even if it is assumed that addition is initially complete, there are still to be considered several secondary sources of error in methods such as those of Marshall and McIlhiney, due to the reagents added to perform the titrations of the analysis. Several workers[16] have observed replacement of chlorine or bromine by iodine in contact with alkali iodide, in certain cases with subsequent cleavage of iodine to restore the original unsaturation, this effect being favored by negative groups (e. g., —COOH, —$COCH_3$, —COOR, —C_6H_5). Contact of the halogenated sample with water, if followed by hydrolysis, will cause low results by methods in which the HX of substitution is determined.[17] Boeseken and Gelber[S] found that after addition of iodine chloride to certain a,@--unsaturated acids, reversible cleavage of hydrogen chloride became measurable in contact with water, the α-iodo-β-lactone being formed. In the analysis of unsaturated esters, partial ester hydrolysis, promoted by the HX of substitution, would liberate acid which might interfere as indicated below. The presence of water further admits possibility of oxidation by HOX.[18]

[18] Kolthoff, "Volumetric Analysis," John Wiley and Sons, Inc., New York, 1928, Vol. I, p. 198.

A third source of error is the presence of an acidic function in the substance analyzed. Such acidity would in general be increased by halogenation, and would affect the results to whatever extent the halogenated sample is able to disengage iodine from iodide–iodate solution. Other errors include possible oxidation by iodate, rupture of a chain or bridge followed by additive halogenation of the nascent free ends, and finally the formation of perhalides.[19]

A hitherto unexplained feature of the McIlhiney or Marshall method is that with certain substances the calculated addition values are negative, i. e., the HX found, when multiplied by 2, indicates the halogen consumed in "substitution"[21] to be more than the total halogen brought into reaction. While in some cases negative error is undoubtedly due to incomplete addition, this cannot safely be assumed from the fact that the calculated addition value is low (unless the total consumption of halogen is also low), for the reason that errors due to certain of the secondary interferences mentioned above would also cause low results even when addition was initially strictly quantitative. With existing procedures it is often impossible to determine whether an error is due to unsuccessful halogenation or to secondary reactions during the titrations. Since the latter are caused by contact of the halogenated sample with water, iodide and iodate, it was concluded that a satisfactory study of analytical halogenation could best be made if such contact were avoided. To this end there was developed the aeration procedure for bromination, now to be described.

II. Aeration Method for Determination of Unsaturation by Bromination

Bromination by a solution of bromine in carbon tetrachloride was effected in an evolution apparatus (Fig. *2)* at a suitable temperature, and the excess bromine and the hydrogen bromide produced were removed in a current of dry nitrogen, absorbed in potassium iodide solution, and determined as usual. Except in the case of very volatile substances this procedure avoided contact of the halogenated sample with water, iodide and iodate. In experimental trials of the new procedure, brominations were conducted at 75°, at 20–25° and at 0°. About forty organic substances of various kinds, both unsaturated and saturated, were examined. Comparative analyses were in all cases made by the method of McIlhiney, the bromination period being arbitrarily set at the maximum (eighteen hours).

Apparatus and Reagents

The apparatus consisted of an all-glass evolution flask with a trapped receiver (Fig. *2).* For the aeration, nitrogen from a cylinder was passed through Drechsel bottles charged with (1) alkaline pyrogallol, *(2)* concd. sulfuric acid and (3) granular calcium chloride.

---

[19] Kolthoff, Ref. 18, p. 200.

The bromine solution was about 0.28 *N*, containing 7 cc. of bromine per liter of carbon tetrachloride. The best procurable carbon tetrachloride may absorb some bromine and form some hydrogen bromide. It was therefore refluxed for several hours with bromine, cooled, and washed with sodium carbonate solution, dried well over calcium chloride, and distilled through a 5-stage Snyder column, the first and last portions being rejected. It appears that the drying must be thorough, as the presence of moisture was perhaps the cause of subsequent formation of hydrogen bromide in some solutions.

The bromine solution was measured with a 25-cc. Lowy automatic pipet, filled by pressure as suggested in Fig. 1 to avoid the inconvenience and the small loss of bromine involved in filling the pipet by suction.

To standardize the bromine solution, 25 cc. was pipetted into 150 cc. of 15% potassium iodide solution in a 500-cc. iodine flask, and the iodine was titrated with 0.2 *N* thiosulfate, 5 cc. of 0.5% soluble starch indicator being added near the end-point. There was added 10 cc. of 2% potassium iodate solution, and any iodine liberated was titrated. The liquid was shaken vigorously in the stoppered flask near the end of each titration to extract iodine completely from the carbon tetrachloride layer. The second (acid) titration was generally small and sometimes zero.

The 0.2 N sodium thiosulfate was prepared in the usual way, and was standardized against potassium iodate.[20]

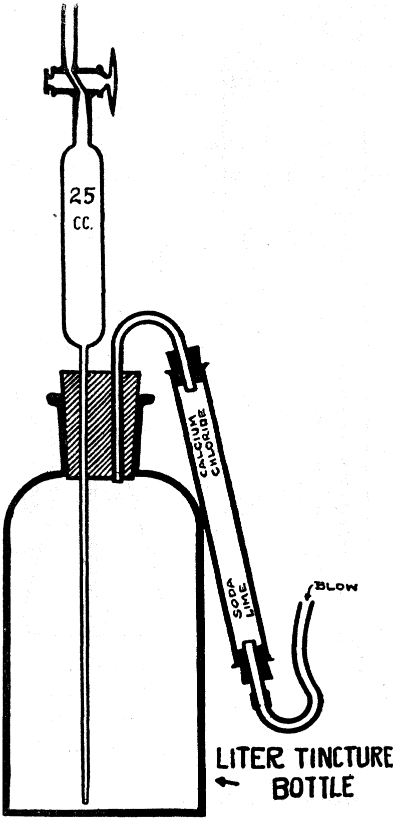

Fig. 1.

Procedure.—Receiver A was charged with 100 cc. of 15% potassium iodide solution, and trap B with 10 cc. of the same, together with about 0.5 cc. of the standard thiosulfate solution, the last being accurately measured from a buret (and its volume finally added to the titration of excess bromine). The sample, in a small glass cup if non-volatile, or in a thin glass bulb or from a Lunge weighing-pipet if a volatile liquid, was introduced into the bromination flask C, and dissolved in 5 cc. of pure carbon tetrachloride. The apparatus was assembled and 25 cc. of the bromine solution introduced by means of the automatic pipet, the tip of which was thrust well into the constriction of D. A gentle suction applied at the trap quickly drew the solution into the flask without loss of bromine. A slow stream of nitrogen (about 20 bubbles per minute) was passed during the ensuing bromination period, at the end of which the flow of gas was increased to about 150–200 bubbles per minute in order to transfer excess bromine, and hydrogen bromide of reaction, as rapidly as possible into the receiver. Repeated blank trials had shown that this operation involved no loss of bromine. The time required for aeration at room temperature was about three and one-half hours.

For bromination at 75° the flask C was immersed, almost to the level of the liquid

---

[20] McNabb and Wagner, *Ind. Eng. Chem., Anal. Ed.*, **1**, 32 (1929).

within, in a water-bath at that temperature. During the aeration, which at 75° required only about thirty minutes, carbon tetrachloride was added at intervals to replace that which distilled.

For bromination at 0° the flask C was surrounded by ice, the bromine solution introduced and chilled (with the apparatus assembled), and the sample, in a cup or bulb, introduced into D and washed into the flask with chilled carbon tetrachloride (the bulb being first broken with a glass rod). The aeration at 0° required about six hours.

When the aeration was complete, the apparatus was disconnected at E, the contents of the trap transferred to the main receiver, and the excess bromine and the hydrogen bromide of reaction determined as in the standardization. To calculate, the acid titration, less that of the standardization, was multiplied by 2 and subtracted from the volume of thiosulfate equivalent to the total bromine brought into reaction.

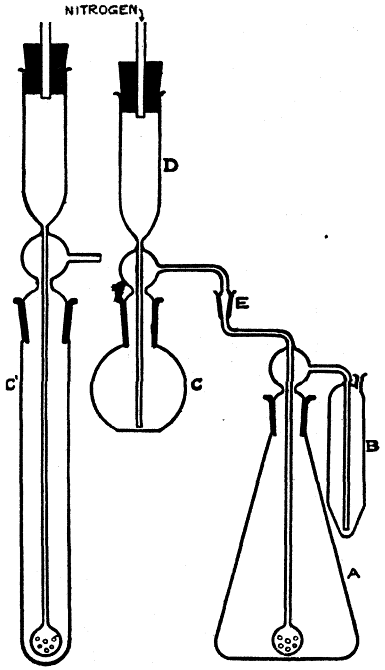

Fig. 2.—A, Receiver, 500-cc. cap.; B, trap, 25-cc. cap.; C, bromination flask, 100-cc. cap.; C′, modified form of C; D, funnel; E, ground joint.

Comparative Results by the Aeration Procedure and by McIlhiney's Method.—Results of comparative trials by the two procedures are grouped below according to the general types of compounds examined, or according to the point to be tested. The tables give total atoms of bromine consumed, atoms of bromine used in "substitution,"[21] atoms of bromine added, and percentage of bromine added, *i. e.*, the bromine number. Check analyses by McIlhiney's method represent duplicates run not in the same series but on different days.

1. Determination of Unsaturation of Some Hydrocarbons.—Results for a number of unsaturated hydrocarbons of several types are given in Table I.

Comments.—A distinct temperature effect is shown for cyclohexene, phenanthrene, indene and especially for retene. The case of pinene, for which both methods yielded values converging upon three atoms of bromine added, recalls similar results obtained by Ingle[1] and by Klimont,[4] and also by Wallach.[22] The facts appear to suggest rupture of the isopropyl bridge.

---

[21] As this word is used here and elsewhere in this paper when enclosed in quotation marks, it refers to the apparent substitution indicated by analysis. This is calculated from the hydrogen bromide liberated, whatever its source. When the hydrogen bromide found is believed to include that actually due to substitution and some due also te secondary cleavage of hydrogen bromide during the bromination, the process will be termed "substitution."

2. Determination of Unsaturation of Some Compounds with Acidic Character.—Since an iodide–iodate solution is sensitive to acids generally, the effect of an acidic function in the substance analyzed, as was mentioned in the introduction, is to increase the acid titration (after addition of iodate), and to decrease the addition value by double this error. In some cases such acidic function will register quantitatively its acidity, for which deduction can be made in the calculation. If the acidity, however, is of a low order it will introduce an indeterminate error, such irregularity being sometimes suggested by an unusually marked impermanence of the second end-point. Since the causes for error in the bromination of acidic substances are, in general, operative only in the presence of water, etc., such substances are well adapted to test the predictable advantages of the aeration procedure over that of McIlhiney. Results for some unsaturated compounds with acidic function are listed in Table III.

Comments.—The resistance of crotonic acid to halogenation is shown by the ineffectiveness of bromination at room temperature. In McIlhiney's

[a] For 1 double bond and molecular weight 302. [b] According to McIlhiney.[2]

method the sample indicated its acidity quantitatively in contact with aqueous iodide–iodate, the titration due to this effect being deducted to obtain the stated substitution value zero. With cinnamic acid the total consumption of bromine in the McIlhiney method was the theoretical, and results would be excellent if the acid titration were ignored. In contact with water, iodide and iodate, however, the dibromide appeared not only to exert its effect as an acid, but also to suffer extensive hydrolytic breakdown.[24]

In the examination of abietic acid the negative and erratic results obtained by McIlhiney's method, and the rapid and persistent return of color after the acid titration seemed at first to be clear indications of interference by water, etc. The inadequacy of this explanation is shown by the fact that the aeration method at higher temperatures and in absence of water yielded negative values just as large. The improvement between 75 and 0° is relatively enormous, and the largest positive value obtained may still be a partial one, a temperature of 0° being possibly too high for normal bromination. The results indicate roughly one double bond, which duplicates the findings of certain other workers.[25] The behavior of rosin, as would be expected, is similar to that of abietic acid.

3. Bromination of Some Other Compounds.—Results for several other compounds of types not yet considered are given in Table IV. **Ex**amination of cumene, cymene and menthane was undertaken to study the behavior of the isopropyl group, since it seemed possible that bromination of its tertiary carbon might yield a condition susceptible to removal of bromine by hydrolysis, or to cleavage of hydrogen bromide.

Comments.—The addition of bromine to menthane, cumene and cymene was in all cases slight, the titrations being small (0.18 and 0.31 cc. for menthane). The negative values for cymene by McIlhiney's method were probably due to hydrolytic action. No connection between structure and behavior upon bromination is obvious in the rather unsatisfactory results obtained for these hydrocarbons.

III. The Cleavage of Hydrogen Bromide from Brominated Compounds

The bromine values obtained by the aeration procedure were for certain substances remarkably affected by temperature, the indicated addition decreasing with higher temperatures and even becoming negative in several cases. Lower temperature appeared to favor normal bromination, and was effective in producing normal values with some substances whose bromine numbers at room temperature or at 75° were useless. The total consumption of bromine (addition plus "substitution"), on the other hand, was much increased by higher temperature. Briefly stated, *at higher temperature (e. g., 75°), when the indicated addition was at a minimum or was even negative, the total amount of bromine consumed was at a maximum.* This is illustrated by the following data taken from previous tables.

It seems unlikely that under conditions of maximum consumption of bromine an olefinic condition could escape initial saturation, but even if this were admitted it would provide no explanation for negative addition values obtained in the absence of water. A negative value can here mean only one thing: *hydrogen bromide is being produced in excess of that properly considered as hydrogen bromide of substitution.* Since the aeration procedure excluded contact of the sample with water, iodide and iodate, the production of hydrogen bromide due to hydrolysis or to other causes mentioned in the introduction can be dismissed from consideration. There remains the conclusion that hydrogen bromide may have split out

TABLE V

RELATIONSHIP BETWEEN EXTENT OF "SUBSTITUTION" AND INDICATED ADDITION VALUE

Compound	Temp., °C.	Indicated addition, % Br	Indicated "substitution," % Br
Retene	75	−11.8	255.2
	0	+67.0	129.0

	0	+ 0.1	0.2

spontaneously from a heavily brominated molecule due to instability at the existing temperature. To test this conclusion, samples of several substances were brominated at lower temperatures, freed from bromine and hydrogen bromide in the usual way, and were then heated for thirty to forty-five minutes in the aeration apparatus, any volatile products of this operation being collected in potassium iodide solution in the receiver. The solution in the receiver was treated with starch indicator (no color, showing no free bromine retained in the sample or split out on heating), iodate solution was added, and any liberated iodine was titrated. Excepting menthane, the substances so tested, exhaustively brominated at 0°, yielded hydrogen bromide when heated to 75°, and several lost hydrogen bromide on warming only to room temperature. The hydrogen bromide obtained in these experiments was not merely a qualitative trace, but in several cases approximated in amount the excess hydrogen bromide indicated by the abnormal results of analysis at the higher temperature, though no attempt was made to complete the elimination of hydrogen bromide.

The hydrogen bromide split out of two specimens of abietic acid brominated at low temperature and heated to 75°, if multiplied by two as in the analysis, and subtracted from the addition values at 0°, changes these to —59.8 and —38.6%. Similarly the "corrected values for rosin become —24 and —1.2. The addition value for retene is in the same way reduced from 67 to 23, and that for phenanthrene from 90.8 to 60.8. It is, therefore, shown that the abnormal addition values obtained by bromination at too high temperature may be approached artificially by brominating at low temperature and then splitting out hydrogen bromide by heat.

The cleavage of HX from halogenated organic molecules is, of course, not a new idea,[26] but its possible interference with analytic brominations appears to have been overlooked, That the accumulation of negative atoms or radicals inclines molecules to instability and to cleavage is well known.[27] Cleavage of hydrogen bromide during analysis involves dehydrogenation (oxidation) of the molecule by bromine. The separation of some carbon when paraffins are chlorinated, and especially when methane and chlorine are exploded (with formation of hydrogen chloride in both cases), and many condensations by oxidation, are similar dehydrogenations. So also are such reactions as the formation of hydrogen iodide by heating rosin and iodine,[28] and of hydrogen sulfide by heating paraffin and sulfur.

The simplest result of hydrogen bromide cleavage would be the introduction of a double bond, and under conditions suitable for the saturation of double bonds. A more intimate knowledge of such reactions may show that double bonds are thus introduced in positions inaccessible to subsequent bromination, due to proximity of negative radicals, including bromine atoms firmly held,[29] or to a structural condition such as conjugation. Whatever the explanation, the fact of hydrogen bromide cleavage appears to be established, and its importance in analytic bromination is obvious.

IV. Conclusion

Tables I–IV show that in all but a few cases the aeration method, under suitable temperature conditions, yielded better results than did McIlhiney's method. It is to be noted that by proper temperature control of the brominations negative results were completely eliminated.[30]

The aeration procedure has yielded an explanation for the low or negative bromine values obtained for certain substances, since by exclusion of other sources of error it has brought into prominence the spontaneous cleavage of hydrogen bromide (other than that properly attributable to substitution) from such substances when exhaustively brominated at a

---

[26] Kharasch and Darkis [*Chem.* Rev., 5, 601 (1928)] cite the thermal cleavage of hydrogen bromide from triphenylethylene dibromide; and the ready loss of HX from the 9,10-anthracene dihalides is familiar.

[27] See e. g., Henrich (Johnson–Hahn), "Theories of Organic Chemistry," John Wiley and Sons, Inc., New York, 1922, p. 581.

[28] Kastle and Bullock, Am. *Chem. J.*, 18,105 (1896).

[29] *Cf.* Cohen, "Organic Chemistry," Arnold and Co., London, 1928, Vol. I, pp. 125–128.

[30] The accuracy of McIlhiney's method in difficult cases might be improved by operating at 0°, but some error would persist with compounds which before or after bromination are reactive with aqueous iodide–iodate. This interference, while often not important, is apparently quite general in analyses by the McIlhiney procedure, as is shown by the return of the starch–iodide color after the end-point of the acid titration. This secondary liberation of iodine was in several cases (controlled by blanks) observed to continue for weeks.

too high temperature. This conclusion was verified by experimental elimination of hydrogen bromide from several substances brominated at low temperature and then warmed to 75°.

The practical application of the findings by the aeration procedure requires the use of bromination temperatures low enough to prevent excessive consumption of bromine by reactions other than addition, and thereby to prevent or minimize spontaneous cleavage of hydrogen bromide in excess of that actually due to substitution. Some substances brominate normally at 75°, others at room temperature, while others yield entirely meaningless results unless brominated near 0°, which for some substances is perhaps still too high a temperature. The new procedure permits the necessary temperature regulation, and appears to be unique in that it permits bromination at elevated temperature and avoids complications due to contact of water, iodide and iodate with the brominated sample. There is now under investigation a new aeration apparatus designed to effect bromination with a minimal excess of bromine, thus decreasing the quantity of bromine to be transferred by aeration and shortening the analysis, especially when low temperatures are used.

PSEUDO BASES. I. CERTAIN N-METHYLPYRAZINIUM SALTS AND THEIR CORRESPONDING BASES

BY JOHN G. ASTON

RECEIVED AUGUST 27, 1930 PUBLISHED DECEMBER 18, 1930

The work of Hantzsch and of Decker[1] has demonstrated that a quaternary base of the type $[-N^{+}R{=}C<]\,OH^{-}$ in which the $N{=}C$ grouping is part of a closed ring (e. g., N-methylpyridinium hydroxide) may exist in two tautomeric modifications. One of these with the formula written above is a quaternary ammonium compound and therefore in aqueous solution necessarily a strong electrolyte.[2] The other weakly basic modification has the formula  $\underset{\displaystyle OH}{-NR-\overset{}{C}<}$ and has been called by Hantzsch a "pseudo base;" it is a tertiary amine and has, to a certain extent, the properties of a carbinol. We shall speak of the equilibrium mixture between these two forms as a "pseudo basic system."

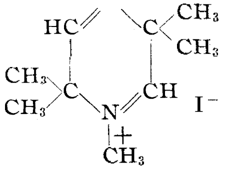
[1] Hantzsch and Kalb, Ber., 32, 3109 (1899); Decker, J. *prakt. Chem.*, 192, 425 (1911).

[2] Lewis, "Valence and the Structure of Atoms and Molecules," The Chemical Catalog Company, New York, 1923, p. 111.

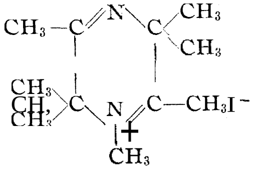
Although certain evidence regarding the properties of and the equilibrium between the two forms has been obtained in the case of some N-methylated pyridines, quinolines and acridines and of cotarnine and berberine,[1] wider information upon a variety of simpler compounds is necessary in order to make any generalizations regarding the effect of structure on the properties of a pseudo basic system.

In order to study the effect of ring conjugation in such a system it was decided to prepare and investigate certain pyrazine derivatives in which a pseudo basic system formed part of the pyrazine nucleus and to study the effect of reduced conjugation caused by partial hydrogenation of the nucleus.

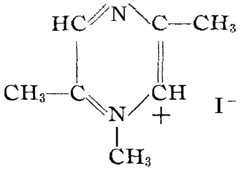
Two salts, 1,2,2,5,5-pentamethyldihydropyrazinium iodide (Formula I) and 1,2,2,3,5,5,6-heptamethyldihydropyrazinium iodide (Formula II) were prepared by the action of methyl iodide on the corresponding dihydropyrazines.



I



II



III

In addition, 1,2,5-trimethylpyrazinium iodide (Formula III), already described by Stoehr,[3] was prepared and studied. Bases were prepared from these salts by the action-of potassium hydroxide.

A quarternary salt of the general type $\left[R{-}N{=}C{-}CH_2R\right]^+X^-$ in which the dotted line represents the rest of a cyclic system, might yield the true base, A, $\left[R{-}N{=}C{-}CH_2R\right]^+OH$ or the pseudo base, B, $R{-}N{-}C(OH)CH_2R$. The pseudo base might lose water to form C, $R{-}N{-}C{=}CH{-}R$, or D, $\left[R{-}N{-}C(CH_2R){-}\right]_2O$. In addition the pseudo base may split at the N—C linkage to form E, $RNH\quad COCH_2R$. The form C can also be formed directly from the true base A by a type of change discussed later. A base of the general formula D was obtained by Hantzsch and Kalb[1] as an anhydride of N-methylquinolinium hydroxide. Anhydro bases of the form C are discussed by Decker.[4] The salt I cannot yield a base of the type C. With this exception all five types of base might be yielded by any of the salts.

By the addition of potassium hydroxide to 1,2,2,5,5-pentamethyldihydropyrazinium iodide a base, 1,2,2,5,5-pentamethyl-6-hydroxypyrazine,

---

[3] Stoehr, *J. prakt. Chem*., **47**, 463, 470 (1893).

[4] Decker, *Ber.*, 38, 2493 (1905).

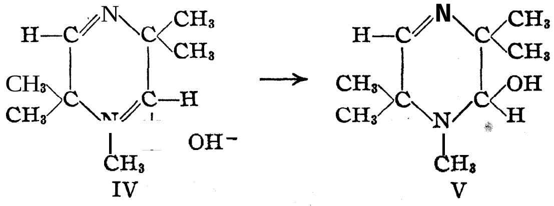
m. p. 110° (Formula V), was isolated. The base is of type B. It is associated in benzene but shows normal molecular weights in water. The normal molecular weight in water shows that the ring system is in all probability stable to water over at least short periods.

By the method of Kohler, Stone and Fuson[5] it was shown that the base reacted with slightly more than two molecules of methylmagnesium iodide per molecule and liberated one molecule of methane, which further points to the presence of the hydroxyl group.

It does not seem likely, in view of these results, that the base to which Formula V has been assigned has undergone ring fission to yield a base of type E, especially as in the open chain the remaining —C=N— would probably be hydrolyzed. Further, no carbonyl derivatives could be obtained from solutions of the base.

Measurement of the conductivity of a dilute solution of equimolar quantities of the iodide and sodium hydroxide by the method of Stewart and Maeser[6] for detecting association of hydroxyl ion showed that there was no strong base present even at 0° immediately after mixing, the base formed having $K_b < 3 \times 10^{-5}$.

In the pseudo basic system from salt I the equilibrium between IV and V is evidently established quite rapidly and is in the direction of the pseudo base, V.



When the base, V, was titrated in water solution with hydrochloric acid, using methyl orange as indicator, at first the neutralization was instantaneous and the indicator stayed yellow until one equivalent of acid per mole had been added. More acid then caused the indicator to turn red but upon standing the yellow color slowly returned. Further increments of acid caused the same effect and finally when two equivalents of acid had been added per mole the red color became permanent.

An explanation of this effect is that the base strength of the pseudo basic system involved in the equilibrium between IV and V is much less than that of the unmethylated nitrogen which is consequently titrated first. Upon adding a fraction of the second equivalent of acid the methylated nitrogen in the strongly basic form (IV) reacts, the methylated nitrogen in the pseudo basic form (V) being so weak that it reacts but slightly

---

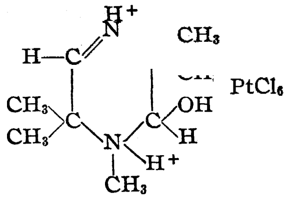
[5] Kohler, Stone and Fuson, This Journal, 49, 3181 (1927).

[6] Stewart and Maeser, *ibid.*, 46, 2583 (1924).

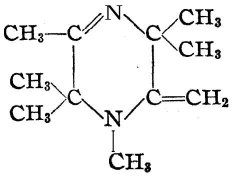
before the methyl orange changes to red. The system being now no longer in equilibrium, more pseudo base changes into the strong base, which reacts with the added acid and the system becomes basic, causing the reappearance of the yellow color.

As would be expected, the original iodide from which the base was prepared, when dissolved in water, produces a system in all ways similar to that produced by adding one equivalent of acid to the base, Addition of hydrochloric acid to the former produced the same changes as those produced by further increments of hydrochloric acid to the latter.

If the iodide of Formula I is changed into the chloride and treated with chloroplatinic acid, a chloroplatinate is obtained whose analysis corresponds to the Formula VI. The same platinum double salt is obtained from the base itself. The possibility that this salt is a hydrated form of the salt of the base IV is unlikely since it is obtained in better yields from solutions of the base in which V predominates.



VI

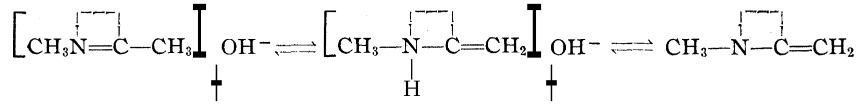


VII

By the addition of concentrated potassium hydroxide to a solution of heptamethyldihydropyrazinium iodide a liquid anhydro base of the type C (Formula VII) was obtained. It showed a normal molecular weight in benzene. This base dissolved slowly in water, yielding a strongly basic solution whose electrolytic conductivity corresponded to a base with a basic dissociation constant of $K_B = 4 \times 10^{-3}$, and was the same as that obtained for an equivalent mixture of original salt and sodium hydroxide after subtracting the conductivity due to the sodium iodide.

The second basic nitrogen in heptamethyldihydropyrazinium iodide was too weak to be titrated using methyl orange as indicator. When the base was titrated rapidly with 0.1 *N* hydrochloric acid using methyl orange as indicator, only one equivalent of acid reacted per mole, the second equivalent of base being too weak to react under these circumstances. Upon allowing a solution of the base, which had a slight excess of acid over one equivalent, to stand, none of the excess acid was used up even on standing. Solutions of the base in water to which no acid had been added underwent slow decomposition and upon titration, after standing, part of the second equivalent of basic nitrogen could be titrated to methyl orange. This pointed to cleavage of the ring in alkaline solution.

It seems necessary in this case to attribute the strong basicity to the methylated nitrogen, which can exist in the quaternary form because the unmethylated nitrogen is formally tertiary and has no possibility of becoming a quaternary base (except by the addition of hydrogen ion). A simple tertiary amine has not been found with $K_B > 10^{-3}$. It is reasonable to assume that the base (Formula VII) is formed from the quaternary base by the following mechanism



$$\left[CH_3N{=}C{-}CH_3\right]^{+} OH^- \rightleftharpoons \left[CH_3{-}\underset{H}{\underset{|}{N}}{-}C{=}CH_2\right]^{+} OH^- \rightleftharpoons CH_3{-}N{-}C{=}CH_2$$

If the pseudo base $\left(CH_3{-}N{-}COHCH_3\right)$ were an intermediate in the production of VII, this would mean that the system is in equilibrium with the pseudo base. Equilibrium with the pseudo base was attained in the basic system from 1,2,2,5,5-pentamethyldihydropyrazinium iodide and an extremely feeble basicity of the methylated nitrogen resulted. If the pseudo bases were in equilibrium with the system under discussion, a weak basicity would also be expected. However, the basic properties of the methylated nitrogen are, in this case, far from weak and therefore equilibrium with the pseudo base or any reaction involving it is thought unlikely. Equilibrium with the quaternary base is probably responsible for the strongly basic properties of VII.

Addition of chloroplatinic acid to concentrated aqueous solutions of the base yielded a chloroplatinate whose analysis corresponded to the chloroplatinate of a base of type B. This same platinum double salt was obtained when a concentrated heptamethyldihydropyrazinium chloride solution which had stood for several days was treated with chloroplatinic acid. It is probable, however, that these chloroplatinates are hydrated forms of salts of bases of type A, especially in view of the large yields (66%) in which it is obtained from the salt.

The above results show that when ring conjugation is absent the mere substitution of a simple methyl group on the carbon atom attached to nitrogen in the system $\left[CH_3\overset{|}{N}{=}\overset{|}{C}{-}\right]^{+} OH^-$ can give rise to a relatively stable anhydro base of type C.

Attempts to obtain a solid or liquid base from 1,2,5-trimethylpyrazinium iodide (Formula III) in a pure state have failed. However, certain evidence has been obtained that in water solution the base, immediately after liberation from the salt, is of the type A in rapid equilibrium with a very small amount of the pseudo base (type B), which slowly changes into an anhydro base of type D. This evidence will be presented in the second paper of this series, where a more detailed study of the equilibrium in and the mechanism of some of the above reactions, which further substantiates the conclusions reached in this paper, is presented.

Experimental

1,2,2,5,5-Pentamethyldihydropyrazinium Iodide.—Thirty-four and a half grams (0.25 mole) of 1,2,2,5,5-tetramethyldihydropyrazine and 34.0 g. (0.24 mole) of methyl iodide dissolved in 123 cc. of sodium-dried ether were allowed to react for thirteen days at room temperature. At the end of this time about 100 cc of dry ether was added and the mixture stirred. The crystalline salt was washed with dry ether; yield, 54.0 g. (0.193 mole) (80.4% of the theoretical); m. p., with decomp., 204°. The material was recrystallized by dissolving in methyl alcohol (1 7 cc. per g) heating to boiling to dissolve and while hot adding twice the volume of n-butyl alcohol. The salt crystallized on cooling, leaving a red solution. The red color is not due to iodine. The crystals were washed with ether; m. p., with decomp , 194". The lowered melting point on crystallization is peculiar.

Anal. Calcd. for $C_9H_{17}N_2I$: I, 45.3. Found: I, (Volhard), 44.69. Recrystallization did not alter this analysis.

1,2,2,3,5,5,6-Heptamethyldihydropyrazinium Iodide.—A solution of 12.2 g. (0.073 mole) of anhydrous hexamethyldihydropyrazine and 12.2 g. (0.069 mole) of methyl iodide in 40 cc, of sodium-dried ether was sealed up in a bomb tube and heated to 85–110° for three days. At the end of this time 100 cc. of dry ether was added to the contents of the bomb tube. The crystalline salt was filtered off and washed with dry ether; yield, 16.6 g. (0.054 mole) (78% of the theoretical); m. p. 249.5° with decomposition. The salt was recrystallized in substantially the same manner described for pentamethyldihydropyrazinium iodide using the same solvents. The mother liquor from the crystallization was also dark red; m. p. of recrystallized product, 249° with decomp

Anal. Calcd. for $C_{11}H_{21}N_2I$: I, 41.1. Found: I (Volhard), 40.4.

Recrystallization did not change this analysis. Rate of heating did not affect the melting point.

When the preparation of this compound was carried out by allowing the same quantities to stand at room temperature for eighteen days the yield was only 26% of the theoretical. Evidently the two extra methyl groups have a marked effect in slowing down the rate of addition of methyl iodide.

1,2,2,5,5-Pentamethyl-6-hydroxytetrahydropyrazine.—Fifteen grams (0.054 mole) of 1,2,2,5,5-pentamethyldihydropyrazinium iodide was dissolved in 30 cc. of water and 100 cc. of 33% potash was added with vigorous stirring. The oil which first separated crystallized to a crust which was filtered off by suction through a Witt plate without filter paper. The excess potassium hydroxide was removed by pressing on a porous plate. The material was dried over calcium chloride and dissolved in 17 cc. of hot benzene. To the hot filtered solution 5 cc. of ligroin (b. p. 40–60°) was added and the mixture shaken. Upon cooling crystallization took place. Finally, after cooling in the ice box, the crystals were filtered off and washed with petroleum ether; yield, 7.6 g. (0.045 mole) (83% of the theoretical); m. p. 108–110°. Further recrystallization in the same way did not alter this melting point.

Anal. Calcd. for $C_9H_{18}N_2O$: C, 63.50; H, 10.65; N, 16.48. Found: C, 63.78; 63.85; H, 10.75, 10.79; N (Dumas), 16.80. Molecular weight in water (freezing point): H_2O, 20.2 g.; sample, 0.3637, 0.3007; ΔT_F, 0.206, 0.160°. Calcd. for $C_9H_{18}N_2O$: mol. wt.. 170.2. Found: mol. wt.. 163, 170.

In Table I are given the results of molecular weight determinations on this compound in benzene. ΔT_F is the lowering of the pure solvent caused by the given total weight of added compound.

Behavior of **1,2,2,5,5-Tetramethyl-6-hydroxytetrahydropyrazine on Titration with Acid.**—Sample: 0.0993 g. of $C_9H_{18}N_2O$ in 50 cc. of water; indicator, methyl orange.

TABLE I

MOLECULAR WEIGHT DETERMINATIONS

Wt. of benzene, 17.4 g.	I	II	III	IV
Total wt. of added compound, g.	0.0698	0.1563	0.1996	0.3354
ΔT_F, °C.	.123	.221	.272	.334
Molecular weight	167	208	216	286.5

These results show that the compound is quite highly associated in benzene.

The solution was titrated dropwise with vigorous shaking, using 0.1339 *N* hydrochloric acid solution. After 6.3 cc. of acid had been added the indicator turned definitely orange but changed back to yellow in forty-five seconds. Further increments of acid changed the indicator to red but the yellow color returned after about five-minute intervals. After 8.65 cc. of acid had been added the indicator became permanently red. Calcd.: cc. of 0.1339 N HCl required for 1st equivalent. 4.35; 2d equivalent, 8.70.

Addition of excess acid and back titration with alkali to the orange-yellow end-point after allowing to stand for two hours showed that the total acid required by the compound was 8.72 cc. Equivalent weight, calcd., 85.1. Found: 85.0.

Behavior of 1,2,2,5,5-Pentamethyldihydropyrazinium Iodide on Titration with Acid.—A solution of 0.1970 g. of the salt in 50 cc. of water was titrated with 0.1339 N hydrochloric acid as in the above experiment. After 2.80 cc. of acid had been added the methyl orange changed from yellow to red and then, over a distinct time interval, back to yellow. After 3.53 cc. had been added, a 0.74-cc. increment of acid produced a red color which changed back to orange-yellow in about five minutes. This effect continued throughout the titration. After 5.60 cc. had been added the solution became permanently red. Back titration with alkali showed 5.42 cc. of acid to have been used (calculated, 5.25 cc.). Alkali equivalent to all the acid which had been added was introduced and the titration repeated after allowing to stand for seven minutes. After 3.16 cc. of acid had been added, a red color changing back to yellow appeared. The effect continued until all the added alkali had been used up. Unquestionably, the effect is reversible.

The Reaction of **1,2,2,5,5-Tetramethyl-6-hydroxytetrahydropyrazine** with **Methyl** magnesium Iodide.—The apparatus and method used was as described by Kohler, Stone and Fuson[6] with slight modifications.[7] To 0.0995 g. of compound was added 4.31 cc. of a 0.573 *M* solution of methylmagnesium iodide in isoamyl ether; 14.6 cc. of methane (corrected to S. T. P.) was liberated. The excess Grignard reagent upon treatment with water (4.05 cc.) yielded 25.1 cc. of methane (corrected to S. T. P.). Methane per mole of compound, 1.11 moles. Total CH_3MgI used per mole of compound, 2.31.

1,2,2,5,5-Pentamethyl-6-hydroxytetrahydropyrazine Chloroplatinate.—Thirty-four hundredths g. (0.002 mole) of **pentamethyl-6-hydroxytetrahydropyrazine** was dissolved in 5 cc. of water. Excess of 1 N chloroplatinic acid was added. The precipitated chloroplatinate was insoluble in hot alcohol and in hot water and could not be crystallized; yield, 0.74 g. (0.00127 mole) (63% of the theoretical); m. p. (with decomp.) 282°. The temperature of the bath in which this salt decomposed in ten seconds was 320°.

Anal. Calcd. for $C_9H_{20}N_2O{\cdot}PtCl_6$: Pt, 33.66. Found: Pt, 33.88.

By allowing the base to stand with hydrochloric acid for twenty minutes before adding the chloroplatinic acid, the above yield was reduced to 30%.

The same platinum double salt could be obtained from 1,2,2,5,5-tetramethyldi-

---

[7] We wish to thank Mr. J. D. Pickens, Research Fellow in Chemistry at The Pennsylvania State College for these results.

hydropyrazinium iodide. A solution of 1.4 g. (0.005 mole) of 'the salt in 10 cc. of distilled water was stirred with 0.01 mole of silver chloride for sixteen hours. The chloroplatinate was precipitated with excess *M* chloroplatinic acid from the filtered solution of the chloride; yield, 0.3 g. (0.00052 mole) (10% of the theoretical); m. p. with decomp. 284–285° (started with bath at 130°). In the bath at 320° it decomposed in ten seconds.

Anal. Calcd. for $C_9H_{20}N_2O \cdot PtCl_6$: Pt, 33.66. Found: Pt, 33.65.

The two salts were unquestionably identical.

1,2,2,3,5,5-Hexamethyl-6-methylenetetrahydropyrazine.—Fourteen grams of heptamethyldihydropyrazinium iodide was dissolved in 35 cc. of water and 62 cc. of 40% potassium hydroxide was added. The non-aqueous layer was separated and dried for two hours over potassium hydroxide sticks and for one hour over anhydrous potassium carbonate. The filtered liquid was distilled *in vacuo* under 6.5 mm. pressure and the distillate collected in two portions: (1) 70 (about)–78.°, 1.1 g.; (2) 78.0–78.2°, 5.4 g. Both fractions were colorless; total yield of both fractions, 6.5 g. (79% of the theoretical). The fraction of b. p. 78.0–78.2° was used for analysis, molecular weight determinations, etc.

Anal. Calcd. for $C_{11}H_{20}N_2$: C, 73.28; H, 11.18. Found: C, 72.75, 73.08; H, 10.76, 10.83. *Molecular weight* by freezing point lowering in benzene: C_6H_6, 17.4 g.; sample, 0.1580, 0.1986 g.; ΔT_F, 0.261, 0.325". Mol. wt. calcd. for $C_{11}H_{20}N_2$: 180.2. Found: 178.2, 179.9.

The base undergoes decomposition slowly at room temperature to yield a red viscous oil.

Titration of 1,2,2,3,5,5-Hexamethyl-6-methylenepyrazine with Hydrochloric Acid.—The base was dissolved in 50 cc. of water and titrated immediately and rapidly to the yellow-orange end-point of methyl orange. Sample: 0.1754 g. required 7.45 cc. of 0.1339 N HCI. Eq. wt.: calcd. for $C_{11}H_{20}N_2$ (as a mono-acid base), 180.2. Found: 175.8. This equivalent weight was checked by adding excess acid and back titrating with alkali. Excess alkali equivalent to 5 cc. of the acid was then added and solution allowed to stand for three and one-half hours at room temperature. Upon back titrating to the yellow-orange end-point, the total acid used up by the base was found to have increased by 2.89 cc., corresponding to about 50% decomposition. In another experiment the base was allowed to stand in 50 cc. of water for about five minutes and then titrated to the orange end-point of methyl orange. Sample: 0.2243 g. required 10.80 cc. of 0.1339 *N* HCl. Eq. wt., found: 155.1, *i. e.*, 1 mole of base yielded 1.161 eqts. of titratable base, corresponding to 16.1% decomposition in five minutes at room temperature. Excess acid was added and the solution after standing for four hours was back titrated. The net amount of acid required by the base was unchanged. This points to the stability of the base in acid.

Upon titration 0.5674 g. of the heptamethyldihydropyrazinium iodide was found to require 0.09 cc. of 0.1339 N hydrochloric acid to reach the orange end-point of methyl orange.

The chloroplatinates from 1,2,2,3,5,5,6-heptamethyldihydropyrazinium iodide and from 1,2,2,3,5,5-hexamethyl-6-methylenetetrahydropyrazine were prepared by methods already described. The salt from the two sources was apparently the same; chloroplatinate from iodide, m. p. about 285° with decornp.; yield, 66%.

Anal. Calcd. for $C_{11}H_{24}N_2O \cdot PtCl_6$: Pt, 32.10. Found: Pt, 31.99.

These chloroplatinates underwent decomposition when crystallization was attempted. The large yield from the salt seems to indicate that the chloroplatinate is a hydrated form of the salt of the quaternary base.

Attempted Isolation of a Base Corresponding to 1,2,5-Trimethylpyrazinium Iodide.—

1,2,5-Trimethylpyrazinium iodide was prepared by the methylation of 2,5-dimethylpyrazine and recrystallized as described by Stoehr.[8] The product melted at 238° with decomposition whereas Stoehr records 230°.

Two grams of the iodide was dissolved in 5 cc. of water and 15 cc. of water and 15 cc. of 33% potassium hydroxide was added. The gum which separated was pressed out on a porous plate and dissolved in pure pyridine. After drying with solid potassium hydroxide for one hour the solution was treated with three times its volume of dry ether. A yellow crystalline material separated. This was filtered off by suction and washed several times with ether. The substance became dark red on standing. Its analysis varied from C, 53.2; H, 6.94, to C, 49.5; H, 6.63 on standing in a dry atmosphere for a day. This analysis does not correspond to that of any of the expected bases. Upon melting it gave a curious behavior. Heated slowly, it blackened at about 88° and melted at 179–190°, but, placed in a bath at 146°, it melted immediately. Evidently decomposition took place on slow heating. This compound will be investigated further. Various other attempts to obtain a pure base failed.

The experimental data upon the base strength of the above bases are recorded in the second paper of this series.

Summary

1. 1,2,2,5,5-Pentamethyldihydropyrazinium iodide and 1,2,2,3,5,5,6-heptamethyldihydropyrazinium iodide have been prepared.

2. 1,2,2,5,5-Pentamethyldihydropyrazinium iodide yields the base 1,2,2,5,5-pentamethyl-6-hydroxytetrahydropyrazine, whereas 1,2,2,3,5,5,6-heptamethyldihydropyrazinium iodide yields 1,2,2,3,5,5-hexamethyl-6-methylenetetrahydropyrazine. The ease of formation of the latter compound is attributed to lack of conjugation.

3. Possible tautomeric systems arising from these bases are discussed and related to their behavior on titration and salt-forming properties.

4. No base corresponding to 1,2,5-trimethylpyrazinium iodide could be isolated.

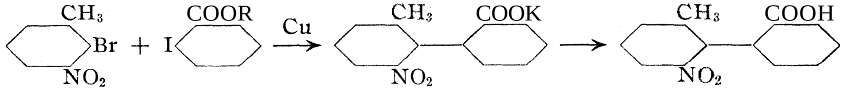
STEREOCHEMISTRY OF DIPHENYL COMPOUNDS. THE PREPARATION AND RESOLUTION OF 2-METHYL-6-NITRO-2'-CARBOXYDIPHENYL. XI[1]

BY R. W. STOUGHTON[2] AND ROGER ADAMS

RECEIVED OCTOBER 3, 1930 PUBLISHED DECEMBER 18, 1930

In a recent article[3] the desirability of studying 2,2',6'-trisubstituted diphenyls in connection with the stereochemistry of the diphenyl series was pointed out. In this first communication of several covering such compounds is given the description of the preparation and properties of 2-methyl-6-nitro-2'-carboxydiphenyl (I). This is the first diphenyl prepared which has had merely three groups substituted in the two rings, and in addition it is the first in which each of the 2,2',6'-positions has been filled by different groups.[4]



(I)

The compound was resolved and the two optical antipodes isolated. They racemized only very slowly and the properties were essentially in accord with what had been predicted from the x-ray data.

By boiling in butyl alcohol or in acetic acid, racemization took place partially over a period of thirty to forty hours. On the other hand, on boiling a sodium hydroxide solution of the compound, partial racemization occurred in four hours. Kuhn and Albrecht[6] have found when working with diphenyl derivatives that the decrease in optical activity obeys the law of a first order reaction and have expressed the speed of racemization in terms of the half-life periods. This furnishes at least a semi-quantitative measure of the stability of such compounds under different conditions. Using the same method, the half-life period at 117° in butyl alcohol is forty-two hours; at 118° in acetic acid is thirty-four hours; and at 100° in 0.1 N sodium hydroxide solution, four and one-half hours. This compound was stable to racemization at room temperatures in any of the solvents mentioned above.

[4] During the preparation of this manuscript an article has appeared by Lesslie, and Turner [J. Chem. *Soc*, 1758 (1930)] describing another compound of this latter type 2,4-dinitro-6-carboxy-2'-methyldiphenyl.

[5] Kuhn and Albrecht, Ann, **455, 272 (1927); 458, 221 (1927).**

From x-ray data[6] the distances between the groups can be estimated. Using the values and calculations similar to those given in a previous paper, the interference between the methyl and the carboxyl groups will be \$0.39 Å., between the nitro and the carboxyl groups +0.58 Å.; hence stability to racemization might be expected. The hydrogen and the nitro group or the hydrogen and the carboxyl group will not collide (—0.06 Å. and −0.42 Å., respectively).

In previous papers[2,3] the possibility of the rings bending toward each other when approaching the same plane so as to allow free rotation was discussed and this may account for the gradual racemization observed at high temperatures over a period of time. In sodium hydroxide solution at 100° the rate of racemization was almost ten times as fast as in butyl alcohol at 117°. Since it is known that an ionized carboxyl group is smaller than one which is un-ionized, such a difference in racemization rate is to be expected.

Kuhn has studied the ease of racemization of 2,4′-dinitro-6,6′-dicarboxydiphenyl and 2,4,4′-trinitro-6,6′-di-carboxydiphenyl and found them more easily racemized than the compound just described. This might be expected in the light of the same reasoning previously outlined.

The 2-methyl-6-nitro-2'-carboxydiphenyl was prepared by condensing under carefully specified conditions 3-nitro-2-bromotoluene with methyl o-iodobenzoate by means of copper. The resulting mixture was saponified, which allowed the removal of the alkali-insoluble 2,2′-dinitro-6,6′-dimethyldiphenyl. There was apparently little or no 2,2′-dicarboxydiphenyl found, so that on acidification essentially pure 2-methyl-6-nitro-2'-carboxydiphenyl was obtained. The compound was resolved through the brucine salt. The conversion of this nitro compound to the corresponding amine and thence to the corresponding halogen compounds is now under way so that a direct comparison of several groups on rate of racemization may be obtained.

Experimental

2-Bromo-3-nitrotoluene.—A solution of **38** g. of 3-nitro-o-toluidine (prepared by the method of **Hadfield** and **Kenner**),[7] in **650** cc. of glacial acetic acid, 60 cc. of water and 39 g. of **concd.** sulfuric acid, was cooled in an ice-salt bath and to it a solution of **45** g. of sodium nitrite in **75** cc. of water was added slowly with constant stirring. At the same time a **cuprous** bromide solution was prepared by refluxing a mixture composed of 46 g. of crystallized copper sulfate, **125** g. of sodium bromide, **75** g. of copper turnings, **80** g. of concd. sulfuric acid and **325** cc. of water, until its color was light yellow. After standing for two hours in the cold, the **diazotized** solution was added to the cuprous bromide solution and steam distilled. The distillate was extracted with ether. The product amounted to **37** g. **(68%)**, boiling at **161–164°** at **30 mm**. and melting at **39–40.5°**.[8]

---

[6] Stanley and Adams, This Journal, **52,1200 (1930).**

[7] **Hadfield** and Kenner, Proc. Chem. *Soc.*, **30,253 (1914).**

[8] Gibson and Johnson, **J.** Chem. *Soc.*, **1244 (1929)**, give the boiling point as **135.** at 6 mm., **157°** at 22 **mm.**, and the melting point as **41–42'.**

Methyl *o*-Iodobenzoate.—*o*-Iodobenzoic acid was prepared by the method of Wachter[9] and esterified in the following manner. A solution of 62 g. of o-iodobenzoic acid in 500 cc. of absolute alcohol was saturated with dry hydrogen chloride and refluxed for five hours. This solution was then poured into water, neutralized with potassium carbonate and extracted with ether. It was finally distilled under diminished pressure. A yield of 50 g. (78%) boiling between 165–168° at 25 mm. was obtained.

2-Methyl-6-nitro-2'-carboxydiphenyl.—In a 200-cc. 3-necked flask fitted with a mechanical stirrer and reflux condenser, was placed 37 g. of bromonitrotoluene and 38 g. of methyl-o-iodobenzoate. This was heated in a metal-bath and as soon as the contents just began to boil, 50 g. of copper bronze was slowly added. During the addition, which required about three-quarters of an hour, the temperature of the bath was kept between 270 and 280°. When all of the copper had been added, the bath temperature was raised to 300° for fifteen minutes. During the course of the reaction the mixture turned dark brown and considerable heat was evolved. After cooling, it was thoroughly extracted with ether and filtered. The ether was removed by evaporation and the oily residue saponified by refluxing for four hours with 10% sodium hydroxide. A little black tar insoluble in the alkali remained, which proved to be 2,2'-dimethyl-6,6'-dinitrodiphenyl. This was removed by filtration and the filtrate acidified slowly with dilute hydrochloric acid. A brownish-black tar separated which quickly solidified. This crude product was dissolved in 400 cc. of benzene, boiled with norite for ten minutes and filtered. The color of the solution changed at this time from a dark brown to an orange red. After concentrating to 50–60 cc., the benzene solution was extracted twice with 10% sodium hydroxide, and upon acidification with dilute hydrochloric acid, 16 g. of crude yellow product was obtained. No diphenic acid, the third theoretical product of this reaction was isolated. The crude product was recrystallized three times from dilute alcohol. A yield of 12 g. (27%) of pure product was obtained. Pure methyl nitrocarboxydiphenyl is a pale yellow solid melting at 171–172°, soluble in the common organic solvents but insoluble in cold water.

Anal. Calcd. for $C_{14}H_{11}NO_4$: C, 65.35; H, 4.31. Found: C, 65.56; H, 4.44.

Resolution of 2-Methyl-6-nitro-2'-carboxydiphenyl.—To a boiling solution of 2 g. of 2-methyl-6-nitro-2'-carboxydiphenyl in 1500 cc. of water was added 3.07 g. of anhydrous brucine. As soon as solution was complete, it was filtered and at the end of one-half hour 2.1 g. of flaky white crystals had deposited. These were collected and after three recrystallizations from water yielded one gram of salt of constant rotation melting from 169–175°. This salt was found to contain water which corresponds to one molecule of water of crystallization. The analytical sample was dried over phosphorus pentoxide in a vacuum at 117° for twenty-four hours. The melting point of the anhydrous form is 173–175°.

Rotation. Hydrated l-salt: 0.1368 g. made up to 25 cc. with chloroform at 20° gave $\alpha_D = +0.33°$; $l = 2$; $[\alpha]^{20}_D +30.4°$.

Anal. 0.3304 g. lost 0.0086 g. on drying. Calcd. for $C_{37}H_{37}N_3O_8{\cdot}H_2O$: H_2O, 2.69. Found: H_2O, 2.60. Calcd. for $C_{37}H_{37}N_3O_8$: C, 68.17; H, 5.73. Found: C, 67.67; H, 5.75.

Upon concentrating the mother liquors to 100 cc., 1.8 g. of impure d-salt was obtained. This was recrystallized from water and on each crystallization the very first crystals that separated were discarded. Five recrystallizations in this manner yielded 0.5 g. of salt with a constant rotation melting from 145–155°. This salt appears to contain water equivalent to one and one-half molecules of water of crystallization. The anhydrous form which was used for analysis melts at 172° with softening beginning at 145°.

---

[9] Wachter, Ber., 26, 1744 (1893).

Rotation. Hydrated d-salt. 0.0850 g. made up to 15 cc. with chloroform at 20° gave $\alpha_D = -0.65'$; 1 = 2; $[\alpha]^{20}_D$ −57.3".

Anal. 0.1780 g. lost 0.0070 g. on drying. Calcd. for $C_{37}H_{37}N_3O_8 \cdot 1.5\ H_2O$; H_2O, 3.98. Found: H_2O, 3.93. Calcd. for $C_{37}H_{37}N_3O_8$: C, 68.17; H, 5.73. Found: C, 67.86; H, 5.93.

l and *d*-**2-Methyl-6-nitro-2′-carboxydiphenyl.**—The active acids were liberated from their salts by treatment with hydrochloric acid in the cold. The organic acid was obtained as a fine cream-colored powder when 0.77 g. of the I-salt (less soluble) was shaken with 6 *N* hydrochloric acid for one hour. This was filtered, washed with dilute hydrochloric acid and finally with water. After two recrystallizations from dilute methyl alcohol, 0.21 g. remained melting at 174–175° with slight softening at 168°.

Rotation. I-acid. 0.2052 g. made up to 25 cc. with methyl alcohol at 20° gave $\alpha_D = -1.11°$; 1 = 2; $[\alpha]^{20}_D$ −67.7'.

The d-acid was obtained in exactly the same way; melting point 171–173° with slight softening at 167°.

Rotation. d-acid. 0.0309 g. made up to 15 cc. with methyl alcohol at 20° gave $\alpha_D = +0.26°$; $l = 2$; $[\alpha]^{20}_D$ +63.1°.

Racemization Experiments

1. A sample of the I-acid was dissolved in ordinary ethyl alcohol and refluxed in a flask with a ground-glass joint for twenty-four hours. No change in rotation was observed.

Rotation. 0.0950 g. made up to 25 cc. with ethyl alcohol at 20° gave $\alpha_D = -0.52°$; $l = 2$; $[\alpha]^{20}_D$ −68.4".

2. **A** second sample of the 1-acid was refluxed in butyl alcohol in the same manner as in ethyl alcohol; 0.0583 g. was made up to 15 cc. at 20°, $l = 2$. $k = l/t \log_{10} \alpha_0/\alpha_t$; half-life period $= l/k \log_{10} 2$.

Time in minutes	α_D	$[\alpha]^{20}_D$	k	Av. k
0	−0.56°	−72.0°	. . . .	
360	− .49°	−63.0"	0.00016	
1080	− .42°	−54.0"	,00012	0.00115
1740	− .35°	−45.0°	.00010	
2460	− .32°	−41.3'	.00010	

Half-life period = 2510 minutes = 42 hrs.

3. **A** sample was then dissolved in glacial acetic acid and treated in the same manner: 0.0840 g. was made up to 15 cc. at 20', 1 = 2.

Time in minutes	α_D		k	Av k
0	−0.97"	−86 6°	. . .	
180	−0 90°	−80 4°	0 00018	
540	−0 82°	−73 2°	00013	0 00015
1080	−0 69°	−61 6°	00014	

Half-life period = 2007 minutes = 34 hrs.

4. The I-acid was dissolved in 5% sodium carbonate and allowed to stand for twenty-four hours at room temperature. The rotation did not change.

Rotation. 0.1148 g. made up to 15 cc. with 5% sodium carbonate solution at 20° gave $\alpha_D = +0.33°$; $l = 2$; $[\alpha]^{20}_D$ +21.6°.

5. A sample of I-acid dissolved in 0.1 N sodium hydroxide solution did not change in rotation upon standing for twenty-four hours at room temperature, nor upon heating for two hours at 80°. The solution was then refluxed but due to the small rotation in sodium hydroxide the rotations were taken on the free acid in methyl alcohol.

Rotation. 0.1140 g. made up to 15 cc. with 0.1 N NaOH at 20° gave $\alpha_D = +0.19°$, $1 = 2$; $[\alpha]_D^{20}$ +12.6°.

Time in minutes	$[\alpha]_D^{20}$ in CH_3OH	k	Av. k
0	−67.7"	....	
120	−50 6°	0.0011	0.00115
300	−29.0"	.0012	

Half-life period = 262 minutes = 4.5 hrs.

Summary

1. The compound 2-methyl-6-nitro-2′-carboxydiphenyl has been prepared and resolved.

2. The active forms racemize slowly in boiling alkali and still more slowly in neutral or acid solvents.

HEXA-OMEGA-TERTIARY-BUTYLPROPINYLETHANE AND SOME NEW ACETYLENIC CARBINOLS

BY I. L. OZANNE AND C. S. MARVEL

RECEIVED OCTOBER 9, 1930 PUBLISHED DECEMBER 18, 1930

In attempting to find some aliphatic unsaturated hydrocarbons which would resemble the hexa-arylethanes, several tetra- and hexa-acetylenic ethanes have been prepared in this Laboratory.[1] All of the compounds which have been described heretofore have had as the acetylenic group the radical *tert.*-butylethinyl, $(CH_3)_3C—C\equiv C—$. In order to learn more about compounds of this general type, the work has now been extended to cover hydrocarbons in which other than tertiary alkyl groups are attached to the ethinyl group. It has been shown[2] that a tertiary alkyl group directly attached to the central carbon of a hexasubstituted ethane has a greater effect in producing dissociation than does a secondary alkyl group, and this in turn has a greater effect than does a primary alkyl group. It has seemed of interest to determine whether this effect is transmitted through the acetylenic structure to the central ethane carbon. As the first step in this study, the preparation and properties of a hexa-

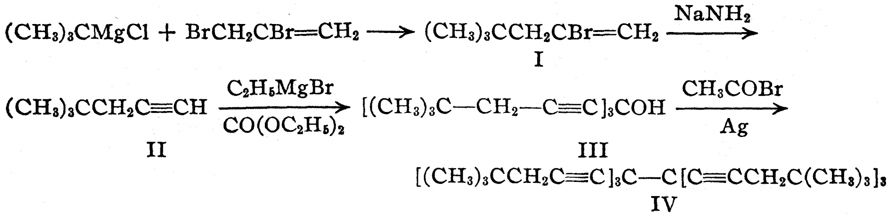
acetylenic ethane which has a primary alkyl group attached to the ethinyl group are described in this communication.

The synthesis of hexa-ω-*tert.*-butylpropinylethane was accomplished in the following manner



$$(CH_3)_3CMgCl + BrCH_2CBr{=}CH_2 \longrightarrow \underset{I}{(CH_3)_3CCH_2CBr{=}CH_2} \xrightarrow{NaNH_2}$$

$$\underset{II}{(CH_3)_3CCH_2C{\equiv}CH} \xrightarrow[CO(OC_2H_5)_2]{C_2H_5MgBr} \underset{III}{[(CH_3)_3C{-}CH_2{-}C{\equiv}C]_3COH} \xrightarrow[Ag]{CH_3COBr}$$

$$\underset{IV}{[(CH_3)_3CCH_2C{\equiv}C]_3C{-}C[C{\equiv}CCH_2C(CH_3)_3]_3}$$

The first two compounds in this series, 4,4-dimethyl-2-bromopentene-1 (I) and 4,4-dimethylpentine-1 (II) were prepared according to the general method of Lespieau and Bourguel.[3] The carbinol (III) was prepared by the method described by Salzberg and Marvel[1] for tri-*tert.*-butylethinylcarbinol. It was impossible to convert this carbinol to a crystalline bromide which could be purified. However, the desired hydrocarbon (IV) was obtained by treating the carbinol with acetyl bromide and then with metallic silver. The same product was obtained when these two reactions were carried out in separate operations that was obtained when all of the reagents were mixed together and the synthesis accomplished in one step.

The structure of the new hydrocarbon was not as easily determined as was that of hexa-*tert.*-butylethinylethane. Treatment of hexa-ω-*tert.*-butylpropinylethane with liquid sodium–potassium alloy gave a colored alkali metal derivative that reacted with dry carbon dioxide to give an acidic compound which could not be purified. Oxidation of the hydrocarbon with ozone gave about 30% of the calculated amount of *tert.*-butylacetic acid. These facts are in agreement with the structure which has been proposed for the hydrocarbon.

The hydrocarbon was not cleaved by 1% sodium amalgam and hence is more stable in this respect than hexa-*tert.*-butylethinylethane. It is less stable in air and does not keep well. After it is a few hours old it begins to develop a yellow color and in one day turns brown due to decomposition or polymerization. The nature of the change has not been determined.

Several other intermediate compounds containing primary alkyl groups attached to an acetylenic linkage have been obtained and are described in the experimental part. However, their conversion to hexasubstituted ethanes has not been accomplished. One hydrocarbon has been described as di-ω-*tert.*-butylpropinyl-tetraphenylethane but this structure is only supported by the method of synthesis.

Experimental Part

4,4-Dimethyl-2-bromopentene-1.—In a three-liter, three-necked flask fitted with a mechanical stirrer, a reflux condenser and a separatory funnel, was placed 200 g. of bromo-allyl bromide and 200 cc. of anhydrous ether. The flask was placed in an ice-bath, and through the separatory funnel was added an ether solution of 1.33 moles of *tert.*-butylmagnesium chloride which had been prepared and titrated previously. The Grignard reagent was added at such a rate that the ether boiled gently. The addition required about thirty to forty-five minutes After the addition was complete, the ice-bath was removed *and* the mixture was gently refluxed on a water-bath for about two hours in order to insure completion of the reaction.

The mixture was then cooled and the excess Grignard reagent was decomposed by adding slowly a solution of 35 cc. of concentrated hydrochloric acid in 350 cc. of water through the separatory funnel. The ether layer was separated, washed with a saturated solution of sodium bicarbonate, dried over calcium chloride and distilled. After the ether was removed, the 4,4-dimethyl-2-bromopentene-1 was collected at 135–138°. The yields varied from 80 to 110 g. (45–62% of the theoretical amount); d_4^{20} 1.030, n_D^{20} 1.4630.

Anal. Subs., 0.1930: 26.26 cc. of 0.04137 N $AgNO_3$. Calcd. for $C_7H_{13}Br$: Br, 45.2. Found: Br, 45.0.

In order to obtain a pure product it was always necessary to use an excess of the Grignard reagent so that no unreacted bromoallyl bromide (b. p. 140") remained in the mixture.

4,4-Dimethylpentine-1.—Sixty-two grams of sodamide was ground in a mortar with 104 cc. of purified high-boiling mineral oil until a fine suspension was obtained. This was transferred to a 1-liter round-bottomed three-necked flask fitted with a reflux condenser protected with a calcium chloride tube, a 500-cc. separatory funnel, and an efficient mechanical stirrer, An additional 125 cc. of mineral oil was used in transferring the suspension from the mortar to the reaction flask. The mixture was heated in an oil-bath at 160–165°, the stirrer was started, and 92 g. of 4,4-dimethyl-2-bromopentene-1 was added from the dropping funnel.

The reaction started at once and ammonia was evolved. Heating and stirring were continued for two hours after the addition of the bromo compound was complete. The mixture was then cooled, diluted with 250 cc. of xylene and this solution was poured onto about 700 g. of cracked ice to which had been added 140 cc. of concentrated hydrochloric acid (sp. gr. 1.19). The oil layer was separated, washed with a saturated solution of sodium bicarbonate, dried over calcium chloride and distilled from a modified Claisen flask.[4] In the first fractionation the material boiling between 50 and 100" was saved. On redistillation the product boiling at 73–75' at ordinary pressures was collected. The yield was 18 g. (37% of the theoretical amount). There was some loss in the preparation due to the heptine passing off with the ammonia. By using ice water in the condenser and washing the ammonia which escaped with the xylene which was used to dilute the reaction mixture, the yield was increased to 45% of the theoretical amount. The new acetylene has the following constants: d_4^{20} 0.7154, n_D^{20} 1.4028.

The acetylene was not analyzed as such, but was converted to the diacetylenic mercury compound $[(CH_3)_3CCH_2C{\equiv}C]_2Hg$ according to the general method recently described by Johnson and McEwen.[5] The mercury derivative melted at 125–126.5° (corr.).

Anal. Subs., 0.1924: Hg, 0.1000. Calcd. for $C_{14}H_{22}Hg$: Hg, 51.28. Found: Hg, 51.9.

[5] Johnson and McEwen, THIS JOURNAL, 48,469 (1926).

Tri-ω-*tert.*-butylpropinylcarbinol.—To 166 cc. of a 3.0 N solution of ethylmagnesium bromide in dry ether was added 48 g. of 4,4-dimethylpentine-1. The ethane generated by the reaction was led out through a well-cooled condenser to avoid loss of the acetylene. When this reaction was complete, 19.7 g. of diethyl carbonate was slowly added. After about fifteen hours the reaction mixture was decomposed with an aqueous ammonium chloride solution which contained a little hydrochloric acid. The ether layer was separated, washed with water and sodium bicarbonate solution and dried over anhydrous sodium sulfate.

The ether was evaporated and the carbinol was distilled under reduced pressure. The product boiled at 140–142° at 0.7 mm. The yield of distilled product was 42 g. The distillate solidified and was recrystallized from petroleum ether. The yield of recrystallized material was 32.3 g. (68% of the theoretical amount) of a product which melted at 50–51°.

Anal. Subs., 0.1853: CO_2, 0.5704; H_2O, 0.1805. Calcd. for $C_{22}H_{34}O$: C, 84.07; H, 10.82. Found: C, 83.95; H, 10.90.

Hexa-ω-*tert.*-butylpropinylethane.—A solution of 1.5 g. of the carbinol and 0.2 cc. of acetyl bromide in about 10 cc. of dry petroleum ether was allowed to stand for about ten minutes. The petroleum ether and excess acetyl bromide were then removed by evaporating under reduced pressure. A few drops of methyl alcohol were added to decompose any excess acetyl bromide and the mixture was evaporated again under reduced pressure. The residue was taken up in dry ether, 0.5 g. of molecular silver added and the mixture shaken overnight. After filtering, the solvent was evaporated and the residue was recrystallized from a mixture of methyl alcohol and ether. There were thus obtained crystals which melted at 127.5–128.5°.

The same hydrocarbon was obtained more readily by shaking a solution of carbinol and acetyl bromide in petroleum ether with molecular silver. To an ice-cold solution of 1.66 g. of carbinol in 20 cc. of petroleum ether was added 1.7 g. of molecular silver and 0.5 cc. of acetyl bromide. The flask was swept out with dry nitrogen and sealed. The mixture was shaken for eighteen hours. It was then filtered and the solvent evaporated. The residue on recrystallization yielded 0.4 g. (24% of the theoretical amount) of a product of m. p. 127.5–128.5°. A mixed melting point showed this product to be identical with the one obtained above.

Anal. Subs., 0.1986: CO_2, 0.6455; H_2O, 0.1985. Calcd. for $C_{44}H_{66}$: C, 88.88; H, 11.11. Found: C, 88.65; H, 11.08.

This hydrocarbon turns yellow on standing in the air for a few hours. In one day the color deepens to brown. If kept at 0° it remains colorless for over a week. A dry ether solution of the ethane reacted almost instantly with liquid sodium–potassum alloy to give a red metal alkyl. The ethane did not react with 1% sodium amalgam. The result with 40% sodium amalgam was inconclusive. It was not possible to convert the metal alkyl to a crystalline acid by the action of dry carbon dioxide followed by mineral acid. Evidence was obtained repeatedly that an acidic compound was produced but it seemed very unstable and turned to a brown tarry product.

***Tert.*-butylacetic Acid.**—A solution of 30 g. of 4,4-dimethyl-2-bromopentene-1 in 200 cc. of carbon tetrachloride was placed in a wash bottle which was packed with an ice–salt mixture. Ozonized air was passed through the solution at the rate of seven liters per minute for about twelve hours. Additional carbon tetrachloride was added occasionally to replace that swept out by the current of air. Some solid ozonide separated from solution. Dilute aqueous alkali was added and the mixture was heated. The carbon tetrachloride layer was separated and evaporated and the residue was again heated with aqueous alkali. The alkaline solutions were combined and acidified with sulfuric acid and the aqueous solution was distilled until no more oil came over. The distillate was extracted with ether and the ether was removed by evaporation. The residue was distilled under ordinary pressure. There was thus obtained 7 g. of acid which boiled at 186–188° and gave a neutral equivalent of 118.3 instead of the theoretical 116. The p-bromophenacyl ester was formed by refluxing an alcohol solution of the sodium salt with *p*-bromophenacyl bromide. After crystallizing repeatedly this product melted at 81–81.5°.

Anal. Subs., 0.3786: 29.56 cc. of 0.04137 *N* $AgNO_3$ Calcd. for $C_{13}H_{17}O_3Br$: Br, 25.56. Found: Br, 25.82.

Ozonization of **Hexa-*ω*-*tert.*-butylpropinylethane.**—An ice-cold solution of 2.94 g. of the ethane in 200 cc. of carbon tetrachloride was treated with a current of ozonized air at the rate of about 4 liters per minute for about two hours. The ozonized mixture was treated with a little water and then sodium hydroxide solution was added. The carbon tetrachloride solution was thoroughly extracted with the aqueous alkali. The alkaline solution was separated, acidified with sulfuric acid and distilled. An oily acid came over. This distillate was titrated with standard alkali and assuming that all of the acidity was due to *tert.*-butylacetic acid the yield was 0.965 g. (28% of the theoretical amount). The neutral solution was evaporated to dryness, the residue was taken up in 35 cc. of 95% alcohol and 2.03 g. of p-bromophenacyl bromide was added. After boiling to complete the reaction, the derivative was isolated and crystallized. It melted at 80.5–81.5° and was shown by a mixed melting point determination to be identical with the derivative prepared before from *tert.*-butylacetic acid.

ω-*Tert.*-butylpropinyl-diphenylcarbinol.—To 19 cc. of 3.7 *N* ethylmagnesium bromide solution was added 7 g. of 4.4-dimethylpentine-1. The mixture was allowed to stand until no more ethane was evolved and then 7.9 g. of benzophenone was added. The mixture was stirred for about five hours and allowed to stand overnight. On working up the reaction mixture in the usual manner, the carbinol was obtained as a liquid boiling at about 135° under 0.4 mm. pressure. It crystallized readily from petroleum ether and then melted at 55–56°. The yield was 10.3 g. (85% of the theoretical amount).

Anal. Subs., 0.2184: CO_2, 0.6886; H_2O, 0.1556. Calcd. for $C_{20}H_{22}O$: C, 86.33; H, 7.91. Found: C, 85.98; H, 7.96.

ω-*Tert.*-butylpropinyl-diphenyl-bromomethane.—A solution of 0.5 g. of the carbinol in 10 cc. of petroleum ether was treated with 0.2 cc. of phosphorus tribromide. After about one-half hour the solution was washed with sodium bicarbonate solution, dried over sodium sulfate and evaporated under reduced pressure. The residue was a light brown liquid which would not crystallize even when cooled in solid carbon dioxide. This liquid was dried in a vacuum desiccator over phosphorus pentoxide and analyzed.

Anal. (Stepanow) Subs., 0.2040: 6.15 cc. of 0.1000 N $AgNO_3$. Calcd. for $C_{20}H_{21}Br$: Br, 23.53. Found: Br, 24.11.

***Sym.*-di-*ω*-*tert.*-butylpropinyl-tetraphenylethane.**—The crude bromide prepared from 2 g. of carbinol and 0.74 g. of phosphorus tribromide in petroleum ether was treated with 1.5 g. of molecular silver and the mixture was shaken for about twelve hours. The mixture was then filtered, the solvent was evaporated and the residue was crystallized from alcohol. There was thus obtained 0.2 g. of a hydrocarbon which melted at 116–118°. Analysis showed that it had the expected composition. It gave a red color when treated in dry ether with liquid sodium–potassium alloy. However, the metal alkyl thus obtained could not be converted into the corresponding acid.

Anal. Subs., 0.1791: CO_2, 0.6000; H_2O, 0.1305. Calcd. for $C_{40}H_{42}$: C, 91.97; H, 8.03. Found: C, 91.38; H, 8.13.

Di-*ω*-*tert.*-butylpropinyl-phenylcarbinol.—This carbinol was prepared in the same general manner described before. From 18 cc. of 3.6 *N* ethylmagnesium bromide solu-

tion, 6.5 g. of **4,4-dimethylpentine-1** and 5.2 g. of ethyl benzoate there was obtained 3.8 g. of a product boiling at 135–137' at 0.4 mm. pressure: d_4^{20} 0.9325; n_D^{20} 1.5080.

Anal. Subs., 0.2139: CO_2, 0.5979; H_2O, 0.1391. Calcd. for $C_{21}H_{28}O$: C, 85.14; H, 9.46. Found: C, 84.60; H, 9.59.

Diphenyl-ω-cyclohexylpropinylcarbinol.—From 21.6 cc. of 3.8 N ethylmagnesium bromide solution, 10.5 g. of cyclohexylpropine and 14.5 g. of benzophenone there was obtained 6 g. of product which boiled at 210–215° at 1.1 to 1.3 mm. pressure; d_4^{20} 1.058; n_D^{20} 1.5750. This product was redistilled at 0.003 mm. pressure and then boiled at 165–166°.

Anal. Subs., 0.2043: CO_2, 0.6505; H_2O, 0.1459. Calcd. for $C_{22}H_{24}O$: C, 86.84; H, 7.89. Found: C, 86.85; H, 7.99.

Phenyl-di-ω-cyclohexylpropinylcarbinol.—From 35 cc. of 4.2 N ethylmagnesium bromide solution, 18.5 g. of cyclohexylpropine and 11.4 g. of ethyl benzoate there was obtained 4 g. of this carbinol; b. p. 180–185° at 0.017 mm. pressure; d_4^{20} 1.014; n_D^{20} 1.5390.

Anal. Subs., 0.1986: CO_2, 0.6258; H_2O, 0.1635. Calcd. for $C_{25}H_{32}O$: C, 86.20; H, 9.19. Found: C, 85.94; H, 9.21.

Summary

1. Hexa-ω-*tert.*-butylpropinylethane has been prepared and has been found to be less readily cleaved by alkali metals than hexa-*tert.*-butylethinylethane. However, it decomposes with greater rapidity in the air.

2. Some new acetylenic carbinols having primary alkyl groups next to the acetylenic linkage have been described.

PHOTOCHEMICAL OXIDATION OF LACTIC ACID[1]

BY G. RICHARD BURNS

RECEIVED OCTOBER 9, 1930 PUBLISHED DECEMBER 18, 1930

The present study is a development and a continuation of an investigation of the action of ultraviolet radiation on lactic acid. In the absence of oxygen it has been shown that the main products of the decomposition are ethanol and carbon dioxide.[2] It was felt that the conflicting results obtained by other investigators[3] of this decomposition were due to the presence of oxygen dissolved in the solution.

The decomposition of lactic acid in the presence of oxygen has never been fully investigated. Some workers[4] in this field have exposed solutions of lactic acid to sunlight and air and have obtained qualitative tests

for acetic acid, pyruvic acid, acetaldehyde and carbon dioxide. Others[5] have exposed solutions of lactic acid containing uranyl sulfate and measured the amount of uranyl sulfate reduced and the amount of acetaldehyde formed.

In the present investigation a solution of lactic acid was shaken with oxygen while being exposed to the visible and ultraviolet radiation from a quartz mercury lamp. Radiation of wave length longer than 2890 Å. was only slightly absorbed. Thermochemical data[6] show that the decomposition of a dilute solution of lactic acid into dilute ethanol and a saturated solution of carbon dioxide evolves about 3.7 kilogram calories. The longest wave length of radiation that accomplishes this change is equivalent to 112 kilogram calories. It is not surprising that the ethanol formed under these conditions reacts with oxygen dissolved in the solution. The main products of the reaction are acetaldehyde, a peroxide and acetic acid. Quantitative data were obtained on all the above products, as well as on the other substances formed in smaller amounts. Ethanol and pyruvic acid were not found in the reaction mixture. The amount of oxygen used was determined.

Apparatus.—The apparatus was substantially the same as that previously described.[2] A Hullet gas buret[7] was introduced between the reaction vessel and the Topler pump by means of a three-way stopcock in order to measure the amount of oxygen introduced. This buret and the gas analysis buret were in a water-bath kept at 25.0° by a thermostat. The shields between the mercury arc and the reaction vessel were removed so that the latter received the same amount of radiation over the full length of its stroke.

Experimental Part

Before all experiments, the quartz windows were cleaned with cleaning solution, the thermostat filled with distilled water, and the temperature brought to 25.0°. The reaction tube contained 21.38 cc. of 1.140 *N* lactic acid, enough to make it about half full. The rate of shaking was 310 r. p. m. with a 6-cm. stroke. With a total pressure of oxygen and water vapor of 760 mm., the solution dissolved 0.70 cc. (2.8×10^{-5} mole) of oxygen. The usual procedure was to evacuate the system, after the reaction vessel containing the solution had been attached, then to introduce a measured quantity of oxygen, start the shaking and illuminate the solution for one hour. During this time the pressure was held at 760 mm. and the decrease in the gas volume observed. Inasmuch as from 5 to 17 cc. of carbon dioxide remained dissolved in the solution, the decrease in volume was large. At the end of an hour the gas was about 50% oyxgen. The gas was then pumped into the gas analysis buret, the reaction vessel being shaken to remove the carbon dioxide in solution, and analyzed for carbon dioxide, decrease in volume on ignition, and carbon dioxide produced by ignition. The oxygen used was

[7] Taylor and R. M. Burns, THIS JOURNAL, 43,1275 (1921).

assumed to be the volume introduced minus the volume recovered. The volume recovered was taken to be the volume of the gases after the removal of the carbon dioxide minus the volume of carbon dioxide produced on ignition. The aldehyde produced had no effect on the gas analysis in the one-hour runs. In the following tables all gas volumes are corrected to the dry gas at 0° and 760 mm. All distillations and analyses were carried out in all-glass apparatus.

Dark Reaction Rate.—As far as could be observed there was no reaction in the dark.

Oxygen–Carbon Dioxide Ratio.—On illumination, the volume of the gas in the system was found to decrease with a slowly diminishing rate for about eighty-five minutes, followed by a sudden evolution of about 4 cc. of gas. For this reason the runs were limited to sixty minutes. Numbers 1 and 2 in Table I are the results of two runs which were continued for five hours with the gas in the system analyzed and fresh oxygen introduced each hour. Run 3 was made with 50% lactic acid. Tables II and IV include one-hour runs.

TABLE I

VALUES IN CC.

	1st hour	2d hour	3d hour	4th hour	5th hour
			Run 1		
Oxygen absorbed	**16.7**	**21.9**	**23.7**	**26.0**	**27.4**
Carbon dioxide produced	**13.62**	**19.87**	**23.07**	**26.01**	**28.08**
Decrease on ignition	**0.13**	**0.13**	**0.27**	**0.28**	**0.30**
Carbon dioxide by ignition	.20	**.20**	.25	**.25**	**.31**
			Run 2		
Oxygen absorbed	**16.6**	**21.0**	**23.0**	**24.4**	**25.8**
Carbon dioxide produced	**13.16**	**19.43**	**22.04**	**24.00**	**25.07**
Decrease on ignition	**0.08**	**0.13**	**0.22**	**0.22**	**0.26**
Carbon dioxide by ignition	.16	**.16**	**.19**	**.21**	**.27**
		Run 3			
Oxygen absorbed	**38.5**	**34.2**	**35.2**		
Carbon dioxide produced	**27.17**	**29.53**	**33.47**		
Decrease on ignition	**0.18**	**0.27**	**0.28**		
Carbon dioxide by ignition	**.36**	**.62**	**.34**		

Carbon Dioxide–Acetic Acid Ratio.—After the aldehyde and the alcohol had been removed from the reaction mixture by distillation through a fractionating column, the residue and washings of the column were made up to 100 cc. and distilled. Water was admitted as fast as it distilled out and the process continued until 300 to 500 cc. of distillate had collected. Preliminary experiments showed that the greater part of the acetic acid distilled with the first 250 cc. This distillate was divided into two equal portions, one titrated with barium hydroxide to find the total acidity, the other oxidized by the Bourcart–Kuriloff[8] method to determine the lactic acid which had also distilled. Under these conditions this amounted

---

[8] Poznanski, THIS JOURNAL, **50,981 (1928).**

to about one-third of the total acid distilling. Table II gives the results of one-hour runs. In order to be sure that the rate of shaking was not a limiting factor, Experiments **3** and 4 of Table II were carried out with half the usual quantity of lactic acid and with the shaking rate increased from **310** to ***375*** r. p. m. In five one-hour runs on the same sample of lactic acid, the yield of acetic based on carbon dioxide was 70.3%.

TABLE II

VALUES IN MOLES X 10^{-6}

Run number	1	2	3	4
Oxygen absorbed	888	819	670	585
Carbon dioxide produced	719	674	577	520
Decrease on ignition	3.5	4		
Carbon dioxide by ignition	6.3	7.6		
Acetic acid formed	536	507	452	400
Yield of acetic on carbon dioxide. %	74.5	75.2	78.4	77.0

Acetaldehyde–Acetic Acid Ratio.—No gas analyses were made in these experiments because of the danger of removing some of the aldehyde. The aldehyde and the alcohol were removed by distillation through a 15-cm. glass bead rectifying column and the residue analyzed in the usual manner. Half the aldehyde–alcohol mixture was analyzed by oxidation, half was analyzed for alcohol after the aldehyde had been removed by distillation from sodium bisulfite and the sulfurous acid removed by distillation from basic solution. At the same time two samples of lactic acid were similarly analyzed for alcohol. No correction was made for the amount of formaldehyde in the acetaldehyde. Colorimetric determinations indicated that a series of five one-hour runs produced over five times the amount of acetaldehyde that was produced in one hour.

TABLE III

VALUES IN MOLES X 10^{6}

Acetaldehyde	236	228
Ethanol	14	13
Ethanol in lactic acid	14	14
Acetic acid formed	597	612
Acetaldehyde oxidized to acetic acid, %	71.7	72 8

Peroxide Formation.—As soon as the period of illumination was over the contents of the tube were run into an acid solution of potassium iodide. At the end of an hour the liberated iodine was titrated. I and II were one-hour runs, III was a five-hour run with fresh oxygen supplied every hour.

I	5.12 cc. of 0.098 N $Na_2S_2O_3$ or 0 000251 moles of peroxide
II	5.40 cc. of .100 *N* $Na_2S_2O_3$ or 000270 moles of peroxide
III	4.56 cc. of .123 N $Na_2S_2O_3$ or .000280 moles of peroxide

When the reaction mixture was allowed to stand for forty-eight hours before analysis the peroxide content dropped to 0.00010 mole and the aldehyde to 0.00012 mole.

Formaldehyde.—The aldehyde fraction of the distillate from the reaction mixture turned Schiff's reagent blue in the presence of sulfuric acid. Formaldehyde gives this reaction while acetaldehyde does not. The approximate amount of formaldehyde present was determined by a colorimetric method based on this reaction. To one-quarter (5 cc.) of the distillate were added **5** cc. of **1** to **3** sulfuric acid and **5** cc. of basic fuchsin almost decolorized by sulfurous acid. The color developed was compared with that developed by 5 cc. of standard formaldehyde solution treated in the same manner. The concentration of the standard solution was determined by oxidation.

One-quarter of distillate was 1.24 stronger than the standard
One-quarter of distillate was 1.23 stronger than the standard
80 cc. standard = 0.56 cc. of 0.200 N $K_2Cr_2O_7$ or 0.000009 mole
10 cc. standard = 0.066 cc. of 0.200 N $K_2Cr_2O_7$ or 0.000008 mole

The residue from the distillation gave a test with Schiff's reagent. The substance giving this test was not identified.

Formic Acid.—No satisfactory test for formic acid in the presence of lactic and acetic acid was found. Formic acid reduces silver nitrate in acid solution while none of the known constituents of the reaction mixture does. The reaction mixture reduces silver nitrate, producing less silver than that reduced by 0.000004 mole of formic acid in a mixture containing lactic acid, formaldehyde and acetaldehyde in the same proportions as the reaction mixture. The residue of the reaction mixture which was left after steam distillation of the acetic acid did not reduce silver nitrate, while the distillate did so.

Quantum Yield.—The quantum yield in the decomposition reaction is probably between 0.5 and 1.0. Absorption measurements on the oxidation reaction mixture show that, after one hour of illumination, it absorbs about **35%** more radiation than the lactic acid. These measurements were made with two thermopiles and galvanometers so that the amount of radiation from the lamp and the amount transmitted by the solution could be determined simultaneously. Several pairs of determinations were made in which the solution was exposed without oxygen for one hour, then oxygen was admitted and the solution exposed for another hour. An attempt was made to keep the radiation constant for each pair of runs. The results are given in Table IV.

Wave Lengths Absorbed.—The following absorption measurements were made in the reaction tube as soon as it was removed from the thermostat. Unoxidized lactic acid absorbed completely to 2535° Å. After one hour of oxidation it absorbed to 2894° Å., after **five** hours some of the

TABLE IV

VALUES IN CC.

	No O_2	O_2	No O_2	O_2	No O_2	O_2
	I		II		111

Times increase in moles of gases		3.02		3.03		3.34

line at 2967 Å. The 50% lactic acid absorbed some of the 2700 Å. line at the start. The alkaline solution of sodium lactate absorbed some of the 3300 Å. line after four hours of oxidation.

Oxidation of the Lactate Ion.—A solution was prepared which contained two equivalents of sodium hydroxide to one of lactic acid, the lactic acid being in the same concentration as in the previous runs. The quantities of oxygen used per hour in a four-hour run were: 3.81, 3.12, 3.29, 2.96 cc.

Subsequent Dark Reactions.—After the gases had been removed the reaction mixture was allowed to stand in the dark for twenty-four hours, the gas formed during this time was removed, and the process repeated at the end of the next twenty-four hours.

TABLE V

VALUES IN CC.

	Run 1		Run 2	
	24 hours	48 hours	24 hours	48 hours
Carbon dioxide	2.36	0.65	1.86	0.66

Carbon dioxide on ignition	.18	.03	.18	.10

Pyruvic Acid.—No pyruvic acid was found in the reaction mixture although the test used would have shown the presence of 5 X 10^{-5} mole.

Discussion of Results

On the basis of the amount of carbon dioxide evolved: the oxygen used was 118%; peroxide formed, 32%; pyruvic acid, none; carbon monoxide, 0.4%. As the oxidation was continued for longer periods, the carbon dioxide given off became equal to the oxygen used. The amount of peroxide in the solution remained constant after the first hour of oxidation. The aldehyde concentration increased. The above results are the only ones that represent the condition of the reaction mixture at the end of the period of irradiation. In the distillation which is necessary for the analysis of the other products, the peroxide may decompose or may react with certain constituents of the reaction mixture. The products isolated by distillation were acetic acid, 75% (on carbon dioxide);

acetaldehyde, 28%; formaldehyde, 1%; ethanol, none; formic acid, not more than 0.4%. When the solution was allowed to stand for forty-eight hours before analysis, an additional 12% of carbon dioxide was evolved, the peroxide content dropped to 10% and the aldehyde to 12%. The quantum yield in this reaction is several times that of the decomposition reaction without oxygen. The above figures are unavoidably subject to certain errors inasmuch as the amount of lactic acid decomposed was extremely small and the separation of the decomposition products from the undecomposed acid and from each other was difficult.

The results do not exclude the possibility that one of the reactions follows this course: the lactic acid is first decomposed into carbon dioxide and ethanol. The ethanol, which must contain part of the energy from the absorbed radiation, is then oxidized to acetaldehyde. This acetaldehyde is oxidized to acetyl peroxide, probably after the absorption of additional radiation. Bowen[9] has recently shown this to be the case with acetaldehyde and oxygen alone. The acetyl peroxide subsequently reacts with acetaldehyde to give acetic acid. In order to account for the amount of oxygen used it would be necessary to assume the formation of some compound other than those described. No such compound could be identified although the reaction mixture contained a non-volatile reducing agent. Work is now being undertaken on propionic acid in the hope that this point will be cleared up. A similar decomposition of pyruvic acid shows that the reaction proceeds iii a manner which is entirely unlike that of lactic acid.

Summary

1. When lactic acid is decomposed by ultraviolet radiation in a solution containing dissolved oxygen, the chief products are carbon dioxide, acetaldehyde, a peroxide and acetic acid. The amount of each of these decomposition products has been measured.

2. Neither ethanol nor pyruvic acid is formed.

STUDIES ON POLYMERIZATION AND RING FORMATION. VII. NORMAL PARAFFIN HYDROCARBONS OF HIGH MOLECULAR WEIGHT PREPARED BY THE ACTION OF SODIUM ON DECAMETHYLENE BROMIDE

BY WALLACE H. CAROTHERS, JULIAN W. HILL, JAMBS E. KIRBY AND RALPH A. JACOBSON

RECEIVED OCTOBER 9, 1930 PUBLISHED DECEMBER 18, 1930

No rationally synthetic and practical methods for the preparation of giant individuals of the simpler homologous series are available, and one of the objects of the experiments here reported was to explore the possibilities of bifunctional Wurtz reactions as a means of access to this realm.

The first step in simple Wurtz reactions is the formation of the corresponding sodium alkyl, RNa.[1] This normally couples with the halide, forming the hydrocarbon R-R, but it may react in other ways and yield by-products. Sodium ethide reacts with diethyl ether

$$C_2H_5Na + (C_2H_5)_2O = C_2H_6 + C_2H_5ONa + C_2H_4{}^{2}$$

and one may expect the formation of considerable amounts of the hydrocarbon RH when the Wurtz reaction is carried out in that solvent,

The experiments presently described are concerned with the action of sodium on decamethylene bromide in ethereal solution, and the normal course of this reaction including that due to the participation of the solvent (but ignoring for the moment the possibility of intramolecular reaction) may be formulated as follows

$$\begin{aligned}
&Br(CH_2)_{10}Br + 2Na = Br(CH_2)_{10}Na + NaBr\\
&Br(CH_2)_{10}Na + (C_2H_5)_2O = H(CH_2)_{10}Br + C_2H_5ONa + C_2H_4\\
&Br(CH_2)_{10}Na + Br(CH_2)_{10}Br = Br(CH_2)_{20}Br + NaBr\\
&H(CH_2)_{10}Br + 2Na = H(CH_2)_{10}Na + NaBr\\
&H(CH_2)_{10}Na + (C_2H_5)_2O = H(CH_2)_{10}H + C_2H_5ONa + C_2H_4\\
&H(CH_2)_{10}Na + H(CH_2)_{10}Br = H(CH_2)_{20}H + NaBr\\
&H(CH_2)_{10}Na + Br(CH_2)_{10}Br = H(CH_2)_{20}Br + NaBr\\
&H(CH_2)_{10}Na + H(CH_2)_{20}Br = H(CH_2)_{30}H + NaBr\\
&H(CH_2)_{10}Na + Br(CH_2)_{20}Br = H(CH_2)_{30}Br + NaBr\\
&H(CH_2)_{30}Br + 2Na = H(CH_2)_{30}Na + NaBr\\
&H(CH_2)_{30}Na + Br(CH_2)_{20}Br = H(CH_2)_{50}Br + NaBr, \text{ etc.}
\end{aligned}$$

The product will be composed of individuals–of the general formula $H[(CH_2)_{10}]_xH$ and possibly of similar chains terminated at one or both ends by bromine atoms. The length of these chains will be determined by the relative rates of reaction of the sodium compounds with the solvent and with the halides. Solubility effects may also come into play.

The suitability of this reaction as a source of straight chain hydrocarbons will depend upon the extent to which it is possible to avoid undesirable

side reactions, and some indications on this point may be had from the known behavior of simple halides. Sodium and n-heptyl bromide at the boiling temperature give tetradecane, 67%; heptane, 9%; heptene, 3%; heneicosane, 3%; hydrocarbons of higher molecular weight, some.[3] Sodium and butyl bromide in ether under specified conditions give *n*-octane, 68%; butane ?, ?%; butene, *ca.* 1.5%; dodecane, *ca.* 0.15%; hexadecane, *ca.* 0.05%.[4] In both these typical cases the principal by-product is probably the hydrocarbon RH. In the reaction of the dihalide, this type of by-product would be identical with one of the normal reaction products. The higher hydrocarbons from butyl bromide and from heptyl bromide are probably not straight chains, and the formation of analogous products from the dihalide would be definitely pernicious because of the difficulty of separating isomeric individuals of high molecular weight. The quoted data on butyl bromide indicate however that in simple Wurtz reactions in ether not more than traces of these higher by-products need be formed.

The action of sodium wire on decamethylene bromide in absolute ether has been studied by Franke and Kienberger.[5] The reaction proceeded smoothly to completion, and the products isolated were: n-decane, 34%; C_{20} hydrocarbon, 30%; a small amount of C_{40} hydrocarbon; and a considerable amount of solid hydrocarbon of higher molecular weight. All of these products were free of halogen. The melting point of the C_{20} hydrocarbon identifies it as n-eicosane. The formation of large amounts of n-decane apparently puzzled Franke and Kienberger, and they repeated their experiments with elaborate precautions to exclude water and alcohol from the solvent and the halide. The results were the same. n-Decane and n-eicosane are, however, strictly normal products of the reaction as it has been formulated above. The fact that Franke and Kienberger could find neither decene nor cyclodecane in the products is worthy of note, for any side reaction would almost certainly be accompanied by the formation of some decene, and any intramolecular reaction by the formation of some cyclodecane. These data indicate that the course of this reaction is, at least for the most part, strictly normal and exclusively intermolecular. The major part of the product is composed of relatively short chains, but this is a matter which may be expected to be susceptible of some control by changes in the experimental conditions, and, as it appears to be in fact, especially by increase in the surface of the sodium.

We had already treated decamethylene bromide in ether with finely divided sodium with stirring before Franke and Kienberger's paper had come to our attention. The product, obtained in good yield, was an ether-in-

[5] Franke and Kienberger, *Monatsh.*, 33, 1189 (1912).

soluble solid, and no material boiling as low as n-decane was present. This product, by extraction and crystallization, was separated into $C_{20}H_{42}$, $C_{30}H_{62}$ and $C_{40}H_{82}$, each fairly pure, representing together about 25% of the total, and a higher fraction, m. p. 108–112°, representing about 75% of the total. This contained 1.39% organic halogen, from which it was freed by heating and stirring it with a small amount of molten sodium in boiling butyl ether. The apparent molecular weight of the resulting hydrocarbon was about 1000. No individuals could be isolated from it by repeated fractional crystallization, and it could not be distilled at 0.1 mm. pressure. It was finally separated into a series of individuals by distillation in the molecular still and by crystallization of the distillates.

Preparation **of the** Hydrocarbon Mixture.—In a 500-cc. flask provided with a reflux condenser and a mercury-sealed mechanical stirrer, **95** g. (**1.52** atoms) of sodium was pulverized under hot xylene. The xylene was removed and replaced by absolute ether, and then **75 g.** (**0.25** mole) of decamethylene bromide was added. The reaction mixture was stirred continuously. It soon developed a deep blue color. It was gently heated for one hour and then allowed to boil without external heating for two and one-half hours. Finally it was heated for two and one-half hours more and then allowed to stand overnight. The excess sodium in the thick mass was decomposed by alcohol, a large volume of water was added, and the mixture was filtered with suction. The only material found in the ethereal layer of the filtrate was **0.5** cc. of an oil boiling at 240–330°. The soft white residue on the funnel liquefied almost completely on being stirred with boiling water and solidified to a crystalline mass on cooling. It weighed **30.5** g. (87.1% calculated as CH_2). It melted from **85** to 100° and contained bromine (found, **2.17**, 2.27%). This solid was heated and vigorously stirred for five hours with **7** g. of molten sodium in boiling butyl ether. The excess sodium was decomposed by alcohol, a large volume of water was added, and the mixture was filtered. The solid residue on the funnel was washed with boiling water and dried. It weighed **21** g. It was free of halogen and melted from **87** to 105°. This is the material which was submitted to fractionation in the molecular still. After the butyl ether had been removed from the non-aqueous layer of the distillate, there remained **6** g. of a soft waxy solid melting at 48–54°.

Separation **of the** Hydrocarbon Mixture.—Eight grams of the solid hydrocarbon, m. p. 87–105°, described above was heated in a small molecular still[6] provided with a water-cooled condenser and a trap cooled with liquid air. The pressure in the system was continually maintained below 10^{-5} mm. Fractions were collected as follows.

Temp. of bath, °C.	Wt. of distillate, g.	M. p. of distillate, °C.
130	0.7	35 – 55
150–160	.27	60 – 75
150–160	.15	60 – 78
150–160	.20	77 – 79
160	.12	78 – 81
180	.20	79 – 84
190	.19	87 – 89

---

[6] Washburn, *Bur. Standards* **J. Research, 2,476 (1929).**

Temp. of bath, °C.	Wt. of distillate, g.	M. p. of distillate, °C.
195	.08	87 - 91
195	.10	90 - 90.5

250	31	94.5– 97
250	.11	96 - 98
250	.20	97 - 99.5
250	.10	98 –100.5
250	.05	99 –101
250	.08	99 –102
300	.47	103 –105
300	.17	103 –106.5
Total	4.02	
Residue	3.16	
Loss	0.82	

The loss is due to the impossibility of quantitatively removing the distillate from the condenser. In this distillation the average area of the evaporating surface was about 18 sq. cm. About twenty hours was required for the collection of each of the above listed fractions. When the temperature of the heating bath was raised above 300° with the view of distilling the residue, the pressure rose and no distillation could be effected.

The distillates were grouped together into eight fractions and redistilled. The rate of distillation from these partially purified materials was very much higher than from the initial mixture. The distillates were crystallized to constant melting points. The properties of all the fractions thus obtained are indicated in Table I.

TABLE I

INDIVIDUAL HYDROCARBONS

Identity **and** Properties of the Hydrocarbons.—The melting points 36.7°[7] and 65.6–66°,[8] respectively, have been assigned to n-eicosane and

---

[7] Krafft, *Ber.*, 19, 2220 (1886). The C_{20} hydrocarbon of Franke and Kienberger (Ref. 5) which melted at 36° was unquestionably n-eicosane; and their C_{40} hydrocarbon, which melted at 72°, was probably a mixture of n-triacontane and n-tetracontane.

[8] Gascard, Ann. *chim.*, [9] 15,332 (1921); Peterson, *Ber.*, 12,741 (1879).

n-triacontane, and these values are in good agreement with our observations. The other four hydrocarbons listed in Table I are all new, and the last one stands six atoms above any paraffin previously described. Several intermediate members of this same series have been described, however, and from the available data it is possible to construct a smooth curve of melting points covering the range C_{18}–C_{70}. The usefulness of such a curve in estimating the most probable values for individual hydrocarbons has already been emphasized,[9] and in the curve presented in Fig. 1 the crosses are Hildebrand and Wachter's estimates of the best values for hydrocarbons in the range C_{19}–C_{36}. We have used a method of plotting similar to that suggested by Austin[10] and have included the values for the three previously known hydrocarbons above $C_{36}H_{74}$. These are $C_{54}H_{110}$, $C_{62}H_{126}$ and $C_{64}H_{130}$, all described by Gascard.[8] Our data and those of Gascard fall very close to the same smooth curve which fits the best data for the lower hydrocarbons, and this fact incidentally affords confirmation of Hildebrand and Wachter's contention that the melting points accepted by the "International Critical Tables" for some of the hydrocarbons in the range C_{24} to C_{32} are much too high.

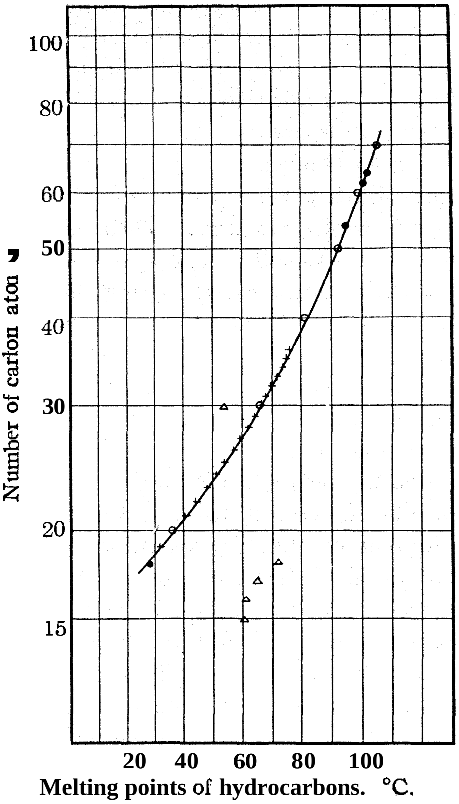

Fig. 1.—Normal paraffins: ●, Gascard, Ann. *chim.*, [9] 15,332 (1921); +, Hildebrand and Wachter, THIS JOURNAL, 51, 2487 (1929); O, new data. Cyclopolymethylenes: △, Ruzicka and co-workers, *Helv. Chim. Acta*, 9, 499 (1926); 11,496 (1928).

Hell and Haegele described dimyricyl in 1889[11] and ascribed to it the formula $C_{60}H_{122}$. This ascription acquired the sanction of recognition by Beilstein (third and fourth editions) and remained unquestioned until evidence that the myricyl radical contains 31 carbon atoms appeared. In 1921 Gascard[8] concluded that Hell and Haegele's hydrocarbon was $C_{62}H_{124}$ and that hexacontane had never been prepared. Our data confirm this

---

[10] Austin, *ibid.*, 52,1049 (1930).

[11] Hell and Haegele. Ber., 22,502 (1889).

conclusion. Hexacontane melts at 98.5 to 99.3°, while the observed melting points ascribed to dimyricyl have ranged from 100.5–102°.

Independent proof of the identity of the six hydrocarbons is furnished by x-ray diffraction patterns which have been obtained by Dr. A. W. Kenney and will be described in a separate publication.

Melting point data are available for only five cyclic polymethylenes above C_{10}. These fragmentary data do not fall on any smooth curve (see Fig. 1), but they are all widely enough separated from the data for the normal paraffins to provide additional assurance that none of our paraffin compounds are cyclic.

Under the heading distillation temperature in Table I are listed the minimum bath temperatures required to effect evaporation at a moderate rate in the molecular still. These temperatures are quite characteristic since they are, in each case, only a few degrees above the temperatures at which no distillation occurs. Using the Langmuir formula[6] it is possible to make a rough calculation of the order of magnitude of the vapor pressures of these hydrocarbons from the minimum distillation temperatures. Such calculations indicate a value less than 0.01 mm. for heptacontane at 300° and a value less than 1 mm. for triacontane at 100°. Heptacontane has a molecular weight of 983, and it is probable that no organic compound of much higher molecular weight than this can ever be distilled under any experimental conditions however favorable. The residue remaining from the removal of the heptacontane undoubtedly contained some octacontane, but none of this distilled out at a bath temperature of 300° and when the temperature was raised higher than this, decomposition set in. This experimental result agrees remarkably well with the inferences to be drawn from the data presented by Meyer and Dunkel.[12] From these data one can calculate that the molecular cohesion of heptacontane will be about 71,000 calories and that of octacontane about 81,000 calories. Since the heat of separation of the carbon-carbon bond is about 75,000 calories, it should be possible to distil the first of these compounds, but not the second. Saturated paraffins have, in general, a lower molecular cohesion for a given molecular weight than any other types of compounds, and hence the limit of distillability will be found at a lower molecular weight for other compounds than hydrocarbons. These results are also in agreement with data of a different kind presented by Burch[13] who, by distilling a Pennsylvania petroleum in a molecular still, obtained as the highest distillable fraction a material having an apparent average molecular weight of 801 and a residue of apparent molecular weight of 1550.

The physical properties of n-heptacontane are similar to those ascribed to dohexacontane and tetrahexacontane. It is very slightly soluble in

[12] Meyer, *Naturw.*, 16, 781 (1928); Dunkel, *Z. physik. Chem.*, 138, 42 (1928).

[13] Burch, Proc. *Roy. Soc.* (London), 123, 271 (1929).

boiling alcohol, ether or petroleum ether, but crystallizes well in the form of minute needles from hot butyl acetate or benzene. It dries to a starch-like powder which has a great tendency to become electrified.

It was hoped that it might be possible to isolate hydrocarbons much higher than heptacontane, since information concerning simple individuals of very high molecular weight would be of great importance to the study of macromolecular materials generally, but there seems little probability of achieving this result without some change in method or advance in technique. The residue from which the n-heptacontane was distilled is a mixture which undoubtedly contains n-octacontane, n-nonacontane, n-decacontane and still higher hydrocarbons. It is readily soluble in hot butyl acetate (except for a trace of insoluble and infusible material), and it separates as a powder melting at 110–114°. Its apparent average molecular weight in boiling benzene is about 1300. (Calcd. for $C_{90}H_{182}$, 1263.) By extraction with hot ethylene chloride, it was separated into fractions melting at 100–107°, 106–111° and 110–114°. In a sense this mixture is a polymeric homologous series, but its solubility is much lower than that of such supposedly analogous series of higher molecular weight as polystyrene and hydro-rubber. It resembles a probably similar but more complex mixture of hydrocarbons obtained by Fischer and Tropsch by the catalytic hydrogenation of carbon monoxide.[14]

There is one point bearing on the behavior of highly polymeric materials which is capable of a rough preliminary test with the series of hydrocarbons described above. It has been suggested[15] that the apparent decrease of molecular weight (decrease of viscosity, etc.), which is observed when rubber and other very high polymers are gently heated or treated with certain mild chemical agents or subjected to mechanical stresses, is real and is due to the fact that the thermal stability of molecules decreases continuously with increasing size, and in these materials has reached so low a value that cracking occurs at slightly above room temperature. Samples of each of the hydrocarbons from C_{30} to C_{70} were sealed off in small bulbs under nitrogen and heated side by side in a metal-bath After five minutes at 400° all the melting points were unchanged. After five minutes at 410° the melting point of C_{70} was lowered from 106–107° to 104–105°. The melt, moreover, was not clear as before but turbid. The turbidity disappeared rather sharply at 110°—like a liquid crystal. The melting points of the other hydrocarbons were substantially unchanged, but, except for C_{30}, they all gave hazy melts which cleared up only at temperatures somewhat above their true melting points. After five minutes more at 420° all the melting points had become lower (that of C_{70} most) and there was some coloration. The C_{30} was white, the C_{40} was cream-colored, and the higher hydrocarbons

[15] Staudinger. Ber., *59*, 3037 (1926).

in regular order were increasingly darker. When the tubes were finally opened after five minutes more at each of the temperatures 430, 450 and 470°, they were found to contain considerable gas—most above the C_{70} and least above the C_{30}. Thus, the decrease in thermal stability with increasing molecular weight which is so marked in passing from methane (*ca.* 700°)[16] to ethane (*ca.* 550°),[17] and from ethane to hexadecane (*ca.* 470°)[18] is still detectable in going from triacontane to heptacontane, but it has already fallen to such a small value that it would be somewhat unsafe to infer that a paraffin hydrocarbon of molecular weight 200,000 or even greater might not persist at room temperature.

Mechanism of the Action of Sodium on Decamethylene Bromide.—It has already been pointed out that all the observed products of this reaction are accounted for by assuming replacement of the bromine atoms of the halide by sodium, and the subsequent coupling of this with other molecules of the halide, or its reaction with the solvent. The absence of cyclic hydrocarbons is not surprising since, although the higher cycloparaffins are no less stable than cyclohexane,[19] the formation of large rings in bifunctional reactions occurs only under very exceptional conditions.[20] In the formation of esters from ω-hydroxy acids, amides from amino acids, and anhydrides from dibasic acids, intramolecular reaction occurs exclusively only if there is a possibility of forming a 5- or a 6-membered ring. The behavior of alkylene halides toward metals however is peculiar in that there seems to be little tendency toward intramolecular reaction even when a 5- or a 6-membered ring might be formed. Thus the action of magnesium on alkylene halides leads to considerable coupling, but even from pentamethylene halides no cyclic hydrocarbon is formed.[21] This suggests that the coupling perhaps occurs largely at the metal surface where the atoms at the ends of the chains may be fixed by forces of adsorption and their freedom of intramolecular approach hindered.

Our main objective in the experiments described above was to prepare normal paraffins of very high molecular weight, and we made a number of attempts to adjust the experimental conditions so as to increase the length of the reaction chains. We treated decamethylene bromide with molten sodium in boiling butyl ether, with liquid sodium–potassium alloy in ethyl ether, with molten sodium in boiling octane and with finely divided sodium in the absence of a solvent. There was no evidence of the formation of considerable amounts of paraffins higher than C_{100} in any of these experi-

ments. We also prepared decamethylene dimagnesium bromide and treated it with cupric chloride in the expectation that products of the formula $BrMg[(CH_2)_{10}]_xMgBr$ would be formed. The chief product (71%), however, after the addition of water, was a volatile liquid apparently chiefly composed of decane and decene. The amount of higher boiling material (20%) did not exceed that which would arise from the coupling products usually produced in the formation of such reagent.: as decamethylene dimagnesium bromide.[21]

Preparation of Decamethylene Bromide.—The preparation, in good yields, of a whole series of polymethylene bromides from the glycols via the esters of the corresponding dibasic acids has been described by Chuit[22] but without great experimental detail. We first attempted to reduce ethyl sebacate by Levene and A len's modification[23] of the original Bouveault procedure.[24] In this modification, which has given good results in the reduction of esters of monobasic acids, the sodium is first granulated by stirring in hot toluene, and the reaction mixture is vigorously stirred during the addition of the alcohol–ester mixture. This procedure gave very poor yields of decamethylene glycol; the yields were increased by diminishing the speed of stirring and became quite good when the stirring was omitted altogether. The procedure finally adopted was almost identical with that of Bouveault, and the details are given below.

A condenser having a length of 2 meters and an inside diameter of about 2.5 cm. is connected with the side neck of a 5-liter two-necked round-bottomed flask, and the central neck of the flask is provided with a 1-liter dropping funnel. One hundred and fifteen grams (5 atoms) of sodium in a single piece or in two or three large pieces is placed in the flask. One hundred and twenty-nine grams (0.5 mole) of ethyl sebacate is dissolved in one liter of thoroughly dried absolute ethyl alcohol and poured into the dropping funnel. One hundred and fifty to two hundred cubic centimeters of the alcohol–ester mixture is allowed to fall onto the sodium at once. After two or three minutes the reaction becomes vigorous and the sodium melts. As soon as the sodium has melted another portion (about 100 cc.) of the alcohol–ester mixture is suddenly added. This causes the molten sodium to break up into fine particles, and the reaction becomes much more vigorous. The rest of the alcohol–ester mixture is then added as rapidly as possible (five to six minutes). As soon as the vigor of the reaction has somewhat subsided, the flask is heated by an oil-bath to 110–115° until most of the sodium has dissolved. The ethyl alcohol is then removed from the reaction mixture by steam distillation, and the glycol is removed from the residue by extended (about seventy-two hours) continuous extraction with ether. The glycol is purified by distillation. The combined yield from nine such runs was 593 *g.* or 75% of the theoretical.

Continuous ether extraction as a means of isolating glycols produced by the reduction of esters has been successfully used by C. S. Marvel;[25] otherwise the above pro-

cedure is similar to that which has also been used by Miiller for preparing a series of glycols.[26]

Using the method described by Chuit,[22] we obtained from decamethylene glycol only a 70% yield of bromide and this was contaminated with bromohydrin. The following modification of this method gave a purer product and a better yield.

Dry hydrogen bromide was led into a well-stirred melt of 255 g. (1.47 moles) of decamethylene glycol in an open flask until the mass was saturated. The temperature of a metal-bath surrounding the flask was kept at 90–95°. After saturation was complete the bath temperature was raised to 135–140° and a slow stream of hydrogen bromide was led in for six hours. The reaction mass was then cooled, diluted with benzene and decanted from a small amount of water remaining in the flask. The benzene was then removed by distillation, and the product distilled under diminished pressure; yield, 376 g. (85.5%); b. p., 168–172° (10 mm.).

Anal. Calcd. for $C_{10}H_{20}Br_2$: Br, 53.33. Found: Br, 53.16, 53.16.

We are indebted to Mr. W. L. McEwen for the preparation of decamethylene glycol.

Summary

By the action of sodium on decamethylene bromide in ether a mixture of paraffins of the general formula $H—[(CH_2)_{10}]_x—H$ has been prepared. By fractional distillation in the molecular still and by crystallization, the following individuals have been isolated from this mixture: n-eicosane, n-triacontane, n-tetracontane, n-pentacontane, n-hexacontane, *n*-heptacontane. The last four of these are new, and the last one has a higher molecular weight than any pure paraffin hydrocarbon hitherto described. The residue remaining from the separation of the hydrocarbons named amounts to about 25% of the total and is composed of still higher members of the same series which it has not yet been possible to separate. The mechanism of the reaction and the properties of the products are discussed.

STUDIES ON POLYMERIZATION AND RING FORMATION. VIII. AMIDES FROM a-AMINOCAPROIC ACID

BY WALLACE H. CAROTHERS AND GERARD J. BERCHET

RECEIVED OCTOBER 9, 1930 PUB ISHED DECEMBER 18, 1930

ε-Aminocaproic acid on being heated reacts with itself and yields two products—the corresponding 7-membered lactam, 20–30%, and an undistillable material of approximately the same composition, 80–70%.[1] The following related facts are of interest. δ-Aminobutyric acid and a-aminovaleric acid readily lose water and yield the corresponding 5- and 6-membered lactams.[2] No corresponding polymers are formed or known. The reaction of ζ-aminoheptoic acid with itself is apparently exclusively intermolecular, for it leads to an undistillable product quite different in its properties from the known &membered lactam.[3] Similar relationships are found among the hydroxy acids: y- and 6-hydroxy acids yield lactones; ε-hydroxy acids yield both lactones and polyesters,[4] and the higher w-hydroxy acids yield only the polyesters,[5] although many of the higher lactones are known.[6] Polyesters have now been studied in some detail,' but (except for polypeptides) little attention has been devoted to the polyamides. In this paper we record some observations concerning the polyamide derived from E-aminocaproic acid.

Water is rapidly evolved when E-aminocaproic acid is heated above its melting point (*e.* g., to 210–220°). The polymer and the lactam which result are readily separated by allowing the latter to distil under diminished pressure, or by extracting it with boiling alcohol. In different experiments the yield of lactam was 20–30% and the polymer 80–70%. The same products were obtained by gradually heating the ethyl ester of the acid from 160 to 200° during six hours, and the yield of lactam was about 38%.

The polymer is a hard gray wax, insoluble in most organic solvents, but soluble in hot formamide, from which it separates as a microcrystalline powder melting at 212–214°. Its analytical composition agrees very closely with that required for the structural unit $—NH—(CH_2)_5CO—$.

Anal. Calcd. for $C_6H_{11}ON$: C, 63.71; H, 9.73. Found: C, 63.35, 63.62; H, 9.93, 10.07. A product from another preparation gave: C, 63.35, 63.45; H, 9.56, 9.43.

It is quantitatively hydrolyzed in six hours by boiling concentrated hydrochloric acid to ϵ-aminocaproic acid (identified by conversion to the *p*-toluenesulfonyl derivative, melting point and mixed melting point, 105–106°).

By partial hydrolysis, polyaminocaproylaminocaproic acids are formed. Thus, a sample of the polyamide was heated to boiling for one hour in concentrated hydrochloric acid solution, and the solution was diluted with water to precipitate the unchanged polymer (about 50%). The material remaining in solution, on being treated with alkali and *p*-toluenesulfonyl chloride, gave a solid product which, after repeated crystallization, showed a neutral equivalent corresponding with the formula C_7H_7-SO_2-$[NH(CH_2)_5CO]_3$-$NH(CH_2)_5COOH$ (calcd., 607; found, 601). The structure of the polymer may, therefore, be represented by the formula

$$? —NH(CH_2)_5CO—[NH(CH_2)_5CO]_x—NH(CH_2)_5CO— ?$$

It is a true condensation polymer and is formed directly from the amino acid by intermolecular reaction. This is proved by the fact that the lactam does not polymerize under the conditions of formation of the polyamide either in the presence or absence of catalysts. Moreover, no lactam can be obtained from the polyamide by heating it to high temperature in high vacuum. Thus there is no such reversible relationship between lactam and polyamide as is found[7c,e] to exist between six-membered cyclic esters and corresponding polyesters. Lactam and polyamide result from the amino acid by two independent and simultaneous processes. The lactam incidentally is really the 7-ring $\underline{\ulcorner NH(CH_2)_5CO \urcorner}$.[8] This was proved by identifying its hydrolytic product with e-aminocaproic acid through its *p*-toluenesulfonyl derivative by means of a mixed melting point.

The polyamide is sufficiently soluble in phenol to permit a determination of molecular weight by cryoscopy. Values obtained ranged from 800 to 1200, and since the errors of this method are such as to lead to low results it may be assumed that at least 10 molecules of the amino acid must have participated in the formation of a single molecule of the polyamide.

The question of the nature of the groups at the ends of the polyamide

---

[8] The shifting of a functional group down a chain in attempts to prepare large rings by bifunctional reactions has been reported by various investigators. See, for example. Blaise and Koehler, Ref. 4.

chains cannot yet be answered. The formation of large rings is very improbable on theoretical grounds,[9] and in the formation of polyesters ring formation is known not to occur—the hydroxyl or carboxyl groups still persist at the ends of the polyester chain.[7b,c,d,5c] However, no certain evidence of the presence of terminal amino or carboxyl group in the molecule of the polyamide could be obtained. The polyamide dissolves readily in cold concentrated hydrochloric acid, but when the solution is diluted with water it separates unchanged and free from more than traces of halogen. It is not soluble in hot or cold aqueous sodium hydroxide nor does it form any sodium salt. It reacts with molten *m*-bromobenzoic anhydride and, in hot pyridine, with *p*-bromobenzene-sulfonyl chloride. The products contain bromine in amounts which correspond with derivatives of minimum molecular weights about 1100 and 1500, respectively, but in view of the failure of other reactions these cannot be accepted as evidence of the presence of free amino groups in the polyamide. At present we are inclined to assume that the amino and carboxyl groups which would normally be present at the ends of the polyamide chains are lost by pyrolysis. (The evolution of carbon dioxide during the formation of the polyamide could not be detected, but the vapors evolved had a strong amine odor.)

Summary

ε-Aminocaproic acid (or its ethyl ester) on being heated reacts with itself both intra- and intermolecularly and yields the 7-ring lactam (*ca.* 30%) and a polyamide (*ca* 70%). The formation of a molecule of the latter probably involves at least ten molecules of the amino acid.

WILMINGTON, DELAWARE

NOTES

A Method for the Determination of Molecular Weights in Liquid Ammonia.—Very recently Schwarz[1] and Signer[2] have published a new method for the determination of molecular weights. This method makes use of the principle that two solutions in the same solvent confined with a common vapor phase will come to the same molecular concentration by diffusion of the vapor.

The advantages of the method are that it enables the molecular weights of substances of low solubility and large molecular weight to be determined accurately; it makes possible molecular weight determinations in the same solvent at different temperatures; and it is adaptable to micro-manipulation.

---

[9] Carothers, THIS JOURNAL, 51, 2556 (1929).

[1] Schwarz, *Monatsh.*, 53, 54, 926 (1929).

[2] Signer, *Ann.*, 478, 246 (1930).

Before these publications appeared, we found, employing the same method, that the slow diffusion of organic solvents was a great disadvantage. To correct this fault we resorted to liquid ammonia as solvent and found that it gave excellent results.

Even with liquid ammonia the time required to reach equilibrium was about 150 hours. The rate of transfer varied from 0.1 to 1.0 cc. per day, depending on the differences in concentrations of the solutions.

Apparatus and Procedure.—The apparatus was made by joining two long calibrated test-tubes with a U-tube at their middle points. The tubing was 1 mm. thick and 8 mm. in internal diameter. Into the U was sealed a 4-mm. tube by which connection was made with the ammonia cylinder. Known quantities of solutes were placed in the calibrated tubes, ammonia introduced and the tubes sealed.[3] The apparatus, with U-tube inverted, was rocked mechanically until equilibrium was attained. The final volumes of the solutions were then read and the molecular weight of the unknown calculated from the formula, $M_2 = (w_2v_1M_1)/(w_1v_2)$. The symbols M, v and w signify molecular weight, final volume and solute weight, respectively. The subscripts 1 and 2 refer in turn to the standard and unknown substances.

Data and Discussion.—The results obtained are summarized in Table I.

TABLE I

MOLECULAR WEIGHTS IN LIQUID AMMONIA

[3] Franklin has described the technique used for handling the liquid ammonia, *J. Phys. Chem.*, 15, 509 (1911).

TABLE I (*Concluded*)

			Volume				Volume		Mol. Wt.	
Expt.	Unknown	Wt., g.	Initial	Final	Standard	Wt.	Initial	Final	Obs.	Calcd.
16	Diphenylamine	0.156	8.58	7.82	Mannitol	0.240	8.18	8.78	133	169
17	Resorcinol	.353	7.44	8.48	Mannitol	.498	7.81	6 75	103	110
18*	Thymol	.148	7.81	5.54	Mannitol	.288	7 56	9.72	164	150
19*	Naphthalene	.180	6.00	6.49	Mannitol	.177	5.54	4.90	140	128
20*	Sorbitol	.209	6.10	5.69	Mannitol	.276	6 05	6.46	157	182
21*	Mannose	.191	11.16	10 00	Mannitol	.301	11.44	12.44	144	180
22*	Fructose	.348	11.38	15 31	Mannitol	.299	10.67	6.61	92	180
23*	a-Methyl glucoside	.228	8.04	7.68	Mannitol	188	7.19	7.44	214	212

The data in the table show what accuracy may be expected by the use of this method. Undoubtedly more accurate results can be obtained if the tubes be put in a constant temperature bath, for better results were obtained in a room where the temperature variation was not more than 2° (starred experiments) than in the laboratory where the variations were much greater (unstarred experiments).

That the method is correct in principle is shown by the results recorded in Expts. 1–7. Here the solutions contained the same solute and reached the same molecular concentrations.

A surprising result was discovered in the case of ammonium chloride. Experiments 12 and 13 indicate that this substance exists in the dimolecular form in liquid ammonia.

The low value obtained for fructose (Expt. 22) is probably due to its reaction with the solvent. That such reaction is likely follows directly from Strain's[4] results obtained with other ketones.

Should a micro method for molecular weight determinations in liquid ammonia be desirable, this method can probably be micrified, because Schwarz[1] has shown that this type of method is adaptable to micromanipulation.

The writers are indebted to Dr. F. W. Bergstrom and the Department of Chemistry of Stanford University for the liquid ammonia required for this investigation.

ω-Alkylalkoxyaminopropiophenones.—It has been shown by Mannich that condensation takes place between ketones, formaldehyde or trioxymethylene and amine hydrochlorides with the formation of β-keto bases.[1] Later he found that the β-keto bases which were formed by the condensation of alkyl aryl ketones with formaldehyde and primary or secondary amines possessed local anesthetic action.[2]

It has been shown that substituted O-alkylhydroxylamines, in general, have the physiological properties of the amines to which they are related.[3] It therefore seemed probable that w-alkylalkoxyaminopropiophenones would be local anesthetics. It has been found, however, that these compounds exhibit only very slight anesthetic action, at least when they are applied to the mucous membrane of the tongue. They were synthesized by the method of Mannich.

One molecular equivalent each of acetophenone and O,N-dialkylhydroxylammonium chloride, two molecular equivalents of trioxymethylene and ten molecular equivalents of absolute alcohol were refluxed for twenty-four hours. The solution was cooled and dry ether was added. The precipitate which formed was dissolved in water and the aqueous solution was extracted with ether in order to remove any trace of acetophenone. Caustic alkali was then added to the solution of the hydrochloride in water. The oil which separated was extracted with ether and the ether solution dried with sodium sulfate. After the ether had been distilled off an oil remained which was distilled in *vacuo*.

w-Methylmethoxyaminopropiophenone was a colorless oil, b. p. (23 mm.) 159"; yield, 50%

COMMUNICATIONS TO THE EDITOR

THE "STAR TRAIL" METHOD FOR THE SPECTROGRAPHIC QUANTITATIVE DETERMINATION OF THE ELEMENTS

Sir:

Diligent search of the voluminous literature has failed to disclose the "Star Trail" method for the spectrographic quantitative determination of the elements as described below. A bright line is isolated from a spectrum by interposing a slotted light stop between the refracting element and the telescope of a spectroscope. The image of the line so isolated falls upon a film affixed to a rapidly rotating drum which spreads out this line into a band. The rotation serves to equalize any flickering due to any cause and to render the band of uniform density, which depends upon the concentration of the given element in the solution employed and upon the time during which the film is exposed to the light. The drum carrying the film can be racked up or down so as to expose different parts of the film, as desired.

Spectra due to different concentrations of the same element, employed as standards, are exposed in a series with the unknown concentration on the same film as a succession of bands, keeping time of exposure and speed of rotation of the film as constants. The bands of different density can be compared directly by cutting the film across all the bands and bringing the latter into direct alignment. Density can also be controlled by the manner of developing the film.

Experiments with sodium chloride in concentrations varying between 0.500 and 0.0250% and exposure of five minutes to a portrait panchromatic film gave satisfactory indications of the value of the method.

Work is now proceeding at the University of Illinois with special reference to the application of the method to the quantitative analysis of the alkali metals.

THE PARACHORS OF TWO ISOMERIC CHLORODINITROBENZENES

Sir:

In a recent communication[1] Sickman and Menzies reported the results of a determination of the parachor of 1-chloro-3,4-dinitrobenzene from surface tension measurements at 40 to 60°. This was found to be approximately the same, allowing for "drift of parachor with temperature," as that evaluated from Jaeger's measurements[2] of the surface tension of the

---

[1] Sickman and Menzies, THIS JOURNAL, 52, 3327 (1930).

[2] Jaeger, *Z. anorg. allgem. Chem.*, 101, 117 (1917).

1-chloro-2,4-dinitro isomer at 60 to 95°. After pointing out that in both these cases the observed parachor is more than 3% lower than that calculated from Sugden's atomic and structural constants,' the authors added, "the latter have been recalculated by Mumford and Phillips." By using these newer constants, the discrepancy is not diminished.. ..." As will be apparent from the following table, however, this statement is incorrect, for the use of the reëvaluated constants materially reduces the difference between calculated and observed values.

TABLE I

PARACHORS OF THE CHLORODINITROBENZENES

Compound	Parachor
1-Chloro-3,4-dinitrobenzene (Sickman and Menzies 40 to 60°)	347.4
1-Chloro-2,4-dinitrobenzene (Jaeger 60 to 95°)	348.2
Calculated for either compound (Sugden)	358.3
Calculated for either compound (Mumford and Phillips)	353.2

The latter value, which was, incidentally, quoted in our original paper on the reevaluation[6] is the algebraic sum of the constants for the constituent atoms (*viz.*, 6 of carbon, 3 of hydrogen, 1 of chlorine, 2 of nitrogen and 4 of oxygen), and those for the various structural features (*viz.*, 1 six-membered ring, 5 non-polar and 2 semi-polar double bonds) together with the *appropriate* strain constants, in this case one of -3 units associated with each of the nitro groups, and a complex one of $-(3.4 + 2.4 + 2.2) = -8$ units due to the unsymmetrical accumulation of three negative groups around the benzene nucleus.

It must be noted further that in the case of Jaeger's data for 1-chloro-2,4-dinitrobenzene, only three measurements at lower temperatures have been utilized by Sickman and Menzies. A considerably higher mean parachor is obtained if the other six determinations are also taken into account, as has been done in Table II.

TABLE 11

JAEGER'S DATA FOR 1-CHLORO-2,4-DINITROBENZENE

[5] Mumford and Phillips, Ref. 4, Table V, p. 2118.

The average of all the measurements is 350.7, but as the parachor rapidly attains and maintains a mean value of about 351.6, it is evident that this should be taken as representative of the compound in question, and the values in the vicinity of the melting point regarded as anomalous. This value, which was quoted in our original paper as the observed parachor of 1-chloro-2,4-dinitrobenzene, is less than 0.5% lower than that calculated from our reevaluated constants, namely, 353.2, and it would, therefore, seem unnecessary to look further for the cause of the apparent discrepancy.

In the case of the 1-chloro-3,4-dinitro isomer the observed parachors likewise increase rapidly with temperature in the vicinity of the melting point and it seems likely that here also a higher and truer mean value would have been obtained had the measurements been extended to higher temperatures.

PARACHORS OF ISOMERIC CHLORODINITROBENZENES

Sir:

Through the courtesy of the Editor, we are enabled to add in this issue a few words on the subject of the foregoing interesting note.

In Table V of their cited article, Mumford and Phillips tabulate 361.2 under the caption "Σ At. P." and −8 under the caption σ (or strain constants). Since the strain constants for the nitro group are not referred to until two pages later, we had not understood that these were included in the value 361.2, which we took to be a misprint for 367.2, the value for the sum of atomic and structural constants. The interpretation of the authors is, therefore, very welcome.

The reason we made our measurements in the temperature range 40–60° was because this was the range used by Müller, whose enormous discrepancy it was our primary purpose to examine.

In comparing the results of Jaeger for the other isomer, we thought it fairest to use the portion of his temperature range closest to 40–60°; and, because we noticed that there was an apparent drift of this parachor with temperature, we corrected the value for drift in order to make the best possible comparison. When a parachor exhibits such drift, the best criterion for its absolute value is, of course, debatable.

THE STRUCTURES OF THE ACETYLMETHYLMANNOSIDES[1]

Sir:

Three new crystalline hepta-acetyl-4-glucosido-methyl-mannosides have been prepared by the Koenigs and Knorr reaction: (a) m. p. 185°, $[\alpha]_D^{20}$ $+26.7°$ in chloroform; (β) m. p. 161°, $[\alpha]_D^{20}$ $-22.3°$ in chloroform; (γ) m. p. 167°, $[\alpha]_D^{20}$ $-12.7°$ in chloroform. These new compounds appear to be analogous to the three previously known acetylmethylmannosides whose structures have been the subject of considerable controversy [Hudson, THIS JOURNAL, 52, 1680 (1930)]. Since the new compounds cannot contain a 1,4-ring, that ring structure is eliminated for compounds of the corresponding types. The new derivative designated "γ" exhibits the reactions characteristic of the acetylmethylglycosides which have recently been assigned an ortho carbonic ester structure by Bott, Haworth and Hirst [*J. Chem. Soc.*, 1395 (1930)] and also independently by K. Freudenberg [*Naturwissenschaften*, **18,** 393 (1930)].

The writer has found that the methoxyl group in one of his new compounds (γ) may be replaced by a hydroxyl group, giving a hepta-acetyl-4-glucosido-mannose, which does not exhibit mutarotation, $[\alpha]_D^{20}$ $+21.7°$ in chloroform. If the methoxyl group in the parent glycoside were combined directly with the first carbon atom upon removing the methoxyl group, the first carbon would be left free and the new substance would exhibit mutarotation. The absence of mutarotation for the new substance indicates that the methoxyl group in the parent hepta-acetyl-4-glucosido-y-methylmannoside was not combined directly with the first or aldehydic carbon. Thus the newly found reactions support the Haworth–Freudenberg ortho carbonic ester structure rather than the 1,3-ring structure for compounds of this type.

THE ACTIVATION ENERGY OF ADSORPTION PROCESSES

Sir:

A rapid development in experimental researches, during the last decade, on adsorption phenomena at solid surfaces having catalytic activity has served to emphasize the existence of adsorption processes in which a high degree of specificity is manifest. This has centered attention on the function of valence forces in determining adsorption. The experimental work has produced a number of results which, from the standpoint of classical adsorption theory, are abnormal. These include abnormal

---

[1] Publication approved by the Director of the Bureau of Standards of the U. S. Department of Commerce.

variations of the extent of adsorption with temperature and pressure, abnormal variations of the heats of adsorption with temperature and pressure, large variations in the velocity of attainment of adsorption equilibrium in different systems and in the velocity of evaporation of adsorbed gases. These several factors also influence the velocity of chemical processes occurring at the surfaces in question.

It has now been found that all of these difficulties can be removed and a unified method of treatment results once it is grasped that adsorption processes, in general, require an activation energy. It can be shown that the activation energies of such adsorption processes may vary from very small values to magnitudes such that the adsorption phenomena may first be obtained at quite high temperatures. Moreover, the magnitude of the activation energy is determined not only by the adsorption process in question but also by the nature of the surface area on which the process occurs. Thus, for example, the adsorption of hydrogen on the most active areas of catalytic metals involves such a small activation energy that the process is rapid at temperatures as low as $-100°$. With various oxide surfaces the adsorption process only manifests itself at temperatures several hundred degrees above room temperature. Numerous examples of these factors involving a variety of surfaces and the gases hydrogen, oxygen, nitrogen, carbon monoxide and water vapor as adsorbates have been collected. The detailed discussion of the subject will be communicated shortly.

NEW BOOKS

Tables annuelles de constantes et **données numériques** de **chimie,** de physique, de biologie et de **technologie.** (Annual Tables of Constants and Numerical Data Chemical, Physical, Biological and Technological.) Published under the auspices of the International Research Council and the International Union of Pure and Applied Chemistry by the International Committee appointed by the Seventh Congress of Applied Chemistry (London, June 2, 1909). Vol. VII, Parts 1 and 2, 1925–1926. McGraw-Hill Book Company, Inc., 370 Seventh Ave., New York, 1930. Part 1, xxxv + 946 pp. Part 2, xv + 950 pp. 22.5 X 28 cm. Price, $25.00 per set.

All workers in the natural sciences will welcome the appearance of this double volume of the Annual Tables covering the years 1925–1926. Naturally the arrangement and mode of treatment followed in the earlier volumes are retained here. There are, however, certain minor changes and additions. English versions of some portions of the French text which might present some difficulties to the reader have been introduced. Two new chapters on Explosions and on Explosions in Gaseous Mixtures have been added and two old chapters treating of Photography and Geophysics have been omitted, since the specialists in charge of these subjects prefer to have them published only once in every two volumes. Numerous detailed indices to the substances mentioned in the tables and to memoirs whose data are not susceptible of inclusion in the Tables have also been added.

Dr. Marie, Secretary of the International Committee, announces that Volume VIII covering the years 1927 and 1928 is already in press and should be published by the beginning of 1931. With the next volume thereafter (Volume IX) covering 1929, the yearly publication of the Annual Tables will be resumed. Dr. Marie also calls attention to the forthcoming General Index covering Volumes I–V and this in the meantime has appeared.

These tables impress one with the beneficient results which can flow from an international cooperative effort of this kind entrusted to intelligent and public-spirited men.

ARTHUR B. LAMB

Non-Interpolating Logarithms, Cologarithms and Antilogarithms. By FREDERICK W. JOHNSON, M.A., Instructor in Chemistry, California College of Pharmacy, University of California. The Simplified Series Publishing Company. 1381 Third Avenue, San Francisco, California, 1930. 16 X 21.5 cm. Price, $1.60.

Five years ago no one would have considered that tables of logarithms offered much scope for any significant improvement. Nevertheless, within that period the graphical tables of Lacroix and Ragot [THIS JOURNAL, 48, 842 (1926)] have appeared and now we have these new tables of four- and five-place logarithms where, within substantially the compass of ordinary tables, logarithms (and antilogarithms) to four and five places, respectively, can be read off by inspection, without any calculation whatever. This is achieved very simply by the ingenious use of a new vertical arrangement and a mixture of bold-faced and ordinary type.

There seems to be no doubt in the case of the five-place logarithms that the new tables save both time and mental effort as compared with the ordinary tables. Moreover, it is not difficult to learn how to use them. In the case of the four-place logarithms the advantages are less pronounced. The elimination of interpolation is of less moment here, because anyone who uses frequently an ordinary four-place table can make the interpolations very quickly and easily. Moreover, the somewhat greater complexity of the new tables is here a noticeable drawback.

There is less to choose between these new tables and the above-mentioned graphical tables. So far as speed is concerned they are about on a par, at least for *a* person equally familiar with both. However, the mental effort involved in the use of the graphical tables, where one must correlate the two abutting scales to obtain the last two figures seems greater than in the use of these new tables.

There are also included in this volume the usual introduction, several pages of conversion factors, trigonometric functions and formulas and a table of "International Atomic Weights." This table besides being out of date (1925) gives logarithms of atomic weights to five places, irrespective of the number of significant figures in the atomic weights themselves.

Anyone who has to use five-place logarithm tables frequently would do well to give these tables a trial.

ARTHUR B. LAMB

Einführung in die technische Behandlung gasförmiger Stoffe. (Introduction to the Technical Methods of Handling Gaseous Materials.) By W. BERTELSMANN, Dipl.-Ing. Dr. phil., and F. SCHUSTER, Dr.-Ing. Verlag von **Julius Springer,** Link-strasse **23–24, Berlin W 9, Germany, 1930. x + 411 pp. 288 figs. 15.5 × 24 cm. Price, unbound, RM. 38; bound, RM. 40.**

The authors state that their book was written for the purpose of acquainting technologists in various fields with the methods technically employed in the generation, handling and purification of gases.

In the introduction (40 pages) an attempt is made to explain and summarize the physical-chemical laws which govern the behavior of gases and the reactions which occur in gaseous systems. Some of the material in this introduction is so elementary that the authors would have been justified in assuming that it would be familiar to the reader The discussion of the more important topics is so condensed that it would be of but little value to a reader who was not already familiar with these topics. The lack of clearness and completeness in the introductory chapter is not, perhaps, a very serious defect, since in the subsequent chapters of the book little reference is made to the underlying theory developed here.

Chapter I, on Warming, Cooling, Compression and Liquefaction of Gases, contains a rather elementary and descriptive discussion of these subjects. The general equation for the rate of flow of heat by conduction is given, but the reader will find little information as to the actual rates of heat transfer to be expected in any specific case.

The second chapter, on the methods for obtaining gases, includes a rather detailed description of the procedure followed in drilling for natural gas. To the reviewer, this topic does not appear to have sufficient general interest to justify the emphasis placed upon it here. The discussion of the fractional distillation of liquefied gases is so elementary and incomplete that it would be of little assistance to the reader who desired to gain even a general knowledge of this subject.

The third, fourth, fifth, sixth and seventh chapters deal with the preparation, purification, measurement, storage and distribution of gases, respectively. The treatment is largely descriptive.

The eighth chapter, on methods of testing and analyzing gases, is **very**

incomplete. Many of the methods and types of apparatus described therein are obsolete. Many of the newer methods actually used in the industries are not described.

In their attempt to cover a wide field in a single volume, the authors have omitted much which would be of great importance to any technologist who is called upon to prepare or handle industrial gases. In the opinion of the reviewer, the material which has been included has not been well selected nor ably presented. The reviewer does not regard this book as a particularly valuable contribution to the technology of gases.

F. H. RHODES

Lehrbuch der organischen Chemie. (Textbook of Organic Chemistry.) By Professor Dr. JULIUS SCHMIDT, Stuttgart. Fourth revised edition. Ferdinand Enke Verlag, Stuttgart, Germany, 1929. xxxvi + 896 pp. 17 figs. 16 × 25 cm. Price, unbound, RM. 4.5.50; bound, RM. 49.

In reviewing so compendious and so excellent a volume as this, one may dismiss the whole matter with a mere word or two of unstinted praise, or proceed to comment on the features good or otherwise. If the latter seem numerous it is only because space forbids the mention of all the good points and the relation between the acceptable and the unacceptable statements in the book is thus not accurately indicated.

The third edition of this splendid text, running to about 800 pages, was called a "Short Textbook." In closer accord with the facts, the present edition, the fourth, 850 pages, has had the adjective dropped from the title, a most pleasing change. The additional pages have permitted the inclusion of much new material as well as an amplification of the biochemical accomplishments of recent years, and have greatly increased the value of the book. The literature references, numerous and well-selected, are also surprisingly up-to-date, publications appearing as recently as 1929 being mentioned. This volume has very good author and subject indices, and the mechanical features of the book's production have been handled in the usual excellent manner of the Enke press.

As in the earlier editions there still appears, in the first part of this book, too much, and some quite superfluous, freshman chemistry; *e.* g., (p. 14) the method of calculating the empirical formula from the analytical results is given in detail. The distinction between an empirical and a molecular formula (p. 16) is not so clearly made as is desirable. It is a poor compliment to the prospective readers of this book that the author felt called upon (p. 29) to take a short section for an explanation of just what constitutes an hydroxyl group.

In discussing the cause of optical activity (p. 44), too much stress is laid on the presence of an asymmetric carbon and too little attention is devoted to the really essential feature, namely, that the molecule shall be asymmetric. A quite needless statement concerning the existence of compounds with water of crystallization (p. 66) is given, and Fig. 17 (p. 68), showing a flask with contents, presumably ready for distillation, indicates the thermometer improperly located. The diagram serves no real purpose in a book of this character. The statement (p. 82) to the effect that monovalent hydrocarbon radicals, aliphatic as well as aromatic, are generally called alkyls is not in line with general American practice at least. It is pleasing to note that the text mentions the members of the paraffin series higher than $C_{60}H_{122}$, since such compounds, though known for some years, are rarely referred to even in supposedly modern texts. It is certainly regrettable that the astonishingly incorrect statement, at least so by inference (p. 91), that Pennsylvania is still the center of the American petroleum industry, should have been permitted to remain in this new edition. The bad impression left with the reader by the foregoing is, however, promptly eliminated by the pleasure in finding the structure of phytol correctly presented. All too few writers have as yet become really aware of the beautifully conclusive work of F. G. Fisher with this interesting and important substance.

One is rather surprised that, under the topic of fat syntheses (p. 189), he finds no mention of materials with an odd number of carbon atoms in the acid chain; this is especially so in connection with this book because the medical aspects of most of the subjects are splendidly presented. The formula for pelargonic acid (p. 194) has a subscript written as an exponent. This slip in proofreading makes the text combine French and German practice. This unintentional stressing of the international aspect of chemistry may, however, be pardoned when one appreciates that this volume is very well supplied with formulas among which are discoverable surprisingly few typographical errors. In the discussion of dynamite (p. 250) reference is still made to the use of infusorial earth with no mention of the fact that wood powder, at least in this country, has long since replaced it.

The introductory statements under carbohydrates (p. 297) indicate that they "unquestionably" occupy first place in the study of foodstuffs. Without meaning to quibble too much, it might be pointed out that, in the absence of proteins, the carbohydrates, important as they are, are still insufficient for the continuance of life. The state of flux that still lingers in the minds of many concerning the nature of the cyclic forms of the hexoses is fairly presented by Schmidt.

In certain equations (p. 347) elementary diatomic gases are indicated without subscripts. As long as coefficients are required, and given, in the equations as presented, there seems to be no good reason why these gases should not be written to conform with common practice. Disodium malonic ester is to be found (p. 369), under the synthesis of a group of ring compounds, with two sodium atoms on the same carbon. Doubtless this formula is so given merely for convenience, but at least a word to indicate that the formula does not represent the accepted views would not come amiss. In this same section compounds are sometimes named, and referred to, in one place on the polymethylene basis and elsewhere the cycloparaffin nomenclature is used. It is to be hoped that in subsequent editions the author will adopt whole-heartedly the latter and more generally accepted naming scheme.

A rather surprising failure to indicate a modern advance in the field of industrial organic chemistry is shown (p. 436) by the appearance of the hoary statement to the effect that halogen on the aromatic nucleus cannot be replaced by hydroxyl by the action of alkali. The Dow phenol process is a daily, and important, refutation of this contention. Perhaps only purists would interpret "artificial camphor" to mean a substance resembling camphor in some of its properties, but not the same structurally, whereas "synthetic camphor" would be taken to mean *camphor* prepared by laboratory methods. If, however, this view is adopted generally by chemists, and many hold it, Schmidt's objection to the term "artificial camphor" is not so potent, or so well taken, as it might be.

The writer is happy to report that here is a text, the first seen by him at any rate, which presents the latest developments of the Beckmann rearrangement, including the *trans* shift. Meisenheimer's work with the oximes of benzil is also included.

The presentation of the subject of alkaloids is more than adequate, and quite unusual in a book of this type; approximately 75 pages are devoted to this important subject. Though the treatment of proteins is very well done, one is rather surprised to note no mention of Svedberg's ultracentrifugal method for determining the molecular weights of these substances. The section devoted to the structure of proteins has been very carefully prepared, and each of the important theories has received considerate attention.

This is an admirable text as far as book-work, content and manner of presentation are concerned—and there is not much more that can be said for a text.

G. ALBERT HILL

ADDITIONS AND CORRECTIONS

NOTICE TO READERS.—For the convenience of those who may wish to cut out the corrections and attach them to the margins of the articles corrected, they have been printed only upon one side of the page, and with ample space between each item.

1928. VOLUME 50

The Tautomerism of Brilliant Cresyl Blue, by Walter C. Holmes.

Pages 1989–1993. The author has supplied an explanatory correction: "The violet coloring matter which was isolated from an acid aqueous solution of cresyl blue by means of chloroform is not, as was mistakenly assumed, the violet tautomer of the dye which is present in aqueous solutions in increasing proportions as the dye concentration is increased. This is proved conclusively by the fact that it may not be thus isolated from other samples of the dye of different manufacture. It has been shown to be a subsidiary coloring matter which may, or may not, be present in varying small proportions in cresyl blue.

"It appears probable, as was suggested to the writer by Barnett Cohen, that the violet dye which is extracted with chloroform is an oxazone compound formed through the displacement of the free amino group in cresyl blue by oxygen. It has long been recognized that this type of hydrolysis occurs with naphthophenazoxine derivatives It has been claimed that it does not occur with diphenazoxine derivatives, of which cresyl blue is an example, but evidence has been obtained that this conclusion is mistaken."—W. C. HOLMES.

1929. VOLUME 51

Kinetic Studies on Ethylene Oxides, by J. N. Bronsted, Mary Kilpatrick and Martin Kilpatrick.

Pages 428–461. The following statement has been transmitted by Dr. Lennart Smith: "In an article by J. N. Bronsted, entitled 'Kinetic Studies on Ethylene Oxides,' published in THIS JOURNAL, 51, 428 (1929), there is the statement on page 431: 'After the present investigation was begun, Smith, Wode and Widhe published measurements on the rates of addition of water to ethylene oxide and to epichlorohydrin at 25° in solutions . . .'

"This statement is incomplete and for that reason misleading. These results were presented in preliminary form in lectures before the Chemical Society at Lund in the autumns of 1923 and 1924, and were reviewed in *Sv. kem. tidskrift*, **36,** 4 (1924), and 37, 30 (1925). In May, 1925, I delivered a summarizing lecture at Copenhagen, where all of the numerical material concerning the ethylene oxides was included. Professor Bronsted attended this last-mentioned lecture and was the first to speak in the discussion of it."—LENNART SMITH.

The Heat of Adsorption of Oxygen on Charcoal, by Melville J. Marshall and Harold E. Bramston-Cook.

Page 2024. "The disagreement between some of the data in Table III and the curve in Fig. 3 is not caused by an error in the data, but is due to the fact that, after the curve had been drawn, slightly more accurate values of $-dc/dQ$ were substituted in that region of the table above Q = 69,800 calories. The extent of the error produced

in the curve by the large difference at Q = 70,000 calories is illusory, as, according to the curve, the values of Q corresponding to the two discrepant values of $-dc/dQ$ differ by less than 1%, due to the almost infinite slope of the curve at this point."—MELVILLE J. MARSHALL.

Subject Index to Volume LII, 1930[1]

ABIETIC ACID, nitration of, and the study of some of its N derivs. **2132**
Absorption, relative rates of, of the gaseous olefins into H_2SO_4 at 25°, 721; role of the liquid stationary film in batch, of gases. 3757, **3769**
Acetals, cyclic—formation of cyclic, of 4,5-dihydroxy-2,6-octadiene, **217**; prepg., **1018**; prepg. —of monohydric alcs. **2892**
Acetamide, as solvent for the electrodeposition of metals. **2693**
Acetates, solubilities of, **507**; quant. study of the influence of, on the activity of maltamylase **1669**
Acetic acid, solns. of salts in pure, **507,** 619; vapor phase esterification of, by **EtOH, 1565;** dielec. polarization of, **1824;** reaction between thiocarbanilide and CH_2ClCO_2H, **2137;** detn. of the strength of weak bases and pseudo bases in glacial, solns., **4436;** kinetics of the polymerization of vinyl ester of, **4708;** strength of org. bases in glacial, soln **5115**
Acetic anhydride, detn. of the purity of. **3366**
Acetin, phys. consts. of. **1978**
Acetoacetic acid, hydrogenation of Et ester of, and certain of its derivs. over Ni. **5192**
Acetolysis, of cellulose. **1542**
Acetone, bromination of, in org. solvents. **2827**
Acetopropionic anhydride, catalysis in the hydration of. **1418**
Acetylaminocresols, Hg derivs. of. **3978**
Acetylchloroaminobenzene, prepn. of, **1721;** rearrangement of. **2973**
Acetylcholine chloride. **307**
Acetylene, homogeneous uncatalyzed reaction between O and, **3785;** photochem. polymerization of, **4613;** kinetics of the, **-**O reaction. **4837**
Acetylenic acids, unsatn. phenomena of, and esters. **4405**
Acetylenic carbinols, **hexa-w-tertiary-butylpropinylethane** and some new. **5267**
Acetylglutamic acid, interpretation of the dehydration of, by means of glutamylthiohydantoin derivs. **1192**
Acetylmethylmannosides, structures of the. **5298**
Acetylphenanthrenes **3704**
Acidity, effect on the oxidation of butyric acid with H_2O_2 **640**
Acids, oxidation of org., by $Ce(SO_4)_2$, **132;** reactions of ethers with, **387, 391;** action of weak mineral, on uronic acids, **2474;** aryl sulfone derivs. of dibasic, **2531;** applicability of the quinhydrone electrode to unsatd., **3233;** isomeric hydroxy, and their relation to dehydrorotenone, **3603;** polyhydric alc.-polybasic, reaction, **3636;** reagent for identifying org., **3715;** inhibition in the decompn. of org., by H_2SO_4, **4742;** potentiometric study of acid-base titration systems in the very strongly acid solvent formic acid, **4795;** thermodynamic properties of weak, in salt solns. and an exact method of detg. their dissocn. consts., **5079;** base and, consts. of glycine from cells without liquid junction **5091;** heteropoly, of Ge. **5154**
Actinometry, precision, with uranyl oxalate, **3139,** (correction). **5309**
Activation, energy of adsorption processes. **5298**
Activity coefficient, of **AgOAc, 1390;** of the chlorides of the bivalent metals, **2272;** of NaCl, KCl and LiCl and HCl at infinite diln. in water-MeOH mixts., 2353; of ions in dil. soln. in EtOH-water mixts., **2759;** of CsCl and CsOH in aq. soln., **3886;** in CsCl solns., **3892;** of $SnCl_2$ and stannous ion, **3967;** of $Cu(IO_3)_2$ in aq. salt solns. **4853**
Acyloins, aliphatic—prepn. **3988**
Addition compounds, preliminary formation of, in substitution reactions of aromatic types **3349**
Adipic anhydride, **4110;** assocn. polymerization and the properties of. **3470**
Adsorbed substances, density of water adsorbed on silica gel. **4635**
Adsorption, of CO_2 and NH_3 by pyrophoric Fe, **150;** of water by wood, **1053;** Der adsorbierende Bodenkomplex und die adsorbierten Bodenkationen als Grundlage der genetischen Bodenklassifikation (Gedroiz, *et al.*, book review), **2158;** of water and benzene vapors by MnO_2, **2170;** potential, **2256;** of H by Ni at low temps., **2325;** of water vapor and CO_2 by samples of MnO_2

---

[1] **This index was prepared in the Editorial Offices of *Chemical Abstracts* through the courtesy of Dr. E. J. Crane and under his direction.**

and hopcalite catalysts. **2411;** of complex NH_4 ions by silica gel. **2584;** of H_3AsO_3 by hydrous ferric oxide. **2785;** in the water–NH_3 system at 20°. **5128;** activation energy of. processes. **5298**

Affinity. electron. of free radicals—electron. of triphenylmethyl **1498**

Agar. structure of. gels from studies of diffusion **1311**

Agricultural chemistry. Ergebnisse der (Honcamp. book review) **1732**

Albedo. pentose and uronic acid content of orange **1209**

Albumin. P_H stability regions of serum. **2855;** mol. wt. of egg. in the presence of electrolytes. **5176;** P_H-stability region of egg **5187**

Alcohols. rate of reaction of certain. with *p*-nitrobenzoyl chloride in anhyd. ether soln., **268;** lability of H-O bond in certain. **753;** test for distinguishing the primary. secondary and tertiary satd., **802;** acetals of monohydric, **2892;** amino.. **3317;** polyhydric. -polybasic acid reaction. **3636;** x-ray examn. of the higher normal primary. **3739;** action of aromatic. on aromatic compds. in the presence of $AlCl_3$, **4484.** cond. and viscosity of solns. of $LiNO_3$ in certain binary alcoholic systems **4762**

Alcoholysis. of certain 1.3-diketones in the presence of HCl. **3212;** of certain 1.3-diketones and *β*-ketonic esters **4391**

Ald-chlorimines, negatively substituted aromatic. **4158;** decompn. of certain aromatic. to form nitriles **4517**

Aldehydes. oxidation of. **407;** prepn. of primary amines from. and monochloroamine. **1108;** condensation of secondary amines with. **1655;** condensation products of aromatic. with Az-angelica lactone, **2024;** condensation of 3-phenyl.2. 4-thiazolidione with aromatic. **2981;** arsonation of aromatic. **4122;** prepn. of nitriles from. **4517;** reaction between the binary system Mg + MgI_2 and aromatic **4967**

Aldehydo-*l*-arabinose tetraacetate **3619**

Aldehydrol. fifth pentaacetate of galactose. its alcoholate and **2464**

Aldobionic acid. compn. of an. from flaxseed mucilage **3711**

Alkalies. cleavage of carbonyl compds. by **3269**

Alkali metal alkyls. reaction between. and quaternary arsonium compds. **376**

Alkali metal compounds. derivs. of phenylated methanes and ethanes. **688;** rearrangement of an organo- **1042**

Alkali metal oxides. cristobalite liquidus in the silica-systems and the heat of fusion of cristobalite **1436**

Alkali metals. sepn. and identification of the alk. earth metals and the. by use of isoamyl alc. **3068**

Alkaline earth metals. sepn. and identification of the alkali and. by use of isoamyl alc. **3068**

ω-Alkylalkoxyaminopropiophenones **5294**

Alkylation, on N of the pyrimidine cycle by application of a new technique involving mol. rearrangements **2001**

Alkyl halides. elec. moments of **2227**

Alkyl phenyl ketones. prepn. of **1267**

Alkyls. thermal decompn. of metal. in H-C_2H_4 mixts. **1111**

Allene, vapor pressure of. as a function of temp.. **2409;** pyrolysis of **4540**

Allene tetrabromide. **1138.** (correction) **5307**

Alloys. Kontgenographie der (Neuburger. book review) **1730**

Allylanilines. pyrolysis of **4586**

Allyl aryl sulfides. pyrolysis of **3356**

Alumina. thermochemistry of the compds. occurring in the system CaO–SiO_2 80.910. **3927**

Aluminum. Cs_2SO_4 as a confirmatory reagent in the detection of. **3579;** direct detn. of Na in the presence of **4247**

Aluminum alloys. x-ray study of the constitution of some. with Cu. Ni and Mn.. **3833**

Aluminum bromide. scission of the methylenedioxyl group with **2988**

Aluminum chloride. yield of benzophenone from benzoyl chloride and C_6H_6 with $FeCl_3$-, mixts. as catalysts. **4365;** action of aromatic alcs. on aromatic compds. in the presence of. **4484;** in der org. Chemie (Kränzlein, book review) **4618**

Aluminum salts. behavior of cellulose toward solns. of **3448**

Amalgams. reduction of benzophenone to benzopinacol by means of Mg. **1128;** as lubricants **2421**

Amandin, mol. wt. of **279**

Amides, aromatic, of *N*-**arylglycinearsonic** acids, 2019; use of **aryl** esters for the prepn. of, 2149; from ε-**aminocaproic** acid.......... 5289

Amines, cyclic quaternary NH_4 salts from halogenated aliphatic tertiary, 287: prepn. of primary, from aldehydes and **monochloroamine,** 1108; reactions of glycidol with secondary, 1528; condensation of secondary, with aldehydes and naphthols, 1655; formation of pyrrolidine derivs. from diethyl α,α'-**dibromoadipate** and certain secondary, 2985; indirect method of studying the oxidation–reduction potentials of unstable systems, including those from. 5204

Amino acids, **dissocn.** consts. and heats of ionization of some simple.......... 863

Aminoalcohols.......... 3317

Aminoarsanilic acid, condensation products of **arsanilic** acid and.......... 229

p-**Aminobenzophenone** hydrazone.......... 3437

ε-**Aminocaproic** acid, **amides** from.......... 5289

Aminocymene, dyes from.......... 2118

4-**Aminohydantoin,** new rearrangement leading to the formation of, derivs..... 3676

p-**Aminoresorcin dimethyl** ether, Skraup's reaction with.......... 3196

Ammino compounds, A Text-book of Inorg. Chemistry. Vol. X. The Metal-**ammines** (Friend, Sutherland, book review), 436; of Cu selenate, 3857; of Cu selenite, 3881; Cobaltammines (Meyer, book review).......... 4675

Ammonia, thermodynamic properties of—compressibility of and an equation of state for gaseous—vapor pressure of liquid, 6; adsorption by pyrophoric Fe and the use of pyrophoric Fe in the, synthesis, 150; distribution between toluene and aq. silver ammonia chloride and hydroxide, 192; action of Na on β-**chloro**-**α,α,α**-**triphenylethane** in liquid, 1042; quant. study of the oxidation of, 1493; photosensitization by, 2150; poisoning action of water vapor at high pressure on Fe synthetic, catalysts, 2682; action of Na on some org. halides in liquid, 2823; reactions of, on the system $ZnCl_2$–NH_4Cl–H_2O, 3083; equil. in the NH_4 carbamate–urea–water–, system, 3088; study of the products obtained by the reducing action of metals upon salts in liquid, soln., 3573; optimum H:N ratio for, formation in the Haber equil., 4239; reaction between $CHCl_3$ and $(CH_3)_3SnNa$ in liquid, 4426; reduction of cystine in liquid, by metallic **Na,** 4500; density, surface tension and adsorption in the **water–,** system at 20°, 5128; detn. of mol. wts. in liquid.......... 5291

Ammonium carbamate, equil. in the **urea–water–**NH_3–, system.......... 3088

Ammonium chloride, action on benzotrichloride, 2951; reactions of NH_3 on the system $ZnCl_2$–H_2O–.......... 3083

Ammonium hydroxide, velocity of **sapon.** of Et **formate** by, in the presence of NH_4 salts.......... 2604

Ammonium ions, adsorption of complex, by silica gel.......... 2584

Ammonium phosphates, acidity of mono- and di-.......... 3901

Ammonium salts, cyclic quaternary, from halogenated aliphatic tertiary amines, 287; velocity of **sapon.** of Et **formate** by NH_4OH in the presence of.......... 2604

Ammonium zinc phosphate, effect of PH upon the pptn. of.......... 120

Ammonofuraldehydes.......... 1216

Ammonolysis, of ketones.......... 820

Amylase, quant. study of the influence of acetate and phosphate on the activity of malt, 1669; influence of certain neutral salts upon the activity of malt...... 2436

Amylenes, autoxidation of the.......... 4345

Analysis, use of the **ICl** end-point in volumetric, 894, 901; applications of $Ce(SO_4)_2$ in volumetric, 1443, 2347; micro detn. of halogens and metals in org. compds., 1893, (correction), 5307; **Anorgan.-chem. Praktikum—Qual.** (**Riesenfeld,** Klement, book review), 3027; "machine" for, with Grignard reagents, 3736; magneto-optic method of **chem.,** 3796; use of the Poulsen arc as a means of detecting traces **of impurities** in metals, 4169; Select Methods of Metallurgical (**Naish, Clennell,** book review), 4177; some errors in analytical bromination—detn. of org. **unsatn.,** 5241; "star trail" method for the spectrographic quant. detn. of the elements.......... 5295

Anesthetics, local, in the **pyrrole** series, 235; local, derived from **dialkylamino**-propanediols, 2115; **phenylurethan,** 2583; local, derived from **quinoline** and **isoquinoline**.......... 4013

Anethol, oxidation of.......... 739

Δ_2-**Angelica lactone,** condensation **products** of aromatic aldehydes with.......... 2024

Anhydrides, reactions of ethers with..........387, 391

Anils, forced reaction between *p*-**thiocresol** and.......... 4573

Anions. relative influence of cations and. upon the equil. $2Fe(CN)_6^{---} + 3I^- \leftrightarrows 2Fe(CN)_6^{----} + I_3^-$ 876
Anisalchlorimine 2050
Anthrone series 4884, 4887
Antilogarithms. Non-Interpolating (Johnson. book review) 5300
Antimony. heat capacity at low temps. of 2712
Antimony compounds. derivs. of diphenyl 2046
Antimony oxides. heat capacities at low temps. of Sb_2O_3, Sb_2O_4 and Sb_2O_5, 2712; vapor pressure of Sb_2O_3 3869
Apocynin. synthesis of some new compds. related to 4076
Apocynol. synthesis of some new compds. related to 4076
Araban. compn. of Salkowsbi's 4509
Arabinogalacturonic acid. derived from orange pectin 1209
l-**Arabinose, action of KOH on** 3680
Arachidonic acid. occurrence of. in lard 1135
Argon. soly. in water and some org. solvents 68
Arsanilic acid. condensation products of aminoarsanilic and 229
Arsenate ion. quant. pptn. of CaC_2O_4 in the presence of 4285
Arsenates. potentiometric titration of. with $AgNO_3$ 583
Arsenic. detg. the. content of org. arsenicals. 638; heat capacity of. at low temps 2296
Arsenic chlorides. phase system $AsCl_3$–pyridine 1720
Arsenic compounds. detg. the As content of org., 638; derivs. of diphenyl. 664; isolation of an. of pyridine and some observations concerning the phase system $AsCl_3$–pyridine, 1720; properties and mol. state of certain org. arsenicals. 2946
Arsenic oxides. heat capacities of As_2O_3 and As_2O_5 at low temps 2296
Arsenious acid. titration of. with permanganate and with ceric sulfate. 901; adsorption by hydrous ferric oxide 2785
Arsenites. potentiometric titration of. with $AgNO_3$ 583
Arsonation. direct. of benzene derivs.. 3284; of aromatic aldehydes 4122
Arsonium compounds. reaction between alkali metal alkyls and quaternary 376
N-**Arylglycinearsonic** acids. aromatic amides of 2019
Aryl sulfides. chemistry of di- 3623
Atomic nucleus. attempt to det. nuclear moments 3024
Atomic weights. 36th annual rept. of the committee on—detns. published during 1929 357
Atomistics. L'Atomistica Moderna e la Chimica (Haissinsky. Parravano. book review) 2587
Atoms (Ruark. Urey. book review). 2588; surface reactions of radicals and. 1910; deformation of electron shells. 3112. 4306; The Analytical Expression of the Result of the Theory of Space Groups (Wyckoff. book review). 3473; reactivity of. and groups in org. compds 5066
Azido-carbondisulfide 2799
Azido-dithiocarbonic acid. alkyl and acyl derivs.. 1928; salts of 2806
Azo compounds. azo indicators. 2397; Skraup reaction with certain 3974
Azoxybenzene. effect of org. bases upon the extent and mechanism of the reducing action of Na methylate on 1531
Azoxy compound. new cyclic 1122

BACILLUS. chemistry of the lipoids of tubercle—occurrence of mannose in the phosphatide from human tubercle. 1252; cyclobutylalkylalkylacetic acids and their bactericidal action toward B. leprae. 1259; prepn. and bacteriol. action toward B. leprae of certain olefinic acids. 1281; certain dialkyl acetic acids contg. 12. 13 and 14 C atoms and their bactericidal action toward B. *leprae*, 1289; chemistry of the lipoids of the tubercle—occurrence of inosite in the phosphatide from human tubercle. 1607; chemistry of the lipoids of tubercle—polysaccharide occurring in the phosphatide from the human tubercle 5023
Bacteria. compn. of the gum produced by root nodule 3659
Bactericidal action. of cyclobutylalkylalkylacctic acids toward B. *leprae*, 1259; toward B. leprae of certain olefinic acids. 1281; certain dialkyl acetic acids contg. 12. 13 and 14 C atoms and their. toward *B. leprae*, 1289; of certain pentadecanoic. heptadecanoic and nonadecanoic acids 2540
Barbituric acid. 5,5-substituted, 1676; dialkyl derivs 2440
Barium chloride. elec. conductance of aq. solns. of. as a function of the concn 2245
Bases. in the kerosene distillate of Calif. petroleum. 1239; effect of org., upon

the extent and mechanism of the reducing action of Na methylate on nitrobenzene and azoxybenzenc. 1531; action on α,β-dibromoketones and related substances. 3728; detn. of the strength of weak. and pseudo. in glacial AcOH solns., 4436; potentiometric study of acid–base titration systems in the very strongly acid solvent formic acid. 4795; pseudo. in the isvxazole series. 4943; thermodynamic properties of weak. in salt solns. and an exact method of detg. their dissocn. consts., 5079; acid and. consts. of glycine from cells without liquid junction. 5091; strength of org., in glacial AcOH soln., 5115; pseudo. 5254

Benzaldehyde. oxidation of. in the gaseous phase 974

Benzamidine. action of. hydrochloride upon glyoxal Na bisulfite 2026

Benzene. distribution of HCN between. and aq. $HAg(CN)_2$, 192; dipole moments of the disubstituted. 1919; adsorption of. vapor by MnO_2, 2170; in the electrodeless discharge. 2578; direct arsonation of. derivs., 3284; detn of the soly. of water in. 3568; yield of benzophenone from benzoyl chloride and. with $FeCl_3$-$AlCl_3$ mixts. as catalysts. 4365; emission spectra of some simple. derivs. 4755

Benzene ring. polarities and the orienting influences of substitutes in the 206

Benzidine. mercurated azo dyes derived from 2528

Benzil. condensation with Et cyanoacetate 3377

Benzilic acid. rearrangement 252

Benzohydrylmagnesium chloride. and the apparent prior formation of free benzohydryl radicals 3984

Benzohydryl radicals. benzohydrylmagnesium chloride and the apparent prior formation of free 3984

Benzoic anhydride. action of diazomethane on 1558

Benzoin. condensation. 2031; condensation with Et cyanoacetate 3377

Benzoins. mixed 220. 4107

Benzophenone. reduction of. to benzopinacol by means of Mg amalgam. 1128; yield of. from benzoyl chloride and C_6H_6 with $FeCl_3$-$AlCl_3$ mixts. as catalysts. 4365

Benzopinacol. reduction of benzophenone to. by means of Mg amalgam. 1128; effect of substituents upon the rearrangement of 3596

Benzotrichloride, action of NH_4Cl on 2951

o-Benzoylbenzoic acid. dehydration of derivs. of 1024

Benzoyl chloride. yield of benzophenone from C_6H_6 and. with $FeCl_3$-$AlCl_3$ mixts. as catalysts 4365

β-Benzoyldibromoacrylic acids. synthesis and structure of cis and *trans.* and some of their derivs 3405

Benzoylformic acid 1623

Benzylamine. action of heat on 4151

Benzylation. of o-cresol 4484

5-Benzyl-2-furfuraldoxime. sweetening power of 2010

Benzyl halides. comparative reactivities of some substituted 1640

9-Benzyl-9-phenplfluorenes. supposed existence of 2 stereoisomeric 3290

Benzylpinacolones. and their reduction products 347

1-Benzyl-4-piperidones, catalytic reduction of 1030

Benzyl sulfide. addn. compds. of Cu halides and $AgNO_3$ with 1353

Berberine. Pictet and Gams'. synthesis 660

Beryllium (Meyer. book review). 4614; electrodeposition of metallic 2581

Biochemistry. Outlines of (Gortner. book review) 3474

Biographies. August Kekulé (Anschiitz. book review) 433

Biology. Die Kolloide in (Bechhold. book review). 3744; Tables annuelles de constantes et données numériques de (book review) 5299

Bismuth. heat capacity at low temps 2720

Bismuthazido-dithiocarbonate 2806

Bismuthcesiumiodide 907

Bismuth nitride. as nitridizing agent 2425

Bismuth oxide. heat capacity of Bi_2O_3 at low temps 2720

Blood serum. P_H stability regions of. albumin and of. globulin 2855

Body fluids. Handbuch der biol. Arbeitsmethoden—Methoden zur Bestimmung der kolloid-osmotischen Druckes in (Wreschner. book review) 1731

Boiling points. influence of the period of heating upon the. of certain liquids used in ebullioscopy with a note on testing the purity of volatile liquids by isothermal distn. 4699

Bonds. polarity of the C-halogen, 93; measurement of the relative lability of. by means of rates of reactions and of temps. on decompn.—H O bond in certain alcs., **753;** linking C to C **2919**

Behandlung gasförmiger Stoffe (Bertelsmann. Schuster). 5301; Lehrbuch der org. Chemie (Schmidt) 5302
Boric acid. sulfonation of 2-naphthol in presence of 2835
Boron 4414
Brazil nut oil 4114
Bridge. screened. for the measurement of electrolytic conductance 1793
Brilliant cresyl blue. tautomerism of. (correction) 5305
Bromate. autocatalytic reduction of. by H_2O_2 in acid soln 1427
Brominated substances. thermal cleavage of HBr from 5241
Rromination. of vinylacrylic acid. 326; of 2.4-dimethoxycinnamic acid. 341; of acetone in org. solvents. 2827; of Et 2-furylacrylate. 3349; synthesis and configurations of unsatd. 1.4-diketones and ketonic acids and the stereochem. mechanism of. 3423; of hexane. 3465; of 1.5-dihydroxynaphthalene. 4872; some errors in analytical 5241
Bromine. action on phenolphthalein. 646; reaction between $MgPh_2$ and 1181
8-Bromoalkyl ethers. synthesis of. and their use in further syntheses 651
Bromobenzoylacrylic acid. structural isomers of 2094
5-Bromofurfural. prepn. of. and some of its derivs 1170
Bromo-iodo-anilines. constitution of certain 1572
Bromo-iodo-benzenes. constitution of certain 1572
Bromonitrobenzenes. comparative reactivities of some chloronitrobenzenes and .. 1650
p-Bromophenacyl esters. of some higher fatty acids 818
Bubbles. coagulation of Fe_2O_3 sols by gas 2730
Buffer solutions. rate of coupling of diazonium salts with phenols in. 1220; quant. pptn. of sulfides in 5135, 5141
Burton-Bishop rule. chloride-free Fe_2O_3 hydrosols and the 2598
Butadiene. prepn. and chlorination of 4043
Butanes. kinetics of the thermal dissocn. of the 1262
Butenes. qual. estn. of the compn. of mixts. of. by distn. methods. 1949; analysis of mixts. of the normal. 1953; compn. of mixts. of. resulting from the catalytic decompn. of the normal butyl alcs 1964
Butter. I in 541
n-Butylacetoacetic acid. decompn. of Et ester of. into caproic acid and methyl n-amylketone 5005
tert.-Butyl alcohol. system water. salts and. at 30° 2282
Butyl alcohols. compn. of butene mixts. resulting from the catalytic decompn. of the normal 1964
Butyraldehyde. polymerization expts. with 1659
Butyric acid. effect of acidity on the oxidation of. with H_2O_2, 640; dielec. polarization of 1824
Butyrin, phys. consts. of mono-normal 1978

CADMIUM. study of the $-PbCl_2$ voltaic cell 4831
Cadmium azido-dithiocarbonate 2806
Calcium. detn. of. 1888; sp. heat of 4686
Calcium aluminate. heat of soln. of tricalcium aluminate and its hydrates in HCl .. 3927
Calcium chloride. e. m. f. measurements with. solns 2265
Calcium hexosediphosphate. action of KOH 0x1—comparison with that of glucose and fructose 4065
Calcium hydride. use of. for the detn. of the soly. of water in benzene. CCl_4 and toluene. 3568; reduction reactions with 3655
Calcium hydroxide. heat of soln. of. in $HCl{\cdot}200H_2O$ 80
Calcium oxalate. quant. pptn. of. in the presence of the phosphate ion. 1469; quant. pptn. of. in the presence of the arsenate ion 4285
Calcium oxide. See *Lime.*
Calcium perchromate 1851
Calorimeters. heats of neutralization by the continuous flow 3806
Capillary chemistry (Freundlich, Bikerman. book review) 3033
Caproic acid. decompn. of ethyl n-butylacetoacetate into methyl n-amyl ketone and 5005
Carbamic acid. equil. in the NH_4 carbamate–urea–water–NH_3 system 3088
Carbithioic acid. studies 332. 4991
Carbo-ethoxy derivatives. representative. related to ethylene glycol 3720

Carbohydrates, mechanism of oxidation of, **294**, **3680**, **4065**; reactions relating to, **3257**, **3448**, **3995** (correction).. **5309**

Carbon, polarity of the, –halogen bond, **93**; Na_2O_2-, fusion for the decompn. of refractories, **574**; oxidation–reduction potentials at W and, electrodes, **2773**; linking, to C, **2919**; catalysis by NaCl of oxidation of, **3025**; high temp. equil. of TiO_2 and, with TiC and CO.. **3956**

Carbonates, representative, related to ethylene glycol........................ **3720**

Carbon dioxide, adsorption by pyrophoric Fe, **150**; equil. of the reaction between N and, in the elec. arc, **156**; equil. in the system $Co–CO_2–CoO–CO$—indirect calcn. of the water gas equil. const., **1782**; adsorption by samples of MnO_2 and hopcalite catalysts, **2411**; dissocn. of, in the electrodeless discharge, **3152**; sensitized photosynthesis of, at low Cl pressures.................... **3562**

Carbonic acid, glycol esters of.. **314**

Carbon monoxide, preferential catalytic oxidation of, in the presence of H, **437**, **445**; compressibility isotherms of, **1374**; equil. in the system $Co–CO_2–CoO–CO$—indirect calcn. of the water gas equil. const., **1782**; photochem. 0-, reaction, **3471**; high temp. equil. of TiO_2 and C with TiC and, **3956**; ignition of, –O mixts.. **4225**

Carbon tetrachloride, kinetics, statics and energetics of the thermal reaction $CH_2I–CH_2I = CH_2{=}CH_2 + I_2$ in, solns., **956**; detn. of the soly. of water in. **3568**; photochem. formation of ClO_2 from Cl_2O in, soln.................. **4288**

Carbonyl compounds, identification of, by use of 2,4-dinitrophenylhydrazine, **2955**; cleavage by alkalies.. **3269**

2-(2-Carboxy-6-chlorophenyl)-pyridine-3-carboxylic acid.......................... **4528**

3-(2-Carboxyphenyl)-6-phenylpyridine-2,4-dicarboxylic acid.................... **4528**

Caryophyllin.. **1722**

Casein, mol. wt. of.. .241, **701**

Catalysis, in org. chemistry—reactions of ethers with acid chlorides, acids and anhydrides, **387**, **391**; in org. chemistry—decompns. of esters by anhyd. $ZnCl_2$, **395**; preferential catalytic oxidation of CO in the presence of H—activity of two water gas conversion catalysts, of CuO, of MnO_2 and of a mixt. of these oxides, **437**; preferential catalytic oxidation of CO in the presence of H—activity of 2-component hopcalites, **445**; in "coupling" of MnO_2 with H_3PO_4 or H_2SO_4 as an oxidizing agent, **640**; in reduction of O-alkyl substituted oximes, **669**; catalytic reduction of 1-phenyl- and 1-benzyl-4-piperidones, **1030**; hydrogenation in the chlorophyll series, **1233**; in the hydration of propionic anhydride, **1410**; in the hydration of acetopropionic anhydride, **1418**; autocatalytic reduction of bromate by H_2O_2 in acid soln., **1427**; Ag ion, of persulfate oxidations, **1493**; compn. of butene mixts. resulting from the catalytic decompn. of the normal butyl alcs., 1964; normal valerolactone prepn. by the catalytic reduction of levulinic acid with H in the presence of Pt oxide, **3010**; by NaCl of oxidation of C, **3025**; promoter action in reactions of oxidation concomitant with the catalytic decompn. of H_2O_2, **3035**; app. for micro-catalytic hydrogenation, **3359**; in reduction of nicotine and metanicotine, **3385**; of the thermal decompn. of $Ag_2C_2O_4$ by Ag_2SO_4, **3468**; hydrogenation of acetoacetic ester and certain of its derivs. over Ni....... **5192**

Catalysts, in the preferential oxidation of *CO* in the presence of H, **437**; hydrogenation over metallic Cs, **892**; adsorption of water vapor and CO_2 by samples of MnO_2 and hopcalite, **2411**; poisoning action of water vapor at high pressure on Fe synthetic NH_3, **2682**; study of vapor phase oxidation of org. compounds by use of rare earth oxides as, **3535**; use of Ni as a, for hydrogenation, **4349**; mixed, in the Friedel and Crafts reaction—yield of benzophenone from benzoyl chloride and C_6H_6 with $FeCl_3–AlCl_3$ mixts, as, **4365**; decompn. of ethylene glycol in the presence of.......................... **4558**

Catechol, constitution of, **1672**; behavior of allyl derivs. of, toward heat........ **1700**

Catechol group, synthesis of thiazoles contg.................................. **1585**

Catechol sulfonephthalein.. **3463**

Cations, relative influence of anions and, upon the equil. $2Fe(CN)_6^{---} + 3I^- \rightleftharpoons 2Fe(CN)_6^{----} + I_3^-$, **876**; Die adsorbierten Bodenkationen als Grundlage der genetischen Bodenklassifikation (Gedroiz, Kuron, Ehrenberg, book review), **2158**

Cells, electrolytic, cond., for eliminating electrode effects in measurements of electrolytic conductance.. **1806**

Cells, voltaic, with liquid–liquid junctions, **1315**; Hg-basic mercuric sulfate, **1407**; e. m. f. measurements on, contg. $ZnCl_2$, **2272**; influence of the solvent on the e. m. f. of Ag–Ag halide, 3477; ionization const. of water at 25° from the e. m. f. of, without liquid junction, 3877: study of the Cd–$PbCl_2$, 4831; acid and base consts. of glycine from, without liquid junction................ 5091

Cellulose, action of NaOH on, 1013; optical rotation of sol., in alkali, 1508; acetolysis of, 1542; sulfonic acid ester, 2849; state of dispersion of, in cuprammonium solvent, 3047; differences between the state of dispersion of isolated wood, and cotton, in cuprammonium solvent, 3062; constitution of alkali, 3257, (correction) 5309; behavior toward solns. of Al salts.............. 3448

Cellulose acetate, measurements of the fluorescence of, in ultraviolet light...... 3846

Cellulose sulfonic acid ester.. 2849

Cellulosic materials, optical rotation of.................................. 1508

Centrifuge, effect of ions on sedimentation of colloidal particles by means of the centrifuge.. 1009

Cerium ions, use of methyl red, erio glaucine and erio green indicators in the reaction between ceric and ferrous ions.................................. 2347

Cerium sulfate, $Ce(SO_4)_2$ as a volumetric oxidizing agent, 36, 132, 553, 557; titration of H_3AsO_3 with $Ce(SO_4)_2$, 901; applications of $Ce(SO_4)_2$ in volumetric analysis—oxidation of hydroquinone by $Ce(SO_4)_2$, 1443; applications of $Ce(SO_4)_2$ in volumetric analysis.. 2347

Cesium. hydrogenation over metallic....... 892

Cesium bismuth iodide.................... 907

Cesium chloride, activity coeff., of, in aq. soln., 3886; activity coeff. and dissocn. of water in, solns... 3892

Cesium hydroxide, activity coeff. of, in aq. soln.......................... 3886

Cesium sulfate, as a confirmatory reagent in the detection of Al.............. 3579

Chalcones, decompn. by alkali.. 2538

Charcoal, nature of the sorption by, of gases and vapors under great pressure, 2198; sorption of org. vapors by highly evacuated, activated sugar, 2668; heat of adsorption of O on. (correction).. 5306

Chemical constitution, relations between rotatory power and, in the sugar group, 1270. 1680, 1707, 2101, 2106, 2519, 2534, 4168, (correction) 5307; Leipziger Vortrage 1929—Dipolmomente und (Debye, book review), 1293; attempted correlations with sweet taste in the furan series......................... 2010

Chemistry, Smith's College (Kendall, book review), 434; A Lab. Outline of Smith's College (Kendall, book review), 435; General (Babor, book review), 851; Lab. Manual in General College (Babor, Lehrman, book review), 852; A Chem. Dictionary (Hackh, book review), 1726; Cours de chimie à l'usage des candidats à l'école des hautes etudes commerciales et aux instituts de chimie (Isabey, book review), 1727; The Beginnings of (Beale, book review), 1728; Einführung in die theoretische Wirtschaftschemie (Koetschau, book review), 2152; L'Atomistica Moderna e la Chimica (Haissinsky, Parravano, book review), 2587; Annual Survey of Am (West. book review), 3028; The Condensed Chem. Dictionary (Turner. et *al.*, book review), 3742; A Comprehensive Treatise on Inorg. and Theoretical (Mellor, book review), 4176; Tables annuelles de constantes des données numériques de (book review)... 5299

Chloraloses, structure of the.. 3191

Chlorides, reactions of ethers with acid, 387, 391; action of diazomethane on some aromatic acyl, 1504, (correction), 5307; activity coeffs. of the, of the bivalent metals. 2272; influence of acid, on the color test for reactive organometallic compds.. 9494

Chlorimines... 2050, 4158, 4517

Chlorination, of vinylacrylic acid, 812; of butadiene......................... 4043

Chlorine, equil. between bivalent and quadrivalent Pd and, in HCl soln.. 985; induced addn. of ethvlene and, 2869; substitution of 1 atom of N for 3 atoms of, in org. compds., 2951; sensitized photosynthesis of CO_2 at low, pressures, 3562; at. wt. of... 3586

Chlorine oxides, photochem. formation of ClO_2 from Cl_2O in CCl_4 soln......... 4288

Chloroacetic acid. dissocn. of, in aq. soln., 1404; reaction between thiocarbanilide and, in alc. and in AcOH soln..................................... 2137

Chloro-alkyl furfuryl sulfides, vesicant action of............................ 2141

Chloroamine, prepn. of primary amines from aldehydes and.................... 1108

o-Chlorobenzalchlorimine.. 2050

3-Chlorocrotonic acid, oxidation of.. 3176

Chlorodinitrobenzenes. parachors of 2 isomeric.................... 3327, 5295, 5297

Chloroform. reaction between $(CH_3)_3SnNa$ and. in liquid NH_3................ **4426**

a-Chlorohydracrylic acid. reaction of Na phenoxide with...................... **3364**

Chlorohydrins. prepn. of some new.. **1164**

Chloro-iodo-anilines, constitution of certain.............................. **1572**

Chloro-iodo-benzenes, constitution of certain............................... **1572**

Chloronitrobenzenes. comparative reactivities of some bromonitrobenzenes and... **1650**

p-Chlorophenacyl esters. of some higher fatty acids........................ **818**

Chlorophenolred.. **4611**

Chlorophyll series.. 1233, **3013**

β-Chloro-α,α,α-triphenylethane, action of Na on. in liquid NH_3............... **1042**

β-Chlorovinylarsines.. **4164**

Cholesterol. prepn. and antirachitic activation of some derivs. of................ **2512**

Chromium. direct detn. of Na in the presence of............................ **4247**

Cinnamic acid. **methylpiperidinoalkyl** esters of............................ **2007**

Citric acid. decompn. by H_2SO_4.. **4729**

Citronellal. reaction between some *organomagnesium* halides and. 3588; action of ultraviolet light on.. 4093

Cobalt (Meyer. book review). **4615;** detection and estn. of. in presence of Ni. **464;** **equil.** in the system Co–CO_2–CoO–CO–, **1782;** detection of. as Cs cobaltinitrites... **4857**

Cobaltammines (Meyer. book review).. **4615**

Cobalt compounds. complexes of thioglycolic acid........................... **4418**

Cobalt oxide. **equil.** in the system Co–CO_2–CoO–C0—indirect calcn. of the **water gas equil. const**.. **1782**

Cobalt sulfate. elec. conductance of. solns..................................... **2648**

Cobalt sulfide. quant. pptn. in buffered solns................................ **5135**

Cocosin. mol. wt. of.. 4400

Cohesion. abs.. in metals.. **534**

Colloids. (See also ***Gelatin;*** Particles; ***Silica;*** etc.) (Kruyt. book review). **3033;** ferric oxybromide hydrosols. **456;** prepn. of negative colloidal Fe_2O_3 by hydrolysis of Prussian blue. **1337;** Handbuch der **biol.** Arbeitsmethoden—. **Methoden** der Kolloidforschung—Methoden der Viscosimetrie **kolloider** Losungen—Methoden zur Bestimmung des kolloid-osmotischen Druckes in **biol.** Fliissigkeiten—Methoden **zur** Bestimmung der elek. **Struktur kolloider** Stoffe. insbesondere der Biokolloide (Abderhalden. ***et al.***, book review). **1731;** Symposium Monograph.—Colloid Symposium Annual (Weiser. book review). **2156;** The Chemistry of the Colloidal State (Ware. book review). **2593;** chloride-free Fe_2O_3 hydrosols and the Burton-Bishop rule. **2598;** coagulation of Fe_2O_3 sols by gas bubbles. **2730;** Eine Darstellung der Chemie der. und verwandter Gebiete (Freundlich. Bikerman. book review). **3033;** Die. in Biologie und Medizin (Bechhold. book review). **3744;** coagulation of pure $Fe(OH)_3$ sols. **4170;** colloidal Pt and its behavior as a typical acidoid sol... **4621**

Cologarithms. Non-Interpolating (Johnson. book review)..................... **5300**

Color. stability and proportionality of. produced by small amts. of I. **2768;** fluorescence emission spectrum which accompanies a change of................. **4170**

Columbium (Friend. Marks. book review)...................................... **1727**

Combustion, gas, pipet.. **2811**

Compressibility. of gaseous NH_3, 6; isotherms of H, N and a 3:1 mixt. of these gases. **1363. isotherms** of CO.. **1374**

Condenser. for **low-temp.** evapn. of H_2O................................... **4334**

Condition equation. See ***Equation of state.***

Conductivity. electric. temp.–conductance curves of solid halides of Li, **1340;** screened bridge for the measurement of. **1793;** cond. cell for eliminating electrode effects in measurements of. **1806;** of aq. solns. of $BaCl_2$ as a function of the concn., **2245;** of $CoSO_4$ solns., **2648;** sp., of liquid H_2S, **3045;** of solns. of $LiNO_3$ in certain binary **alc.** systems..................................... **4762**

Conjugated systems. **326. 812. 1574. 4043;** oxidation of.................... **3188**

Constants. Tables annuelles **de,** et **données numériques** de chimie de physique de biologie et de **technologie** (book review)................................ **5299**

Copper. 2 delicate tests for the detection of. **2222;** prepn. of Ag-free............ 3165

Copper alloys. x-ray study of the constitution of some. with Ni, Al and Mn...... 3833

Copper-ammonia-cellulose, state of dispersion of cellulose in cuprammonium

Diphenyltrichloroethane, action of metallic Na on **3633**
Dipyridyls, prepn. of the phenanthrolines and related **397**
Disaccharide ketose, synthesis of a new, from lactose **2101**
Disaccharides, comparative hydrolysis of some polysaccharides and **3995**
Disruptive negative pressures, in metals **534**
Disruptive volumes, for metals **534**
Dissociation, pressures of certain metal pyridine thiocyanates, **4069;** attempt to measure the velocity of, of N_2O_4 by the method of sound waves **4661**
Distillation, differential fractional, **2420;** testing the purity of volatile liquids by isothermal, **4699;** vacuum fractionation of phlegmatic liquids **4714**
Dithiourazole, constitution of the so-called, of Martin Freund **4860**
Ditolyltrichloroethane, action of metallic Na on **3633**
Drying, intensive **4191**
Dyes, "Pechmann dyes" problem, 837; methyl isopropyl thioindigoid, from *p*-cymene and aminocymene, **2118;** methyl isopropyl thioindigoid, from p-cymene—from Na cymenesulfonate, **2125;** mercurated azo, derived from benzidine and o-tolidine, **2528;** S. **3388**

EBULLIOSCOPY. See Boiling points.
Economic chemistry, Einführung in die theoretische (Koetschau, book review) **2152**
Egg albumin, mol. wt. of, in the presence of electrolytes, **5176;** P_H stability region of **5187**
Ekatantalum, analytical chemistry of, and its'difference from Ta. **1742**
Elaidic acid, epoxy acids from oleic acid and **1186**
Electric arc. equil. of the reaction between N and CO_2 in the, **156;** use of' the Poulsen, as a means of detecting traces of impurities in metals, **4169;** constricted Hg **4337**
Electric discharge, benzene in the electrodeless, 2578; decompn. of hydrocarbons in the electrodeless, **3026;** dissocn. of CO_2 in the electrodeless, **3152;** condensation of hydrocarbons by, **4450;** chem. behavior of some benzenoid hydrocarbons in the Tesla, **4552;** spectroscopic study of the decompn. and synthesis of org. compds. by **5165**
Electric moments, Leipziger Vortrage **1929** (Debye, book review), **1293;** of certain substituted phenols and their relation to the stereochemistry of the O atom, **1356;** of simple derivs. of cyclohexane and of dioxane, **1831;** use of dioxane as a solvent for, studies, **1838;** dipole moments of the disubstituted benzenes, **1919;** of a series of derivs. of normal heptane, **1993;** of the alkyl halides and halogenated methanes **2227**
Electrochemistry, Grundziige der theoretischen und angewandten (Grube, book review) 3030
Electrodeposition, of metallic Be, **2581;** acetamide and formamide as solvents for the, of metals **2693**
Electrodes, oxidation potential of the PbO_2, in $HClO_4$ soln. **1;** detg ionization consts. with a quinhydrone reference, **23;** behavior of glass, of different compns., **29;** cond. cell for eliminating, effects in measurements of electrolytic conductance, **1806;** measurements of the e. m. f. of the calomel, against the H, at low concns. of HCl, **2179;** 0, **2256;** potential of In against $InCl_3$ solns., **2372;** manganous-MnO_2 and the manganous-permanganate, **2595;** oxidation-reduction potentials of MnO_2, **2624;** oxidation-reduction potentials at **C** and W, **2773;** applicability of the quinhydrone, to unsatd. acids **3233**
Electrolysis, of Grignard solns **4904**
Electrolytes, interpretation of the colligative properties of weak, **1814;** mol. wt. of egg albumin in the presence of **5176**
Electrons, electronic decompn, of $KClO_3$, **527;** The Chem. Effects of (Lind, book review), **1294;** affinity of free radicals—affinity of triphenylmethyl, **1498;** deformation of electron shells 3112, **4308**
Energy, free, of some Ag compds., **178;** chem. effects of x-rays and the, relations involved, **465;** free, of perchlorate ion, **549;** free, of some satd., non-benzenoid hydrocarbons, **1032;** free, of **12** aromatic hydrocarbons, **1547;** free, of the isomeric heptanes, **3241**; free, of stannous hydroxyl chloride and the activity coeff. of $SnCl_2$ and stannous ion, **3967;** effect of unsatn. on the free, of some hydrocarbons and other compds., **4381;** calcn. of free, from spectroscopic data, **4808;** free, and dissocn. of H, **4816;** activation, of adsorption processes. 5298
Entropy, of $KClO_4$ from **12** to 298° abs.—of perchlorate ion, **549;** of some satd.,

non-benzenoid hydrocarbons, **1032;** of **12** aromatic hydrocarbons, **1547;** of the isomeric heptanes, **3241;** effect of unsatn. on the, of some hydrocarbons and other compds., **4381;** chem. consts. and, of Mg from spectroscopic data, **4686;** of H and the third law of thermodynamics **4816**

Epichlorohydrin, reaction of various Grignard reagents with **1164**

Epinine, synthesis of **4119**

Epoxy acids, from oleic and elaidic acids **1186**

Equation of state, for gaseous NH,, **6;** consts. of the Beattie–Bridgeman, with Bartlett's P–V–T data on N **1382**

Equilibrium, high-temp., between Si nitride, Si and N, **48;** of the reaction between N and CO_2 in the elec. arc, **156;** involving some complex ions of Ag, **178;** Et acetate, **869;** relative influence of cations and anions upon the, $2Fe(CN)_6^{---} + 3I^- \leftrightarrows 2Fe(CN)_6^{----} + I_3^-$, **876;** dissocn. const. of water from an, involving HgO and HgBr, **921;** in the synthesis and decompn. of methanol, **926;** between bivalent and quadrivalent Pd and Cl in HCI soln., **985;** electromotive behavior of single Zn crystals—potential, **1000;** in the system Co–CO_2–CoO–CO—indirect calcn. of the water gas, const., **1782;** in the NH_4 carbamate–urea–water–NH_3 system, **3088;** between methanol and its decompn. products, **3165;** high temp., of TiO_2 and C with TiC and CO, **3956;** thermodynamic treatment of chem., in systems composed of real gases—optimum H:N ratio for NH_3 formation in the Haber, **4239;** in the Fe–H–O system—indirect calcn. of the water gas, const., **4268;** keto-enol, of Et a-phenylacetoacetate. **4358;** effect of light on the ferrocyanide-ferricyanideiodine-iodide **4770**

a-Ergostenol, and its isomerization to β-ergostenol **2016**

β-Ergostenol, a-ergostenol and its isomerization to **2016**

Ergosterol, new esters of. **2015;** prepn. and antirachitic activation of some derivs. of **2512**

Ergot, sterols of **2013, 3688**

Erio glaucine, use of, indicator in the reaction between ceric and ferrous ions **2347**

Erio green, use of, indicator in the reaction between ceric and ferrous ions **2347**

Essences, Les, Naturelles (Craveri, book review) **855**

Esterification, vapor phase, of AcOH by EtOH, **1565;** attempted use of activated silica gel in the, of salicylic acid and β-naphthol **3023**

Esters, decompns. of, by anhyd. $ZnCl_2$, **395;** course of the addn. of Na enol alkyl malonic, to α,β-unsatd **4598**

Ethane, heat capacity of satd. liquid, from the b. p. to the crit. temp. and heat of fusion of the solid, **611;** alkali metal derivs of phenylated **688**

Etherates, of $MgBr_2$ **3523**

Ethers, reactions of, with acid chlorides, acids and anhydrides, **387, 391;** synthesis of β-bromoalkyl, and their use in further syntheses, **651;** phenolic decompn. of certain mixed, **1944;** prepn. of solid derivs. for the identification of **4087**

Ethyl acetate, equil **869**

Ethyl alcohol, vapor phase esterification of AcOH by, **1565;** reaction between thiocarbanilide and CH_2ClCO_2H in, **2137;** activity coeffs. of ions in dil. soln. in, -water mixts., **2759;** vapor phase oxidation of, **3535;** effects of substituents on quantum efficiency in the quinone, reaction, **3556;** effect of added salts upon the soly. of other salts in **3962**

Ethylamine, action of heat on **4151**

Ethylammino boron trifluoride, action of Li on **4414**

Ethylene, effect upon the activity of diastase and invertase, **797;** kinetics, statics and energetics of the thermal reaction $CH_2I–CH_2I = CH_2{=}CH_2 + I_2$ in CCl_4 solns., **956;** thermal decompn. of metal alkyls in mixts. of H and, **1111;** non-catalytic polymerization and hydrogenation of, **1158;** chain characteristics of the, -O reaction. **2399;** induced addn. of, and Cl **2869**

Ethylene glycol. See Glycol.

Ethylene iodide, kinetics, statics and energetics of the thermal reaction $CH_2I–CH_2I = CH_2{=}CH_2 + I_2$ in CCl_4 solns., **956;** mechanism of the formation and decompn. of 3132

Ethylene oxide, action on the thioureas, **3322;** kinetic studies on derivs. of, (correction) **5305**

Ethylene succinates, **711,** (correction) **5307**

Ethyl ether, rate of reaction of certain alcs. with *p*-nitrobenzoyl chloride in anhyd., soln **268**

2-Ethylmercapto-5-carbethoxy-6-thiocyanopyrimidine, rearrangement of, into its isothiocyanate modification **1580**
Europium, sepn. by electrolytic reduction **2782**
Evaporation, condenser for low temp., of water 4334
Excelsin, mol. wt. of **279**
Explosions, chain reaction theory of the rate of, in detonating gas mixts., **3120**; in detonating gas mixts. 3905

FATTY ACIDS, assocd. with wheat starch, **808**; phenacyl, *p*-chlorophenacyl and *p*-bromophenacyl esters of some higher, **818**; anaerobic oxidation of **3308**
Feeding stuffs, Essential Chem Elements that Constitute a Balanced Food (Kinney, book review) **3034**
Ferricyanide ion, relative influence of cations and anions upon the equil. $2Fe(CN)_6^{---} + 3I^- \rightleftarrows 2Fe(CN)_6^{----} + I_3^-$ **876**
Ferricyanides, effect of light on the **ferrocyanide–ferricyanide** iodine–iodide equil. **4770**
Ferrocyanide ion, relative influence of cations and anions upon the equil. $2Fe(CN)_6^{---} + 3I^- \rightleftarrows 2Fe(CN)_6^{----} + I_3^-$ **876**
Ferrocyanides, effect of light on the ferrocyanide–ferricyanide iodine–iodide equil. **4770**
Films, role of the liquid stationary, in batch absorptions of gases, **3767, 3769**; Soap— (Lawrence, book review) **4178**
Fish poison, constituent of the South American, Cracca toxicaria **2461**
Flaxseed, compn. of an aldobionic acid from, mucilage **3711**
Fluorane, from the dry distn. of Cu phthalate **3003**
Fluorene, attempts to resolve derivs. of **3437**
Fluorescence, measurements of the, of cellulose acetate, cellulose nitrate and gelatin in ultraviolet light, **3846**; quenching of the, of NO_2 **3920**
Fluorine, vapor pressure and crit. temp. of **3839**
Fluorite, quantum efficiency of O_3 formation in the, region **559**
Foods, Essential Chcm. Elements that Constitute a Balanced Food (Kinney, book review) **3034**
Formaldehyde, oxidation of, in the gaseous phase, **974**; action of PH_3 on **2995**
Formamide, as solvent for the electrodeposition of metals **2693**
Formic acid, vapor pressure and heats of fusion and vaporization of, **1874**; velocity of sapon. of Et ester of, by NH_4OH in the presence of NH_4 salts, **2604**; potentiometric study of acid-base titration systems in the very strongly acid solvent **4795**
Friedel and Crafts reaction, mixed catalysts in the, 4365; with 8 hydroxyquinoline **4433**
Fries reaction, mechanism and application of the **352**
Fructose, action of KOH on Ca hexosediphosphate—comparison with that of **4065**
Fumaric acid, soly., sp. gr. and *n* of aq. solns. of **2602**
Furan, prepn. and properties of some new, deriv., **2079**; simple halogen derivs. of **2083**
Furan series, attempted correlations of constitution with sweet taste in the **2010**
Furfural, direct nitration of, **4165**; chemistry of **4477**
α-**Furfuryl** group, rearrangement of the **1284**
2-Furylacetic acid **1284**
2-Furylacrylic acid, bromination of Et ester of **3349**

GADOLINIUM BROMIDE, absorption spectra of $GdBr_3{\cdot}6H_2O$ at room temp and at that of liquid air and their comparison with those of $GdCl_3{\cdot}6H_2O$ **3747**
Gadolinium chloride, absorption spectra of $GdBr_3{\cdot}6H_2O$ at room temp and at that of liquid air and their comparison with those of $GdCl_3{\cdot}6H_2O$ **3747**
Galactose, fifth penta-acetate of, its alcoholate and aldehydrol **2464**
Gas, illuminating and fuel, preferential catalytic oxidation of CO in the presencr of H—activity of two water gas conversion catalysts, **437**; indirect calcn of the water gas equil. const., **1782, 4268**; mechanism of the formation of higher hydrocarbons from water gas **3221**
Gases, sp. heats of, at high pressures, **108, 5111**; nature of the sorption by charcoal of under great pressure, **2198**; detg. the viscosity of corrosive, **2619**, removal from liquids, 3576; role of the liquid stationary film in batch absorptions of, **3757, 3769**; gaseous oxidations, **3785**; thermodynamic treatment of chem. equil. in systems composed of real, **4239**; Einfuhrung in die techn. Behandlung gasformiger Stoffe (Bertelsmann, Schuster, book review). **5301**
Gelatin, structure of, gels from studies of diffusion, **1295**; diffusion of non-elec-

trolytes in. gels. **1305;** **ultracentrifugal** study **of,** solns., **2897;** measurements of the fluorescence of. in ultraviolet light **3846**

Geologic time. isotopes and the problem of **3161**

Germanic nitride. prepn. and properties of **5160**

Germanium. **2369. 2779. 3553;** heteropoly acids of **5154**

Germanium compounds. org..some triphenyl derivs. and their reactions. **372;** studies relating to org., **3690. 4031;** with N **5160**

Germanium diphenyl **4031**

Germaniummonohydride **2369**

Germaniummonosulfide **3553**

Germaniummonoxide **3553**

Germanium tetraethyl. thermal decompn. of gaseous **4372**

Germanomolybdic acid **5154**

Glass. behavior of. electrodes of different compns., **29;** thermoluminescence in. which contains **2** activators **5146**

Globulin. P_{H} stability regions of serum **2855**

d-a-Glucoheptose. conversion of. to a new ketose. d-glucoheptulose **2106**

d-Glucoheptulose **2106**

Glucose. action of KOH on Ca hexosediphosphate—comparisonwith that of **4065**

Glucose pentaacetate. isolation of **2 cryst.** forms of **1542**

Glucosidoferulic acid. synthesis of **5049**

Glutamylthiohydantoin. interpretation of the dehydration of acetylglutamic acid bymeansof. derivs **1192**

Glyceric acid. **S** analog of. **1105;** monophenyl ethers of **2340**

Glycerides. synthetic. ns. of known constitution **365**

Glycerol monochlorohydrin. glycidol prepu. from **1521**

Glycerol trinitrate. viscosity of **3669**

Glycidol, prepn. from glycerol monochlorohydrin. **1521;** reactions with secondary amines **1528**

Glycine. density of. **2420;** prepn. of. **4166;** acid and base consts. of. from cells withoutliquidjunction **5091**

Glycol. esters of H_2CO_3. **314;** esters of oxalic acid. **3292;** reaction with phthalic anhydride. **3636;** viscosities of glycerol trinitrate and certain related. nitric esters. **3669;** representative carbonates and carbo-ethoxy derivs. related to. **3720;** decompn. of. in the presence of catalysts **4558**

Glyoxal sodium bisulfite. action of guanidine carbonate and of benzamidine hydrochloride upon **2026**

Gold, soly. in Hg **1842**

Gold azido-dithiocarbonate **2806**

Gold chloride carbonyl **2919**

Gold compounds. chemistry of org **2919**

Goldfish. study of toxicity by use of **3440**

Grignard reaction. prepn. of 2-alkyl and 2-aryl pyridines and quinolines by the **2845**

Grignard reagents. reaction of various. with epichlorohydrin. **1164;** "machine" for analysis with. **3736;** compn. of the. **4412;** distn. of. **4480;** electrolysis of solns. of. **4904;** formation of a complex mixt. of many RMgX compds. from the reaction between a simple RX compd. and Mg, **5017;** replacement of halogen by H in a-haloketones under the influence of the. **5036;** historical note on the first prepn. of an alkylmagnesium halide **5045**

Guanidine carbonate. action upon glyoxal Na bisulfite **2026**

"Gum levan," structure of **2582**

Gums. compn. of the. produced by root nodule bacteria; **3659;** compn. and structure of mesquite **4461**

HALIDES. action of Na on some org.. in liquid NH_3 **2823**

Halogens. polarity of the C–halogen bond. **93;** detn. in org. compds., **1195. 3466.** micro detn. of. in org. compds., **1893.** (correction). **5307;** estn. of org., **3023;** replacement of. by H in α-haloketones under the influence of the Grignard reagent **5036**

Halohydrins. action on the thioureas **3322**

a-Haloketones. replacement of halogen by H in. under the influence of the Grignard reagent **5036**

Haloplatinates. relative stabilities of **4316**

Haplophyton *cimicidum,* mannitol from **3739**

Heat. capacity and entropy of $KClO_4$ from 12 to 298° abs. 549; capacity of satd. liquid ethane from the b. p. to the crit. temp., 611; capacity of satd. liquid N and CH_4 from the b. p. to the crit. temp., 622; data on org. compds.—capacities of some satd., non-benzenoid hydrocarbons. 1032; capacities of 12 aromatic hydrocarbons. 1547; capacities of As, As_2O_3 and As_2O_5 at low temps., 2296; capacity of Si at low temps., 2301; capacities at low temps. of Sb. Sb_2O_3, Sb_2O_4 and Sb_2O_5, 2712; capacities of Bi and Bi_2O_3 at low temps., 2720; capacities of the isomeric heptanes, 3241; thermal data on org. compds.—effect of unsatn. on the heat capacities of some hydrocarbons and other compds. 4381
Heating. influence of the period of. upon the b. p. of certain liquids used in ebullioscopy with a note on testing the purity of volatile liquids by isothermal distn. 4699
Heat of activation. nature of—calcn. of the. from band spectra data 1733
Heat of adsorption. of O on charcoal. (correction) 5305
Heat of combustion. of aromatic nitro compds. 115
Heat of dilution. of KCl in sucrose and urea solns. as solvents below 0.1 M at 25°. 4218
Heat of dissociation. of O 3468
Heat of formation. of aromatic nitro compds. 115; of ZnO, 2159; of mol. 0.2580, 3467
Heat of fusion. of solid ethane. 611; of cristobalite. 1436; of formic acid 1874
Heat of hydration. of CaO 910
Heat of ionization. of some simple amino acids and peptides 863
Heat of neutralization. of $Na_2Cr_2O_7$ by NaOH, 3098; by the continuous flow calorimeter 3806
Heat of solution. of $Ca(OH)_2$ in $HCl\cdot 200H_2O$, 80; of $KClO_4$, 549; of tricalcium aluminate and its hydrates in HCl 3927
Heat of vaporization. of formic acid 1874
Helium. soly. in water and some org. solvents 68
Helium group gases. calcn. of rates of explosions in mixts. of H and O and the influence of 3905
Heptaacetyl-α-methylcellobioside 2571
Heptaacetyl-β-methylcellobioside 2571
Heptadecanoic acids. prepn. and bactericidal properties of certain 2540
Heptane. investigation of a series of derivs. of normal—prepn., identification and phys. consts., 1982; investigation of a series of derivs. of normal—dipole moments and mol. constitution. 1993; heat capacities. entropies and free energies of the isomers of 3241
Hexa-ω-*tert*-butylpropinylethane. 5267
Δ-1,5-Hexadiene, behavior toward HCl 1519
Δ-2,4-Hexadiene, behavior toward HCl 1519
Hexahydronicotine. reduction of nicotine and some derivs. of 2543
N-Hexahydrophenylpyrrolidine, synthesis of 804
Hexamethylbenzene. vapor pressure of. 1998. (correction) 5309
Hexane. bromination of 3465
2,4,6,2′,4′,6′-Hexanitro-3,3′-dicarboxydiphenyl, prepn. and resolution of 2054
Hexaphenylethane. kinetics of the reaction of. with O 255
Hexenoic acid. oxidation of 3188
Hexosediphosphatase. acidity optimum of yeast 4117
Hopcalites. preferential catalytic oxidation of CO in the presence of H—activity of 2-component, 445; adsorption of water vapor and CO_2 by. catalysts 2411
Hormones. relaxative. of the corpus luteum 3340
Hydantoins 3676
Hydration. catalysis in the. of propionic anhydride. 1410; catalysis in the. of acetopropionicanhydride 1418
Hydrazine. thermal decompn. of. 970; diaryl acyl. series. 2815; oxidation of 3035
Hydrazodithiodicarbonamides. isomerism of 4860
Hydrobromic acid. reaction with Si, 1464; thermal cleavage from brominated substances 5241
Hydrocarbons. heat capacities. entropies and free energies of some satd., non-benzenoid, 1032; heat capacities. entropies and free energies of 12 aromatic. 1547; decompn. in the electrodeless discharge. 3026; mechanism of the formation of higher. from water gas. 3221; nuclear synthesis of unsatd., 3396; quenching of Hg resonance radiation—satd., 3825; effect of unsatn. on the heat capacities. entropies and free energies of some, 4381; condensa-

tion of, by elec. discharge-comparison with condensation by a-rays, **4450**, chem. behavior of some benzenoid, in the Tesla discharge **4552**

Hydrochloric acid, heat of soln. of $Ca(OH)_2$ in $HCl\cdot 200H_2O$, **80**; temp. coeff. of the synthesis of, by light and by a-radiation, **593**; compn. of const. boiling, at pressures of **50** to **1220** mm., **633**; equil. between bivalent and quadrivalent Pd and Cl in, soln., **985**; behavior of Δ-1,5-hexadiene and Δ-2,4-hexadiene toward, **1519**; b. ps. of const. boiling, **1747**; application of moving boundaries to a study of aq. mixts. of KC1 and, **1897**; measurements of the e. m. f. of the calomel electrode against the H electrode at low concns. of, **2179**; activity coeff. of, at infinite diln. in water–MeOH mixts, **2353**; effect of ICl on the photosynthesis of, **2793**; alcoholysis of certain 1,3-diketones in the presence of, **3212**; heat of soln. of tricalcium aluminate and its hydrates in **3927**

Hydrocyanic acid, photochem. dissocn. of, **61**; distribution between benzene and aq. $HAg(CN)_2$ **192**

Hydrofluoric acid, f. ps. of the system water– **3843**

Hydrogen, interference of nitro groups on the Zerewitinoff method for the quant. estn. of active, **405**; preferential catalytic oxidation of CO in the presence of, **437, 445**; lability of, –O bond in certain alcs., **753**; thermal decompn. of metal alkyls in mixts. of C_2H_4 and, **1111**; compressibility isotherms of N and, and of a **3:1** mixt. of these gases, **1363**; photochem., –O reaction, **1868**; measurements of the e. m. f. of the calomel electrode against the, electrode at low concns. of HCl, **2179**; reduction of metal oxides by, **2314**; adsorption by Ni at low temps., **2325**; reaction between N and, in the presence of Hg vapor, **2418**; prepn. of normal valerolactone by the catalytic reduction of levulinic acid with, in the presence of Pt oxide, **3010**; calcn. of rates of explosions in mixts. of O and, and the influence of rare gases, **3905**; optimum H:N ratio for NH_3 formation in the Haber equil., **4239**; equil. in the Fe–H–O system, **4268**; entropy of, and the third law of thermodynamics—free energy and dissocn. of, **4816**; replacement of halogen by, in α-haloketones under the influence of the Grignard reagent, **5036**; thermal, –O combination **5106**

Hydrogenation, over metallic Cs, **892**; non-catalytic polymerization and, of C_2H_4, **1158**; in the chlorophyll series, **1233**; app. for micro-catalytic, **3359**; use of Ni as a catalyst for, **4349**; of acetoacetic ester and certain of its derivs over Ni **5192**

Hydrogen azide, quantum yield in the photochem. decompn. of **124**

Hydrogendisulfide **2184**

Hydrogen-ion concentration, effect on the pptn. of $Zn NH_4$ phosphate, **120**; effect on the rate of thermal decompn. at **100**" of the oxytocic principle of the posterior lobe of the pituitary gland, **824**; kinetic detn. of, in aq. soln., **1394**; Pa-stability regions of serum albumin and of serum globulin, **2855**; *P*H-stability region of egg albumin **5187**

Hydrogen peroxide, dielec. consts., ns and ionizing power of, and its aq. solns, **489**; effect of acidity on the oxidation of butyric acid with, **640**; concn. of, solns., 950; autocatalytic reduction of bromate by, in acid soln., **1427**; promoter action in reactions of oxidation concomitant with the catalytic decompn. of, **3035**; thermal H–O combination—formation of, and the influence of surface nature **5106**

Hydrogen sulfide, reaction between Ag and, **885**; reactions in liquid—sp. conductance of liquid **3045**

Hydrolysis, inhibitory effect of water on the acid, of halogen naphthols, **93**; of cyanamide in alk. solns., **195**; comparative, of some disaccharides and polysaccharides **3995**

Hydroquinone, oxidation of, by ceric sulfate **1443**

Hydroxylamino acids, O-alkyl substituted, and esters. **1078**

Hydroxylamino alcohols, O-alkyl substituted **1078**

Hydroxymethylanthrones, synthesis of some . . . **4887**

2-Hydroxynaphthalenesulfonic acids, electrometric studies on **211**

8-Hydroxyquinoline, prepn. of benzeneazo derivs. of, **4164**; Friedel and Crafts reaction with 4433

Hypobromous acid, addn. to phenylbutadiene 1574

Hypochlorous acid, addn. to phenylbutadiene, **1574**; oxidation of crotonic acid with **3185**

IGNITION, of CO–O mixts 4225

Imides, constitution of salts of certain cyclic 1028

Iminothiobiazolones, isomerism of. . . . 4860

Iminothiolthiobiazoles, isomerism of. 4860

Indicators, use of methyl red, erio glaucine and erio green, in the reaction between ceric and ferrous ions, **2347;** azo, **2397;** properties of diphenylamine and diphenylbenzidine as oxidation–reduction . . **4179**

Indigoids, formation of quinoline derivs. from certain . . **769**

Indium, electrode potential of, against $InCl_3$ solns . . **2372**

Indium chloride, electrode potential of In against solns. . . **2372**

Indolylbutyric acid, synthesis of, and some of its derivs **5029**

Industry. Conférence d'Actualitiés Scientifique et Industrielles, 1929 (Lemoine) **2587**

Inorganic chemistry, Ein Lehrbuch zum Weiterstudium und zum Handgebrauch (Ephraim, book review), **435;** A Text-book of (Friend, Sutherland, book review), **436,** (Friend, Marks, book review), **1727;** Anorgan. chem. Praktikum—Qual. Analyse und anorg. Praparate (Riesenfeld, Klement, book review), **3027;** A Comprehensive Treatise on (Mellor, book review), **4176;** Gmelins Handbuch der (Meyer, book review). **4614, 4615**

Inositol, occurrence of, in the phosphatide from human tubercle bacilli, **1607;** oxidation with HNO_3. . . . . **2483**

Interfacial tension, detn. of, from the max. pull on a ring. **1751**

Interferometry, Die Anwendung der, in Wissenschaft und Technik (Berl, Ranis, book review). **4176**

Invertase, effect of C_2H_4 upon the activity of. **797**

Iodates, reaction of, and tetravalent V in alk. solns **480**

Iodic acid, org. oxidations by. **3647**

Iodide ion, oxidation by persulfate ion, **608;** relative influence of cations and anions upon the equil. $2Fe(CN)_6^{---} + 3I^- \leftrightarrows 2Fe(CN)_6^{----} + I_3^-$. . . **876**

Iodides, titration of, **894;** starch–iodide reaction, **2768;** effect of light on the ferrocyanide–ferricyanide iodine iodide equil. **4770**

Iodination, of phenol and cresol ethers. **1570**

Iodine, detn. of traces of—in milk, butter, oil and urine, **541;** kinetics, statics and energetics of the thermal reaction $CH_2I–CH_2I = CH_2{=}CH_2 + I_2$, in CCl_4, **956;** detn. of traces of—in small quantities of thyroid and other tissues, 980; cyanogen iodide as an impurity in, 2415; stability and proportionality of color produced by small amts. of, **2768;** effect of light on the ferrocyanide–ferricyanide iodine–iodide equil **4770**

Iodine chloride, use of the. end-point in volumetric analysis, **894.901**; effect on the photosynthesis of HCl. **2793**

Iodine oxide, I_2O_2. . . . . **3580**

Ionization, electrolytic, comparison method for detg., consts. with a quinhydrone reference electrode, **23;** power of H_2O_2 and its aq. solns., **489,** consts. and heats of ionization of some simple amino acids and peptides, **863;** const of water from an equil. involving HgO and HgBr. **921;** of CH_2ClCO_2H in aq. soln., **1404;** incompatibility between any theory of complete, and migration data, **2336;** relation between, potentials, and ionic potentials, **3076;** titration consts. of multivalent substances, **3518;** const. of water at 25° from the e. m. f. of cells without liquid junction, **3877;** of water in CsCl solns., **3892;** thermodynamic properties of weak acids and bases in salt solns. and an exact method of detg. their, consts. **5079**

Ions, electrolytic, ionic ratios in the waters of the north Pacific Ocean, **915;** effect on sedimentation of colloidal particles by means of the centrifuge, **1009;** incompatibility between any theory of complete dissocn. and migration data, **2336;** transference phenomena and the existence of complex ions as interpreted by their magneto-chem. behavior, **2632;** activity coeffs. of, in dil. soln. in EtOH–water mixts., **2759;** relation between ionizing potentials and ionic potentials, **3076;** line spectra of, in the solid state in the visible and ultraviolet regions of the spectrum, **3747,** complex, **4316;** paramagnetism independent of the temp. and the existence of electronic isomers in polyatomic **4671**

Iron, pyrophoric, **142;** properties of pyrophoric–adsorption of CO_2 and NH_3 and the use of pyrophoric, in the NH_3 synthesis, **150;** poisoning action of water vapor at high pressure on, synthetic NH_3 catalysts, **2682;** equil. in the Fe–H–0 system **4268**

Iron chlorides. yield of benzophenone from benzoyl chloride and C_6H_6 with $FeCl_3$–$AlCl_3$ mixts. as catalysts.......... 4365
Iron hydroxide. coagulation of pure $Fe(OH)_3$ sols.......... 4170
Iron ions, use of methyl red. erio glaucine and erio green indicators in the reaction between ceric and ferrous ions.......... 2347
Iron nitride. dissocn. pressure of Fe_4N.......... 1456
Iron oxide. prepn. of negative colloidal Fe_2O_3 by hydrolysis of Prussian blue. 1337; chloride-free Fe_2O_3 hydrosols and the Burton–Bishop rule. 2598; coagulation of Fe_2O_3 sols by gas bubbles. 2730; adsorption of arsenious acid by hydrous Fe_2O_3.......... 2785
Iron oxybromide. hydrosols.......... 456
Isoamyl alcohol. sepn. and identification of the alkali and alk. earth metals by use of.......... 3068
Isocitric acid.......... 2928
Isomerism. possible. of certain analogs of resolvable diphenyl compds., 2959; of hydrazodithiodicarbonamides. iminothiolthiobiazoles and iminothiobiazolones, 4860; tautomerism of brilliant cresyl blue. (correction).......... 5305
Isomers. existence of electronic. in the solid state and in soln., 2702; paramagnetism independent of the temp. and the existence of electronic. in polyatomic ions.......... 4671
Isoprene, polymerization expts. with. 1659; 4-methyl-4-octene by. ethylation... 2075
Isoquinoline. local anesthetics derived from.......... 4013
Isorotenone, toxicity to goldfish.......... 5051
Isotherms. compressibility. of H, N and a 3:1 mixt. of these gases. 1363; compressibility. of CO.......... 1374
Isotopes. and the problem of geologic time.......... 3161
Isotubaic acid. identity of rotenic acid and.......... 2480
Isoxazole series. pseudo bases in the.......... 4943
Isoxazoline oxides. 2038; reduction of.......... 4520

JAMIN EFFECT. in cylindrical tubes.......... 1346

KEKULÉ, AUGUST (Anschütz. book review).......... 433
Kerosene. bases in the. distillate of Calif. petroleum.......... 1239
Keto–enol equilibrium. of Et a-phenylacetoacetate.......... 4358
Ketones. condensation reactions of cyclic. 769; ammonolysis of. 820; prepn. of alkyl phenyl. 1267; action of Se oxychloride upon. 1588; delicate color test for Michler's, 1604; alcoholysis of certain 1,3-di-, in the presence of HCl, 3212; metallic salts of. 3383; configuration of the unsatd. dibromo 1,4-di-, and ketonic acids. 3405; synthesis and configurations of unsatd. 1,4-di-, and ketonic acids and the stereochem. mechanism of the addn. of Br. 3423; action of bases on α,β-dibromo- and related substances. 3728; cleavage of certain unsymmetrical 1,3-di-, 4036; alcoholysis of 1,3-di-.......... 4391
Ketonic acids. configurations of the unsatd. dibromo 1.4-diketones and. 3405; synthesis and configurations of unsatd. 1.4-diketones and. and the stereochem. mechanism of the addn. of Br.......... 3423
β-**Ketonic** esters. alcoholysis of certain.......... 4391
Ketose. conversion of d-a-glucoheptose to a new.......... 2106
Kieselguhr. Diatomaceous Earth (Calvert. book review).......... 4617
Kinematics. of phosgene.......... 3132
Kolm, at. wt. of U Pb from Swedish.......... 4848
Krypton.......... 4173

LABORATORIES. A Report of the Natl. Research Council Committee on the Construction and Equipment of Chem. (Coyle. *et al.*, book review).......... 3030
Lactal. oxidation of.......... 3472
Lactalbumin. mol. wt. of.......... 3650
Lactic acid. photochem. oxidation of.......... 5272
Lactones. two cryst., of l-rhamnonic acid. 1270; 1.4- and 1.5-rhamnonic–crystallographical and optical properties. 1276; isolation and identification of d-mannuronic acid. from the *Macrocystis pyrifera*, 2130; prepn. of certain γ-.......... 3702
Lactose. synthesis of lactulose from.......... 2101
Lactulose, synthesis from lactose.......... 2101
Lamps. capillary Hg-vapor.......... 2151

Lard, occurrence of arachidonic acid in **1135**

Lead, potential of, -Pb ion, **589;** at. wt. of U, from Swedish kolm, 4848; at. wt. of uraninite, from Wilberforce, Ontario, Canada **4851**

Lead azido-dithiocarbonate **2806**

Lead bromide, thermodynamic properties of molten solns. of $PbCl_2$ in **4641**

Lead chloride, thermodynamic properties of molten solns. of, in $PbBr_2$, **4641;** thermodynamic properties of solns. of molten $ZnCl_2$ and, **4655;** study of the Cd-, voltaic cell **4831**

Lead chromate, soly. in HNO_3 and in $HClO_4$ **2402**

Lead compounds, prepn. of diethyl Pb dichloride and triethyl Pb chloride **1975**

Lead iodate, soly. in water and in **0.1** *N* salt solns **2791**

Lead ion, potential of Pb- **589**

Lead molybdate, soly. in HNO_3 and in $HClO_4$ **2402**

Lead oxides, oxidation potential of the PbO_2 electrode in $HClO_4$ soln **1**

Lead perchlorate, prepn. and properties of **2391**

Lead sulfate, soly. in HNO_3 and in $HClO_4$ **2402**

Leather, The Chemistry of, Manuf. (Wilson, book review) **856**

Lecithin, prepn. of **1718**

Legumin, mol. wt. of **3279**

Lemon juice, prepn. and properties of vitamin C fractions from **420**

Levan, structure of **2582**

Levulinic acid, prepn. of normal valerolactone by the catalytic reduction of, with H in the presence of Pt oxide, **3010;** and its esters **4880**

Light. (See also ***Photochemistry***) Dissocn. of triatomic mols—HCN, **61;** decompn. of nitrosyl chloride by, **102;** quantum yield in the decompn. of HN_3 by, **124;** decompn. of $KClO_3$ in, **527;** temp. coeff. of the synthesis of HCl by. **593;** synthesis of phosgene by, **1853;** formation of vitamin D by monochromatic, **2304;** mechanism of decompn. of O_3 by, **2377;** decompn of NO_2 by, **2584;** chain reactions produced by, **2743;** effect on the ferrocyanide–ferricyanide iodine–iodide equil **4770**

Light, ultraviolet, and Vitamin D in Nutrition (Blunt, Cowan, book review), **2593;** measurements of the fluorescence of cellulose acetate, cellulose nitrate and gelatin in, **3846;** action on terpenes **4093**

Lignin, from oat hulls **793**

Lime, thermochemistry of the compds. occurring in the system $Al_2O_3–SiO_2–$, **80; 3927;** thermochemistry of the compds. occurring in the system, $–Al_2O_3–SiO_2$— heat of hydration of **910**

Lipoids, chemistry of the, of tubercle bacilli 1252, **1607, 5023**

Liquids, dielec. polarization of, **1824, 2227, 3546;** removal of gases from, **3576;** role of the liquid stationary film in batch absorptions of gases, **3757, 3769;** influence of the period of heating upon the b. p. of certain, used in ebullioscopy with a note on testing the purity of volatile, by isothermal distn., **4699;** vacuum fractionation of phlegmatic **4714**

Lithium, detection and estn. of small amts. of, **2754;** action on ethylammino boron trifluoride **4414**

Lithium bromide, thermodynamic properties of molten solns. of, in AgBr **4650**

Lithium chloride, activity coeff. at infinite diln. in water-MeOH mixts **2353**

Lithium halides, temp.–conductance curves of solid **1340**

Lithium nitrate, cond. and viscosity of solns. of, in certain binary alc. systems **4762**

Lodal, synthesis of **4119**

Logarithms, Non-Interpolating (Johnson, book review) **5300**

Lubricants, inorg. stopcock, **635;** inorg., **2421, 2813, 4335;** inorg., for temps. above and below normal **4858**

MACROCYSTIS PYRIFERA, isolation and identification of *d*-mannuronic acid lactone from the **2130**

Magnesium, action of the system Mg + $MgBr_2$ upon triphenylcarbinol, triphenylbromomethane and triphenylmethyl, **2455;** prepn. of Mn-free, **2776;** action of Mg + $MgBr_2$ on phenylbiphenylenemethyl, **3287;** reaction of triphenylmethyl, a small amt. of Mg halide and, **4412;** sp. heat of—entropy and chem. consts. of, from spectroscopic data, **4686;** vapor pressure consts. of, **4696;** detn. of, with 8-hydroxyquinoline, **4752;** reaction between the binary system Mg + MgI_2 and aromatic aldehydes, **4967;** formation of a complex mixt. of many RMgX compds. from the reaction between a simple RX compd. and **5017**

Magnesium alloys, reduction of benzophenone to benzopinacol by means of Mg amalgam.... 1128

Magnesium bromide, action of the system Mg +, upon triphenylcarbinol, triphenylbromomethane and triphenylmethyl, 2455; action of Mg + $MgBr_2$ on phenylbiphenylenemethyl, 3287; etherates of.... 3523

Magnesium chloride, reduction of benzophenone to benzopinacol by means of Mg amalgam and some observations concerning.... 1128

Magnesium compounds, first prepn. of phenylmagnesium bromide, 1181; reaction between triphenylisoxazoline oxide and org., 2038; prepn. of Hg dialkyls from organomagnesium halides, 3314; prepn. of phenylmagnesium chloride, in the absence of a solvent, 3330; reaction between citronellal and some organo-Mg halides, 3588; benzohydrylmagnesium chloride and the apparent prior formation of free benzohydryl radicals, 3984; reaction between highly phenylated compds. and org., 4128; reaction of triphenylmethyl, Mg and a small amt. of Mg halide, 4412; influence of acid chlorides and of pyrrole on the color test for reactive organometallic compds.—constitution of pyrrylmagnesium halides, 4949; reducing action of compds. contg. the group $>$CHOMgI, 4973; formation of a complex mixt. of many RMgX compds. from the reaction between a simple RX compd. and Mg, 5017; historical note on the first prepn. of an alkylmagnesium halide.... 5045

Magnesium dialkyls.... 5045

Magnesium diphenyl, reaction between Br and.... 1181

Magnesium iodide, reaction between the binary system Mg +, and aromatic aldehydes.... 4967

Magnesium ion, use of *o,p*-dihydroxyazo-*p*-nitrobenzene as a test for.... 1812

Magnetic moments, attempt to det. nuclear.... 3024

Magnetic susceptibility, of the manganocyanide ion, 1012; of $Sm_2(SO_4)_3 \cdot 8H_2O$ and its variation with the temp.... 2702

Magnetism, paramagnetism independent of the temp. and the existence of electronic isomers in polyatomic ions.... 4671

Magneto-chemistry, transference phenomena and the existence of complex ions as interpreted by their magneto-chem. behavior.... 2632

Maleic acid, soly., sp. gr. and *n* of aq. solns. of.... 2602

Malic acid, soly., sp. gr. and n of aq. solns. of i-, 2602; decompn. by H_2SO_4.... 2746

Malonic acid, course of the addn. of Na enol alkylmalonic esters to α,β-unsatd. esters, 4598; influence of the structure of the substituents on the temp. of decompn. of certain derivs. of.... 5066

Malt, quant. study of the influence of acetate and phosphate on the activity of, amylase, 1669; influence of certain neutral salts upon the activity of, amylase. 2436

Maltose, action of KOH on.... 294

Manganese alloys, x-ray study of the constitution of some, with Cu, Ni and Al.. 3833

Manganese dioxide, in preferential catalytic oxidation of CO in the presence of H, 437; catalytic "coupling" of, with H_3PO_4 or H_2SO_4 as an oxidizing agent, 640; adsorption of water and benzene vapors by, 2170; adsorption of water vapor and CO_2 by, 2411; manganous-, and the manganous-permanganate electrodes, 2595; oxidation-reduction potentials of, electrodes.... 2624

Manganese salts, manganous-MnO_2 and the manganous-permanganate electrodes. 2595

Manganocyanide ion, magnetic susceptibility of.... 1012

Mannitol, from *Haplophyton cimicidum*.... 3739

γ-*d*-Mannonic lactone, prepn. of.... 403

Mannose, in the phosphatide from human tubercle bacilli.... 1252

d-Mannuronic acid, lactone from the *Macrocystis pyrifera*.... 2130

Manometers, low pressure measurements with the abs., 3159; direct reading oil, 4728; for the measurement of small pressure differentials at high pressures.. 5102

Mass action, effects in systems composed of real gases.... 4239

Mathematics, Non-Interpolating Logarithms, Cologarithms and Antilogarithms (Johnson, book review).... 5300

Medicine, Am. Illustrated Med. Dictionary (Dorland, Miller, book review), 2154; Die Kolloide in (Bechhold, book review).... 3744

Melting, exptl. study of an incongruent, at pressures up to 12,000 atm.... 4252

Melting points, relation between the mol. wts. and, of org. compds., 1049; app. for the detn. of.... 3128

Mercaptans, decompn. in alkali solns.... 4338

Mercapto grouping, reducing action of the.... 4573

Mercuration, of β-**resorcylic** acid 4369

Mercury. **detn.** of. 557. 569; -basic mercuric sulfate voltaic cell. 1407; **soly.** of Au in. 1842; reaction between N and H in the presence of. vapor and the resonance radiation of. 2418; some organo-mercuric nitrates and a method of analysis for. applicable to dil. solns. of such compds., 2820; quenching of. resonance radiation. 3825; constricted. arc 4337

Mercury **azido-dithiocarbonate** 2806

Mercury bromide. **dissocn. const.** of water from an equil. involving **HgO** and 921

Mercury chlorides. measurements of the e. m. f. of the calomel electrode against the H electrode at low concns. of **HCl,** 2179; x-ray photochem. reaction between $K_2C_2O_4$ and 2612

Mercury compounds. mercurated azo dyes derived from **benzidine** and *o*-**tolidine,** 2.528; prepn. of some organo-mercuric nitrates and a method of analysis for Hg applicable to dil. **solns.** of such compds., 2820; **derivs.** of **acetylamino-cresols.** 3978; constitution of some Hg derivs. of **acetylenic** acids 4405

Mercury dialkyls. prepn. of. from organomagnesium halides 3314

Mercury nitride. as nitridizing agent 2425

Mercury oxide. **dissocn. const.** of water from an equil. involving **HgBr** and 921

Mercury sulfate. Hg-basic mercuric sulfate voltaic cell 1407

Mesitylene series. **trihalomethyl** ketones of the 3269

Mesquite gum. compn. and structure of 4461

Metallurgy. Select Methods of Metallurgical Analysis (Naish, Clennell. book review) 4177

Metals. *See* also Electrodeposition; abs. cohesion in. —disruptive negative pressures and crit. disruptive vols., 534; Rontgenographie der (Neuburger. book review). 1730; study of the products obtained by the reducing action of. upon salts in liquid NH_3 soln., 3573; use of the Poulsen arc as a means of detecting traces of impurities in 4169

Metanicotine. catalytic reduction of 3385

Methane. heat capacity of satd. liquid. from the b. p. to the crit. temp., 622; alkali metal derivs. of phenylated. 688; elec. moments of halogenated 2227

Methanol. equil. in the synthesis and decompn. of. 926; activity **coeffs.** of **NaCl, KCl** and **LiCl** and **HCl** at infinite diln. in water.. mixts., 2353; **equil.** between. and its **decompn.** products. 3165; vapor phase oxidation of 3535

Methionine, synthesis of 2575

α-(*p*-Methoxyphenyl-β-phenyl)ethyl ether 4893

Methylacetylene. pyrolysis of 4540

Methylacetylene tetrabromides. 1138. (correction) 5307

Methyl alcohol. See *Methanol.*

Methyl n-amyl ketone. decompn. of ethyl n-butylacetoacetate into caproic acid and 5005

Methylation. new. process 4012

α-Methylcellobioside, prepn. of 2571

Methyldiethylmercaptoglucose **2147,** 3465

Methylene chloride. action of $(CH_3)_3SnNa$ on 695

Methylenedioxyl group. scission of the. with $AlBr_3$ 2988

5-Methylfuroic acid 1284

a-Methyl-d-galactoside and tetraacetates 2534

β-Methyl-*d*-galactoside and tetraacetates 2534

2-Methyl-6-nitro-2′-**carboxydiphenyl,** prepn. and resolution of 5263

4-Methyl-4-octene by isoprene ethylation 2075

Methylpiperidinoalkyl cinnamates 2007

n-Methylpyrazinium salts. certain. and their corresponding bases 5254

.Methyl red. use of. indicator in the reaction between **ceric** and ferrous ions 2347

α-Methyl-γ-tetrahydro-2-furylpropylmagnesium bromide 2144

N-3-Methyl-5-tyrosylhydantoin-1-phenylacetic acid. 2494; isomerism of certain unsatd. acids obtained in the synthesis of 2505

Michler's ketone. delicate color test for 1604

Microörganisms, An Index to **the Chem.** Action of. on the Non-Nitrogenous **Org.** Compds. (**Fulmer,** *et al.*, book review) 3745

Microscopy, Handbook of **Chem.** (**Chamot,** Mason. book review) 2155

Milk, I in 541

Mixtures. effect of temp. on the mol. surface energy of binary. 14. 1448; **dielec. consts.** of **binary** **1356,** 1831. 1838

Molecular volume. of Nd perchlorate. 3112; of certain rare earth salts 4308
Molecular weights. relation between the. and m ps. of org. compds., 1049; detn. of. in liquid NH_3 5291
Molecules (**Ruark, Urey,** book review). 2588; effect of temp. on the mol. surface energy of binary mixts., 14; photochem. dissocn. of triatomic. 61; mol. diam. of N_2O_5, 2619, 3972; mol. ray expts.—chem. activity of mol. and at. O. 3864; Soap Films—A Study of Mol. Individuality (Lawrence. book review) 4178
Monosaccharides. ring structures of various 1680
Moureu, Charles. obituary of .... *Proc.* 31
Moving boundaries. application of. to a study of aq. mixts. of HCl and KC1 1897
Mucilage. compn. of an aldobionic acid from flaxseed 3711

NAPHTHALENE. compd. formation in the system m-dinitrobenzene– 945
1-Naphthoic nitrile, prepn. from 1-naphthylamine 4550
Naphthol. studies 4872
2-Naphthol. sulfonation of. in presence of boric acid. 2835; attempted use of activated silica gel in the esterification of salicylic acid and 3023
2-Naphthol-1.6-disulfonic acid 2835
Naphthols. inhibitory effect of water on the acid hydrolysis of halogen. 93; condensation of secondary amines with 1655
1-Naphthylamine, prepn. of 1-naphthoic nitrile from 4550
Neodymium perchlorate. absorption spectrum. mol. vol. and refraction of 3112
Neon. soly. in water and some org. solvents 68
Nervonic acid. synthesis of 4536
Neutral **salt** action. 876; upon the activity of malt amylase 2436
Nichols. William Henry. obituary of .... *Proc.* 47
Nickel. adsorption of H by. at low temps., 2325; use as a catalyst for hydrogenation. 4349; hydrogenation of acetoacetic ester and certain of its derivs. over 5192
Nickel alloys. x-ray study of the constitution of some. with Cu. Al and Mn 3833
Nickel sulfide. quant. pptn. in buffered solns 5141
Nicotine. effect of temp. on the mol. surface energy of mixts. of water and. 1448; reduction of. and some derivs. of hcxa- and octa-hydronicotines. 2543; catalytic reduction of 3385
Nitration. of abietic acid and the study of some of its N derivs., 2132; direct. of furfural. 4165; of sym-diphenylethane 5040
Nitric acid. soly. of Pb sulfate. chromate and molybdate in. 2402; oxidation of inositol with 2483
Nitridation 2425
Nitriles, salts of. 1069. 2524; identification of. 1267; structure of the salts of aromatic. 1971; decompn. of certain aromatic ald-chlorimines to form.—**prepn. of, from aldehydes** 4517
Nitrobenzene. effect of org. bases upon the extent and mechanism of the reducing action of Na methylate on 1531
p-Nitrobenzoyl chloride. rate of reaction of certain alcs. with. in anhyd. ether soln. 268
Nitrocellulose. measurements of the fluorescence of. in ultraviolet light 3846
Nitro compounds. relative rates of reduction of aromatic. 88; heats of combustion and formation of aromatic. 115; some highly phenylated aliphatic 761
Nitrocyclopropanes 424
Nitrofurfural 2550
Nitrofurylacrylic acid 2550
γ-Nitro-β-furylbutyrophenones 4965
Nitrogen. high-temp. equil. between Si nitride. Si and. 48; equil. of the reaction between. and CO_2 in the elec. arc. 156; heat capacity of satd. liquid. from the b. p. to the crit. temp., 622; compressibility isotherms of H and. and of a 3:1 mixt. of these gases. 1363; consts. of the Reattie–Bridgeman equation of state with Bartlett's *P–V–T* data on. 1382; alkylation on. of the pyrimidine cycle by application of a new technique involving mol. rearrangements. 2001; reaction between H and. in the presence of Hg vapor. 2418: substitution of 1 atom of. for 3 atoms of Cl in org. compds., 2951; distribution in pollen of. extd. by various solvents. 3591; optimum H-. ratio for NH_3 formation in the Haber equil 4239
Nitrogen chlorides. interaction between NCl_3 and NO at −150°—further evidence for the formation of NCl_2 and of mono-oxygen-dinitrogen-dichloride 4298

Nitrogen compounds, of Ge. **5160**

Nitrogen oxides, decompn. of N_2O_5 in inert solvents, **1472;** decompn. of N_2O_5 in chemically active solvents, **1486;** photochem. decompn of NO_2, **2584;** mol. diam. of N_2O_5, **2619, 3972;** surface tension of liquid N_2O, **2723;** quenching of the fluorescence of NO_2, **3920;** interaction between NCl_3 and NO at −150°, **4298;** attempt to measure the velocity of dissocn. of N_2O_4 by the method of sound waves. **4661**

Nitro groups, interference of, on the Zerewitinoff method for the quant. estn. of active H. **405**

Nitrones, cyclic. **1590**

2-Nitrooctane, optically active salts of. **3332**

Nitropyrocatechols, reduction of. **834**

Nitrosyl chloride, photochem. decompn of. **102**

Nonadecanoic acid, prepn. and bactericidal properties of certain. **2540**

Nucleic acids, action of diazomethane on the pyrimidine constituents of. **1536**

Nucleosides, synthesis of. **4489**

Nutrition, Ultraviolet Light and Vitamin D in (Blunt, Cowan, book review). **2593**

OAT HULLS, lignin from. **793**

Obituaries, Charles Moureu, *Proc.* **31;** William Henry Nichols,. . . . . . . *Proc.* **47**

Octahydronicotine, reduction of nicotine and some derivs. of. **2543**

Octaphenylgermanopropane. **4031**

Oils, I in, **541;** Les Essences Naturelles (Craveri, book review), **855;** effect of dissocd. water vapor on certain vegetable, **2454;** detn. of S in sulfur, **3655;** brazil nut, **4114;** Essences naturelles et parfums (Delange, book review), **4620;** antirachitic properties of shrimp. **4940**

Olefinic acids, prepn. and bacteriol. action toward B. *leprae* of certain. **1281**

Olefins, relative rates of absorption of the gaseous, into H_2SO_4 at 25°, **721;** aliphatic di-, 1519; α-. **3396**

Oleic acid, phenylation of, **1172;** epoxy acids from elaidic acid and. **1186**

Optical rotation, relations between, and structure in the sugar group, **1270, 1680, 1707, 2101, 2106, 2519, 2534, 4168,** (correction), **5307;** of cellulosic materials—, of sol. cellulose in alkali. **1508;** Optical Activity and High Temp. Measurements (Jaeger, book review). **4174**

Orange, pentose and uronic acid content of, albedo and an arabinogalacturonic acid derived from, pectin. **1209**

Organic chemistry, catalysis in, **387, 391, 395;** A Concise Summary of Elementary (Constable, book review), **853;** An Introduction to Modern (Coles, book review). **854;** Org. Syntheses. Vol. X (Clark, *et al.*, book review), **2157;** Jahrbuch der (Schmidt, book review), **2590;** A Brief Introduction to the Use of Beilstein's "Handbuch der" (Huntress, book review), **2591;** Die Methoden der (Houben, book review), **2591;** Lehrbuch der (Karrer, book review), **3032;** Trattato di (Oddo, book review), **3473;** Organisch-chem. Praktikum (Orthner, Reichel, book review), **4617;** Aluminiumchlorid in der (Kranzlein, book review), **4618;** Lehrbuch der (Schmidt, book review). **5302**

Organic compounds, irreversible oxidation of, **407;** reactivity of atoms and groups in, **753, 5066;** thermal data on, **1032, 1547, 3241, 4381;** relation between the mol. wts. and m. ps. of, **1049;** detn. of S in, **1075, 1086, 3275;** detn. of halogens in, **1195, 3466;** micro detn. of halogens and metals in, **1893,** (correction), **5307;** study of mol., **1939;** spectroscopic detn. of the decompn. products of. **2578;** sorption of org. vapors by highly evacuated, activated sugar charcoal, **2668;** substitution of 1 atom of N for 3 atoms of Cl in, **2951;** viscosities of several aq. solns. of, **3507;** study of vapor-phase oxidation of, by use of rare earth oxides as catalysts, **3535;** An Index to the Chem. Action of Microorganisms on the Non-Nitrogenous (Fulmer, *et al.*, book review), **3745;** action of aromatic alcs. on aromatic compds. in the presence of $AlCl_3$, **4484;** spectroscopic study of the decompn. and syntheses of, by elec. discharges, **5165;** detn. of org. unsatn. 5241

Osmium, detn. by means of strychnine sulfate. **42**

Osmotic pressure, Handbuch der biol Arbeitsmethoden—Methoden zur Bestimmung des kolloid-osmotischen Druckes in biol. Flüssigkeiten (Wreschner, book review). 1731

Oxalic acid, glycol esters of, **3292;** effect of SO_2 on the decompn. of. by H_2SO_4. . . . 4737

Oxidase, iodimetric method for detg., **activity**. **3614**

Oxidation. potential of the PbO_2 electrode in $HClO_4$ soln., 1; of org. acids by $Ce(SO_4)_2$, **132**; mechanism of carbohydrate, **294**, 3680, **4065**; of *m*-xylorcinol, **358**; irreversible, of org. compds.—of aldehydes, **407**; preferential catalytic, of CO in the presence of H, **437**, 445; of iodide ion by persulfate ion, **608**; effect of acidity on the, of butyric acid with H_2O_2, **640**; auto-, reactions—of anethol, etc., **739**; of benzaldehyde and CH_2O in the gaseous phase, **974**; of hydroquinone by $Ce(SO_4)_2$, **1443**; Ag ion catalysis of persulfate—of NH_3, **1493**; of inosite with HNO_3, **2483**; of "diisobutylene" by O_3, **2547**; -reduction potentials, **2624**; –reduction potentials at C and W electrodes, **2773**; catalysis by NaCl of, of C, **3025**; promoter action in reactions of, concomitant with the catalytic decompn. of H_2O_2—, of hydrazine, **3035**; of unsatd. compds., **3167**; of 3-chlorocrotonic acid, **3176**; of crotonic acid with HClO and perbenzoic acid, **3185**; of conjugated systems—of pentenoic and hexenoic acids, **3188**; anaerobic, of fatty acids, **3308**; of lactal, **3472**; study of vapor phase, of org. compds. by use of rare earth oxides as catalysts, **3535**; org., by iodic acid, **3647**; gaseous, **3785**; properties of diphenylamine and diphenylbenzidine as, –reduction indicators, **4179**; autoxidation of the amylenes, **4345**; –Reduction Potentials (Michaelis, book review), **4615**; potentials of some unstable, –reduction systems, **4915**; indirect method of studying the, –reduction potentials of unstable systems, **5204**; photochem., of lactic acid. **5272**

Oxides, reduction of metal, by H ... **2314**

Oxidizing agent, $Ce(SO_4)_2$ as a volumetric, **36**, **132**, 553, **557**; catalytic "coupling" of MnO_2 with H_3PO_4 or H_2SO_4 as an ... **640**

Oximes, catalytic reduction of O-alkyl substituted ... **669**

Oxygen, kinetics of the reaction of hexaphenylethane with, **255**; lability of H-, bond in certain alcs., **753**; elec. moments of certain substituted phenols and their relation to the stereochemistry of the, atom, **1356**; action on 1,4-dimethylcyclohexane, **1609**; photochem. H-, reaction, **1868**; electrode, 2256; chain characteristics of the C_2H_4-, reaction, **2399**; heat of formation of mol., **2580**, **3467**; heat of dissocn. of, **3468**; photochem. CO-, reaction, **3471**; homogeneous uncatalyzed reaction between C_2H_2 and, **3785**; chem. activity of mol. and at., 3864; calcn. of rates of explosions in mixts. of H and, and the influence of rare gases, **3905**; ignition of CO-, mixts., **4225**; equil. in the Fe–H–O system, **4268**; kinetics of the C_2H_2-, reaction, **4837**; thermal H-, combination, **5106**; heat of adsorption of, on charcoal (correction) ... **5305**

Oxygen–dinitrogen dichloride ... **4298**

Oxytocic principle, rate of thermal decompn. of the, of the posterior lobe of the pituitary gland ... **824**, 1098

Ozone, quantum efficiency of, formation in the fluorite region, 559; mechanism of the photochem. decompn. of, **2377**; oxidation of "diisobutylene" by, **2547**

PALLADIUM, equil. between bivalent and quadrivalent Cl and, in HCl soln. ... **985**

Papaveraldine, modified synthesis of ... **3610**

Papaverine, attempted Rügheimer synthesis. **310**; modified synthesis of ... **3610**

Parachors, of isomeric chlorodinitrobenzenes ... 3327, **5295**, **5297**

Paraffins, polarization and refraction of the normal, **3546**; normal, of high mol. wt. prepd. by the action of Na on decamethylene bromide ... **5279**

Particles, effect of ions on sedimentation of colloidal, by means of the centrifuge .. **1009**

Partition, of NH_3 between toluene and aq. silver ammonia chloride and hydroxide, and of HCN between benzene and aq. $HAg(CN)_2$ ... **192**

"Pechmann dyes," problem ... **837**

Pectin, arabinogalacturonic acid derived from orange ... **1209**

Pentadecanoic acids, prepn. and bactericidal properties of certain ... **2540**

1,4-Pentadiene, synthesis of ... **5060**

Pentamethylbenzene, vapor pressure of, **1998**, (correction) ... **5309**

2,4,6,2′,4′-Pentanitro-3-carboxydiphenyl, prepn. and resolution of ... **2070**

Pentenoic acid, oxidation of ... **3188**

Pentoses, content of orange albedo ... **1209**

Peptides, dissocn. consts. and heats of ionization of some simple ... **863**

Perbenzoic acid, oxidation of crotonic acid with ... **3185**

Perchlorate ion, entropy and free energy of ... **549**

Perchloric acid, oxidation potential of the PbO_2 electrode in, soln, 1; soly. of Pb sulfate, chromate and molybdate in ... **2402**

Perchromate, new type of red ... 1851

Perfumes (Delange, book review) 4620
Periodic system 3076
Permanganates, manganous–MnO_2 and the manganous, electrodes 2595
Persulfate ion, iodimetric estn of, 608; oxidation of iodide ion by, 608; Ag ion catalysis of oxidations of, 1493; kinetics of the reaction between thiosulfate ion and. in dil. aq. soln 4779
Petroleum, bases in the kerosene distillate of Calif. 1239
Pharmaceutical Chemistry (Oddo, book review). 3743
Phenacyl esters, of some higher fatty acids 818
Phenanthrene, purification of 4363
Phenanthrene series, syntheses in 3704
Phenanthrolines, prepn. of the, and related dipyridyls 397
Phenazine, formation of a, compd. from a diphenyl ether deriv. 3199
o-Phenetylurea 4167
Phenol ethers, iodination of 1570
Phenol group, synthesis of thiazoles contg. 1585
Phenolphthalein, action of Br on—further evidence of the tautomeric character of. 646
Phenols, synthesis of some iodated diphenyl-sulfide, 1146, rate of coupling of diazonium salts with, in buffer solns, 1220: elec. moments of certain substituted, and their relation to the stereochemistry of the O atom, 1356; phenolic decompn. of certain mixed ethers, 1944; indirect method of studying the oxidation–reduction potentials of unstable systems, including those from 5204
a-Phenylacetoacetic acid, keto-enol equil of Et ester of 4358
Phenylated compounds, reaction between highly, and org Mg compds. 4128
Phenylation, of oleic acid 1172
Phenylbiphenylenemethyl, action of Mg + $MgBr_2$ on 3287
Phenylbiphenylenemethylmagnesium bromide 3287
Phenylbutadiene, addn. of HClO and HBrO to 1574
α-Phenylbutyronitrile, Na deriv. 2524
Phenyl compounds, stereoisomerism of di-, 1200, 2054, 2070, 5263; possible isomerism of certain analogs of resolvable di- 2959
Phenylenediamines, Skraup's reaction applied to the 397
Phenyl ether, derivs. of, 1205, 3353; formation of a phenazine compd. from a, deriv 3199
Phenylethylbarbituric acids, substituted 224
Phenylhydrouracil, detn. of the constitution of alkylation products of 4993
Phenylmagnesium halides. See *Magnesium compounds.*
p-Phenylphenacyl bromide, as reagent for identifying org. acids. 3715
1-Phenyl-4-piperidones, catalytic reduction of 1030
Phenylpiperidylcarbinols 4006
Phenylpropanolamine, homologs and analogs of 3317
Phenylpyridine compounds, stereochemistry of 4528
N-Phenylpyrrolidine, synthesis of. 804
Phenyl sulfide, synthesis of some iodated hydroxy derivatives of, 1146, (correction), 5307; derivs of di- 3353
3-Phenyl-2,4-thiazolidione, condensation with aromatic aldehydes 2981
Phenyluracil, detn. of the constitution of alkylation products of 4993
Phenylurethans, 2115; anesthetics 2583
Phlegmatic liquids, vacuum fractionation of. 4714
Phosgene, photochem. formation of, 500; test for, 1604; synthesis of, by light and a-radiation, 1853; kinematics of 3132
Phosphates, potentiometric titration of, with $AgNO_3$, 583; quant. pptn. of CaC_2O_4 in the presence of, 1469; quant. study of the influence of, on the activity of malt amylase 1669
Phosphatides, mannose in the, from human tubercle bacilli, 1252 inosite in the, from human tubercle bacilli, 1607; polysaccharide occurring in the, from the human tubercle bacilli 5023
Phosphine, action on HCHO 2995
Phosphoric acid, catalytic "coupling" of MnO_2 with H_2SO_4 or, as an oxidizing agent, 640; mixts. as inorg lubricant 2813
Phosphorus compounds, derivs. of diphenyl 2933
Photochemistry. (See also *Light; α-Rays; Rays, Röntgen.*) Photochem. formation of phosgene, 500; electronic and photochem. decompns. of $KClO_3$,

527; quantum efficiency of O_3 formation in the fluorite region, 559; **photochem.** H-O reaction, 1868; photochem. O-CO reaction, 3471; photochem. formation of ClO_2 from Cl_2O in CCl_4 soln.. 4288; photochem. **polymerization** of C_2H_2, 4613; **photochem.** oxidation of lactic acid...................... 5272
Photosensitization, by NH_3.. 2150

Polarity, of the C-halogen bond, 93; and the orienting influences of substitutes in the benzene ring.. 206
Polarization, dielectric, of liquids—AcOH and butyric acid, 1824; of liquids, 2227; of liquids—of normal paraffins................................ 3546
Pollen, chem. studies on, and, exts.—distribution of N extd. by various solvents.. 3591
Polymerization, of cyanamide in alk. solns., 195; ring formation and, 314, 711, 3292, 4110, 5279, 5289, (corrections) 5307; non-catalytic hydrogenation and, of C_2H_4, 1158; reactions under high pressure, 1659; assocn., and the properties of adipic anhydride, 3470; of asymmetrical diphenylethylene, 4021; photochem., of C_2H_2, 4613; kinetics of the, of vinyl acetate.......... 4708
Polymethylbenzenes, 1998, 4144, (corrections)............................. 5309
Polypeptide-hydantoin, synthesis of the, *N*-3-methyl-5-tyrosylhydantoin-1-phenylacetic acid...2494, 2505
Polysaccharides, reactions relating to, 3257, 3448, (corrections) 5309; reactions relating to—hydrolysis of some, 3995; occurring in the phosphatide from human tubercle bacilli.. 5023
Potassium, sensitivity and applicability of the picric acid test for, 953; use of dispersoids in the detection of traces of, by Zr sulfate, 2666; at. wt. of, from plant ash.. 4332
Potassium bicarbonate, double salt formation among the carbonates and bicarbonates of Na and K.. 3813
Potassium carbonate, double salt formation among the carbonates and bicarbonates of Na and K.. 3813
Potassium chlorate, electronic and photochem. decompns. of.................. 527
Potassium chloride, application of moving boundaries to a study of aq. mixts. of HCI and, 1897; activity coeff. at infinite diln. in water-MeOH mixts., 2353; heats of diln. of, in sucrose and urea solns. as solvents below 0.1 M at 25°.. 4218
Potassium hydroxide, action on maltose, 294; action on *l*-arabinose and d-xylose, 3680; action on Ca **hexosediphosphate-comparison** with that of glucose and fructose.. 4065
Potassium iodide, reaction rates of, with 1,2- and 2,3-dibromobutane............ 1953
Potassium methide, thermal decompn. of.................................. 1254
Potassium oxalate, x-ray photochem. reaction between $HgCl_2$ and.............. 2612

Potassium perchlorate, heat capacity and entropy of, from 12 to 298° abs.—heat of soln. of.......... 649
Potassium permanganate, titration of H_3AsO_3 with.......... 901
Potassium sesquicarbonate, bydrated.......... **3817**
Potato, sepn. and properties of the 2 main components of, starch.......... **2907**
Potential, electric, oxidation, of the PbO_2 electrode in $HClO_4$ soln., **1**; of Pb-Pb ion, 589; electromotive behavior of single Zn crystals—equil., **1000**; measurements of the e. m f. of the calomel electrod eagainst the H electrode at low concns. of HCl, 2179, adsorption, **2256**; e. m. f. measurements with $CaCl_2$ solns., **2265**; e. m. f. measurements on cells contg. $ZnCl_2$, **2272**; electrode potential of In against $InCl_3$ solns., **2372**; oxidation–reduction, **2624**; oxidation–reduction, at C and W electrodes, **2773**; relation between ionizing, and ionic, **3076**; influence of the solvent on the, of Ag-Ag halide cells, **3477**; ionization const. of water at 25° from the, of cells without liquid junction, **3877**; Oxidation--Reduction Potentials (Michaelis, book review), **4615**; of some unstable oxidation–reductionsystems, **4915**; indirect method of studying the oxidation–reduction, of unstable systems.......... 5204
Poulsen arc, use of the, as a mrans of detecting traces of impurities in metals,.......... **4169**
Pressure, sp. heats of gases at high, **108, 5111**; consts. of the Beattie–Bridgeman equation of state with Bartlett's P–V–I' data on N, **1382**; polymerization reactions under high, **1659**; nature of the sorption by charcoal of gases and vapors under great, **2198**; low, measurements with the abs. manometer, **3159**; exptl. study of an incongruent mrlting at, up to **12,000** atms., **4252**; manometer for the measurement of small pressure differentials at high.......... **5102**
Promoter action, in reactions of oxidation concomitant with the catalytic decompn. of H_2O_2.......... **3035**
Propane, kinetics of the thermal dissocn. of.......... **1262**
Propin, phys. consts. of.......... **1978**
Propionic anhydride, catalysis in the hydration of.......... **1410**
Propylene, pyrolysis of.......... **4978**
Protoactinium, origin of.......... **163**
Prussian blue, prepn. of negative colloidal Fe_2O_3 by hydrolysis of.......... **1337**
Pseudocumene, prepn. and phys. properties of pure.......... **4144**
Pyrethrins, relation between maturity and content of, of pyrethrum flowers, **680**; content of, of different com. varieties of pyrethrum flowers. **684**; relative toxicities of, I and II.......... **3300**
Pyrethrum, flowers—relation between maturity and pyrethrin content, **680**; flowers—pyrethrin content of different com. varieties, 684; flowers.......... **3300**
Pyridine, isolation of an As compd. of, and some observations concerning the phase system $AsCl_3$–, 1720; prepn. of 2-alkyl and 2-aryl pyridines by the Grignard reaction, 2845; dissocn. pressures of certain metal, thiocyanates.......... **4069**
Pyrimidines, 1152, **1580, 4489, 4511, 4993**; action of diazomethane on the, constituents of nucleic acids, **1536**; alkylation on N of the pyrimidine cycle.......... **2001**
Pyrolysis, of allyl aryl sulfides, **3356**; of allene and methylacetylene, **4540**; of allylanilines, **4586**; of propylene.......... **4978**
y-Pyrones, absorption spectra of.......... **4895**
Pyrophoric iron, prepn. and properties, **142**; properties of,—adsorption of CO_2 and NH_3 and the use of, in the NH_3 synthesis.......... **150**
Pyroxonium salts, absorption spectra of.......... **4895**
Pyrrole, influence on the color test for reactive organometallic compds... 4949
Pyrrole series, local anesthetics in the.......... **235**
Pyrrolidine, formation of, derivs from diethyl α,α-dibromoadipate and certain secondary amines.......... **2985**
Pyrrylmagnesium halides, constitution of.......... **4949**

QUANTUM (Ruark, Urey, book review), **2588**; yield in the photochem. decompn. of HN_3, **124**; efficiency of O_3 formation in the fluorite region. **559**; effects of substitutents on, efficiency in the quinonealc. reaction.......... 3556
Quantum theory, L'Ancienne et la Nouvelle (Bloch, book review).......... **3742**
Quercetin, reduction of.......... **2864**
Quinazolines.......... **3696**
Quinhydrone, detg. ionization consts. with a, reference electrode, **23**; constitution of, **3204**; applicability of the, electrode to unsatd. acids.......... 3233
Quinol, reactions of, arid a contribution to the constitution of quinhydrone.......... 3204

Quinoline, formation of, derivs. from certain indigoids, 769; syntheses, 2422; prepn. of 2-alkyl and 2-aryl quinolines by the Grignard reaction, 2845; modification of the Skraup synthesis of, 3685; local anesthetics derived from. . 4013

Quinone, chemistry of the acyl derivs. of, 837; effects of substituents on quantum efficiency in the, alc. reaction. 3556

Quinonedithioglycolic acids, two isomeric. 2451

RADIATION, resonance, of Hg, 2418; quenching of Hg resonance. 3825

Radicals, electron affinity of free, 1498; surface reactions of atoms and. 1910

Raman effect, for dioxane. 4612

Rare earth oxides, study of vapor phase oxidation of org. compounds by use of, as catalysts. 3535

Rare earths. 2782, 4264

Rare earth salts, absorption spectrum, mol. vol. and refraction of certain. 4308

Rays, mol., expts. 3864

a-Rays, temp. coeff. of the synthesis of HCl by, 593; The Chem. Effects of (Lind, book review), 1294; synthesis of phosgene by, 1853; chain reactions produced by, 2743; condensation of hydrocarbons by. 4450

Rays, Rontgen, chem, effects of, and the energy relations involved, 465; Röntgenographie der Metalle und ihrer Legierungen (Neuburger, book review), 1730; photochem. reaction between $K_2C_2O_4$ and $HgCl_2$, 2612; x-ray study of the constitution of some Cu-Ni-Al-Mn alloys, 3833; investigations on rubber. 4612

Reactions, temp. coeff. of, in soln., 95; surface, of atoms and radicals, 1910; chain, produced by light and by a-radiation, 2743; in liquid H_2S, 3045; rapid, 3098; chain, 3132; role of the liquid stationary film in batch absorptions of gases involving irreversible chem., 3769; bimol. 3973

Reaction velocity, in a changing environment, 52; of hexaphenylethane with O, 255; of certain alcs. with *p*-nitrobenzoyl chloride in anhyd. ether soln., 268; measurement of the relative lability of bonds by means of, 753; of the thermal reaction $CH_2I-CH_2I = CH_2{=\!=}CH_2 + I_2$ in CCl_4 solns., 956; of KI with 1,2- and 2,3-dibromobutane, 1953; in the neutralization of $Na_2Cr_2O_7$ by NaOH, 3098; chain reaction theory of the rate of explosion in detonating gas mixts., 3120; kinetics of the reaction between persulfate and thiosulfate ions in dil. aq. soln., 4779; of the C_2H_2–O reaction. 4837

Reactivity, of atoms and groups in org. compds. 753, 5066

Rearrangement, of an organo-alkali compd 1042

Reduction, relative rates of, of aromatic nitro compds., 88; catalytic, of O-alkyl substituted oximes, 669; of mononitropyrocatechols, 834; catalytic, of 1-phenyl- and 1-benzyl-4-piperidones, 1030; of benzophenone to benzopinacol by means of Mg amalgam, 1128; in the chlorophyll series, 1233; autocatalytic, of bromate by H_2O in acid soln., 1427; effect of org bases upon the extent and mechanism of the reducing action of Na methylate on nitrobenzene and azoxybenzene, 1531; of metal oxides by H, 2314; of nicotine and some derivs. of hexa- and octahydronicotines. 2543; oxidation-, potentials, 2624, (Michaelis, book review), 4615; oxidation-, potentials at C and W electrodes, 2773; of quercetin, 2864; prepn. of normal valerolactone by the catalytic, of levulinic acid with H in the presence of Pt oxide, 3010; catalytic, of nicotine and metanicotine, 3385; study of the products obtained by the reducing action of metals upon salts in liquid NH_3 soln., 3573; reactions with CaH_2, 3655; properties of diphenylamine and diphenylbenzidine as oxidation–, indicators, 4179; of *p*-dimethylaminobenzil, 4495; of cystine in liquid NH_3 by metallic Na, 4500; of isoxazoline oxides, 4520; reducing action of the mercapto grouping, 4573; of 1-cystine to 1-cysteine, 4610; potentials of some unstable oxidation–. systems, 4915; reducing action of compds. contg. the group $>$CHOMgI, 4973; indirect method of studying the oxidation–, potentials of unstable systems. 5204

Refraction, of Nd perchlorate, 3112; of the normal paraffins, 3546; of certain rare earth salts. 4308

Refractive indices, of glycerides of known constitution, 365; of H_2O_2 and its aq. solns. 489

Refractories, Na_2O_2–C fusion for the decompn. of. 574

Resonance, radiation of Hg, 2418; quenching of Hg, radiation. 3825

Resorcinol, behavior of allyl derivs. of, toward heat. 1700

Resorcinols. halogen derivs. of acyl and alkyl. 4866

β-Resorcylic acid. mercuration of. 4369

Retene. some new monosubstitution derivs. of 5009

Rhamnonic acid. 2 cryst. lactones of l-, 1270; 1,4- and 1.5- lactone—crystallographical arid optical properties.. 1276

Rickets. antirachitic activation of some derivs. of ergosterol and cholesterol, 2512; antirachitic properties of shrimp oil.. 4940

Ring closures. in the cyclobutane series.. 4074

Ring enlargement. with diazomethane in the hydroaromatic series............ 3456

Ring formation. polymerization and. 314, 711, 3292, 4110, 5279, 5289, (correction). 5307

Rotatory power. See Optical *rotation*.

Rotenic acid. identity of isotubaic acid and.................................. 2480

Rotenol, cleavage of.. 4595

Rotenone. 1088. 1091, 2480. 2878. 3207. 3603. 4595; constitution of. 1102; soly. and optical rotation in certain org. solvents. 2554; alkali fusion of some derivs. of. 4505; toxicity to goldfish.. 5051

Rubber. natural and synthetic. 2075. 2077; detn. of S in. 3655; x-ray investigations on.. 4612

Rugheimer synthesis.. 310

SAGITTOL.. 3446

Salicylic acid. attempted use of activated silica gel in the esterification of. and 8-naphthol.. 3023

Salts. (See also *Neutral salt* action.) Solns. of. in pure AcOH, 507. 519; temp.-conductance curves of solid. 1340; systems water. tertiary butanol and. at 30. 2282; soly. of $Pb(IO_3)_2$ in 0.1 *N*, solns., 2791; study of the products obtained by the reducing action of metals upon, in liquid NH_3 soln., 3573: effect of added, upon the soly. of other. in EtOH, 3962; thermodynamic properties of weak acids and bases in solns. of.. 5079

Samarium. new line in the absorption spectrum of 1937

Samarium sulfate. magnetic susceptibility of $Sm_2(SO_4)_3{\cdot}8H_2O$ and its variation with the temp.. 2702

Saponification. velocity of. of Et formate by NH_4OH in the presence of NH_4 salts. 2604

Science, Conférences d'Actualités Scientifiques et Industrielles. 1929 (Lemoine. book review). 2587; Stuff—The story of Materials in the Serivce of Man (Beery. book review).. 3029

Sedimentation. effect of ions on. of colloidal particles by means of the centrifuge. 1009

Selenium (Mellor. book review) 4176

Selenium chlorides. properties of Se Cl_4, 3483; vapor pressures of $SeCl_4$—existence of $SeCl_2$.. 4680

Selenium compounds. org.. 1588

Selenium oxychloride. action upon ketones.................................. 1588

Semicarbazide. prepn. of.. 1250

Sesquiterpene alcohol. sagittol.. 3446

Shrimp oil. antirachitic properties of.. 4940

Silica. thermochemistry of the compds. occurring in the system $CaO–Al_2O_3–$, SO. 910. 3927; cristobalite liquidus in the alkali oxide-. systems. 1436; adsorption of complex NH_4 ions by. gel. 2584; attempted use of activated. gel in the esterification of salicylic acid and β-naphthol, 3023; density of water adsorbed on. gel.. 4635

Silicon. high-temp. equil. between Si nitride. N and. 48; reaction of HBr with. 1464: heat capacity of. at low temps.. 2301

Silicon nitride. high-temp. equil. between Si. N and.......................... 48

Silver, reaction between H_2S and, 885; rhodanine test of Feigl for. 2222; influence of the solvent on the e. m. f. of Ag–Ag halide cells.......................... 3477

Silver acetate. activity coeff. of.. 1390

Silver ammonia chloride. distribution of NH_3 between toluene and aq............ 192

Silver ammonia hydroxide. distribution of NH_3 between toluene and aq......... 192

Silver azido-dithiocarbonate.. 2806

Silver bromide. thermodynamic properties of molten solns. of LiBr in.......... 4650

Silver chloride. action of Na on. 3573; soly. of.......................... 3586

Silver compounds. equil. involving some complex ions of Ag and the free energy of some.. 178

Silver cyanide. distribution of HCN between benzene and aq. $HAg(CN)_2$...... 192

Silver halides, influence of the solvent on the e. m. f. of Ag–, cells 3477

Silver iodide, action of Na on 3573

Silver ions, equil. involving some complex, 178; catalysis of persulfate oxidations. 1493

Silver nitrate, potentiometric titrations of phosphates, arsenates and arsenites with, 583; addn. compds. with benzyl sulfide 1353

Silver oxalate, catalysis of the thermal decompn. of, by Ag_2SO_4 3468

Silver sulfide, catalysis of the thermal decompn. of $Ag_2C_2O_4$ by 3468

Skraup reaction, applied to the phenylenediamines, 397; with *p*-aminoresorcin dimethyl ether, 3196; modification of the, of quinoline, 3685; with certain azocompds 3974

Soap, Films (Lawrence, book review) 4178

Sodium, action on β-chloro-α,α,α-triphenylethane in liquid NH_3, 1042; volumetric estn. of, 1349; vapor pressure and vapor density of, 2654; action on some org. halides in liquid NH_3, 2823; vapor pressure of, 3159; action on AgI and AgCl, 3573; action of metallic, on diphenyl- and ditolyltrichloroethanes, 3633; direct detn. of, in the presence of Al and Cr, 4247; reduction of cystine in liquid NH_3 by metallic, 4500; normal paraffin hydrocarbons of high mol. wt. prepd. by the action of, on decamethylene bromide 5279

Sodium alcoholates, interaction of 2,4-dichloroquinazoline with Na phenates and, with the replacement of one halogen to form halogen–0 ethers 3696

Sodium bicarbonate, double salt formation among the carbonates and bicarbonates of Na and K 3813

Sodium carbonate, double salt formation among the carbonates and bicarbonates of Na and K 3813

Sodium chloride, activity coeff. at infinite diln. in water-MeOH mixts., 2353; catalysis by, of oxidation of C, 3025: system Na_2SO_4–NaF–H_2O–, 4202, 4210: melting curve of, dihydrate 4252

Sodium dichromate, velocity and heat effects involved in the neutralization of, by NaOH 3098

Sodium fluoride, system Na_2SO_4–NaCl–H_2O– 4202, 4210

Sodium hydroxide, action on cellulose, 1013; velocity and heat effects involved in the neutralization of $Na_2Cr_2O_7$ by 3098

Sodium methide, thermal decompu. of 1254

Sodium methylate, effect of org. bases upon the extent and mechanism of the reducing action of, on nitrobenzene and azoxybenzene 1531

Sodium peroxide, –C fusion for the decompn. of refractories 574

Sodium phenoxide, reaction with a-chlorohydracrylic acid, 3364, interaction of 2,4-dichloroquinazoline with Na alcoholates and, with the replacement of one halogen to form halogen-0 ethers 3696

Sodium phenylacetonitrile 1069

Sodium sulfate, system NaF–NaCl–H_2O– 4202, 4210

Sodium trimethyl tin, action on CH_2Cl_2, 695; reaction between $CHCl_3$ and, in liquid NH_3 4426

Sodiumzincacetate 519

Soils, Der adsorbierende Bodenkomplex und die adsorbierten Bodenkationen als Grundlage der genetischen Bodenklassifikation (Gedroiz, Kuron, Ehrenberg, book review), 2158; uronic acids in 4907

Solubility, effect of added salts upon the, of other salts in EtOH 3962

Solutions, of salts in pure AcOH, 507, 519; soly. of $Pb(IO_3)_2$ in 0.1 *N* salt, 2791; viscosities of several aq., of org. substances, 3507; thermodynamic properties of weak acids and bases in salt 5079

Solvents, decompn. of N_2O_5 in inert, 1472; decompn. of N_2O_5 in chemically active, 1486; use of dioxane as a, for elec. moment studies, 1838; acetamide and formamide as, for the electrodeposition of metal , 2693; influence of the, on thee. m. f. of Ag–Ag halide cells, 3477; heats of diln. of KCl in sucrose and urea solns. as, below 0.1 *M* at 25° 4218

Sorption, nature of the, by charcoal of gases and vapors under great pressure, 2198; of org. vapors by highly evacuated, activated sugar charcoal 2668

Sound, attempt to measure the velocity of dissocn. of N_2O_4 by the method of, waves 4661

Space groups, The Analytical Expression of the Results of the Theory of (Wyckoff, book review) 3473

Specific heats, of gases at high pressures, 108, 5111; of Tl, Ca and Mg measured to 10° abs. 4686

Spectrography, "star trail" method for the spectrographic quant. detn. of the elements 5295

Spectroscopy, spectroscopic detn. of the decompn. products of org. compds, 2578; calcn. of free energy from spectroscopic data, 4808; spectroscopic study of the decompn. and synthesis of org. compds. by elec. discharge 5165

Spectrum. (See also *Raman effect*) Calcn. of the heat of activation from band, data, 1733; new line in the absorption, of Sm, 1937; absorption, of Nd perchlorate, 3112; line, of ions in the solid state in the visible and ultraviolet regions of the spectrum—absorption, of $GdBr_3 \cdot 6H_2O$, 3747; continuous (or band) fluorescence emission, which accompanies a change of color, 4170; absorption, of certain rare earth salts, 4308; emission, of some simple C_6H_6 derivs., 4755; absorption, of the y-pyrones and pyroxonium salts 4895

Spirans, with 4 aromatic radicals on the spiro C atom 2881

Stannous. See *Tin,* etc.

Starch, fatty acids assocd. with wheat, 808; -iodide reaction, 2768; sepn. and properties of the 2 main components of potato 2907

Stereochemistry, elec. moments of certain substituted phenols and their relation to the, of the O atom, 1356; of diphenyl compds., 2054, 2070; synthesis and configurations of unsatd. 1,4-diketones and ketonic acids and the stereochem. mechanism of the addn. of Br, 3423; of diphenylbenzenes, 4098; stereochem. study of diphenyl-2,2′-disulfonic acid, 4471; of phenylpyridine compds.. 4528; of diphenyl compds 5263

Stereoisomerism, of diphenyl compds 1200

Sterols, of ergot 2013, 3688

Stopcock, inorg., lubricant 635

Stuff (Beery, book review) 3029

Styrenes, diacyl 384

Substituents, polarities and the orienting influences of, in the benzene ring, 206; effects of, on quantum efficiency in the quinone-alc. reaction, 3556; effect upon the rearrangement of benzopinacol, 3596; influence of the structure of the, on the temp. of decompn. of certain derivs. of malonic acid 5066

Substitution, of one atom of N for 3 atoms of Cl in org. compds., 2951; preliminary formation of addn. compds. in, reactions of aromatic types 3349

Succinic anhydride, action of diazomethane on 1558

Sucrose, heats of diln. of KCl in, and urea solns. as solvents below 0.1 *M* at 25". 4218

Sugars, relations between rotatory power and structure in the sugar group, 1270, 1680, 1707, 2101, 2106, 2519, 2534, 4168, (correction), 5307; structure of methylated, 1627; ring structures of various compound, 1707, (correction), 5307; action of $TiCl_4$ on derivs. of, 2563, 2568, 2571; Constitution of (Haworth, book review), 4618; cupro-potassium carbonate solns. in the detn. of reducing 4960

Sulfides, quant. pptn. of, in buffered solns 5135, 5141

Sulfonation, of 2-naphthol in presence of boric acid 2835

Sulfonephthaleins, new series of halogenated 4954

Sulfones, prepn. and properties of certain 2060; aryl, of dibasic acids 2531

Sulfoxides, prepn. and properties of certain 2060

Sulfur (Mellor, book review), 4176; detn. in org. compds., 1075, 1086, 3275; micro-detn. of, by fusion, 1291; detn. in sulfur oils and rubber 3655

Sulfur hexafluoride, prepn. of, and some of its phys properties 4302

Sulfuric acid, action on thiocyanates, 581; catalytic "coupling" of MnO_2 with H_3PO_4 or, as an oxidizing agent, 640; relative rates of absorption of the gaseous olefins into, at 25°, 721; decompn. of malic acid by, 2746; decompn. of citric acid by, 4729; effect of SO_3 on the decompn. of oxalic acid by, 4737; inhibition in the decompn. of org. acids by 4742

Sulfur oils, detn. of S in 3655

Sulfur trioxide, effect on the decompn. of oxalic acid by H_2SO_4 4737

Surface, approach to the problem of specific, action, 1910; thermal H-O combination—formation of H_2O_2 and the influence of, nature 5106

Surface energy, effect of temp. on the mol., of binary mixts 14, 1448

Surface tension, detn. of, from the max, pull on a ring, 1751; theory of the ring method for the detn. of, 1772; drop wt. method for the detn. of, 2287; of *aq.* solns. of p-toluidine, 2289; of liquid N_2O, 2723; in the water–NH_3 system at 20° 5128

Sweetening power, of 5-benzyl-2-furfuraldoxime 2010

TANTALUM (Friend. Marks. book review) 1727
Tartrates. effect of several factors on the soly. of 2241
Taste. attempted correlations of constitution with sweet. in the furan series 2010
Tellurium tetrachloride. properties of 3488
Tellurous acid. detn. of 553
Temperature. effect on the mol. surface energy of binary mixts., 14. 1448; coeff. of reactions in soln., 95; coeff. of the synthesis of HCl by light and by α-radiation, 593; new regulator allowing rapid changes in the setting of the thermostat. 636; conductance curves of solid salts. 1340; consts. of the Beattie-Bridgeman equation of state with Bartlett's P–V–T data on N, 1382; heat capacities of As. As_2O_3 and As_2O_5 at low. 2296; heat capacity of Si at low. 2301; adsorption of H by Ni at low. 2325; heat capacities at low. of Sb, Sb_2O_3, Sb_2O_4 and Sb_2O_5, 2712; heat capacities of Bi and Bi_2O_3 at low. 2720; absorption spectra of $GdBr_3 \cdot 6H_2O$ at room. and at that of liquid air and their comparison with those of $GdCl_3 \cdot 6H_2O$, 3747; vapor pressure and crit., of F. 3839; high. equil. of TiO_2 and C with TiC and CO. 3956; Optical Activity and High. Measurements (Jaeger. book review). 4174; method and app. for sp. heats at high 5111
Terpenes, action of ultraviolet light on 4093
Tetraacetyl-a-cyclohexylglucoside 2568
Tetraacetyl-β-cyclohexylglucoside 2568
Tetraacetyl-a-n-hexylglucoside 2563
Tetraacetyl-β-*n*-hexylglucoside 2563
Tetraaryldiarsyls 780
Tetracyclohexyldiphenylethane 2976
Tetraethyldiaminodiphenylfurylmethane hydrochloride, prepn. of 4477
a-Tetrahydrofurfuryl chloride 3251
a-Tetrahydrofurfuryl ethers 3251
Tetramethylbenzenes. vapor pressures of. 1998. (correction) 5309
Tetramethyloctadiene 2077
Thallium. detn. of, 36; sp. heat of 4686
Thallium azido-dithiocarbonate 2806
Thallium compounds. triorgano 2998
Thallium diethyl triphenylmethyl 2998
Thalliumtriethyl 2998
Thermochemistry. of the compds. occurring in the system $CaO–Al_2O_3–SiO_2$, ...80. 910. 3927
Thermodynamics (Schottky. Ulich. Wagner. book review). 852; properties of NH_3, 6; treatment of chem. equil. in systems composed of real gases. 4239; properties of molten solns. of $PbCl_2$ in $PbBr_2$, 4641; properties of molten solns. of LiBr in AgBr, 4650; properties of solns. of molten $PbCl_2$ and $ZnCl_2$, 4655; entropy of H and the third law of. 4816; properties of weak acids and bases in salt solns. and an exact method of detg. their dissocn. consts 5079
Thermoluminescence. in glasses which contain 2 activators 5146
Thermostat. new regulator allowing rapid changes in the temp. setting of the ... 636
Thiazoles, synthesis of. contg. phenol and catechol groups. 1585; synthesis of amines of. possessing pharmacol. interest 3724, 4139, 4141
Thiocarbanilide. reaction between CH_2ClCO_2H and. in alc. and in AcOH soln ... 2137
p-Thiocresol. forced reaction between anils and 4573
Thiocyanates. action of H_2SO_4 on. 581; volumetric detn. of. with I and iodate. 2698; dissocn. pressures of certain metal pyridine 4069
β-Thioglyceric acid 1105
Thioglycolic acid. Co complexes of 4418
Thiosulfate ion. kinetics of the reaction between persulfate ion and. in dil. aq. soln 4779
Thiothyronine. synthesis of 3623
Thioureas, action of the halogen hydrins and of ethylene oxide on the 3322
dl-Threonic acid. synthesis of 3176
Thymine series. mol. rearrangements in the 4511
Thyroid gland. I in small quantities of. tissues 980
Thyroxine (Kendall, book review) 4619
Tin chlorides. free energy of stannous hydroxyl chloride and the activity coeff. of $SnCl_2$ 3967
Tin compounds. methyl Sn derivs., 695. 4426; free energy of stannous hydroxyl

chloride and the activity coeff. of $SnCl_2$ and stannous ion, 3967, alkyl- $[(CH_3)_3SnOH]_2 \cdot (CH_3)_3SnBr$ 4056
Tin ion, activity coeff. of stannous ion.... . . 3967
Tissue, animal, I in small quantities of thyroid and other 980
Titanium bromides, anhyd. lower..... 4233
Titanium carbide, high temp. equil. of TiO_2 and C with, and CO . 3956
Titanium dioxide, high temp. equil. of C and, with TiC and CO 3960
Titanium tetrachloride, action on derivs. of sugars............. 2563, 2568, 2571
Titration, consts of multivalent substances, 3518; potentiometric study of acid-base systems in the very strongly acid solvent formic acid 4795
o-Tolidine, mercurated azo dyes derived from 2628
Toluene, distribution of NH_3 between, and aq silver ammonia chloride and hydroxide, 192; detn. of the soly. of water in . . 3568
p-Toluidine, surface tension of aq. solns. of . . 2260
Tolyl-4-carbithioic acid, and certain dcrivs ... 332
Toxicarol 2461
Toxicity, study of, by use of goldfish . 3440
Toxicological chemistry (Oddo, book review) 3743
Tribromometbylphenylcarbinol, esters of 50.59
Triethyl lead chloride, prepn. of......... . . 1975
Trihalomethyl ketones, of the mesitylene series.... . 3269
Triiodide ion, relative influence of cations and anions upon the equil $2Fe(CN)_6^{---} + 3I^- \rightleftarrows 2Fe(CN)_6^{----} + I_3^-$. 876
Trimethyl germanium bromide 2779
Triphenylbromomethane, action of the system $Mg + MgBr_2$ on . 2455
Triphenylcarbinol, action of the system $Mg + MgBr_2$ on..... 2456
Triphenylisoxazoline oxide, reaction between org. Mg compds. and 2038
Triphenylmethyl, electron affinity of, 1498, action of the system $Mg + MgBr_2$ on, 2455; reaction with Mg and a small amt. of Mg halide 4412
1,1,3-Triphenyl-3-methylhydrindene, prepn. of. . . 4021
Triphenylmethyl salts, quinonoid structure of some . 4567
Triphenylselenonium hydroxide, salts of (correction) 5307
Tubaic acid, structure of 3207
Tubanol, structure of... 3207
Tubercle bacilli. See *Bacillus*
Tubes, Jamin effect in cylindrical 1345
Tungsten, oxidation-reduction potentials at C and, electrodes 2773
Turanose, prepn. of cryst 2519

UNSATURATED COMPOUNDS, oxidation of.............3167, 3176, 3185, 3188
Unsaturation, effect of, on the heat capacities, entropies and free energies of some hydrocarbons and other compds., 4381; phenomena of acetylenic acids and esters, 4405; detn. of org.. 5241
Uraninite, at. wt. of, Pb from Wilberforce, Ontario. Canada.................. 4851
Uranium lead, at. wt. of, from Swedish kolm............................... 4848
Uranyl oxalate, precision actinometry with, 3139, (correction)................ 5309
Urea, use of aryl esters for the prepn. of derivs. of, 2149; equil. in the NH_4 carbamate–water–NH_3–, system, 3088; heats of diln. of KC1 in sucrose and, solns. as solvents below 0.1 M at 25°............................... 4218
Urine, I in.. 541
Uronic acids, detn. of, 775; content of orange albedo, 1209; action of weak mineral acids on, 2474; in soils.. 4907
Urson.. 1722

VALEROLACTONE, normal,—its vapor pressure, 2028; normal............. 3010
Valves, capillary gas.. 1936
Vanadium (Friend, Marks, book review), 1727; reaction of iodate and tetravalent, in alk. solns., 480; at. wt. of.. 2638
Vanadium pentoxide, as catalyst in the decompn. of ethylene glycol........... 4558
Vanillin. Cl derivs. of, and some of their reactions.......................... 4576
Vapor pressure, of liquid NH_3, 6; of formic acid, 1874; of the tetramethylbenzenes and of penta- and hexa-methylbenzenes, 1998, (correction) 5309; of normal valerolactone, 2028; of allene as a function of temp., 2409; of Na, 2654, 3159; of F, **3839;** of Sb_2O_3, 3869; of $SeCl_4$, 4680; consts. of Mg................. 4696

Vapors. nature of the sorption by charcoal of. under great pressure............ **2198**
Vesicant action. of chloro-alkyl furfuryl sulfides............................ **2141**
Vinyl acetate. kinetics of the polymerization of............................ **4708**
Vinylacrylic acid. bromination of. **326;** chlorination of........................ **812**
Viscometers. standardization of a modified Ostwald......................... **3493**
Viscosity. Handbuch der biol. Arbeitsmethoden—Methoden der. kolloider Lösungen (Kohler. book review). **1731;** detg. the. of corrosive gases. **2619;** of several aq. solns. of org. substances. **3507;** of glycerol trinitrate and certain related glycol nitric esters. **3669;** of solns. of $LiNO_3$ in certain binary alcoholic systems.. **4762**
Vitamins. prepn. and properties of vitamin C fractions from lemon juice. **420;** formation of vitamin D by monochromatic light. **2304;** Ultraviolet Light and Vitamin D in Nutrition (Blunt. Cowan, book review)................ **2593**
Volume. consts. of the Beattie-Bridgeman equation of state with Bartlett's *P–V–T* data on N... **1382**

WATER. effect on the acid hydrolysis of halogen naphthols. **93;** dielec. consts. of. at various temps. **483;** ionic ratios in the. of the north Pacific Ocean. **915;** dissocn. const. of. from an equil. involving HgO and HgBr, **921;** adsorption by wood. **1053;** effect of temp. on the mol. surface energy of mixts. of nicotine and. **1448;** systems: tertiary butanol. salts and. at 30°, **2282;** temp. coeff. of the dielec. const. of. **2811;** reactions of NH_3 on the system $ZnCl_2$–NH_4C–, **3083;** equil. in the NH_4 carbamate–urea–NH_3–, system. **3088;** use of CaH_2 for the detn. of the soly. of. in benzene. CCl_4 and toluene. **3568;** f. ps. of the system HF–. **3843;** ionization const. of. at **25°** from the e. m. f. of cells without liquid junction. **3877;** dissocn. of. in CsCl solns., **3892;** system Na_2SO_4–NaF–NaCl–, **4202. 4210;** condenser for low temp. evapn. of. **4334;** density of. adsorbed on silica gel. **\$635;** density. surface tension and adsorption in the. –NH_3 system at **20**.................................... **5128**
Water vapor. adsorption by MnO_2, **2170;** adsorption by samples of MnO_2 and hopcalite catalysts. **2411;** effect of dissocd., on certain vegetable oils. 2454; poisoning action of. at high pressure on Fe synthetic NH_3 catalysts........ **2682**
Weights. standardization of.. **1938**
Wheat. fatty acids assocd. with. starch.................................. ***808***
Wood. adsorption of water by. **1053;** differences between the state of dispersion of isolated. cellulose and cotton cellulose in cuprammonium solvent.......... **3062**

XANTHALINE. modified synthesis of..................................... **3610**
Xenon... **4173**
Xylan. elementary compn. of.. **2091**
β-Xylochloralose.. **3191**
***m*-Xylorcinol,** oxidation of.. **358**
***d*-Xylose, action of KOH on**.. **3680**

YEAST. acidity optimum of. hexosediphosphatase......................... **4117**
Ytterbium. sepn. of. by electrolytic reduction............................ **4264**

ZINC. nephelometric analysis of. **938;** electromotive behavior of single. crystals. **1000;** iodimetric detn. of small amts. of.............................. **3093**
Zincacetate... **519**
Zinc ammonium phosphate. effect of PH on the pptn. of...................... **120**
Zinc azido-dithiocarbonate.. **2806**
Zinc chloride. decompns. of esters by anhyd., **395;** e. m. f. measurements on cells 'contg., **2272;** reactions of NH_3 on the system NH_4Cl–H_2O–, **3083;** thermodynamic properties of solns. of molten $PbCl_2$ and....................... **4655**
Zinc oxide. heat of formation of... **2159**
Zincsodiumacetate... **519**
Zirconium. **2666;** metallic pptn of.. **3741**
