INFLUENCE OF THE SOLVENT ON THE ELECTROMOTIVE FORCE OF SILVER–SILVER HALIDE CELLS

BY ALEXIS S. AFANASIEV

RECEIVED MARCH 13, 1930 PUBLISHED SEPTEMBER 5, 1930

Introduction

Many investigations in recent years have given ample justification for the extension of Nernst's osmotic theory and the ordinary laws of thermodynamics to non-aqueous solutions. On this basis A. E. Brodsky[1] has given a formula for the change in electromotive force (e. m. f.) with solvent for the cell

$$M \mid MX, M'X(c_1) \mid M'Y(c_2), MY \mid M$$

in two solvents (M, metal; MX and MY, slightly soluble salts (depolarizators) of the metal; M'X and M'Y, very soluble salts; $c_1 = c_2$, equal concentrations of the salts). Brodsky's formula

$$E - E' = \frac{RT}{nF} \ln \frac{L_1\nu_1 \times L_2'\nu_2'}{L_1'\nu_1' \times L_2\nu'_2} \tag{1}$$

in which E and E' represent the e. m. f.'s of the cell in Solvents I and II, and L and ν are the solubilities and activity coefficients of the salts M'X and M'Y in saturated solutions in Solvents I and II. In saturated solutions in the different solvents the relationships $\nu_{M'X} = \nu'_{M'X}$ and $\nu_{M'Y} = \nu'_{M'Y}$ are approximately true. This has been demonstrated for α in the classic theory by Walden and van Laar,[2] and then

$$E - E' = \frac{RT}{nF} \ln \frac{L_1 \times L_2'}{L_1' \times L_2} \tag{2}$$

This formula is a consequence of the general formula given by Brodsky,[1] and has been deduced thermodynamically through a series of two cycles relating the free energy of reaction both in solution and without solvent, the initial activities and the activities of salts in saturated solutions. The

equilibrium in solution may be calculated from thermal data by means of these cycles. Formula 2 may be applied only in dilute solutions. Professor Brodsky has demonstrated the correctness of this formula, using the cell

$$\mathrm{Hg} \mid \mathrm{Hg_2Cl_2},\ \mathrm{KCl}\ (c_1) \mid \mathrm{KBr}\ (c_2),\ \mathrm{Hg_2Br_2} \mid \mathrm{Hg}$$

and suggested to the writer the problem of applying the formula to the cell

$$\mathrm{Ag} \mid \mathrm{AgCl},\ \mathrm{KCl}\ (c_1) \mid \mathrm{KBr}\ (c_2),\ \mathrm{AgBr} \mid \mathrm{Ag}$$

in ethyl alcohol–water and methyl alcohol–water mixtures, using various concentrations of potassium chloride and bromide.

Experimental

The potentials of the Ag–AgCl and Ag–AgBr electrodes vary considerably depending on the methods of preparation, as has been shown by numerous investigators during the last thirty-five years. For example, the e. m. f. of the cell

$$\mathrm{Ag} \mid \mathrm{AgCl},\ \mathrm{KCl}\ (1\ M) \mid \mathrm{KCl}\ (1\ M),\ \mathrm{Hg_2Cl_2} \mid \mathrm{Hg}$$

in water at 25° has been measured by a number of workers since 1917, and has given values of E varying from +0.0422 to +0.0467.[3] Further data have been presented by Bronsted[4] and by Abegg and Cox.[5] The theoretical value given by Lewis and Randall[6] is $E = 0.0466$ v. These differences may be ascribed to the lack of a uniform method of electrode preparation. The variable manipulatory and thermal conditions under which silver and its halides are prepared have a marked effect on the characteristics of the surfaces of the products and, as a result, the silver has different solution tensions ("elektrolytische Lösungstension" of Nernst) and the halides differ in solubility. These points have been discussed in detail by Lewis, Randall, and others.[7]

In the early part of this work, electrolytically coated silver–silver halide electrodes were used, prepared according to the directions of Goodwin, Jahn and Halla.[8] A pure white silver layer was prepared by electrolysis on a carefully cleaned platinum wire. The electrolysis lasted for five to six days and

was carried out in a $KAg(CN)_2$ solution containing an excess of KCN, using a current density of **0.9** milliampere per sq. cm., with 15-20 electrodes in each set. The electrolyte was prepared as directed by Ullmann.[9] The electrodes were not protected from diffused daylight. After completion of the electrolysis, they were soaked in distilled water for one or two days, then immersed in a dilute silver nitrate solution and short-circuited to eliminate occasional differences in potential. The electrodes were then coated with a layer of silver halide by electrolysis **as** anodes in **0.75** M hydrochloric or hydrobromic acid, with a current density of **0.2** milliampere per sq. cm. The electrolysis was carried out in complete darkness and lasted for five to six hours. After completion the electrodes were placed in dilute potassium chloride or bromide solution, short-circuited and kept in the dark.

Despite the careful preparation, these electrodes were reproducible only to within 0.1–0.2 mv., whereas other investigators have prepared electrodes of this type reproducible to within 0.01–0.5 mv.[10] It seems that the reproducibility of electrodes of this type depends upon many factors which are either accidental or imperceptible. Carmody[10] has noted the influence of the absorption of cyanide ion and of exposure to daylight, both of which may be possible explanatory factors. Since the reproducibility of this type of electrode was unsatisfactory, they were used only in the early part of the work (water and ethyl alcohol–water solutions).

Subsequent work was carried out with electrodes of the type recommended by Noyes and Ellis[3] and by Lewis.[7] This type differs from that of Goodwin and Jahn in that the electrolytic layer is replaced by a silver sponge produced by thermal decomposition of silver oxide on the silvered platinum. The method of halogenizing was the same as before. The electrodes as prepared differed by about **0.01** mv. both in water and alcohol solution. Other workers[11] have obtained a reproducibility of **0.00–0.25** mv.

Other workers with this type of electrode have been Harned and Fleysher, THIS JOURNAL, 47, 82 (1925); Harned and Douglas. *ibid.*, 48, 3095 (1926); Harned and Brumbaugh, *ibid.*, 44, 2729 (1922); Harned and Robinson, *ibid.*, 50, 3157 (1928); Lucasse, *ibid.*, 47, 743 (1925); *ibid.*, 51, 2598, 2605 (1929); Randall and Young, Ref. **3.**

with this type of electrode. The writer also replaced the electrolytically silvered platinum spiral with unsilvered spirals of pure silver, but the potential was not changed.[12]

The type of electrode recommended by Noyes and Ellis is definitely to be preferred. The third type, similar to the Hg–Hg_2Cl_2 electrode is of no particular interest. The electrodes were protected from actinic light during and after halogenizing, and the measurements were carried out by the light of a dark yellow incandescent lamp. Each type of electrode was used exclusively in half of the work, the Goodwin–Jahn type in the first half and the Noyes–Ellis type in the last half; this necessitated great care in washing the electrodes whenever the solutions were changed. The apparatus was as usual: wire bridge, Weston normal cell, galvanometer (sensitive to 10^{-9} ampere). The apparatus was not thermostated, since the temperature variation was not over 0.1–0.2° during a series of measurements, corresponding to a difference in measured e. m. f. of less than the experimental error (about 0.03 mv.). The precision of the e. m. f. measurements was about 0.1–0.2 mv. All materials and reagents were chemically pure and many times crystallized (the potassium chloride, for example, was 99.85% pure). The solvents were prepared from Kahlbaum's "Methanol zur Analyse" and from C. P. ethyl alcohol. The electrodes were prepared in the same way both in water and alcohol, and the compositions are given in "gewicht prozent."

Results

The e. m. f. values given are the average of three measurements on three different pairs of electrodes, the separate values differing from one another by not more than 0.1–0.3 mv. The temperature coefficients were measured approximately at 15–30°.

TABLE I

TEMPERATURE COEFFICIENT DATA

		Ethyl alcohol		Methyl alcohol	
Solvent	Water	24.67%	50 60%	26.32%	45.03%
dE/dT, v.	−0.00018	−0 00017	−0.00012	−0.00017	−0.00014

No correction was made for diffusion potential since the mobilities of Cl^- and Br^- are practically the same in equal concentrations of potassium chloride or bromide, and they are unknown for water–alcohol mixtures. No activity correction is necessary, since the activities of Cl^- and Br^- are almost identical in equal concentrations of the potassium salts.[13]

One point which should be noted is the systematic decrease of e. m. f. as the concentration is diminished, notwithstanding that c_{KCl} remains equal to c_{KBr}. This same effect was observed by A. E. Brodsky[14] on the cell

---

[12] See also Randall and Young, Ref. **3**.

[13] Harned, THIS JOURNAL, 51, 416 (1929).

[14] Brodsky, *Z. Elektrochem.*, 32, 5 (1926), and Ref. 1.

$$\mathrm{Hg} \mid \mathrm{Hg_2Cl_2},\ \mathrm{KCl}\ (c_1) \mid \mathrm{KBr}\ (c_2),\ \mathrm{Hg_2Br_2} \mid \mathrm{Hg}$$

The writer has made the same observation on the same cell at concentrations of **0.1** to **0.0001 M.** The value found for the e. m. f. may be compared with Goodwin's results. Goodwin measured the e. m. f. of the cell

$$\mathrm{Ag} \mid \mathrm{AgCl},\ \mathrm{KCl}\ (c_1) \mid \mathrm{KBr}\ (c_2),\ \mathrm{AgBr} \mid \mathrm{Ag}\ (c_1 = c_2)$$

and found in water an e. m. f. of **0.148** mv. at 25° (c = **0.1 M), 0.149** v. (c = 0.05 M). Must be **0.150** v. at 15° (c = **0.1 M), 0.151** v. (c = **0.05** *M*). The writer's measurements at 15° give an e. m. f. of **0.1533** v. at $c = 0.1\ M$ and **0.1528** v. (interpolated) at c = **0.05 M.** The discrepancy is explainable on the basis of insufficient precision in Goodwin's measurements made in 1894, since his individual observations at the same concentration and temperature differed by 4–6 mv. The observed increase of e. m. f. with diminishing concentration is easily accounted for on this basis.

The average deviation between $E'_{\text{meas.}}$ and $E'_{\text{calcd.}}$ is about 1.8%. These differences may be due to the somewhat uncertain values for the solubilities in the concentrated alcohols (the absolute values are not very large) The observed data demonstrate the validity of Formula 2 and its premises. A comparison of these results with recent data obtained in this Laboratory[16] indicates the correctness of the premises and shows that Nernst's osmotic

---

[16] Brodsky arid Trachtenberp, *Z. physik.* Chem , **143A, 287 (1929);** Brodsky **and** Boruhowich, J. *chim. phys* , *26,* 542 **(1929).**

theory is applicable to the usual electrodes as well as to oxidation–reduction electrodes.

The writer wishes to express his thanks to Professor A. E. Brodsky both for suggesting the problem and for help in carrying it out. Part of the material presented appeared in *Z. Elektrochem.*, **39,** 220 (1929). Slight corrections are necessary to part of the published data; the corrections have been applied in this report.

Summary

1. The methods of preparation of silver–silver chloride and silver–silver bromide electrodes have been studied, and it has been found that the procedure recommended by Noyes and Ellis is to be preferred.

2. Measurements have been made of the e.m.f. of the cell Ag | AgCl, KCl (c_1) | KBr (c_2) ($c_1 = c_2$), AgBr | Ag in water and in ethyl and methyl alcohol–water mixtures of various concentrations.

3. The results obtained justify the application of Nernst's osmotic theory to non-aqueous solutions, as has been carried out by Professor A. E. Brodsky.

THE PROPERTIES OF SELENIUM TETRACHLORIDE[1]

BY J. H. SIMONS

RECEIVED MARCH 31, 1930 PUBLISHED SEPTEMBER 5, 1930

The tetrahalogen compounds of the electronegative elements in group number six of the periodic table are of considerable interest from the point of view of molecular structure. On the Lewis theory the central atom should be represented with a shell of ten electrons, four pair of which are shared with the halogen atoms and one pair which is not shared. Henley and Sugden[2] propose a shell of eight electrons with two of the halogen atoms held by single electron bonds.

Of these compounds the following are known: SCl_4, SF_4, $SeBr_4$, $SeCl_4$, SeF_4, TeI_4, $TeBr_4$ and $TeCl_4$. The formulas of most of these have, however, been assigned from only an analysis of the crystalline compound. The molecular weights and therefore the number of atoms in the molecule have not been determined. In fact, a number of these compounds are very unstable crystalline substances, the crystal structures of which are not known. The stability of these compounds increases in the expected man-

---

[1] Part of this work was done while the author was a National Research Fellow at Cambridge University.

[2] Henley and Sugden, *J. Chem. Soc.*, **1058** (1929).

ner as one proceeds from the iodide to the fluoride and also as one changes the central atom from sulfur to tellurium. SI_4, SBr_4 and SeI_4 are not known, undoubtedly because they are too unstable to exist under any ordinary laboratory conditions. SCl_4, $SeBr_4$ and TeI_4 are known only as very unstable solids which decompose upon heating. $SeCl_4$ and $TeBr_4$ are crystalline solids which can be sublimed. SF_4, SeF_4 and $TeCl_4$ form liquids under ordinary pressures. TeF_4 would be expected to be a stable compound but it has not yet been isolated.

Before these compounds can be used in a discussion of molecular structure, it is necessary that more information be obtained about them. In this paper a report of a study of selenium tetrachloride will be given.

Several attempts have been made to determine the molecular weight of selenium tetrachloride. Clausnitzer[3] reports that the vapor density by the Dumas method is one-half the normal value for $SeCl_4$ but does not record the temperature of the determination. Evans and Ramsay,[4] however, found the vapor density normal below 200° and the material half decomposed at 288°. Chambrie[5] finds the vapor density at 360° to be one-half normal. Beckmann[6] determined the freezing point lowering of selenium tetrachloride in acetic acid at 16.5' and obtained molecular weights varying from 142 to 152 depending on the concentration. He made very modest claims for these determinations, for he accounted for the results by a reaction with the solvent, a dissociation of the selenium tetrachloride, or a reaction with water in the solvent.

Preparation of Selenium Tetrachloride.—Elementary selenium was treated with pure dry chloride in a pyrex glass apparatus, which consisted of several tubes sealed into one another. The selenium was placed in the first tube, the air in the apparatus was flushed out with chlorine, and then the tube containing the selenium was placed in a small electric furnace. By proper control of the temperature the tetrachloride could be sublimed into the first tube out of the furnace, at the same time that a chlorine stream entered the tube in the furnace. When all of the selenium had reacted, the entire apparatus was heated to drive out any oxychloride that might be present. After this the apparatus was allowed to cool, admitting more chlorine to keep out air and then it was evacuated and sealed off. After the product had been sublimed out of the first tube, this was sealed off, and the second one placed in the furnace to sublime the product into the small tubes in which it was to be contained for storage and use. These small tubes could then be sealed off and preserved.

Vapor Density.—The apparatus used for measuring the vapor density is shown in Fig. 1. The furnace was made of a piece of copper pipe one and three-quarters inches inside diameter, ten inches long, and with a wall one-half inch thick. It was covered with asbestos paper, uniformly wound with nichrome wire, covered with alundum cement, packed with magnesia into a metal can and cemented at the openings with fire clay. Copper disks one-half inch thick served as base and cover. The lower one con-

tained an opening for the thermocouple and the upper one an opening for the capillary. Two loops of heavy copper wire formed handles for the cover A copper tube one-quarter inch inside diameter, one inch outside and about six inches long was connected to nichrome wires which could be used to lift, carry or support it. This tube fitted over the capillary of the glass bulb and was kept at a higher temperature than the furnace by means of a gas flame.

The pyrex glass bulb had a volume of about 135 cc. The depression in the bottom kept the material in the bulb to the outside and so near the source of heat.

The thermocouple was of copper–constantan. The wires were slipped into a capillary tube of hard glass which was then heated and bent. To prevent oxidation of the wires the tube was filled with dry carbon dioxide and the ends were sealed with cement.

To check the uniformity of the temperature in the furnace as well as assist in the calibration of the thermocouple, a glass bulb similar in shape and size to those used in the determinations was sealed to a capillary tube which connected to a two-atmosphere open-tube manometer. The bulb was filled with dry nitrogen and used as a constant volume gas thermometer. **A** comparison of the calibration of the thermocouple by this means with its calibration by use of fixed points showed no deviation within the precision of the measurements. This showed that the temperature within the furnace was uniform. The fixed points used were the boiling points of water and sulfur and the freezing points of tin and lead. The thermocouple was read by a potentiometer so arranged that one scale division on the instrument corresponded to less than one-tenth of a degree centigrade.

A small sample tube of selenium tetrachloride with the tip opened was placed in the bulb before the capillary was drawn, the bulb at that time being filled with dry nitrogen. After the capillary was drawn, the bulb was evacuated and sealed. The excess material was allowed to escape through the capillary by opening it when the temperature of the furnace was held constant at slightly above the subliming temperature. The capillary was sealed and the bulb removed from the furnace and weighed. Repeated determinations could be made by opening the tip of the capillary with a small flame when the temperature of the furnace was ten or more degrees above the temperature of the previous determination, and the tube again sealed by removing a small piece of the capillary. The barometric pressure and the temperature of the balance case were recorded for each determination. The volume of the bulb and the weight of the glass of bulb, tips, etc., were found at the end of the series of determinations. The results are given in Table I. The calculations were made using the perfect gas law.

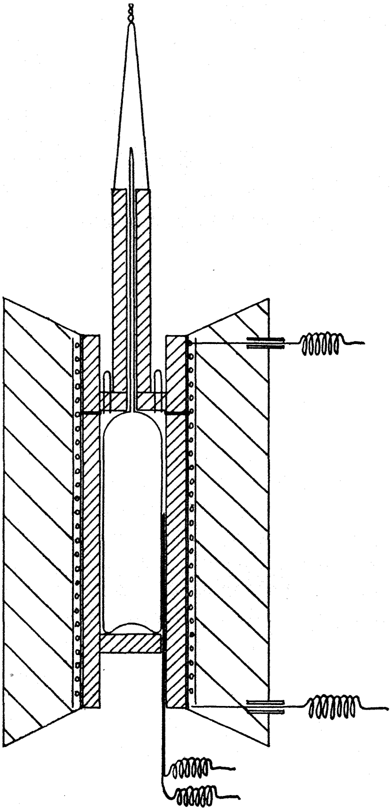

Fig. 1.—Vapor density apparatus.

The color of the bulb filled with gas just as it was taken out of the furnace varied as the temperature was raised. At the lower temperatures in the vicinity or less than 250" the gas was light yellow. As the temperature was raised, it became darker and darker until it was about the density of color of bromine vapor at atmospheric pressure. This was despite the fact that the density of the gas was decreasing as the temperature was raised. Above about 500° the shade of color seemed to remain constant.

[a] Not averaged.

Melting and Subliming Points.—Voigt and Biltz[7] report the only attempt at determining a melting point of selenium tetrachloride. They state that between 400 and 500° the material melted in a sealed tube but a gas was evolved and the tube exploded. A thick-walled six-millimeter tube containing selenium tetrachloride was carefully sealed and placed in a furnace which had an opening so that the tube could be watched with a telescope. The temperature of the furnace was raised until the crystalline material seemed to melt; then the temperature was lowered until it crystallized again. This alternate melting and freezing was repeated a number of times. The average temperature of these determinations was 305 * 3'. The liquid formed is very dark red (almost black) and this makes it difficult to observe the formation of the crystals.

To determine the temperature at which the vapor pressure of the material is one atmosphere (the subliming point), the bulb as set up for the vapor density experiments was used. Before all the solid was allowed to escape, the capillary was sealed; then, by a careful control of the temperature of the furnace, the end of the capillary was tested with a flame to see when the glass blew out a little and when it sank in. A mean of these temperatures was taken for the value. It is 196 ± 1°.

Solubility Relations.—In order to study the solubility of selenium tetrachloride in a non-polar solvent, a small amount of the solid was placed in a tube of dry carbon tetrachloride, the tube sealed, placed in a water-bath and heated to about 100°. There was no indication of any solubility. Methyl cyanide was considered for use as a polar solvent; it, however, reacted with the crystals.

Discussion

The insolubility of this compound in non-polar solvents and apparent solubility in polar solvents[6] seems to indicate that it is polar in nature. However, due to its high melting point its solubility in non-polar solvents

---

[7] Voigt and Biltz, Z. *anorg. allgem. Chem.*, 133,277 (1924).

would be small even if it were non-polar, but in that case it should be more inert to polar solvents.

The vapor density is about one-half that which the formula $SeCl_4$ would indicate. As this value remained constant for the entire temperature range of the experiments, it shows that the vapor is completely dissociated under these conditions. This confirms the results of Clausnitzer and of Chambrie but is not in agreement with those of Evans and Ramsay. This would seem to indicate a dissociation of this kind

$$SeCl_4 = SeCl_2 + Cl_2$$

However, $SeCl_2$ is not recorded in the literature. The same result for vapor density would be obtained from the reaction

$$2SeCl_4 = Se_2Cl_2 + 3Cl_2$$

as suggested by the earlier workers. There seems to be a change in the substance as heat is applied, as seen by the change in color. This is, of course, no proof but it may be an indication, for SCl_2 and $TeCl_2$ are both known, the former being red in color and the latter so dark red that it is almost black. Also SCl_2 is much deeper in color than S_2Cl_2 and so we expect $SeCl_2$ to be deeper in color than Se_2Cl_2. The author would like to suggest that the decomposition takes place to form Se_2Cl_2 at the lower temperatures (250°) and $SeCl_2$ at higher ones (500°).

As these experiments show the vapor of the material to be completely dissociated in the gas phase over the range of temperature from 200 to 600°, the mechanism of subliming must be the formation of a lower chloride and chlorine and a recombination to form the crystalline material upon cooling. The depth of color of the liquid formed by melting the crystals, as well as the very high pressure necessary, indicates a dissociation in the liquid state probably to $SeCl_2$. This may cast some doubt as to whether the molecular species $SeCl_4$ as such exists at all, for without x-ray crystal studies we do not know the molecular form in the crystal state.

Summary

A method of preparing pure selenium tetrachloride is described.

The vapor density of selenium tetrachloride has been determined from 200 to 600° at one atmosphere pressure. The vapor is completely dissociated under these conditions.

The apparent melting and subliming points of selenium tetrachloride are determined.

The solubility relations of selenium tetrachloride indicate the material to be polar in nature.

The existence of $SeCl_2$ is indicated in these experiments.

THE PROPERTIES OF TELLURIUM TETRACHLORIDE[1]

BY J. H. SIMONS

RECEIVED APRIL 14, 1930 PUBLISHED SEPTEMBER 5, 1930

In a former paper[2] the author has pointed out the fact that although the tetrahalogen compounds of sulfur, selenium and tellurium are of considerable interest in theories of molecular structure, very little is known about them.

A study of tellurium tetrachloride has added interest because of the recent investigation of Drew[3] in which he showed that $Te(CH_3)_2X_2$ went over readily to a double salt $Te(CH_3)_3X\cdot TeCH_3X_3$. This indicates that the compound has a tendency to get away from the unstable ten electron shell by two molecules associating, giving an eight electron shell to one tellurium atom and a twelve to the other. It would be interesting to see whether tellurium tetrachloride has double molecules in the gas phase.

Michaelis[4] made Victor Meyer determinations of the vapor density of tellurium tetrachloride with the following reported results.

Temp., °C.	Vapor density Experimental		Calcd. $TeCl_4$ (referred to air at same temperature)
448	9.028	9.224	9.32
530	8.859	8.464	9.32

Preparation of Tellurium Tetrachloride.—The tellurium tetrachloride was prepared in a similar manner and in an apparatus similar to that used for selenium tetrachloride.[2] As the tellurium compound distils rather than sublimes, the necks of the small reserve bulbs were restricted to facilitate sealing off. One more distillation was obtained by having an additional distilling bulb in the chain.

Melting and Boiling Points.—The melting point was obtained from the cooling curve after the material had been fused in a small electric furnace. The melting point thus determined is 225°.

The boiling point was obtained by using a glass jacketed thermocouple immersed in the vapor above the boiling liquid. The boiling point thus determined is 390° at 755.6 mm.

Solubility Relations.—Tellurium tetrachloride was found not to dissolve appreciably in carbon tetrachloride by sealing a small amount of the compound in a tube containing the dry solvent and heating in a bath of boiling water. It was found to react with solvents which would be expected to dissolve it, such as CH_3CN. No convenient solvent was found in which to determine its conductivity and freezing point lowering. Its solubility relations indicate that it is a polar compound, salt-like in nature.

Vapor Density.—The apparatus and method used to measure the vapor density of

tellurium tetrachloride was the same as that for selenium tetrachloride. The results as shown in Table I give higher values below 500" for the apparent molecular weight than the theoretical for $TeCl_4$, and lower values at more elevated temperatures. The higher values may be due either to association of the molecules or to some difficulty in removing the material from the bulb as, for example, due to its adsorption on the walls.

TABLE I

VAPOR DENSITY OF TELLURIUM TETRACHLORIDE

480	277.7	573	257.3	486	276.2	581	251.8
493	273.3	587	253.6	501.5	272.9	595	246.6
507	273.2	601	250.5	515.5	268.4		

The latter explanation was suggested by the difficulty experienced in boiling out the material from the bulb at a few degrees above the boiling point. Repeated determinations gave similar results to those recorded here. As the apparatus and method functioned very well for selenium tetrachloride, it was thought that the difficulty might be due to the fact that tellurium tetrachloride is a polar liquid, and as such would be difficult to remove from the glass surface.

Above 500" the color of the vapor in the bulb became darker with higher temperature. This indicated dissociation, for $TeCl_2$ is dark red.

In order to investigate the material in the gas phase at lower temperatures to determine whether or not the molecules were associated, the following work on the vapor pressure was done.

Vapor Pressure.—The apparatus, as shown in Fig. 1, consisted of a pyrex tube containing a sealed-in bubbler joined to another tube by a ground-glass connection. The latter tube had an outlet to the air. This apparatus was placed in a furnace so that the lower end of the second tube projected below the end of the furnace. This was to allow the vapor to condense.

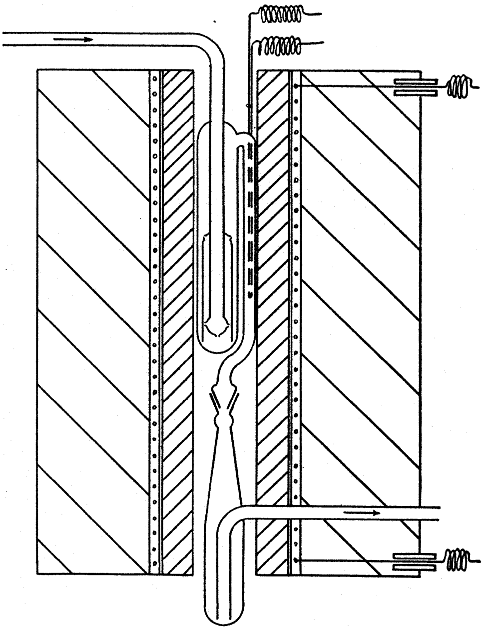

Fig. 1.—Apparatus for determining the vapor pressure of tellurium tetrachloride.

The dynamic vapor pressure method was used. A known quantity of purified and dried nitrogen was passed slowly through the apparatus while it was kept at a constant temperature in the furnace. The decrease in weight of the tube containing the tellurium tetrachloride gave the amount carried off by the nitrogen. The rate of passage of the gas was sufficiently slow to reach equilibrium with the tetrachloride, as shown by the fact that increasing or decreasing the rate had no influence on the results.

The cylinder used to measure definite volumes of nitrogen is shown in Fig. 2. Small glass points fixed in position and pointing upward provided the measuring device. A light reflected from the surface of the water showed very easily whether the point was just raising the surface of the water or was just below it. The volumes between the points could be calibrated closer than to one-hundredth of a cubic centimeter, but this was more than sufficient for our purpose. By test it was found that the eye could detect a difference in height of the water of about one three-hundredths of a millimeter, when the surface was just touching the point.

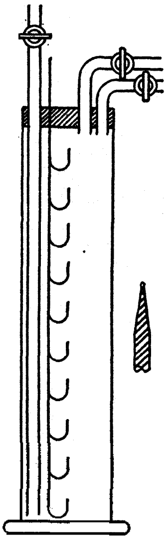

Fig. 2.—Gas measuring cylinder.

The results of these determinations are given in Table II. When the molecular weight is assumed to be the formula weight of $TeCl_4$ and the logarithms of the vapor pressure, calculated by using this assumption, are plotted against the reciprocal of the temperature, a straight line results, and this line includes the point given by the boiling point of the compound. This curve is shown in the graph. The point marked * is the boiling point. If double the formula weight is used as the assumption in the calculations, then the curve as shown by the crosses results. The true vapor pressure should give a straight line on this graph, the slope being a measure of the heat of vaporization, by the equation, $\partial \ln p/\partial(1/T) = \Delta H/R$.

761.8	104.3	27 4	.004346	766.6	,3610	328	001342	181.0	102.7
765.4	47.07	26.0	.001980	767.6	,2880	345	.001070	269.5	165.3
766.0	47.07	25 0	.001988	766.7	,5738	360	,002132	396.5	268
763.2	37.60	19.8	.001610	757.4	1.7284	376	,00641	605.0	503
				Boiling point		390		755.6	

These results indicate that the molecules are not associated, or at least that there is very little association. If the molecules were double the formula weight, then the crosses should fall on a straight line. If association began below the boiling point, the line drawn on the assumption of single molecules should begin to curve at this point. This tends to prove that the high apparent molecular weight at the lower temperatures obtained in the vapor density measurements is not due to association, for if it were a very considerable association would be expected 200° lower at the temperatures of the vapor pressure measurements. This would at least be sufficient to cause a break in the vapor pressure curve, The heat of vaporization calculated from this curve is 18,400 calories per mole.

Density of Liquid.—The apparatus used in determining the density of the liquid was made of pyrex glass and is shown in Fig. **3.** The volume of the lower bulb and tube connected to it was determined by filling it with mercury to various heights and weighing it. **A fine** scratch on the glass just above the bulb was used as a reference mark from which to measure the level of the mercury. **A** telescope containing cross hairs was mounted on a traveling microscope bed for the measuring device.

Tellurium tetrachloride was run into the apparatus carefully so as not to expose it to the air. The level of the liquid in the measuring bulb was adjusted by pouring the liquid from one bulb to the other. The secondary bulb was sealed off when this was accomplished. The apparatus was then placed in a furnace which was made with copper walls one-half inch thick. It had a slit in the side so that observations could be made on the apparatus inside it. The height of the liquid in the tube was noted at different temperatures.

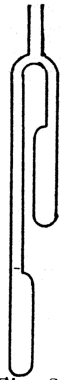

Fig. 3.—Density bulb.

The results of these determinations are given in Table III. Corrections were made both for the curvature of the meniscus and for the expansion of the glass of the bulb.

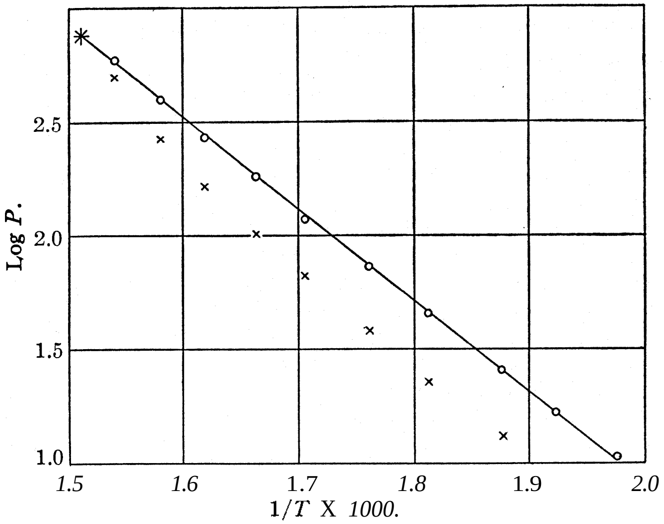
furnace; after it had been kept heated for some time to make sure that the glass was wetted, the measurements were made. These covered a considerable temperature range. A close examination gave no indication of a finite angle of contact between liquid and glass. These results are given in Table IV. Corrections were made for the expansion of the glass and for the curvature of the meniscus.

The parachors[5] were calculated from thrse surface tension measurements. They are given in Table IV. The density of the vapor was calculated from the vapor pressure.

In all this work the same thermocouple was used as in the work on selenium tetrachloride.



Pig. 4.—Vapor pressure of $TeCl_4$.

Discussion

These experiments show that tellurium tetrachloride exists as $TeCl_4$ in the gas phase. Three ways of explaining its structure are the ionic form $TeCl_3^+Cl^-$, the structure containing two single electron bonds as recommended by Sugden,[6] and a form in which a ten electron shell is assigned to the central atom, four pairs of these being shared by chlorine atoms. It is difficult to understand how the first form could exist in the gas phase as a normal gas. The second form involves the assumption of single electron bonds, which is an extremely questionable hypothesis. The third form gives a structure which agrees well with the properties of the compound.

Of the tetrahalogen compounds of this family of elements tellurium tetrachloride is the only one that lends itself readily for study. The only others that are stable enough to exist in anything but a crystalline form are the fluorides and these are difficult to handle due to their reactivity with glass. The properties of tellurium tetrachloride are, therefore, to be

---

[5] See Sugden, *J. Chem. Soc.*, 125, 1177 (1924).

[6] Sugden, *ibid.*, 1058 (1929).

considered as representing the general properties of ten electron shell compounds in which one electron pair of the central atom is not shared.

Summary

A method for the preparation of pure tellurium tetrachloride is described.

The melting point and boiling point of tellurium tetrachloride are determined to be 225 and 390°, respectively.

The vapor density of tellurium tetrachloride is measured from above the boiling point to 600°.

The vapor pressure of liquid tellurium tetrachloride is measured.

The heat of vaporization is determined to be 18,400 calories per mole.

The vapor of the compound is concluded to consist of single molecules of $TeCl_4$ from the melting point to about 500°, where dissociation begins.

The density of liquid tellurium tetrachloride is determined from the freezing point to above the boiling point.

The surface tension of tellurium tetrachloride is determined over the same range.

Tellurium tetrachloride is concluded to have a ten electron shell surrounding the central atom, four pairs of these being shared with the chlorine atoms.

THE STANDARDIZATION OF A MODIFIED OSTWALD VISCOMETER

BY H. M. CHADWELL AND B. ASNES

RECEIVED APRIL 18, 1930 PUBLISHED SEPTEMBER 5, 1930

A viscometer conforming essentially to Washburn and Williams,[1] modification of Ostwald's viscometer has been used by one of us[2] to determine the viscosities of several aqueous solutions, without attempting to determine how accurately the instrument reproduced true viscosities. The viscosities were calculated both by the simple law of Poiseuille and by assuming a value of 1.12 for m, the coefficient of the correction term which has been variously called the kinetic energy, Hagenbach, or inertia correction. Washburn and Williams reported experiments on changing time of flow with changing pressure, to support the conclusion that the law of Poiseuille, without a correction, should be used, but their method of calculation has since been questioned.[3] Since the magnitude of m is thought to be dependent upon the shape of the terminal of the capillary as well as

[1] Washburn and Williams, THIS JOURNAL, 35, 739 (1913).

[2] Chadwell, *ibid.*, 48, 1912 (1926).

[3] Dorsey, J. Opt. *Soc. Am.*, **14**, 45 (1927).

upon the velocity of flow,[3] the present investigation was undertaken to determine how nearly an instrument of this type reproduced absolute viscosities.

At least two methods of standardizing a viscometer are available. The method usually adopted is to vary the time of flow of a standard substance by varying the pressure by known amounts. The necessary apparatus is complicated.[4] The second method is based on the measurement of times of flow for liquids of known viscosity. Of the data for the various liquids recommended as reference materials, those for water are the most trustworthy. A variation in time can be obtained by varying the temperature.

This paper reports the use of three viscometers, similar to one another in size of capillary and general construction, but differing in the shape of the ends of the capillary tube, ranging from a decided trumpet to the square end of a fractured tube. The dimensions of these viscometers were measured carefully, and the time of flow of water was measured at seven temperatures ranging from 15 to 30°. The resulting data are compared with the viscosity of water as given by previous investigations. The viscosities of aqueous solutions of urethan, determined at 20 and 25°, are given to provide standard solutions to be used as reference materials for future calibration.

Apparatus and Results for Water.—The three viscometers were all of the same type and constructed of pyrex glass, similar to that used before by one of us.[2]

Viscometer I had its capillary sealed into the instrument in such a way that its ends were decidedly trumpet shaped. The capillaries of Viscometer II and III were taken from the same piece of tubing. The capillary in Viscometer II was not sealed into the instrument, but connected by ground joints, sealed on the outside with de Khotinsky cement. Its ends were the square fractures obtained by breaking the tubing. Viscometer III had its capillary sealed in, but with more abrupt endings than Viscometer I, instructions being given to the glass-blower to make the endings as abrupt as possible. The inside diameter of the tubes into which the capillaries delivered the liquid was 8 mm.

Each viscometer was mounted on a brass frame in such a way that the capillary was held in a vertical position in the thermostat. Each frame had three brass reference points that fitted into corresponding small conical cups inside the thermostat.

The thermostat was made from a deep glass jar, insulated as usual, and was fitted with a copper cooling coil, a stirrer and an automatic electrical heating unit. The temperature remained constant to within ±0.002° at all temperatures except 15°, where the variation was slightly larger. Into the jar was built a superstructure of brass to hold the frame of the viscometer in a rigid and definite position. It was found convenient to construct a frame outside of the thermostat with the reference points in similar positions to facilitate the measuring of the dimensions of the instruments. Windows through the packing of plumber's wool were provided so that the movements of the liquid past the scratches could be viewed easily.

The temperatures which the thermostat maintained were obtained with a series of

---

[4] Bingham, "Fluidity and Plasticity," McGraw-Hill Book Co., Inc., New York, 1922.

Beckmann thermometers that were used as secondary standards, each one being compared with a platinum thermometer. The platinum thermometer had been calibrated by the Bureau of Standards and has been described in THIS JOURNAL.[5] Each comparison with the platinum thermometer was made within 0 01° of the desired temperature, so that any corrections to the Beckmann were eliminated It is believed that these temperatures were accurately reproduced within a few thousandths of a degree.

The diameters of the capillary tubes were determined by measuring the length of a small drop of mercury at a known temperature. The mercury was later weighed on an assay balance with weights that had been compared with weights certified by the Bureau of Standards. The measurements of length were made with a "Universal Reading Microscope," manufactured by P W G Pye & Co. The screw with micrometer head read to 0.005 mm. The larger scale, 18 cm long, could be read with a vernier to 0.05 mm.

In the determination of the radius of the capillaries the mercury used had been purified by washings with nitric acid followed by distillation. The readings of the length of the thread of mercury were made at points equally distributed along the capillary. The results of these measurements are given in Table I.

[a] Omitted in the calculation of the mean because of evident irregularity.

In the values of the "mean length" and the "radius," the last decimal place is significant only in determining the next figure. The "No. of settings" refers to the number of measurements of the length of each drop of mercury as it appeared at different positions in the capillary.

In calculating the radius of each capillary from the weight of mercury and the length of the drop, a correction was applied for the meniscus.

---

[5] Chadwell, THIS JOURNAL, 49,2795 (1927).

This correction was calculated by measuring the height of the meniscus with a microscope having a magnification of 100 and fitted with a micrometer eyepiece. The latter was calibrated by a Bausch and Lomb test plate graduated in 0.01 mm. It was assumed that the meniscus was a spherical segment.

The values of the radius given above are calculated on the assumption that the bore is cylindrical. Formulas[6] have been advanced for capillaries which do not conform with this condition. If the capillary is elliptical

$$\frac{2B^3C^3}{B^2 + C^2} \tag{1}$$

is substituted for R^4 in the formula for viscosity, where B and C are the major and minor semi-axes of the cross section. If the capillary is a frustum of a circular cone, R^4 is replaced by

$$\frac{3R_1{}^3R_2{}^3}{R_1{}^2 + R_1R_2 + R_2{}^2} \tag{2}$$

where R_1 and R_2 are the radii at the two ends. If the capillary is a frustum of an elliptical cone, R^4 is replaced by

$$\frac{3R_3{}^3R_4{}^3}{R_3{}^2 + R_3R_4 + R_4{}^2} \times \frac{(1 - E^2)^3}{1 + E^2} \tag{3}$$

where R_3 and R_4 are arithmetical means of the major and minor axes at their respective ends, and $E = (B - C)/(B + C)$. B and C have the same meaning as in (1).

To determine how great an assumption was introduced in using the simplest method of calculating the radius, the individually determined radii of Viscometer I were plotted against the position of the drop of mercury and the curve extrapolated to give the radii at the ends. The results were 0.02430 and 0.02388. If these data are substituted in expression (2), the corrected value for R^4 comes out equal to 0.0633669, while that used in the calculations was 0.0633650, a difference of 0.06%.

A short section of the capillary used in Viscometers II and III was examined under a microscope fitted with a micrometer eyepiece and previously calibrated with a Bausch and Lomb test plate. This showed the cross section to be circular within the accuracy of the examination (between 1 and 2%). If there was a difference in the semi-axis of 2%, the difference in the value of R^4 would be only 0.04%. As a consequence of these measurements, it was felt that the first values for the radius could be used with safety.

The other dimensions of the instruments were determined in the usual way, with corresponding accuracy. They are summarized in Table II.

In the determination of the time of flow of water the usual precautions were taken in regard to cleanliness and absence of dust. The water was

thrice distilled, from alkaline permanganate and dilute sulfuric acid, using tin condensers. The time of flow was measured, as in the former investigation,[7] by a stop watch having an excellent Swiss movement and recording time to one-fifth of a second. It was verified frequently and kept in a constant state as regards winding and position.

The times of flow for water for the different temperatures, as recorded in Table III, are average results of at least three runs in which the variation was not greater than the accuracy of measuring the time of flow (1/5 sec.). Table III also includes the data for the density of water in air and the viscosity, expressed as poises, as given by the Bureau of Standards[8] and the "International Critical Tables."[9] These data are used in subsequent calculations.

Calculation of Results

The viscosity is related[10] to the dimensions of the viscometer by the formula

$$\eta = \frac{\pi r^4 p t}{8V(l + e)} - \frac{m\rho V}{8\pi(l + e)t} \tag{4}$$

where η is the coefficient of viscosity (in poises), r the radius (cm.) of the capillary assumed to be cylindrical, p the over-all driving pressure, t the

time of flow in seconds for a volume of V (ml.) through a tube of length l cm., e the Couette correction, m a numerical factor usually taken as 1.12, and p the density of the liquid.

It follows from this formula that if $\eta/\rho t$ is plotted as ordinates and $1/t^2$ as abscissas for liquids of different known viscosity, the slope of the line to the axis of abscissa is

$$tan\,\Theta = -\frac{mV}{8L\pi}$$

where Θ is the angle between the line and the axis and L is the effective length ($L = l + e$). The intercept on the axis of abscissa is π^2r^4hg/mv^2 and the intercept on the axis of ordinates is $\pi r^4hg/8$ VL where "h" is the effective height causing the liquid to flow by its own hydrostatic pressure ($p = h\rho g$) and g is the force of gravity. If m is zero, the line will be parallel to the axis of ordinates.

It should be emphasized, in support of this method, that one can conclude whether m has a value other than zero quite independently of any measurements of the dimensions of the capillary. If it is zero, the conclusion depends upon the values of viscosity taken as standard, the density of the liquid and the time of flow; if m does not equal zero, its value is calculated from measurements of the volume of the liquid and length of capillary, not upon the radius.

This method of evaluating m is not new. It is similar to the method of Knibbs[11] where one liquid is used to calibrate a viscometer by allowing it to flow under different pressures, and then plotting pt against $1/t$. Nor is it very dissimilar from that of Herschel,[12] who uses a series of liquids of known viscosity and plots Reynolds' criterion ($R = vd\rho/\eta$ where v, the velocity, is equal to $V/\pi r^2t$, and d is the diameter) against η'/η, the ratio of the viscosity as calculated without the second term of Formula 4 and using the measured length (l), to the true viscosity (η). By this method the intercept on the axis of η'/η is equal to $(1 + e)/l$ and the slope of the line gives the value of m by the formula $m = 32\,l/d\cdot\tan 8$.

Both the method suggested by the authors and Herschel's method of evaluating m presuppose the knowledge of certain viscosities, either of one liquid at different temperatures or different liquids at the same temperature. Since water has been studied more carefully than any other liquid, it was selected as the basis of comparison, and used at different temperatures as described above.

The data for the absolute viscosity of water as determined by various investigators have been recalculated by Bingham, assuming that m has

a value of *1.12.* They have been published in several places.[13] When made the basis for evaluating m for Viscometer I by the first method suggested, the values for $\eta/\rho t$ as given in Table IV result.

TABLE IV

VALUES OF $\eta/\rho t \times 10^5$ FOR VISCOMETER I BASED ON THE ABSOLUTE VISCOSITY OF WATER AS DETERMINED BY VARIOUS INVESTIGATORS

Temp,	Poiseuille					Thorpe and	Bingham and
°C.	A	C	D′	E	Sprung	Rodger	White
15	2.1807	2.1958	2.1960	2.1942	2.1709	2.1690	2.1784
20	2.1803	2.1901	2.1879	2.1931	2.1694	2.1753	2.1860
25	2.1765	2.1921	2.1926	2.1943	2.1880	2.1766	2.1863
30	2.1708	2.2063	2.2049	2.2093	2.2519	2.1727	2.1798

The columns under "Poiseuille" contain his results for four different capillaries. If m for our viscometers had a value of zero, the term $\eta/\rho t$ should be independent of the time of flow; if m had a positive value, $\eta/\rho t$ would have to decrease with a decrease in time (increase in temperature). It is evident from the data of this table that any conclusion concerning m would be uncertain.

The determinations of the absolute viscosity of water have been critically appraised by two reviewers[8] The Bureau of Standards has accepted the formula

$$t = A(\varphi + D) + C - \frac{B}{\varphi + D} \tag{5}$$

to define the changes in fluidity with temperature, where t is the centigrade temperature, φ the fluidity and A, B, C and D are arbitrary constants having the values *0.23275,* 8676.8, *8.435* and *1.20,* respectively. The second set of data were compiled by the editors of the "International Critical Tables."[9] No information is available concerning the basis of their selection. Both sets of values have been included in Table III. They are the basis for calculating the values of $\eta/\rho t$ given in Table V.

The values of $\eta/\rho t$ are remarkably consistent for the Bureau of Standards data. Viscometer II, having fractured ends, is slightly less regular (the value for 15° is evidently in error) but shows no tendencies that can be attributed to the configuration of the terminals of the capillary. *It is to be concluded that viscosities corresponding to the Bureau of Standards data (Bingham and Jackson) could be reproduced by any of the viscometers at the velocities studied, on the assumption that m equals zero, in other words, by calculating the results by the simple Poiseuille formula.*

The values of $\eta/\rho t$ calculated from the "International Critical Tables" data show a decided trend. From them a value of m for each viscometer can be calculated. The data for 15° are so discordant that they are mean-

ingless, and so are not included. For Viscometers I and III, having the capillaries sealed into the glass and as a consequence having trumpet-shaped openings, the values can be determined graphically (by the method outlined above). Figure 1 shows the plot of $\eta/\rho t$ against $1/t^2$. The slopes of the lines are -0.0355 and -0.0487, leading to values of m of 2.15 and 2.27. The data for Viscometer II (having squarely cut ends) are not close enough to a straight line to insure much confidence in the result. The slope of the most probable straight line was calculated by the method of least squares as -0.0364, which corresponds to values of m equal to 2.93. It would seem that the data from the Bureau of Standards, with the accompanying conclusions, are the most trustworthy.

When Herschel's method is applied to these data, the conclusions regarding m are, of course, the same, but it also produces the Couette correction. This method has been applied to the data for the three viscometers, using the viscosity of water according to the Bureau of Standards. The results are given in Table VI, where R represents Reynolds' criterion. In order for m to have a value other than zero, the data for η'/η would have to show a definite trend, for m is a function of the slope of the line when R is plotted against η'/η.

According to this method the Couette correction (e) is given by the

TABLE VI

[a] Not included in the average.

expression $e = l(a - 1)$ where a is the intercept on the η'/η axis corresponding to $R = 0$. The calculated corrections are 0.064, 0.315 and 0.255 cm. for the three viscometers. It is not to be expected that these values of the Couette correction would bear the relationship to the radius as derived from theoretical considerations. They really represent a correction to one particular measured dimension of the capillary to counteract inaccuracies in the others. The real Couette correction for these viscometers is almost negligible, for the ratio of l/r is so large, the correction being much smaller than the uncertainty in measuring the length of a capillary terminating in trumpet-like openings.

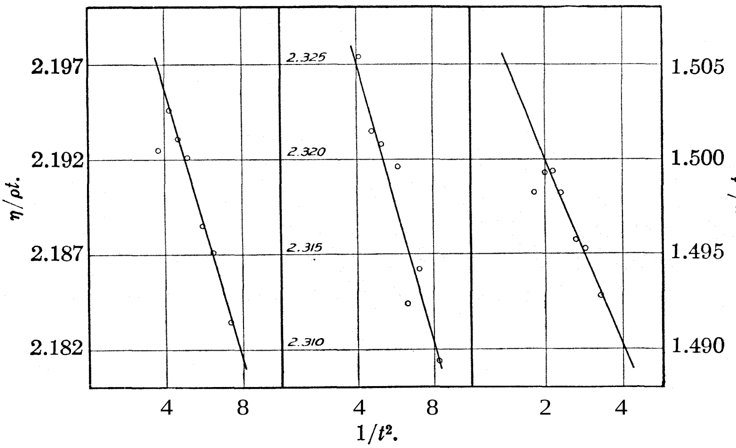

Fig. 1.—The values of η/pt ($\times 10^5$), using the data of "International Critical Tables" for the viscosity of water, are plotted against $1/t^2$ ($\times 10^6$) for the three viscometers. The slopes of the lines give the values of m.

These results are of interest in relation to Dorsey's[14] interpretation of

---

[14] Dorsey, *Phys. Rev.*, 28, 833 (1926); and *J. Opt. Soc. Am.*, 14, 45 (1927).

Poiseuille's and Bond's[15] experiments on the flow of liquids through capillaries. Dorsey maintains that the data show that when Reynolds' number (R) is less than 10, m has a value of zero and the Couette correction (e) is 1.146 r. If R is greater than 10, two regimes are possible if the capillary is long and free from mechanical vibration. In the one case m still remains equal to zero; in the other, and the more likely, m is probably equal to unity and e is half as large as before. A theoretical interpretation of the stability of these regimes is given, based on the premises "that the free surface of the liquid in each reservoir is great compared with the sectional area of the capillary, that the edge at each terminus of the capillary is sharp and smooth, that at each end of the capillary the terminal face is normal to the axis of the capillary, and that the radial extent of this face, in every direction, and all other distances from the terminus to the wall of the reservoir are severally so great that the distribution of the flow of the liquid is essentially the same as if they were infinite." It is further pointed out that departures from these ideal conditions will result in different values of m and e, and probably account for the variations actually found in determined values of m between 1.0 and 2, and averaging 1.12. Variation in the configurations of the terminals of the capillaries are probably the most significant.

The velocities of flow through the three viscometers studied were sufficiently large to allow either of the two regimes to be satisfied, for the values of Reynolds' number were between 25 and 65. Furthermore, Viscometer II had a capillary with terminals which fulfilled the postulated conditions, particularly that of a sharp-edged face normal to the axis of the capillary, while the others had terminals that were trumpet-like, Viscometer III having a more abrupt opening than Viscometer I. Yet there is little or no evidence in the data given above to show that the configuration of the capillary ends in these particular viscometers played a part in determining m.

Equation 4 has been used in various ways to evaluate different dimensions of the viscometer. Reference has already been made to Knibbs' method, which produces the value of m and r, and to Herschel's method yielding m and e. Dryden's equation[16] for the evaluation of the hydrostatic head causing the flow is still another modification, but these methods can hardly be used simultaneously.[17] The value to be used for the over-all driving pressure (p) is particularly hard to evaluate for a viscometer of the Ostwald type, for the hydrostatic head is varying during the flow of liquid. The average head is certainly in error.[18] The chronological average head

[18] See Lidstone, *Phil. Mag.*, [VI] 43, 354 (1922).

has sometimes been evaluated by an integration method applied to observed changes of head at intervals of time throughout the flow. This pressure is more generally calculated from the approximation formula of Meissner

$$h = \frac{h_1 - h_2}{\log^* h_1/h_2} \qquad (6)$$

where h_1 is the initial and h_2 the final hydrostatic head. This latter method when applied to our viscometers produced the values listed under the heading "h" in Table II. To determine how different these values of effective heads are, the correct value to be used to give the mean value of $\eta/\rho t$ in Table IV was calculated from $h = \frac{8VL}{\pi r^4 g}\left(\frac{\eta}{\rho t}\right)_{\text{mean}}$ assuming the Couette correction to be that given by Dorsey. The results are summarized in Table VII.

TABLE VII

HYDROSTATIC HEADS CALCULATED BY VARIOUS METHODS

No. of viscometer	h_a	h_m	h_η
I	21.029	20.880	20.838
II	19.278	19.120	18.805
III	19.988	19.841	19.571

Here the arithmetic average of the initial and final heads'is given as h_a, the values by Meissner's formulas as h, and the values calculated from the viscosity as h_η. The percentage differences between the last two columns are 0.2, 1.6 and 1.4, respectively, for the three viscometers.

The above comparison should not be interpreted to measure the approximation of Meissner's formula, for all of the inaccuracies in measurements of the dimensions of the capillaries are automatically included. It is rather disconcerting, however, that the capillary for Viscometer II, which was the easiest to measure, shows the largest deviation. Furthermore, it should be remembered that Meissner's formula was derived on the assumption that the two limbs of the viscometer are cylindrical and equal, and these conditions are not satisfied in the design of the viscometers in question.

For an exact determination of m, the length of the capillary tube should be relatively small so that the kinetic energy correction is large. This procedure was followed by Rieman,[19] who concluded that the value of m was 1.12. A Bingham viscometer was used, modified to the extent that the capillary was mounted in rubber tubing and had, presumably, squarely fractured ends. The times of flow under varying pressure were determined and the value of m calculated by the method of Knibbs. The velocities of flow were very different from those reported in the present investigation, Reynolds' number varying from 192 to 1013.

---

[19] Rieman, THIS JOURNAL, 50, 46 (1928).

In the standardization here reported, the primary objects were to determine how exactly a viscometer essentially of the Washburn and Williams type reproduced absolute viscosities, and to determine the effect of different configurations in the terminals of the capillary. We believe that the investigation has shown that these viscometers would reproduce viscosities comparable to the values of water accepted by the Bureau of Standards (Bingham and Jackson), and at the velocities used, on the assumption that *m* equals zero. If further investigation changes the absolute viscosities of water, the data determined by these viscometers must be changed. We would emphasize the need of evaluating *m* for a given viscometer, and for a given range of velocities of flow. We do not wish that our conclusions be interpreted to mean that the kinetic energy correction can be neglected in determining viscosity.

The Viscosity of Aqueous Solutions of **Urethan.**—In order to have liquids available for standardization of other viscometers, the viscosities of several aqueous solutions of urethan were determined with Viscometer I.

Urethan was selected primarily because of its ease of purification by recrystallization. Other substances have been recommended for standardizing purposes, particularly aqueous solutions of alcohol and of sucrose. The latter was discarded from consideration because of the difficulty of purification and because the solutions were liable to mold. Alcohol is a difficult substance to free from aldehyde and water. At the beginning of this investigation it was thought that alcohol–water mixtures could be used as well as water in the preliminary standardization, but the results in the literature were more discordant than those of water, and several weeks spent in purifying alcohol led to the conclusion that although relatively pure alcohol could be prepared, the sample obtained would not be comparable to those of previous investigators and certainly could not be easily reproduced in the future.

Purification of Materials

Urethan.—Urethan ($NH_2COOC_2H_5$) from a reliable source was crystallized four times from water, the crystals being separated from the mother liquor by a centrifuge. The material was dried and kept in a desiccator over solid sodium hydroxide until the solutions were prepared.

The melting points were determined by immersing a standardized tenth degree thermometer in a mush of the melted urethan, surrounded by an air jacket and immersed in a bath of warm sulfuric acid. The thermometer reading was corrected for emergent stem, zero point and scale deviation. The melting point of the material after four crystallizations was the same as after three, namely, 48.19°. This is slightly higher than the values obtained previously of 47.94 and 47.99°.[20]

---

[20] Richards and Chadwell, THIS JOURNAL, **47**, 2283 (1925). For other values for the melting point, see Ref. 7 in that paper.

Water.—The water was triply distilled as usual and was purified directly before the solutions were prepared.

Preparation of **Solutions** and Measurement of Viscosity.—The solutions were prepared in 100-cc. graduated flasks, their concentrations being determined by weighing to milligrams on an analytical balance. Precautions were taken to prevent evaporation by adding the water last, and by keeping the bottles sealed with collodion. In a few cases the solution contained small particles of lint, in which event it was filtered rapidly into another flask. Vacuum corrections were not applied for they would have changed the percentage by only 0.01%.

The densities were determined in duplicate in 10-cc, Ostwald pycnometers, weighing against a sealed counterpoise,[21] and corrected to the vacuum standard.

The technique of making a viscosity measurement was the same as with water. All of the runs were made with Viscometer I, the determinations at 25° being completed before the thermostat was changed to 20°. Frequent runs were made with water to ascertain that the apparatus was functioning properly. The time for each solution was the mean of at least two runs, concordant within the accuracy of measuring time.

In Table VIII are given the results of these experiments. In the first column is given a letter to represent the order of runs, in the second the percentage of urethan by weight and in the third the number of moles of urethan (mol. wt., 89.062) per 1000 g. of solution. The values for density are corrected to the vacuum standard. When used in calculating the viscosity they are changed to the density in air by subtracting the weight of 1 ml. of air. The viscosities are expressed as centipoises (the viscosity in poises $\times$ 100) and were calculated by the formula $\eta = 2.1851\, pt \times 10^{-5}$ based on the results given in Table V. In other words, the viscosities given above are referred to the viscosity of water as given by the Bureau of Standards.[22]

Table IX includes the viscosities (in centipoises) and fluidities (in reciprocal poises) for these urethan solutions obtained by interpolation from the curve of the ratio of change in viscosity to molarity plotted against molarity (η solution $- \eta H_2O/c$ vs. c). The data in Table VIII are consistent with the exception of Solution E, whose viscosities at both temperatures are slightly high.

---

[21] Richards and Chadwell, THIS JOURNAL, 47, 2286 (1925).

[22] These results at 20° are in good agreement with those determined by Richards and Palitzsch [*ibid.*, 41, 63 (1919)]. Their values for the relative viscosity, which they calculated by the simple Poiseuille formula, are as follows

%	9.12	16.69	28.62	44.51	50.07	55.65
η	1.206	1.398	1.730	2.250	2.471	2.716

By interpolation of our results we get for viscosities at the three lowest concentrations the following: 1.206, 1.402 and 1.730. Our density values are slightly lower than those of Richards and Palitzsch.

It might be argued that it was unsafe to assume that the viscometer would reproduce viscosities over a greater range than was used in the standardization, that m might change from its value of zero. If we base a conclusion on Dorsey's analysis, this might very well be the case for greater velocities of flow, but quite improbable for smaller. As a consequence, confidence is felt that these solutions can be used for future standardizations. It would be interesting to see what the viscosities of these solutions would be if determined with an instrument with which it had been demonstrated that m had a value different than zero, and which reproduced the Bureau of Standards data for water.

We are indebted to the Elizabeth Thompson Science Fund for providing a grant to aid this investigation.

Summary

Three viscometers of the Ostwald type as modified by Washburn and Williams have been constructed similar to each other with the exception of the configuration of the ends of the capillaries, which varied from gradual trumpets to squarely fractured ends. The dimensions of these viscometers were determined as accurately as possible.

The times of flow with water were determined with the three instruments

at 15, 18, 20, 22, 25, 27 and 30°. In terms of Reynolds' criterion the velocities of flow varied between 25 and 63.

The resulting data were compared with previously determined viscosities of water in a manner to show any variations in m. It was found that any of the three viscometers reproduced the Bureau of Standards data for water on the assumption that *m* was zero. No evidence was found for believing that *m* changed in value due to the configuration of the capillary ends.

These results were discussed in relation to Dorsey's interpretation of m.

The viscosities of urethan solutions up to 4.5 moles/1000 g. of solution were determined at 20 and 25° for future use in standardizations. These data were given in reference to the Bureau of Standards data for water.

THE VISCOSITIES OF SEVERAL AQUEOUS SOLUTIONS OF ORGANIC SUBSTANCES. II

BY H. M. CHADWELL AND B. ASNES

RECEIVED APRIL 18, 1930 PUBLISHED SEPTEMBER 5, 1930

A study of the compressibilities and volume changes upon solution of several organic substances in water[1] has shown that with these properties, the effect of a change in the polymerization of the solvent is most apparent. The viscosities of these same solutions determined at 25°[2] showed no effect that could be ascribed to such a change in molecular state, for it was found that although the solutes had viscosities very much less than water, the aqueous solutions possessed a viscosity greater than water. If a depolymerization of the solvent was brought about by the presence of solute, the viscosity should be decreased, for the depolymerized water is supposed to possess a lower viscosity.[3] Determinations made at a lower temperature, where the water is supposedly richer in polymer, might show this effect more vividly. As a consequence, one of the viscometers (Viscometer I) whose standardization was described in the preceding paper, was used to measure this property at 10° of aqueous solutions of diethyl ether, methyl and ethyl acetates and urethan.

It has been reported[4] that aqueous solutions of urea show "negative viscosity," or viscosity less than water. Since this seems to be an exception to the general rule that aqueous solutions of non-electrolytes possess a viscosity greater than water, determinations were made at 5, 10,

15, 20 and 25°. No evidence was found within the range of concentrations studied that this was an exceptional substance.

Purification of Materials

Water.—Thrice distilled water, similar to that described in the previous paper, was used for these experiments.

Methyl and Ethyl Acetates.—Samples of esters which had been purified for a previous investigation[2] were shaken with solid sodium carbonate, treated with phosphorus pentoxide, and distilled in an all glass apparatus consisting of a Richards–Barry flask and condenser. Practically all of the material boiled at the same temperature as in the first purification, 77.15" for the ethyl ester and 57.2" for the methyl acetate (760 mm.). Their densities ($d_4^{10}{}_{\text{vac.}}$) were 0 9127 and 0.9466, respectively.[5]

Urea.—Urea of the highest purity from a reliable commercial source was crystallized twice from water, the saturated solutions being prepared at 60° and the crystals separated and washed in a centrifuge. It was dried for several days in a desiccator over sodium hydroxide, dried in an oven at 50° and then kept in a desiccator over sodium hydroxide until used. The urea used in the 5, 10 and 15% solutions was purified in the same way from material of a different source.

The crystallizations were carried out rapidly and at comparatively low temperatures because of the possibility of changing urea into ammonium cyanate. Fawsitt[6] showed that such a change, caused by heating a solution at 100" for an hour, would increase the relative viscosity slightly.

Urethan.—The urethan was purified in a similar manner to urea, twice crystallized from water with centrifuging, washing and drying.

Apparatus and Technique

The apparatus used in these experiments has been described in the foregoing paper. (Viscometer I, having a capillary radius of 0.241 mm., was used throughout.) All of the precautions for accurate work were observed; for instance, the solution was moved from the lower to the higher bulb in the viscometer by an application of pressure of dry air rather than by suction.

The temperature of the thermostat was determined by a tenth degree thermometer that had been standardized by the Bureau of Standards. Variations of temperature were measured by a Beckmann thermometer. At 5° the thermostat remained constant to ±0.01°; at higher temperatures it was more constant, ±0.003°.

The solutions were made up by weight immediately preceding the experiment in all cases except the 5, 10 and 15% solutions of urea; in the latter cases a large amount of solution was prepared and used at the different temperatures.

The densities were determined in 10-cc. Ostwald pycnometers which were provided with a small bulb beyond the graduation scratch on the side arm. All densities were calculated to the vacuum standard.

Experimental Results

The experimental results are given in Tables I and II.

Table I contains the results for various solutions at approximately 10°, while Table II shows how urea solutions change with temperature. In

C	444.4	1.0376	1.126$_4$

fourth relative viscosity. The headings of the columns in Table II have the same meanings. The relative viscosity was calculated by the formula

$$\eta_r = \frac{t_s \rho_s}{t_o \rho_o}$$

Here the subscript *s* refers to the solution while o refers to water. The density (ρ) is that in air, obtained from the value of density in vacuum given in the table, by subtracting the weight of 1 ml. of air (0.0012).

The use of the simple formula for calculating viscosity is justified by the fact that in the preceding paper it was shown that this viscometer would reproduce the viscosities of water as accepted by the Bureau of Standards over the temperature range of 15 to 30° when the value of *m* (Formula 4, preceding paper) was taken as zero. From Dorsey's analysis of the flow of liquids through tubes, it is logical to assume that this same condition would be fulfilled for flows of smaller velocity.[7]

[7] The absolute viscosities are not reported for the reason that the viscosities of water at 10 and 5° as calculated from the formula $\eta = 2.1851\, t \times 10^{-5}$ (obtained during the standardization of this viscometer and reported in the preceding paper) and the time of flow as given in Table II, are not in good agreement with the previously published values for water. The values are as follows, expressed in centipoises

	5.04°	9.98°
Calculated	1.5249	1.3139
Bingham and Jackson (B. of S.)	1.517$_0$	1.3085
"International Critical Tables"	1.517$_0$	1.3105

The times of flow for water are in agreement with those reported in the preceding

Discussion of Results

The relative viscosities of the urea solutions at different temperatures given in Tables I and II are plotted against moles per 1000 g. water in Fig. 1. The data are consistent except for the 5% solution at 25° which is slightly high (about 0.3%) and the 15% solution at 10° which is low (about 0.2%).

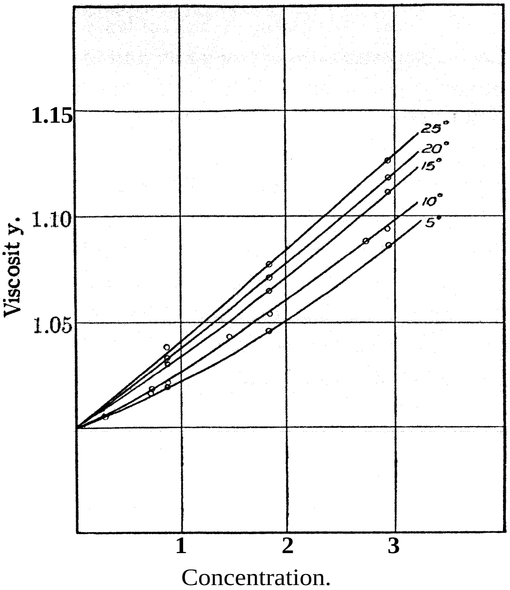

Fig. 1.—The viscosities of aqueous urea solutions at 5, 10, 15, 20 and 25°. The relative viscosities are plotted as ordinates, the concentrations expressed in moles per kg. of water as abscissa.

Rudolf[8] has reported determinations at 25° which show a minimum in the viscosity curve at a value less than that of water, but Fawsitt[9] could not verify his results using very pure urea. Ranken and Taylor[10] redetermined the viscosity of urea solutions at temperatures ranging from 8 to 45° and found that only in one solution was the viscosity less than that of water, namely, in the most dilute solution (0.03125 mole/liter) at 8°, the relative viscosity was 0.9985. This value was reported as reproducible.

---

paper with the exception of that for 20" (462.3 seconds instead of 461.3). Since this difference may have been caused by an accidental shifting of the viscometer in the holder, the time determined at the time of the experiments with the solutions was used in the calculations. An interval of approximately a year separated the two sets of experiments.

	Moles/liter	0.03125	0.125	0.25	0.50	1.0
η_r	8"	.09985	1.0012			
	15°			1.0085	1.0150	1.0325
	25°	1.0020	1.0050			
	30°			1.0113	1.0210	1.0443

Our results are slightly greater at 15° than those determined by Ranken and Taylor; at 20° they are in good agreement with those of Öholm;[11] at 25° they are considerably greater than those of Dunstan and Mussell,[12] up to a concentration of 2.5 moles/kg. of H_2O, and then they are smaller. The viscosities of supersaturated solutions of urea have been reported recently by Taimni.[13]

The curves in Fig. 1 include no evidence for concluding that urea solutions show "negative viscosity"[14]—viscosities lower than that of water. Certainly there is no such phenomenon as exhibited by certain salts. For example, the concentration of ammonium nitrate must be approximately 18% at 25° before the viscosity of the solution exceeds that of water. Bingham[15] has recommended the term "negative curvature" in referring to fluidity-concentration curves, to replace "negative viscosity." The terms are not synonymous, for it is evident that the fluidity curves for urea solutions would show negative curvature. The viscosities of very dilute solutions, preferably at low temperatures, were not investigated because of the necessity of a more refined method of measuring the time of flow.

The experimental results for all of the solutions are represented in Fig. 2, where the viscosity relative to water is plotted as ordinates and the moles of solute per 1000 g. of water as abscissa. There are also included the data for these solutions previously determined[16] at 25°. As would be expected, the relative positions of the curves for the various solutions are the same at 10° as at 25°, the ethyl ether solutions showing the greatest relative viscosity. The solutions of ethyl ether, ethyl and methyl acetates, and urethan have a greater relative viscosity at 10° than at 25°, while urea solutions are opposite, having a viscosity greater at 25° than at 10°. Furthermore, the viscosities of ether and ethyl acetate solutions are linear functions

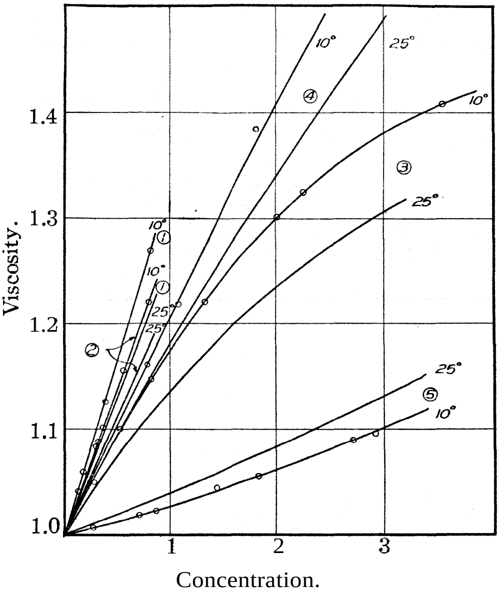
[15] Bingham, Ref. 4, p. 178.

[16] Chadwell, Ref. 2. The values of relative viscosity were calculated from the value of η_I given on p. 1918, for the viscometer was very similar to that used in the present investigation.

of the concentration expressed in the units chosen, while methyl acetate produces a convex curve and urea a concave. If the liquids were soluble in water in all proportions, the resulting curves would all show maxima, for the viscosities of the pure liquids are all very much smaller than that of water.[17] Urea, on the other hand, is a solid, and as the concentration increases, the viscosity of the solute has a more pronounced effect.

In discussing the data determined at 25° it was shown that not only was there a connection between the volume of the dissolved molecules, but that there was a very close connection between the change in viscosity and the change in volume, calculated as the contraction in ml. which took place upon the formation of one liter of solution. When a large contraction took place, the viscosity of the solution would be comparatively great. A similar hypothesis has been developed more extensively by McLeod,[18] who postulated that the viscosity of a mixture as well as of a pure liquid is a function of the free space; that the increase in viscosity upon adding a solute is caused principally by the contraction, which has an effect similar to cooling the material. It is interesting, therefore, to see how this property of changing volume on solution changes with temperature. The necessary calculations could be made from the density data. Such data are summarized in Table III and shown graphically in Fig. 3.



1, Ether; 2, ethyl acetate; 3, methyl acetate; 4, urethan; 5, urea.

Fig. 2.—The viscosities of aqueous solutions of ethyl ether, ethyl acetate, methyl acetate, urethan and urea at 10 and 25°. The relative viscosities are plotted as ordinates, the concentrations expressed in moles per kg. of water as abscissas.

TABLE III

CONTRACTIONS TAKING PLACE UPON SOLUTION. CHANGE IN VOLUME (ML.) UPON FORMATION OF ONE LITER OF SOLUTION

Moles/kg. H_2O	0.2	0.4	0.6	0.8	1.0	1.5	2.0	2.5
			Ethyl Ether in Water					
25°	3.0	6.5	10.1	14.0				
10"	3.0	6.3	9.4	12.5				
			Ethyl Acetate in Water					
25°	1.9	3.7	5.5	7.2				
10"	1.9	3.7	5.6	7.4				
			Methyl Acetate in Water					
25° 10°	1.6	3.1	4.5	6.8	7.1	10.2	13.1	15.5
			Urea in Water					
25°		(0.6)			1.3	1.8	2.1	2.5
20°		(.8)			1.7	2.2	2.8	3.2
15°		(.9)			2.0	2.8	3.4	4.0
10°		(1.0)			2.2	3.1	3.8	4.6
5°		(1.3)			3.0	4.0	4.9	5.6

are the volume changes for solid urea dissolved in water. The densities of solid urea were found by interpolation from the data of Dewar given in the "International Critical Tables."[19] The contraction for each of the solutions was calculated and plotted, and the above values found by interpolation.

The volume changes for urethan solutions were also calculated, for 10, 20 and 25°, making use of the data in the preceding paper, and Block's[20] data for both solid urethan and the supercooled liquid urethan. If the former (for the solid) are used, an expansion results; if the latter, a contraction which decreases with an increase in temperature.[21] The volume

---

[19] "International Critical Tables," Vol. III, p. 45. The data used were

t, °C.	5	10	15	20	25
d_4^t	1.3215	1.3204	1.3194	1.3184	1.3173

The slopes of the curves seem to show that the specific volumes accepted for the urea are too large, that the calculated contractions are consequently too large. No data are available for estimating the specific volume of liquid urea at these temperatures.

[20] Block, *Z. physik.* Chem., 78,397 (1912).

[21] Contraction on formation of urethan solutions (interpolated data)

Moles/kg. H_2O	10°	20°	25°
1.0	4.1 (−0.1)	3.6 (−0.7)	3.3 (−1.1)
2.0	7.2 (− .5)	6.3 (−1.7)	5.9 (−2.3)
3.0	9.5 (−1.5)	8.3 (−3.0)	7.7 (−3.8)

The figures given in parentheses are expansions calculated from the densities of solid urethan; the others are contractions as calculated from supercooled liquid. The data used for the volume of 1 g. of urethan, either liquid or solid, are as follows (interpolated or extrapolated)

	10°	20°	25°
Liquid	0.9149	0.9230	0.9271
Solid	,8641	.8704	.8736

changes upon solution of urethan at 20° have been studied by Richards and Palitzsch.[22] They have pointed out that the expansion upon the solution of solid is probably caused by a large expansion due to the breaking up of the crystalline material counteracted by a contraction caused by the change in polymerized water. Our conclusion drawn from this interpolation is that the specific volume of molten urethan should be used to calculate the contraction, but its value is so uncertain, because of the large extrapolation, that little confidence can be placed in the results; consequently they are not plotted in Fig. 3.

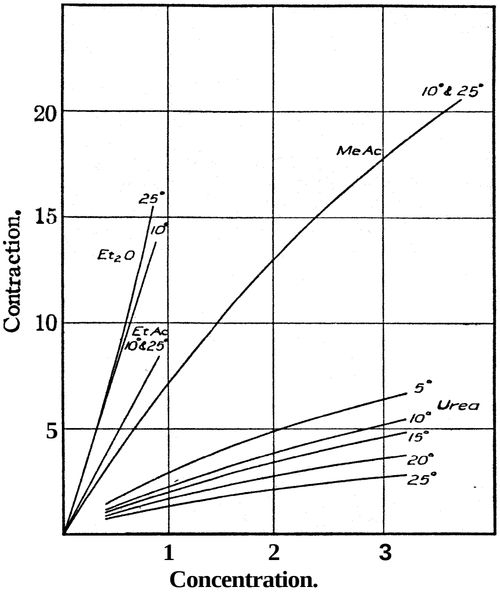

Fig. 3.—The contraction upon formation of aqueous solutions of ethyl ether, ethyl acetate and methyl acetate at 10 and 25°, and of urea at temperatures between 5 and 25°. The decreases in volume (ml.) upon formation of 1 liter of solution are plotted as ordinates, the concentrations expressed in moles per kg. of water as abscissas.

That the volume changes upon solution of the esters are the same at 10 and 25°, within the experimental error, is a surprise. One would expect a greater contraction at the lower temperature if it is assumed that the ester causes a depolymerization of the water, for water must be more highly polymerized at the lower temperature. More accurate density determinations probably would show slight differences.

The changes in volume on formation of solutions are interesting, irrespective of their bearing upon the question of viscosity. The method of representing concentration as moles of solute per 1000 g. of water is so chosen as to represent the effect of relative numbers of molecules of different solutes upon the same quantity (possibly different number of molecules) of water. The contraction is the greatest for ether, and successively less for ethyl acetate, methyl acetate and urea. This confirms the hypothesis that[1] the cohesive forces and internal pressures existing in the liquids play a large part in determining the volume of the systems. The forces under which the molecules of the various solutes exist in solutions of equivalent concentrations are probably about the same, and yet those forces are very different in

---

[22] Richards and Palitzsch, This Journal, 41, 60 (1919). Also Richards and Chadwell, *ibid.*, 47, 2283 (1925).

the pure liquids. When the molecular forces existing in a liquid are weak (small internal pressure), the liquid is light and volatile and possesses a large coefficient of compressibility. If such a liquid is distributed in a second liquid of greater internal forces, it would be exepcted that the volume would not be so large and that the extent to which a contraction took place would depend upon the difference in magnitude of the internal pressures. In the particular cases in question, the magnitudes of the contraction are in the same order as the coefficients of compressibility. The average compressibilities over the pressure range of 100–300 megabars at 20° are: ether 130, ethyl acetate 90 and methyl acetate 88.[1,23]

It is to be noticed that the viscosity and contraction curves in Pigs. 2 and 3 for the different solutes are in the same relative positions for either 10 or 25°; but this correlation does not hold when a single solute is considered, showing that the change in volume is not the only determining factor of the viscosity. The urea solutions, for instance, show the greater relative viscosity at the higher temperature, while the contractions are greater at the lower temperature. This can be explained by postulating that the decrease in viscosity due to the depolymerization of the water, taking place to a greater extent at the lower temperatures, more than balances the tendency to increase the viscosity caused by the contraction. Such a counterbalancing of effects is not apparent in the positions of the curves for other solutes. In support of this hypothesis it should be pointed out that the aqueous urea solutions are more nearly ideal than the others: the internal pressures of the pure substances are very nearly alike, their mutual solubility is great, and the formation of solutions is accompanied by a small volume change.

Viscosity curves of binary liquid mixtures which show maxima have commonly been explained by assuming compound formation. If this is the real explanation, solvation is a very general phenomenon—more general than other properties of solutions would lead us to believe. The relative viscosity of all of these solutions (except urea) diminishes with an increase in temperature. In the case of aqueous solutions of salts[24] this is found to occur only in those solutions which contain highly hydrated materials, and is supposed to be due to the thermal decomposition of the hydrates.

In the cases of our particular solutes, freezing point measurements[25] have been made and the solutions found to be normal. Kendall and Harrison have interpreted the normal depressions caused by esters to mean that

hydrates are formed which counterbalance negative deviations from Raoult's law arising from the fact that the solutions are not perfect.

The development of our knowledge of liquids from the electrical standpoint is only beginning, and yet enough progress has resulted to show that such a property as viscosity may well be considered from this point of view. Jones and Dole,[26] for instance, have shown that the viscosity of dilute salt solutions can best be represented by a formula which takes into account the effect of interionic forces. For binary mixtures of different liquids the shape of the viscosity–concentration curve depends upon the electrical nature of the molecules. If both of the components are non-polar, or one is dipolar (in the sense used by Debye) the curve is concave, but if both components are dipolar, the curve is convex.[27] Our liquid mixtures are composed of dipolar molecules, their electric moments[28] in the liquid state being: water 1.8, ether 1.24, methyl acetate 1.67 and ethyl acetate 1.74 (all X 10^{18}). These polar molecules in solution would be orientated[29] by the electrostatic field produced by other molecules into more or less orderly arrangements which might very well be manifested by an increase in the relative viscosity, as well as a contraction in volume. Furthermore, an increase in temperature reduces this orientation and the viscosity would become less, as is shown by the experimental data. A quantitative analysis of this contributing effect must await more extensive determinations of dielectric constants and the development of the theory of viscosity of liquids.

We wish to express our gratitude to the Elizabeth Thompson Science Fund for financial aid in this investigation.

Summary

The viscosities of aqueous solutions were determined at 10° of diethyl ether, methyl acetate, ethyl acetate, urethan and urea. In addition, measurements were made on urea solutions at 5, 15, 20 and 25°.

The contractions on solution of these substances were calculated from the densities, and the connection between these two properties was discussed.

Aqueous solutions of urea did not possess viscosities less than water at any of the concentrations studied, although the curvature of the viscosity–concentration curve was found to be positive. These solutions do not seem to be exceptions to the rule that aqueous solutions of non-electrolytes pos-

sess a viscosity greater than that of water, irrespective of the viscosity of the solute.

The effect of depolymerization of water upon the property of viscosity was no more apparent at 10° than at 25°, except possibly in the case of the urea solutions.

The results were discussed from the point of view of compound formation and orientation of polar molecules.

THE TITRATION CONSTANTS OF MULTIVALENT SUBSTANCES

BY ALEXANDER L. VON MURALT

RECEIVED APRIL 25, 1930 PUBLISHED SEPTEMBER 5, 1930

It has long been known that the titration curve of a multivalent acid resembles that of a mixture of monovalent acids. Based upon the apparent identity of these two classes of titration curves, as judged by experiment, H. S. Simms[1] has developed equations which correlate the apparent with the true dissociation constants of a multivalent acid. The equations are given for a divalent and trivalent acid, and the same considerations readily yield the equations for any number of valencies.

Apparently without knowledge of Simms' contribution, H. H. Weber[2] has recently treated this problem in a very similar manner. The equations which he obtains are more restricted and not as generally applicable as those developed by Simms, since he introduced the further assumption that the titration curve of the multivalent acid resembles that of a single monovalent acid. In discussing these two papers in our seminar, it became apparent that the assumption of resemblance is unnecessary, for the general equations of Simms may be obtained by a purely mathematical transformation of the classical dissociation equations given by the mass law.[3] This mathematical transformation yields no equations other than those developed by Simms, but in that the same relations are obtained without any assumption, the behavior of multivalent substances as described by the classical equations is vested with a slightly altered interpretation which rendered it desirable to communicate the calculations.

The classical dissociation constants for the n steps of dissociation of a multivalent acid may be written

[1] H. S. Simms, THIS JOURNAL, 48, 1239 (1926).

[2] H. H. Weber, Biochem. Z., 189, 381 (1927).

[3] In a previous seminar Professor Scatchard was able to derive Weber's equations on the assumption that the probability of dissociation was the same for each group, and independent of the number of groups dissociated.

$$
\begin{aligned}
K_1' &= \frac{[\mathrm{H}][\mathrm{H}_{n-1}\mathrm{A}']}{[\mathrm{H}_n\mathrm{A}]} \\
K_1'K_2' &= \frac{[\mathrm{H}]^2[\mathrm{H}_{n-2}\mathrm{A}'']}{[\mathrm{H}_n\mathrm{A}]} \\
&\vdots \\
K_1'K_2'\ldots K_n' &= \frac{[\mathrm{H}]^n[\mathrm{A}^{n-}]}{[\mathrm{H}_n\mathrm{A}]}
\end{aligned}
\qquad (1)
$$

The dissociation of a monovalent as well as of a multivalent acid can be described in terms of the following ratios

$$(1)\quad \frac{\text{Concentration of dissociated hydrogen ions}}{\text{Concentration of undissociated hydrogen ions}} = \alpha$$

$$(2)\quad \frac{\text{Concentration of dissociated hydrogen ions}}{\text{Equivalent concentration}} = \beta$$

$$(3)\quad \frac{\text{concentration of undissociated hydrogen ions}}{\text{Equivalent concentration}} = \rho$$

In terms of the classical dissociation constants these ratios take the form

$$\alpha = \frac{\dfrac{K_1'}{[\mathrm{H}]} + 2\dfrac{K_1'K_2'}{[\mathrm{H}]^2} + \ldots\ldots + (n-1)\dfrac{K_1'K_2'\ldots K_{n-1}'}{[\mathrm{H}]^{n-1}} + n\dfrac{K_1'K_2'\ldots K_n'}{[\mathrm{H}]^n}}{n + (n-1)\dfrac{K_1'}{[\mathrm{H}]} + (n-2)\dfrac{K_1'K_2'}{[\mathrm{H}]^2} + \ldots\ldots + \dfrac{K_1'K_2'\ldots K_{n-1}'}{[\mathrm{H}]^{n-1}}} \qquad (2)$$

$$\beta = \frac{1\dfrac{K_1'}{[\mathrm{H}]} + 2\dfrac{K_1'K_2'}{[\mathrm{H}]^2} + \ldots\ldots + (n-1)\dfrac{K_1'K_2'\ldots K_{n-1}'}{[\mathrm{H}]^{n-1}} + n\dfrac{K_1'K_2'\ldots K_n'}{[\mathrm{H}]^n}}{n\left(1 + \dfrac{K_1'}{[\mathrm{H}]} + \dfrac{K_1'K_2'}{[\mathrm{H}]^2} + \ldots\ldots + \dfrac{K_1'K_2'\ldots K_{n-1}'}{[\mathrm{H}]^{n-1}} + \dfrac{K_1'K_2'\ldots K_n'}{[\mathrm{H}]^n}\right)} \qquad (3)$$

$$\rho = \frac{n + (n-1)\dfrac{K_1'}{[\mathrm{H}]} + (n-2)\dfrac{K_1'K_2'}{[\mathrm{H}]^2} + \ldots\ldots + \dfrac{K_1'K_2'\ldots K_{n-1}'}{[\mathrm{H}]^{n-1}}}{n\left(1 + \dfrac{K_1'}{[\mathrm{H}]} + \dfrac{K_1'K_2'}{[\mathrm{H}]^2} + \ldots\ldots + \dfrac{K_1'K_2'\ldots K_{n-1}'}{[\mathrm{H}]^{n-1}} + \dfrac{K_1'K_2'\ldots K_n'}{[\mathrm{H}]^n}\right)} \qquad (4)$$

These rather complicated expressions[4] can be simplified considerably by a mathematical transformation, known as separation into *partial fractions.* The rational algebraic expression $F(x)/\Phi(x)$ can be expressed as the sum of partial fractions, which have the several factors of $\Phi(x)$ as denominators and which have constants for numerators. In order to show how Equations **2,** **3** and 4 can be separated into partial fractions, the detailed calculation for **3** is given here. With appropriate modifications the same method **can** be applied to **(2)** and (4).

---

[4] The terms in the mass law equations have, for mathematical convenience, been written as stoichiometrical concentrations rather than as activities. Activity coefficients could, of course, be introduced into these series.

The first step which is taken is to render Equation 3 more convenient for further transformation by multiplying both numerator and denominator by $[\mathrm{H}]^n$

$$\beta = \frac{1K'_1[\mathrm{H}]^{n-1} + 2K'_1K'_2[\mathrm{H}]^{n-2} + \ldots\ldots + (n-1)\,K'_1K'_2\ldots K'_{n-1}[\mathrm{H}] + n\,K'_1K'_2\ldots K'_n}{n\,([\mathrm{H}]^n + K'_1[\mathrm{H}]^{n-1} + K'_1K'_2[\mathrm{H}]^{n-2} + \ldots\ldots + K'_1K'_2\ldots K'_{n-1}[\mathrm{H}] + K'_1K'_2\ldots K'_n} \tag{3a}$$

In (3a) the denominator has the form of the expansion of the general polynomial

$$(\kappa_1 + x)\,(\kappa_2 + x)\,(\kappa_3 + x)\ldots\ldots(\kappa_n + x) \tag{4a}$$

which in the expanded form can be written

$$x^n + \Sigma\kappa_1x^{n-1} + \Sigma\kappa_1\kappa_2x^{n-2} + \Sigma\kappa_1\kappa_2\kappa_3x^{n-3} + \ldots + \Sigma\kappa_1\kappa_2\kappa_3\ldots\kappa_n \tag{4b}$$

The symbol $\Sigma\kappa$ represents the sum of the elements $\kappa_1 + \kappa_2 + \kappa_3 + \ldots\kappa_n$, $\Sigma\kappa_1\kappa_2$ the sum of the combinations without repetition of the elements $\kappa_1, \kappa_2, \ldots\kappa_n$ taken two at a time, $\Sigma\kappa_1\kappa_2\kappa_3$ the sum of the combinations without repetition of the elements $\kappa_1, \kappa_2, \ldots\kappa_n$ taken three at a time, and so forth.

Comparison of Equation 4b with the denominator in (3a) shows that both are identical except for the factors of corresponding powers of [H] and x. By equating the undeterminate factors of corresponding powers of [H] and x, n equations are obtained which define completely the new factors κ_1, $\kappa_2, \ldots\kappa_n$ in terms of the old factors $K'_1, K'_2, \ldots K'_n$.

$$\begin{aligned}
K'_1 &= \Sigma\kappa_1 &&= \kappa_1 + \kappa_2 + \kappa_3 + \ldots\ldots\kappa_n \\
K'_1K'_2 &= \Sigma\kappa_1\kappa_2 &&= \kappa_1\kappa_2 + \kappa_1\kappa_3 + \ldots + \kappa_1\kappa_n + \ldots\kappa_{n-1}\kappa_n \\
K'_1K'_2K'_3 &= \Sigma\kappa_1\kappa_2\kappa_3 &&= \kappa_1\kappa_2\kappa_3 + \kappa_1\kappa_3\kappa_4 + \ldots\ldots\kappa_{n-2}\kappa_{n-1}\kappa_n \\
&\ldots\ldots && \ldots\ldots \\
&\ldots\ldots && \ldots\ldots \\
K'_1K'_2\ldots\ldots K'_n &= \Sigma\kappa_1\kappa_2\ldots\kappa_n &&= \kappa_1\kappa_2\kappa_3\ldots\ldots\kappa_n
\end{aligned} \tag{5}$$

Consequently we may write

$$\begin{aligned}
&n\,([\mathrm{H}]^n + K'_1[\mathrm{H}]^{n-1} + K'_1K'_2[\mathrm{H}]^{n-2} + \ldots\ldots + K'_1K'_2\ldots K'_{n-1}[\mathrm{H}] + K'_1K'_2\ldots K'_n) \equiv \\
&\equiv n\,([\mathrm{H}]^n + \Sigma\kappa_1[\mathrm{H}]^{n-1} + \Sigma\kappa_1\kappa_2[\mathrm{H}]^{n-2} + \ldots\ldots + \Sigma\kappa_1\kappa_2\ldots\kappa_{n-1}[\mathrm{H}] + \Sigma\kappa_1\kappa_2\kappa_3\ldots\kappa_n) \equiv \\
&\equiv n\,((\kappa_1 + [\mathrm{H}])(\kappa_2 + [\mathrm{H}])\cdot(\kappa_3 + [\mathrm{H}])\ldots\ldots(\kappa_n + [\mathrm{H}]))
\end{aligned} \tag{6a}$$

The numerator can also be transformed by means of the same set of Equations (5), yielding the following identity

$$\begin{aligned}
&\frac{1K'_1[\mathrm{H}]^{n-1} + 2K'_1K'_2[\mathrm{H}]^{n-2} + \ldots\ldots + (n-1)\,K'_1K'_2\ldots K'_{n-1}[\mathrm{H}] + n\,K'_1K'_2\ldots K'_n}{n\,([\mathrm{H}]^n + K'_1[\mathrm{H}]^{n-1} + K'_1K'_2[\mathrm{H}]^{n-2} + \ldots\ldots + K'_1K'_2\ldots K'_{n-1}[\mathrm{H}] + K'_1K'_2\ldots K'_n)} \equiv \\
&\equiv \frac{1\,\Sigma\kappa_1[\mathrm{H}]^{n-1} + 2\,\Sigma\kappa_1\kappa_2[\mathrm{H}]^{n-2} + \ldots\ldots + (n-1)\,\Sigma\kappa_1\kappa_2\ldots\kappa_{n-1}[\mathrm{H}] + n\,\Sigma\kappa_1\kappa_2\ldots\kappa_n}{n\,((\kappa_1 + [\mathrm{H}])\,(\kappa_2 + [\mathrm{H}])\,(\kappa_3 + [\mathrm{H}])\ldots\ldots(\kappa_n + [\mathrm{H}])}
\end{aligned} \tag{6b}$$

This transformed expression of (3) may now be separated into partial fractions and we may write

$$\begin{aligned}
&\frac{\Sigma\kappa_1[\mathrm{H}]^{n-1} + 2\,\Sigma\kappa_1\kappa_2[\mathrm{H}]^{n-2} + \ldots\ldots + (n-1)\,\Sigma\kappa_1\kappa_2\ldots\kappa_{n-1}[\mathrm{H}] + n\,\Sigma\kappa_1\kappa_2\kappa_n}{n\,((\kappa_1 + [\mathrm{H}])\,(\kappa_2 + [\mathrm{H}])\,(\kappa_3 + [\mathrm{H}])\ldots\ldots(\kappa_n + [\mathrm{H}]))} \equiv \\
&\equiv \frac{1}{n}\left(\frac{\kappa_1}{\kappa_1 + [\mathrm{H}]} + \frac{\kappa_2}{\kappa_2 + [\mathrm{H}]} + \frac{\kappa_3}{\kappa_3 + [\mathrm{H}]} + \ldots\ldots + \frac{\kappa_n}{\kappa_n + [\mathrm{H}]}\right)
\end{aligned} \tag{7}$$

The proof that the separation into partial fractions (7) is correct may be obtained by clearing the left and the right side of fractions. Since this procedure is well known to those familiar with partial fractions, it has been omitted.

Applying the same transformation to Equations 2 and 4, corresponding identities are obtained, which are given without the calculation, as the procedure is very much the same as for Equation **3.**

$$\alpha = \frac{\frac{\kappa_1}{\kappa_1+[H]} + \frac{\kappa_2}{\kappa_2+[H]} + \frac{\kappa_3}{\kappa_3+[H]} + \dots\dots + \frac{\kappa_n}{\kappa_n+[H]}}{[H]\left(\frac{1}{\kappa_1+[H]} + \frac{1}{\kappa_2+[H]} + \frac{1}{\kappa_3+[H]} + \dots\dots + \frac{1}{\kappa_n+[H]}\right)} \qquad (2')$$

$$\beta = \frac{1}{n}\left(\frac{\kappa_1}{\kappa_1+[H]} + \frac{\kappa_2}{\kappa_2+[H]} + \frac{\kappa_3}{\kappa_3+[H]} + \dots\dots + \frac{\kappa_n}{\kappa_n+[H]}\right) \qquad (3')$$

$$= \frac{1}{n}\left(\frac{[H]}{\kappa_1+[H]} + \frac{[H]}{\kappa_2+[H]} + \frac{[H]}{\kappa_3+[H]} + \dots\dots + \frac{[H]}{\kappa_n+[H]}\right) \qquad (4')$$

Equations 2′, 3′ and 4′ were derived from (2), (3) and (4) by separation into partial fractions and by introducing a set of new constants $\kappa_1,\kappa_2,\dots.\kappa_n$ for mathematical convenience. If one formulates the fractions α, β, p for a mixture of monovalent acids, with dissociation constants $G'_1,G'_2\dots G'_n$ (using Simms' notation), an identical set of equations is obtained, in which the $G'_1,G'_2\dots G'_n$ replace the constants $\kappa_1,\kappa_2\dots.\kappa_n$.

$$\kappa_1 = G'_1; \quad \kappa_2 = G'_2; \quad \dots\dots \quad \kappa_n = G'_n$$

These constants which have so far been used as a mathematical convenience without any specific meaning attached to them, are therefore the titration constants, and in order not to complicate the nomenclature can be replaced by the titration constants of Simms. They are related to the classical constants by Equation 5, which is, of course, identical with the equation, previously developed by Simms, with the assumption of similarity. In our treatment we have assumed only validity of the classical mass law equations and the result has been derived by mere mathematical transformation of these equations. It follows, therefore, that between the titration curve of a multivalent acid and a mixture of monovalent acids there is no difference. In other words, if the classical dissociation constants of a multivalent acid are known, it is possible to make a mixture of monovalent acids which will give exactly the same titration curve, provided that the individual dissociation constants of the monovalent acids satisfy Equations 5.

Generally one deals with the opposite problem. From the titration curve the titration constants $G'_1,G'_2\dots G'_n$ are experimentally obtained and the classical constants $K'_1,K'_2,\dots K'_n$ can be determined by using Equations 5. We wish again to emphasize that this is only valid in so far as the classical mass law formulation is an accurate description of the facts. Provided this is the case, there is no difference between the dissociation of a multivalent acid and a properly chosen mixture of monovalent acids, and the titration constants are at the same time the "intrinsic" constants of the groups.[5] This relation of course will hold only if the electrostatic work of ionization and the work which is involved in distortion of the molecule are disregarded.

The formulas given by Weber can also be obtained from Equations 5 by assuming that the $G'_1, G'_2, \ldots G'_n$ are all equal, an assumption which Weber has introduced by stating that the titration curve of the multivalent acid resembles that of a single monovalent acid. On this assumption much simpler identities result. Instead of *n* titration constants, one alone is found, therefore

$$G'_1 = G'_2 = G'_3 = \ldots\ldots = G'_n = G'$$

$$\alpha = \frac{G'}{[\mathrm{H}]} \quad (2'') \qquad \beta = \frac{G'}{G' + [\mathrm{H}]} \quad (3'') \qquad \rho = \frac{[\mathrm{H}]}{G' + [\mathrm{H}]} \quad (4'')$$

and the classical dissociation constants are defined by

$$K'_1 = n\,G'; \quad K'_2 = \frac{n-1}{2}G'; \quad K'_3 = \frac{n-2}{3}G'; \quad \ldots; \quad K'_n = \frac{1}{n}G' \qquad (5'')$$

relations which are of course identical with those of Weber. It is obvious that the values of $K'_1, K'_2, \ldots K'_n$ in Equations $5''$ are not independent of each other, since they are all related to definite fractions of one titration constant G^1.

Similar conditions are obtained from the titration data of proteins. Instead of obtaining *n* independent values for the titration constants G', these constants seem to fall into groups of *m* elements which are identical. Therefore only n/m independent values are obtained. This reduces the number of independent Equations 5, relating the titration constants with the classical constants, to n/m. The *n* classical constants K' fall, therefore, into n/m groups of related constants. The case which has been treated by Weber represents grouping of the titration constants G' into one group of identical constants $(n = m)$. For the corresponding group of classical constants K' the following relation is obtained

$$\frac{K'_1}{n} = \frac{2K'_2}{n-1} = \frac{3K:}{n-2} = \ldots\ldots = \frac{nK'_n}{1} \qquad (5a'')$$

The same transformation is applicable in the case of the formula defining the stepwise dissociation of hemoglobin.[6] The equation for the four steps of dissociation is given as

$$\text{Percentage saturation} = \frac{100\gamma'[\mathrm{Hb_4}]\,(K'_1[\mathrm{O_2}] + 2K'_1K'_2[\mathrm{O_2}]^2 + 3K'_1K'_2K'_3[\mathrm{O_2}]^3 + 4K'_1K'_2K'_3K'_4[\mathrm{O_2}]^4)}{4\gamma'[\mathrm{Hb_4}]\,(1 + K'_1[\mathrm{O_2}] + K'_1K'_2[\mathrm{O_2}]^2 + K'_1K'_2K'_3[\mathrm{O_2}]^3 + K'_1K'_2K'_3K'_4[\mathrm{O_2}]^4)} \qquad (9)$$

Separation into partial fractions gives the simpler identity

---

Percentage saturation =

$$\frac{100\gamma'}{4\gamma'}\left(4-\left(\frac{G'_1}{G'_1+[O_2]}+\frac{G'_2}{G'_2+[O_2]}+\frac{G'_3}{G'_3+[O_2]}+\frac{G'_4}{G'_4+[O_2]}\right)\right) \quad (9a)$$

and the new constants are related to the old constants by the four equations

$$\frac{1}{K'_4} = \Sigma G'_1 = G'_1 + G'_2 + G'_3 + G'_4 \quad (9b)$$

$$\frac{1}{K'_4K'_3} = \Sigma G'_1G'_2 = G'_1G'_2 + G'_1G'_3 + G'_1G'_4 + G'_2G'_3 + G'_2G'_4 + G'_3G'_4$$

$$\frac{1}{K'_4K'_3K'_2} = \Sigma G'_1G'_2G'_3 = G'_1G'_2G'_3 + G'_1G'_2G'_4 + G'_2G'_3G'_4 + G'_1G'_3G'_4$$

$$\frac{1}{K'_4K'_3K'_2K'_1} = \Sigma G'_1G'_2G'_3G'_4 = G'_1G'_2G'_3G'_4$$

Expressing results in terms of classical constants necessitates the use of Equation 5, which is rather complicated. No substantial advantage is gained in doing this. It therefore appears advisable to express results directly in terms of titration constants and to abolish the classical constants altogether.

THE ETHERATES OF MAGNESIUM BROMIDE

BY WARD V. EVANS AND HOWARD H. ROWLEY[1]

RECEIVED APRIL 28, 1930 PUBLISHED SEPTEMBER 5, 1930

The fact that the halides of magnesium are capable of uniting with ether to form compounds similar to hydrates has been known since the beginning of this century. Menschutkin[2] was the first to study them and gave them the name "etherates." He investigated their solubility in ether at various temperatures and found that as the solution became more concentrated, a heavy, oily, immiscible layer separated. He discovered that this heavy layer could be greatly supercooled and that when it did crystallize the magnesium halide was obtained in the form of the di-etherate. Later, Meisenheimer[3] and his co-workers discussed some of the properties of this oily liquid and of the crystalline magnesium halide etherates.

From a review of the literature, it is apparent that very little is known concerning the formulas of these etherates. Some claim that they contain one molecule of ether;[4] others, that they contain two molecules,[5] while some

even claim that they contain three and four molecules[5a,b] of ether per molecule of magnesium halide. On the other hand, Ahrens and Stapler[6] claim that they obtained non-etherated magnesium halides precipitated from ether solution. It is also quite evident that little is known of the properties of these compounds.

Because of these conflicting statements, it was decided to make a study of the above-mentioned compounds using magnesium bromide as a typical magnesium halide.

Experimental Work

Preparation of Crystals.—Pure magnesium turnings were put into an Erlenmeyer flask and 100–200 cc. of dry ether added. All reasonable precautions were taken to eliminate air and moisture. Liquid bromine was then added, a few drops at a time, allowing the solution to clear considerably before the next addition was made. It was frequently advisable to cool the flask to keep the heat of reaction from boiling away the ether. Above a certain concentration (about 3% $MgBr_2$ at room temperature) two layers appeared, the upper one clear, colorless and of about the same density as ether, the bottom one a clear, heavy, oily liquid which usually ranged from very faint yellow to a reddish-brown. Only the faintly yellow layers crystallized but they gave beautiful crystals that seemed very pure. The crystals were prepared in two ways: (I) by separating the heavy bottom layer without contact with air or moisture and with a gentle suction removing part of the ether, leaving a supersaturated solution. Large crystals of magnesium bromide etherate were precipitated from the two layer system after standing for about one month. (II) By cooling the filtered two phase system below 10°, the heavy layer solidified forming white crystals. The clear liquid was decanted and the crystals drained. These crystals were much smaller than those prepared from the supersaturated solution but were easier to make and gave larger yields.

In analysis No. 1 the crystals were made at room temperature, dried in an atmosphere of ether, placed in a weighed test-tube fitted with a one-holed stopper carrying a

---

[6] Felix B, Ahrens and Adolf Stapler, *Ber.*, **38**,3264 (1905).

short piece of glass tubing and weighed. The tube was then evacuated under 50-mm. pressure for twelve hours. It was then reweighed and the loss in ether recorded.

In analysis No. 2 the tube from analysis No. 1 was heated while being evacuated to constant weight. By comparing the last weight with the original weight, it was possible to determine the total weight of ether lost. It is seen that approximately one molecule of ether was lost quite easily by the first evacuation, while the total loss was two molecules, indicating that the crystals investigated contained two molecules of ether originally.

In analysis No. 3 the tube was left for forty hours at room temperature under a pressure of 50 mm. Since these crystals had been exposed for quite a time no effort was made to determine the total amount of ether lost but simply the amount left after the first evacuation.

In analyses Nos. 4, 5 and 6 the crystals were prepared by cooling the heavy layer and then drying the resulting crystals in a stream of carbon dioxide. Since there was no time limit to the passing of carbon dioxide over the crystals and since the tri-etherate has a very high vapor pressure, it is not surprising that these results vary and that they show values too high for a di-etherate and too low for a tri-etherate.

In analyses Nos. 7 and 8 large crystals were formed slowly at room temperature and broken up and the central portion was taken for analysis; hence these values should be quite accurate.

In analyses Nos. 9 and 10 the crystals were made at 0° and transferred to a weighed flask. The weighed crystals were dissolved in water, diluted and an aliquot part taken and analyzed. The results are low but indicate an etherate higher than the di-etherate.

In analyses Nos. 11, 12 and 13 the crystals were prepared at 0° but in a weighed flask. They were drained for one-half hour below 10°, weighed and analyzed. There was little chance for loss of ether due to exposure in these analyses.

From the results it seems clear that there are three definite etherates of magnesium bromide: (1) the tri-etherate which is readily decomposed, (2) the di-etherate which is more common, and (3) the mono-etherate. If the etherate is made at a temperature of about 0° and dried at this temperature and carefully analyzed, we obtain the tri-etherate. If the crystals are at all exposed, owing to their high vapor pressure we have a mixture of the di- and tri-etherates. If the crystals are made at room temperature we get the di-etherate, and if a tube containing the di-etherate is evacuated at room temperature under a pressure of 50 mm., we obtain the mono-etherate.

Analysis of Liquid Layers.—Menschutkin[2] made the statement that the concentration of the di-etherate in the two liquid layers varied with the temperature; therefore, it was decided to verify this. The two-layer systems were made in the usual manner and filtered through glass wool. The mixtures were then placed in flasks surrounded by water at a known temperature. Some of the bottom layer was then drawn into a dry pipet, allowed to run into a tared tube and weighed. The ether was then driven off by suction and heating until the weight of the residue was constant. Considering the residue as anhydrous magnesium bromide and the loss in weight as due to the ether, it was possible to calculate the ratio of ether in the bottom layer to the magnesium bromide.

12	24	Vacuum + heat	1	3.45
		Average	1	3.50

Table II shows but slight change in concentration of the heavy oily layer with temperature. The irregularity of these results is due, no doubt, to the very slowly attained equilibria here involved. There is, however, a definite trend showing more ether in the solution at the higher temperature.

Table III shows a definite increase in magnesium bromide with temperature. The clear upper layer at room temperature always became cloudy and precipitated the heavy oily layer on cooling to a lower temperature. The amount of magnesium bromide in the upper layer at room temperature averaged about 3–3.5% and in the lower layer about 41%.

As to the composition of the top layer, there was very little work done. However, a few determinations were made by withdrawing five cubic centimeters with a pipet, putting it into a weighed crucible and treating with concentrated sulfuric acid. The ether was then burned off, the excess acid evaporated and the residue weighed as magnesium sulfate. From this, it was possible to determine the amount of magnesium bromide per 5 cc. of solution.

General Properties.—Some of the properties of the etherates mentioned in the literature were verified. The fact that the etherates were rather unstable and decomposed on contact with air and moisture, was brought out quite clearly by the analyses.

Action on Water.—The etherates are decomposed by water and ether is given off. Some experiments in which the volume of ether liberated from the di-etherate was measured indicated that one molecule of ether was displaced very readily but that the mono-etherate is more stable and requires a longer time for complete decomposition. This coincides with the work of Meisenheimer and Casper.[3]

Action of Absolute Alcohol.—When absolute alcohol was added to the crystals, ether was evolved as with water but not so vigorously.

Action of Dry Ether.—When ether was added to the di-etherate the crystals softened. When ether was added to the mono-etherate or the non-etherated magnesium bromide, there was a reaction and heat was given off, as was first noticed by Tschelinzeff.[5b]

Transition Points.—After it had been definitely shown that there are three distinct etherates, the next logical step was to determine the temperatures below which the various etherates are stable, that is, the points at which partial liquefaction takes place owing to the fact that ether is split off and the non-etherated or a lower etherated compound formed. Our work seemed to indicate that such points existed. The thermometric method failed; thus crystals prepared at 0° were heated slowly from 0 to 15° and the change in temperature plotted against time, but the curve showed no break. There did seem to be a change in the form of the crystals. The dilatometric method was also tried with no better result. This behavior can be explained on the ground that the equilibrium is very sluggishly attained and that the heat of formation of the etherate is rather low.

In spite of these negative results, experimental evidence strongly indicated a change in form of the crystals at about 13°. Crystals were prepared by cooling and then without decanting the excess liquid the crystals were maintained at some definite temperature for hours. By this method it was discovered that the crystals appeared to melt quite a bit below room temperature. Finally the value of 12.5° was reached, at which the crystals appeared stable. However, after about eight hours at this temperature (within 0.2°) the sharp outline of the crystals disappeared and a slow but nevertheless certain transformation of the crystals could be seen to be taking place.

Experiments were then conducted to approach the point from the other side. The two-layer mixtures were prepared and cooled to a definite constant temperature. They were then seeded with a crystal of the etherates. The temperature was raised each time until finally at 12.4° solidification took place very slowly. At 12.6' the heavy layer did not solidify when seeded. However, if this material stood for a month, crystals would grow in this layer as previously stated, but we considered them to be the di-etherate and not the tri-etherate.

Vapor Pressure Curves of Crystals.—If these etherates of magnesium bromide are definite compounds and have definite transition points, it should be possible to distinguish these points by means of their vapor pressures. It was decided that the static method of determination was best suited for this type of compound.

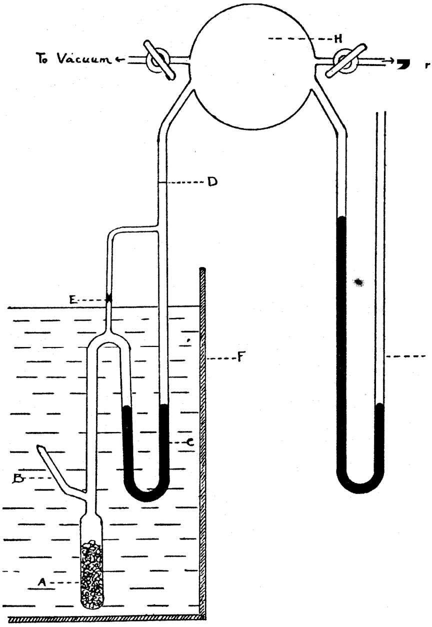

Fig. 1.—Apparatus for determining vapor pressure of crystals.

Apparatus.—Several types of apparatus were tried but due to the extreme ease with which the etherate crystals decomposed, it was found necessary to devise an apparatus in which the volume above the crystals was as small as possible. The apparatus in Fig. 1 was finally adopted as the most satisfactory. The entire apparatus with the exception of the bulb A was made from 8-mm. pyrex tubing. The bulb A and U-tube C were made separately for each determination and sealed to the permanent part at D. The bulb H was connected to the apparatus to give a larger volume and hence greater ease in regulating the height of the mercury in C. A commercial thermostat of standard make was used for all the determinations with this apparatus. The tenth of a degree thermometer used was compared to standard thermometers at frequent intervals.

Loading and Manipulation of Tensimeter.—The apparatus was washed with alcohol, then with ether, finally connected to the vacuum pump and heated with a blowtorch. The bulb A was then surrounded with ice and the crystals introduced through the side arm B, which was then sealed off. Mercury was placed in the U-tube C and the piece sealed to the rest of the apparatus at D. There was no water in the thermostat, the bulb A being surrounded with carbon dioxide snow. The apparatus was then connected to a vacuum oil pump which gave a vacuum of less than 1 mm. and the entire apparatus evacuated until the mercury ceased to rise in the manometer G. At the same time that the pressure became negligible (about one to two minutes), the connecting tube was sealed tight at E where a constriction had already been made. In this way the volume above the crystals was very small and at exactly the same temperature as the crystals themselves. Cold water was then run into the thermostat and as the vapor pressure of the crystals increased, air was let into the apparatus to equalize the levels of the mercury in the U-tube. If the vapor pressure decreased, air was drawn out.

Results.—After much experimenting at different temperatures, it was discovered that the temperature of the crystals at the time of evacuation was a very important factor. If the crystals were at 0° or even at $-10°$ the force of the pump was sufficient to decompose the tri-etherate and give lower values and inconsistent results. On the other hand, if the crystals were at the temperature of carbon dioxide snow, it was found that at this temperature the vapor pressure was only about 4 or 5 mm. and the crystals were not completely decomposed during the short time that the pump was in operation. On warming to a temperature of about 5°, the vapor pressure reached a value of about 233 mm., which is very close to the value for the vapor pressure of pure ether. The value, however, was a little low and reference to Fig. 2 will show how the variation increases with rise in temperature.

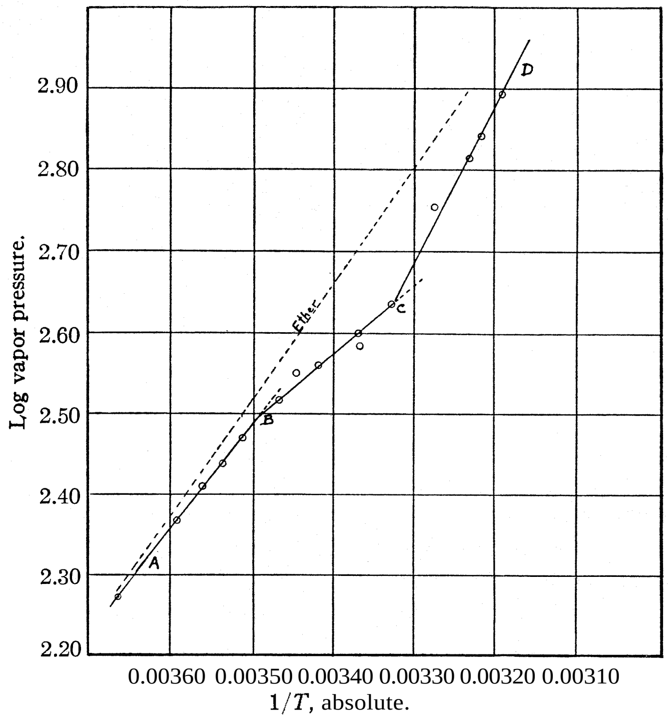

Fig. 2.—Vapor pressure curve starting with magnesium bromide tri-etherate at 5° and raising to 40°.

On raising the temperature of the crystals above 13°, they seemed to become soft with the appearance of some liquid. Above 30° they underwent a marked change with the formation of a large amount of liquid and a fine white precipitate. These changes were evident when the vapor pressure curves were drawn (Fig. 2).

TABLE IV

VAPOR PRESSURES STARTING WITH $MgBr_2 \cdot 3(C_2H_5)_2O$ AT 5° AND RAISING THE TEMPERATURE TO 40°

Temp. of bath, °C.	Barometer, mm.	Manometer, mm.	Vapor press., mm.	Log. V. P.	$1/T$ (abs.)
0.0	728.4	541	187.4	2.2728	0.003665
5.5	746	513	233	2.3674	.003590
7.9	751.5	494	257.5	2.4108	.003560
9.8	741	467	274	2.4378	.003536
11.8	747	452.5	294.5	2.4691	.003511
15 4	746	417.5	328.5	2.5165	.003468
17.3	742.5	387	355.5	2.5508	.003445
19.7	742	378.5	363.5	2.5605	.003416
23.9	737	353.5	383.5	2.5838	.003368
24.1	735.5	332.5	403	2.6053	.003366
27.2	735.5	308.5	427	2.6304	.003331
32.3	748	180	568	2.7544	.003275
36.3	746.5	93	653.5	2.8153	.003233
38.0	739	43	696	2.8426	.003215
40.4	738	+23.5	761.5	2.8817	.003191

In plotting the log of the vapor pressures against the inverse temperature (absolute), a straight line graph was produced (Fig. 2). This graph shows three distinct lines intersecting at two points (B and C). The first break in the curve occurs at 13.5°. The second break occurs at about 28°. Thus, the vapor pressure curves bear out the fact that three etherates of magnesium bromide exist: the tri-etherate, $MgBr_2 \cdot 3(C_2H_5)_2O$, stable below 13°; the di-etherate, $MgBr_2 \cdot 2(C_2H_5)_2O$, stable below 28°; and the mono-etherate, $MgBr_2(C_2H_5)_2O$, formed above 28°.

In reference to Fig. 2, it must be remembered that the lower curve AB is the vapor pressure curve for the system $MgBr_2 \cdot 3(C_2H_5)_2O$, $MgBr_2 \cdot 2(C_2H_5)_2O$, and ether vapor and at the transition point B we have the system $MgBr_2 \cdot 2(C_2H_5)_2O$, $MgBr_2 \cdot 3(C_2H_5)_2O$, solution and ether vapor. Thus, the next curve BC is the vapor pressure curve for $MgBr_2 \cdot 2(C_2H_5)_2O$, solution and ether vapor. In other words, it is the vapor pressure curve for a saturated solution of $MgBr_2 \cdot 2(C_2H_5)_2O$ in ether and not the curve for $MgBr_2 \cdot 2(C_2H_5)_2O$, $MgBr_2 \cdot (C_2H_5)_2O$ and ether vapor. At C, $MgBr_2 \cdot 2(C_2H_5)_2O$, $MgBr_2(C_2H_5)_2O$, solution and ether vapor are in equilibrium and the curve CD represented the system $MgBr_2(C_2H_5)_2O$, solution and ether vapor.

Since we have discovered that these systems reach equilibrium very slowly, it is only natural that if the temperature is raised suddenly, **the** solubility of $MgBr_2\cdot 2(C_2H_5)_2O$ in ether will increase, but if the solid dissolves very slowly to reach its equilibrium, the vapor pressure recorded will be the vapor pressure of an ether solution that is unsaturated with $MgBr_2\cdot 2(C_2H_5)_2O$ and since the vapor pressure decreases with concentration, this vapor pressure will be too high. On the other hand, if the temperature is lowered suddenly from an equilibrium at high temperature, we will have a solution supersaturated with respect to $MgBr_2\cdot 2(C_2H_5)_2O$ and hence a lower vapor pressure than we should have at this temperature. This would explain some of the difficulties encountered with the curves BC and CD in Fig. 2.

TABLE V

VAPOR PRESSURE OF $MgBr_2\cdot 2(C_2H_5)_2O$ SYSTEM

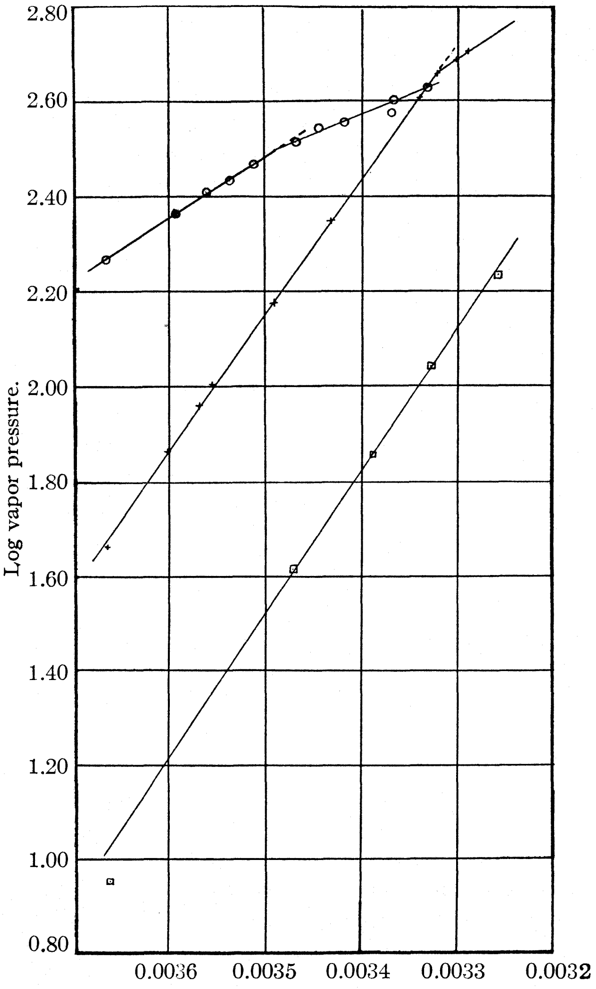
TABLE VI

VAPOR PRESSURE OF $MgBr_2\cdot(C_2H_5)_2O$ SYSTEM

Temp. of bath, °C.	Barometer, mm.	Manometer, mm.	Vapor press., mm.	Log. V. P.	1/T (abs.)
0.0	742	733	9	0.9542	0.003665
15.1	741	699.5	41.5	1.6180	.003471
22.1	742.5	670	72.5	1.8603	.003389
27.5	742.5	630.5	112	2.0492	.003328
34.1	739	566	173	2.2380	.003256

Figure 3 shows the vapor pressure curves of the three etherate crystals. Curve I is that of the tri-etherate, $MgBr_2\cdot 3(C_2H_5)_2O$, $MgBr_2\cdot 2(C_2H_5)_2O$ and ether vapor, showing the break at about 13°, where a solution of the di-etherate in ether is formed. Curve II is that of the di-etherate, $MgBr_2\cdot 2(C_2H_5)_2O$, mono-etherate and ether vapor, showing the point at about 28° where another molecule of ether is given off and a solution of the mono-etherate in ether is formed. The lower curve, III, is that of the mono-etherate crystals, $MgBr_2\cdot(C_2H_5)_2O$, $MgBr_2$ and ether vapor.

If these ether compounds of magnesium bromide are definite crystalline substances, it should be possible to obtain a "step" curve showing the vapor pressures of the different compounds at a constant temperature. A sample of the magnesium bromide–ether compound prepared by cooling the two-layer mixture, as previously described, was placed in a bulb connected to a manometer and fitted with a stopcock connected to a vacuum pump. The procedure consisted of drawing all the gas from the system with the pump, closing the stopcock and allowing the system to come to equilibrium. At first the bulb was immersed in a bath of solid carbon dioxide and acetone during the evacuation, which lasted for about one minute, in order to prevent the complete decomposition of the higher



○, Tri-etherate; +, di-etherate; □, mono-etherate.

Fig. 3.—Vapor pressure curves of etherate crystals of $MgBr_2$.

etherate before measurement could be taken. After closing the stopcock, this low temperature bath was replaced by ice and water, at which temperature the system was allowed to come to equilibrium. When all of the crystals had changed to the di-etherate, the time of evacuation was lengthened until some of the periods were for over an hour. During the latter part of the run the ice-bath was kept in place continually. Plotting vapor pressure of the crystals against the number of times evacuated, we

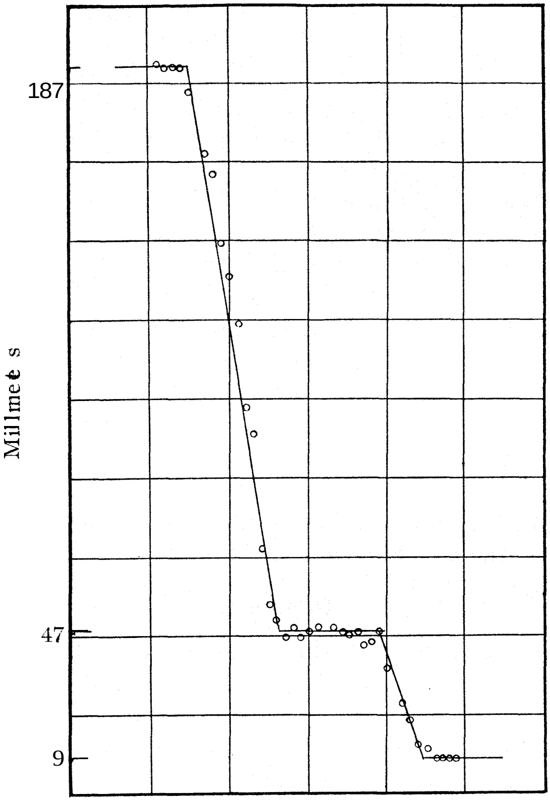


Fig. 4.—Vapor pressure of various etherates at 0°.

obtain a "step" curve as indicated in Fig. 4. The tri-etherate of magnesium bromide is shown with a pressure of 187 mm. at 0°. The pressure then drops to 47 mm., indicating a change to the di-etherate form. From this point it drops to 9 mm., which is the vapor pressure of the mono-etherate of magnesium bromide at 0°. This curve took about thirty days to complete due to slow equilibrium of the system.

Discussion

The most outstanding fact discovered in working with the etherate crystals of magnesium bromide is the slowness with which they change form. This was evident in all the experiments carried out in this Laboratory and was the reason why negative results were obtained in trying to determine the transition point of the crystals by means of the thermometric and dilatometric methods, even though there is quite a noticeable heat change in the transformation. No doubt this fact was also responsible for Menschutkin's statement that the crystals of the di-etherate of magnesium bromide melted at 22.8°.[2] He evidently prepared the crystals by cooling and then tried to determine the melting point in the usual way by slowly raising the temperature. As has been shown above, it is very easy to raise the temperature of the crystals to room temperature before they start to change form. In such a case it is not surprising that he obtained a value of 22.8"; a value, incidentally, which was not found in any of the work done in this Laboratory.

Because of the low transition point of the tri-etherate with extremely high vapor pressure and consequent unstability, it is not surprising that most of the workers reported the di-etherate as the only form, with an occasional mention of the mono-etherate. The principal fact that led to the exact identification of the tri-etherate was the break in the vapor pressure curve at 13°. If this break was the transition point of the di-etherate, it was extremely difficult to explain how it was possible to obtain the di-etherate crystals above this temperature. Thus, experiments were started to prove the existence of the third form with the success shown by the analyses. After the completion of this work, Meisenheimer[7] independently published an article stating the existence and some of the properties of this tri-etherate of magnesium bromide.

Summary

1. The existence of three distinct etherates of magnesium bromide has been shown.

2. Two transition points of the crystals were obtained, one where the tri-etherate changes to the di-etherate at 13 ± 0.5°, and the other where the di-etherate changes to the mono-etherate at 28 ± 1.0°.

3. Some of the properties of the etherates were studied with special reference to the slowness with which transition takes place.

4. The vapor pressures of the crystals were measured and the curves plotted.

RECEIVED MAY 31, 1930 PUBLISHED SEPTEMBER 5, 1930

A large number of metallic oxides act as oxidation catalysts. In general this property can be explained by the fact that they are readily reduced to the metals or to lower oxides by the substances to be oxidized and are then re-oxidized by oxygen. This explanation seems to be adequate for certain oxides, such as the oxides of copper, nickel, cobalt, manganese, molybdenum, vanadium, etc. For certain other oxides, however, the mechanism is not quite so apparent, because, as far as is known, they are not readily reduced to lower oxides. For example, La_2O_3 and Y_2O_3 are active oxidation catalysts, but are not readily reduced.

A great many oxides have been used and with success in certain cases. A review of the literature indicated that even with the more commonly used catalysts there is still much work to be done, especially with regard to finer control and better methods for analyzing the products formed. In many cases the percentage of unoxidized material recovered is given, with no information concerning the method of recovery. In work of this nature where so many factors can influence the results, it is most important to choose analytical methods very carefully and only after thorough trial.

The oxidizing properties of cerium compounds have been known for a long time. In general for vapor phase oxidation at elevated temperatures they have been found to be too active, and the extent of the oxidation could not be easily controlled. The other elements of the rare earth group have not been studied. Apparently no work has been done with mixed catalysts, containing rare earth elements, for vapor phase oxidation.

The purpose of this investigation was two-fold: (1) to obtain quantitative data on the rare earth oxides as catalysts for vapor phase oxidation as compared with some less active catalyst such as copper oxide, and (2) to measure the effect produced by the addition of small amounts of rare earth oxides to some less active catalyst such as copper oxide.

After numerous preliminary experiments, samarium oxide was chosen because of its greater porosity. All of the members of the cerium group were tried and appeared to be equally active. Of the yttrium group only two, yttrium and lanthanum, were used in the preliminary work. They appeared to be less active oxidation catalysts and were much more apt to produce charring.

The preliminary work included oxidation of methyl alcohol, ethyl alcohol, ethylene, benzene and toluene. Some of the products qualitatively determined were not only interesting, but hold much promise for future work. Benzene, for example, yielded small amounts of phenol. Among the oxidation products of toluene, dibenzyl, benzaldehyde and benzoic acid were detected. Due to the greater ease of oxidation of methyl and ethyl alcohols, the rate of reaction, the temperature, etc., are more difficult to control. It was decided, therefore, to investigate carefully the oxidation of these alcohols first, with the hope that the data obtained would be useful in later experiments on the oxidation of substances not so readily oxidized.

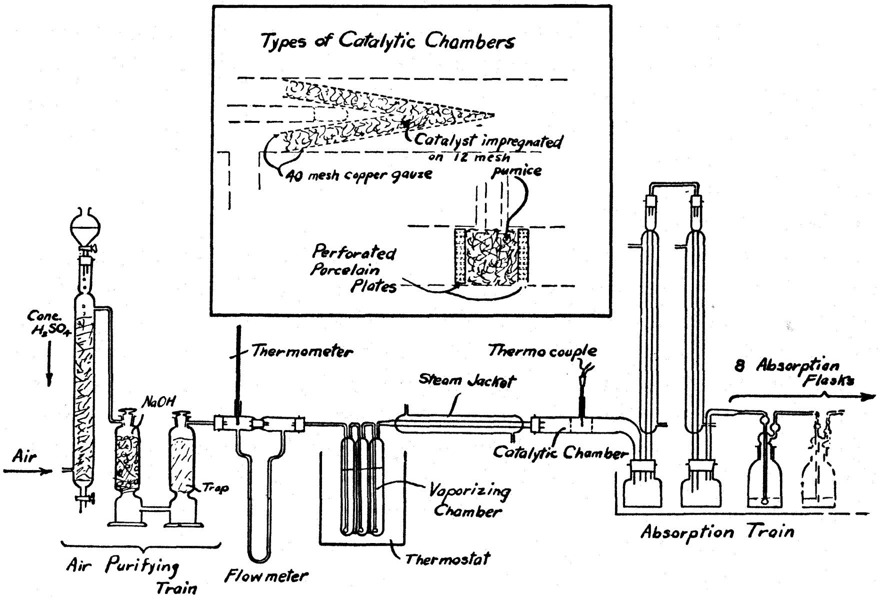

Fig. 1.—Apparatus.

The apparatus used is shown in Fig. 1. The arrangement of the apparatus was similar to that used by Le Blanc and Plaschke.[1] Dry air in definite amounts (as measured by a flowmeter) was passed through the alcohol contained in the vaporizing chamber. The outlet tube leading from the vaporizing chamber to the catalytic chamber was heated by means of a steam jacket to prevent condensation. The alcohol–air mixture was then passed over the catalyst in the pyrex catalytic chamber. The catalyst was supported (in the case of impregnated pumice) at each end by tightly fitting, finely perforated porcelain plates. The catalyst was 15 mm. in length and 17 mm. in diameter. In the cone type of catalyst two concentric cones of fine copper gauze were employed, the space between the cones being filled with catalyst impregnated upon pumice. The height of the outer cone was 60 mm., the diameter 20 mm. The diameter of the inner cone was 10 mm. The thickness of the pumice layer was 5 mm. Before the air–alcohol mixture was admitted to the catalytic chamber, the catalyst was heated to about 350° by means of a small burner. In all cases the heat of the reaction was sufficient to keep the catalyst at a red heat after the reaction had once started. The reaction temperatures were carefully measured by inserting a quartz thermometer or a

---

[1] Le Blanc and Plaschke, *Z. Elektrochem.*, **17**, 45 (1911).

thermocouple in the side arm of the catalytic chamber. The thermocouple arm was protected by a quartz jacket. The end of the thermometer or thermocouple jacket was well buried at what appeared to be the hottest point. It is probable that the actual temperatures were somewhat higher than those recorded, since perfect contact with the catalyst was difficult to attain. The products of the reaction were collected in the cooling system and in the several absorption flasks. The receivers were then carefully emptied and rinsed, and the resulting solution diluted to a definite volume. Aliquots were taken for analysis, check analyses being made in all cases.

In most cases about 0.5 mole of alcohol was passed over the catalyst. In order to determine whether or not the yields varied with the amount of alcohol passed over, longer runs were made in which about 1.5 moles of alcohol was passed over. The yields of aldehyde in all cases checked very well with the yields obtained from the shorter runs. The amount of alcohol used for each run was simply determined by weighing the vaporizing chamber before and after each run.

The alcohols which were used were not perfectly anhydrous. As a result the vapors carried over by the air could not be considered to be purely aicohol vapors. This is a point which has been neglected by many previous investigators. It was found that the percentage of alcohol in the vapors passing over could easily be determined by making blank runs and determining the alcohol in the condensate by means of an immersion refractometer. That is, instead of passing the vapors over a heated catalyst, they were simply passed through an empty tube, condensed and the alcohol content determined as above.

Experimental

Oxidation of Methyl Alcohol

Constant boiling (65") methyl alcohol free from acetone was used. Three different catalysts were used: (1) pure Sm_2O_3 (prepared by heating samarium nitrate in a stream of oxygen at 450–500°); (2) pure CuO impregnated on 12-mesh pumice (prepared by dissolving 3 g. of CuO in nitric acid, to which solution was added 9 cc. of 12-mesh pumice and the mixture carefully evaporated to dryness with stirring; the dry pumice was then heated in oxygen as above); and (3) samarium and copper oxide mixtures on 12-mesh pumice (prepared similarly to the above).

The amounts of catalysts used have been given in the introduction. These figures represent the optimum amounts as carefully determined in the preliminary work.

The optimum bath or thermostat temperature was determined in preliminary experiments. Space does not permit recording all of the results of these experiments. Figure *2* shows that a bath temperature of 40° offers the best conditions (alcohol–air ratios) for obtaining the highest yields of formaldehyde.

Determination of Formaldehyde.—The aldehyde in the condensate was determined by the hydrogen peroxide–sodium hydroxide method.[2] This method gave excellent check results.

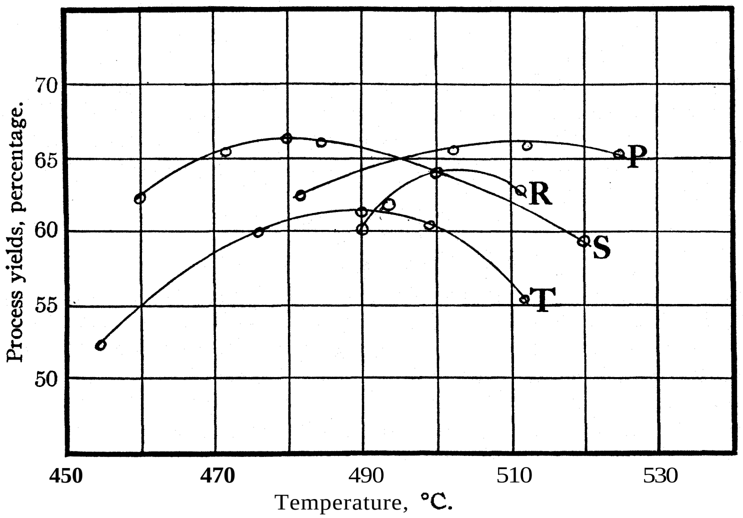
Determination of Unchanged Methyl Alcohol.—This was accomplished with satisfactory results by adding an excess of ammonium hydroxide to an aliquot of the condensate and distilling the solution. The distillate was just acidified with dilute sulfuric acid and then redistilled. The methyl alcohol content in this distillate was then determined by means of an immersion refractometer.

Use of Samarium Oxide as Catalyst.—Three to six cc. of 12-mesh oxide was used. The process yields of formaldehyde (1–5%) clearly indicated that this oxide was too active a catalyst. The catalyst temperature was always very high, never falling below 600°, even when a very low air rate was used. Even when the air supply was much less

---

[2] Haywood and Smith, THIS JOURNAL, 27,1188 (1905).

than the amount theoretically necessary for the oxidation to formaldehyde, the yields were almost as small as before. This fact might be explained in either of two ways: (1) the oxidation does not stop with formaldehyde, but proceeds as far as carbon dioxide and water; or (2) formaldehyde is formed, but at the high temperature of the catalyst is immediately decomposed into hydrogen and carbon monoxide. That either explanation may be correct, depending upon the amount of oxygen used, was easily proved. A definite amount of absolute methyl alcohol was passed over the heated catalyst with almost the exact amount of oxygen (from air) necessary to oxidize the alcohol to formaldehyde. Of 26.97 g. of alcohol passed over, 6.4 g. was recovered. The difference between the two weights (20.57 g.) was oxidized. This amount of alcohol on oxidation to formaldehyde should yield 11.57 g. of water; actually 11.12 g. was formed. Further, it was found that fairly large amounts of hydrogen and carbon monoxide were formed but only traces of carbon dioxide. These facts seem to confirm the second explanation given above.



P, Bath at 37°; R, bath at 42°; S, bath at 40°; T, bath at 45°.

Fig. 2.—NOTE.—Due to the fact that a thermostat temperature of 40° permitted working at lower catalyst temperatures than a thermostat temperature of 37°, the former seemed to offer the more ideal conditions.

When an excess of oxygen is used, oxidation proceeds much further with the formation of larger and larger amounts of carbon dioxide and water.

It may be concluded, therefore, that the low yields of formaldehyde obtained even when insufficient oxygen was used were due to the catalytic decomposition of the aldehyde; and when an excess of oxygen was used the low yields were due primarily to a more complete combustion to carbon dioxide and water.

The results recorded in Table I represent mean results. The process yields were calculated on the basis of moles of methyl alcohol changed to moles of formaldehyde.

TABLE I

MEAN RESULTS (THERMOSTAT, 40°)

Discussion of Results

Preliminary experiments indicated that the best yields of formaldehyde were obtained at a thermostat temperature of 40° and when the alcohol–oxygen ratio was 1 g./0.3–0.31 liter of oxygen. The latter figures are somewhat below the theoretical values, as 0.35 liter of oxygen would be necessary to oxidize 1 g. of methanol completely to formaldehyde. The use of smaller or larger amounts of oxygen was accompanied by lower process yields of the aldehyde. The actual yields (based upon the actual amount of alcohol oxidized) varied inversely with the amount of oxygen used. It was possible to approach 100% actual yields when the amount of oxygen used was small. There was, of course, a corresponding decrease in the process yields, as more alcohol passed through unchanged, due to the lack of oxygen.

The alcohol–oxygen ratios recorded show the efficiency of the type of vaporizing chamber used. The constancy of these ratios certainly indicates that the air passing over the catalyst was saturated with respect to the alcohol regardless of the air rate used. This is a factor which, apparently, has been neglected in much of the previously published work.

Hofmann[3] first accomplished the formation of formaldehyde by passing

---

[3] Hofmann. Ann., 145,357 (1868); Ber., 2,152 (1869); 11, 1686 (1878).

air laden with methyl alcohol over a heated platinum wire. Tollens[4] and Loew[5] improved the process by using copper gauze in place of platinum as a catalyst. Orloff[6] made the first careful investigation of the use of copper gauze. He reported about 50% as the highest process yield. Le Blanc and Plaschke[1] reported that silver gauze was a better catalyst than copper gauze, which fact has been confirmed by others. Fokin,[7] using asbestos impregnated with copper, reported a yield of 47%. Thomas,[8] using copper gauze as a catalyst, reported a maximum process yield of 63.6%. Bobrov[9] used copper gauze in the form of disks and reported an actual yield of 71.5%. From the published records Thomas has obtained the highest process yields.

The process yields given in Table I under A are somewhat higher than Thomas obtained when he used copper gauze. There is even a greater difference in the actual yields. Thomas reported an actual yield of 72% for the same run which gave a 63.6% process yield, whereas the actual yields using CuO on pumice in this investigation never dropped below 85%. This probably can be explained by the fact that his catalyst (copper gauze) was 74 mm. in length, while the catalyst layer (copper oxide on pumice) used in this investigation was only 15 mm. in length. Consequently, the products of the reaction escaped from the heated catalyst more quickly in the latter case with the result that a smaller percentage of aldehyde was decomposed.

All of the previous workers who used copper gauze as the catalyst have used a high air rate, generally two liters of air per minute. The best results obtained in this investigation were obtained at a much lower air rate, about 1.3 liters per minute. This rather curious difference must be due to the difference in the form of the catalyst. A comparison of copper gauze and pumice impregnated with copper oxide was made in the preparation of acetaldehyde (see Oxidation of Ethyl Alcohol).

It will be noted from the results recorded in Table I (B–E) that the introduction of small amounts of samarium oxide decreased the process yields, the decrease being very noticeable when the samarium oxide content reached 5%. The presence of the rare earth oxide had practically no effect on the catalyst temperatures. As the amount of samarium oxide increased, the yields became less and less, due to the decomposing action of this oxide on formaldehyde.

The actual yields also decreased with the introduction of Sm_2O_3, as shown by the following: A, 85–90%; B, 83–90%; C, 80–86%; D, 77–84% and E, 70–76%.

The yields in Table I if plotted against catalyst temperatures would give curves showing a gradual rise in yields and then a gradual drop. Due to the ease of decomposition of formaldehyde, temperature control is undoubtedly the most important factor in its catalytic preparation. A second factor is the length of the catalyst. The preliminary work showed very definitely that the minimum amount of catalyst should be used. When more than this amount was taken, there was a very pronounced decrease in the process yields obtained,

Oxidation of Ethyl Alcohol

Pure ethyl alcohol (97%) free from aldehydes was used for the experiments. Three different catalysts were used: (1) pure samarium oxide; (2) (a) copper gauze in the shape of a cone—two cones were used as previously described, the space between was filled with 12-mesh pumice impregnated with copper oxide (Fig. 1)—(b) pure copper oxide impregnated on 12-mesh pumice and (3) (a) copper gauze cones as above—in this case the pumice layer between the cones was impregnated with samarium and copper oxide mixtures—(b) samarium and copper oxide mixtures impregnated upon 12-mesh pumice. The catalysts were prepared in the manner described under the oxidation of methyl alcohol.

The acidity of the various condensates was so slight that it could scarcely be explained on the basis of the presence of acetic acid. In greater part it was probably due to the presence of carbon dioxide. Ester formation was not noticed at any time during the course of the experiments.

Determination of Acetaldehyde.—The acetaldehyde in the condensate was determined by Ripper's method.[10] Check analyses were made and the results obtained usually agreed within 0.3–0.5%.

Determination of Unchanged Ethyl Alcohol.—The unchanged ethyl alcohol which was present in the condensate was much more difficult to determine. Several methods were investigated and finally the following was adopted. A suitable aliquot was taken, an excess of ammoniacal silver nitrate was added, and the resulting mixture was heated on a steam-bath under an efficient condenser for two to three hours, depending upon the amount of aldehyde present. The time may be shortened somewhat if the mixture is heated under a slight pressure. This effected the complete oxidation of the acetaldehyde in practically every case. The slightly ammoniacal mixture was distilled without filtration. The distillate was then just acidified with sulfuric acid and again distilled until about two-thirds of the solution passed over. The amount of alcohol in the distillate was determined by means of an immersion refractometer. This method proved quite satisfactory.

Use of Samarium Oxide as Catalyst.—Pumice (12-mesh) impregnated with samarium oxide was used as the catalyst. The results obtained were somewhat better than with methyl alcohol. The process yields varied from 6 to 15%. The oxide showed a great tendency to cause charring, and consequently the reactions were difficult to control. Charring was easily prevented by using an excess amount of air, but under those conditions combustion was practically complete.

The catalyst could not be made to continue glowing at an air rate lower than 0.45 liter of air per minute.

Discussion of Results

Preliminary runs proved conclusively that the best results were obtained with a thermostat temperature of 45°. The results of these preliminary runs, when plotted against catalyst temperatures, gave curves similar to those under formaldehyde (see Fig. 2) with the curve for a thermostat temperature of 45° showing the best yields. Consequently, only the results obtained at the latter temperature are recorded here. The preliminary results plainly indicated that the optimum alcohol–oxygen ratio was 1 g. EtOH/0.40–0.43 liter of oxygen. The theoretical ratio is 1 g. EtOH/0.2434 liter of oxygen. The use of smaller or larger amounts of oxygen was always accompanied by a decreased process yield of acetaldehyde. However, as expected, the actual yields varied inversely with the amount of oxygen used. It was possible to approach 100% actual yields when a small enough quantity of oxygen was used; at the same time there was a corresponding decrease in the process yields. The ratios recorded under acetaldehyde again indicate the efficiency of the type of vaporizing chamber used.

As with methyl-alcohol, pure samarium oxide is too active a catalyst to be used for the oxidation of ethyl alcohol. It is not only apt to carry the oxidation too far, but it also probably catalyzes the decomposition of acetaldehyde similarly to formaldehyde.

Orloff[11] was the first to make a careful investigation of copper gauze as a catalyst for the oxidation of ethyl alcohol. He reported 66% as his best process yield.

Simington and Adkins[12] studied the catalytic oxidation of ethyl, isopropyl and n-butyl alcohols, using various catalysts. Using copper gauze they obtained only 37.4% process yield of acetaldehyde; using silver gauze they obtained 43.7%, and using a catalyst composed of 90% Cu and 10% Ag, they obtained 76% yields.

The results recorded in Table II (A and B) correspond more closely (for

---

[11] Orloff, *J. Russ, Phys.-Chem. Soc.*, 40, 203 (1908).

[12] Simington and Adkins, THIS JOURNAL, 50, 1449 (1928).

copper gauze catalyst) to the results obtained by Orloff, although they are somewhat higher than his. Apparently the form of the catalyst has little effect on the yields, for the results under A and B are practically the same. One notable difference between them is evident from a comparison of the catalyst temperatures for the same air rates. For example, using an air rate of 0.83 l./minute, the catalyst temperature in A was 460°; in B, however, the temperature was 501°. This probably was due to the fact that the impregnated pumice offered a larger surface than the gauze. This would explain the fact that the best yields in B were obtained at lower air rates than those in A.

It will be noted from the results in Table II (C–J) that the introduction of small amounts of samarium oxide to the catalyst decreases the process yields, the decrease being especially noticeable when the samarium oxide content reached 5%. It will also be noted (B, D, F, H, J) that with the introduction of samarium oxide the optimum temperatures were materially lowered, *i. e.*, the best results were obtained from CuO on pumice at about 482°, with the catalyst containing 0.5% samarium oxide at 460°, with the catalyst containing 1% samarium oxide at 465°, with the catalyst containing 2% samarium oxide at 395° and with the catalyst containing 5% samarium oxide at 370°. This probably can be explained by the fact that with increasing amounts of samarium oxide the rate of decomposition of acetaldehyde, as well as the extent of oxidation, is increased and consequently best results are obtained at lower temperatures. Something not so easily explained, at present, is the fact that the temperatures measured for the 5% samarium oxide type of catalyst (for the same air rates) were lower than with pure CuO as catalyst, while with the catalysts containing 0.5% and 1% samarium oxide there was a noticeable temperature increase for the same air rates.

The introduction of samarium oxide also decreased the actual yields, as shown by the following: A and B, 76 to 89%; C and D, 76 to 86%; E and F, 75 to 85%; G and H, 75 to 81%; and I and J, 74 to 78%.

The points noted above were not so evident with the use of the double cone type of catalyst. Apparently the impregnated pumice layer was not so active, due to the fact that the copper gauze was effecting the greater part of the oxidation.

The results recorded in Table II, if plotted against catalyst temperatures, would give curves showing a gradual rise to the optimum temperature and then a fairly rapid drop. Certain workers have placed much stress upon the length of time the reacting gases were permitted to remain in contact with the catalyst (which, of course, depends upon the air rate and the length of catalyst layer). This is unquestionably an important factor, but in the case of methyl and ethyl alcohols it would seem that the catalyst temperature is the most important one as far as the yields are concerned.

Another important factor is the amount of catalyst used. In the case of copper gauze the length of the catalyst did not affect the results appreciably, but when impregnated pumice was used, the effect on the yields was quite evident. The use of too much catalyst produced a marked decrease in the yields of acetaldehyde.

Conclusions

The results obtained in this investigation indicated that the presence of rare earth oxides with copper oxide promoted oxidation. With such easily oxidizable substances as methyl and ethyl alcohols this fact was of no apparent advantage, since the oxidation tends to go too far. This enhanced activity should prove to be very advantageous in the oxidation of less readily oxidizable substances. Work has been started along these lines.

It is believed that the presence of rare earth oxides, in small amounts, helps to prevent catalyst poisoning and prolong the life of the catalyst indefinitely. Actual proof has not yet been obtained. Work is being started with rare earth oxides and silver oxide mixtures and it is hoped that this latter point can thus be easily proved.

Summary

1. Data have been obtained on the use of rare earth oxides for the vapor phase oxidation of methyl alcohol and ethyl alcohol, as compared with the results obtained when copper oxide was used for the same purpose.

2. Better yields of formaldehyde and acetaldehyde have been obtained, using pumice impregnated with copper oxide, than have been reported previously by investigators who used some form of copper as the oxidation catalyst.

3. Data have been obtained showing the effect produced on the catalytic activity of copper oxide by the addition of small amounts of rare earth oxides to the copper oxide.

THE DIELECTRIC POLARIZATION OF LIQUIDS. X. THE POLARIZATION AND REFRACTION OF THE NORMAL PARAFFINS

BY R. W. DORNTE AND C. P. SMYTH

RECEIVED JUNE 4, 1930 PUBLISHED SEPTEMBER 5, 1930

This investigation was undertaken with the object of obtaining further information concerning the temperature dependence or independence of the polarization of substances possessing little or no electric moment and of studying the variation of this polarization in an homologous series. Through the kindness of the Ethyl Gasoline Corporation it has been possible to obtain samples of the straight-chain hydrocarbons from pentane to dodecane prepared by Dr. Albert L. Henne of Ohio State University, to whom the writers wish to express their indebtedness. The samples of these liquids were of a high degree of purity boiling over a range of only 0.02 to 0.03°. Although the densities and refractive indices of these substances had been measured previously, the measurements were repeated in order that all the data used should have been determined for the same materials, these materials being of exceptional purity. Moreover, the previous density measurements did not extend over the wide range of temperature which it seemed desirable to employ in the polarization investigations. Wherever the present results overlap data given in "International Critical Tables" excellent agreement is obtained.

In the first of this series of papers[1] the method of obtaining the electric moment of the molecule of a substance has been discussed. The molar polarization of a substance, $P = (\epsilon - 1)/(\epsilon + 2) \times M/d = P_E + P_A + P_M$, in which ϵ is the dielectric constant, M is the molecular weight, d is the density, $P_E + P_A$ is the polarization due to shifts of charges in the molecule inducible by an external field and P_M is the polarization due to the orientation of the permanent electric doublets of the molecules. When P_M is 0, the moment of the molecule must be 0. P_E may be calculated as the molar refraction for light of infinite wave length, MR, $= (1 - \lambda_0^2/\lambda^2)[(n^2 - 1)/(n^2 + 2) \times M/d]$, where n is the index of refraction for light of wave length λ and λ_0 is the wave length corresponding to a characteristic vibration frequency in the ultraviolet region. P_A, the difference between P_E, the polarization due to electronic shifts and the total induced polarization, is commonly attributed to induced shifts of atoms or radicals. The variation of P with the absolute temperature T is shown by the equation, $P = a + b/T$, in which the constant $a = P_E + P_A$, $b/t = P_M$, and the constant $b = 4\pi N\mu^2/9k$, where μ is the electric moment of a single molecule, N is the number of molecules in a gram molecule $= 6.061 \times 10^{23}$, and k is the molecular gas constant $= 1.372 \times 10^{-16}$. Evidently, if P does not

---

[1] Smyth, Morgan and Boyce, THIS JOURNAL, 50, 1536 (1928).

change with changing temperature, it is to be concluded that b is zero and that therefore the moment of the molecule is zero. If the molecule possesses a moment, P should decrease with rising temperature.

The refractive indices were measured with a Pulfrich refractomcter and the molar refractions MR and dispersions calculated in the manner described in the third paper of this series.[2] The densities and dielectric constants were measured with the apparatus described in earlier papers,[1,3] the only modification being the insertion of two stages of amplification in the detector circuit of the capacity bridge. The dielectric constant of the benzene used in calibrating the condenser was taken as 2.2176 at 25". Both the dielectric constants and densities were measured at definite temperature intervals of 20" by adjusting the constant temperature bath to the exact temperatures shown in the following tables, the temperature being held constant to ±0.05° below 0° and above 90° and to ±0.02° at the intermediate temperatures. The experimental data and the polarizations and refractions calculated from them are given in Tables I and II, and in Fig. 1 the values of the polarization are plotted as ordinates against those of the temperature as abscissas. In order to keep the diagram within reasonable dimensions, the ordinates are broken several times, but the same scale is maintained throughout.

In Fig. 1 the scale on which the polarization is plotted is so large that several of the points appear to lie at some distance from the straight lines drawn to represent them. The values for heptane. octane. nonane and decane show an increasing tendency to fall below the straight lines as the boiling point is approached. This deviation from linearity is regular and greater than the probable experimental error, but, as it is not apparent in the pentane, hexane, undecane and dodecane values, for which the same experimental technique was used and to which the same theoretical considerations should apply, its cause must be regarded as obscure and, possibly, accidental. The results indicate, however, that, as in the case of the isomers of heptane[2] previously investigated, the polarization varies but little with temperature, the variation being an approximately linear increase with rising temperature instead of the hyperbolic decrease required by the equation for the temperature variation of the polarization of substances possessing a moment. Cases have been found[3,4] in which pure substances possessing large moments show a rise in polarization with rising temperature instead of the expected fall because the rising temperature decreases the intermolecular action or association which is reducing the

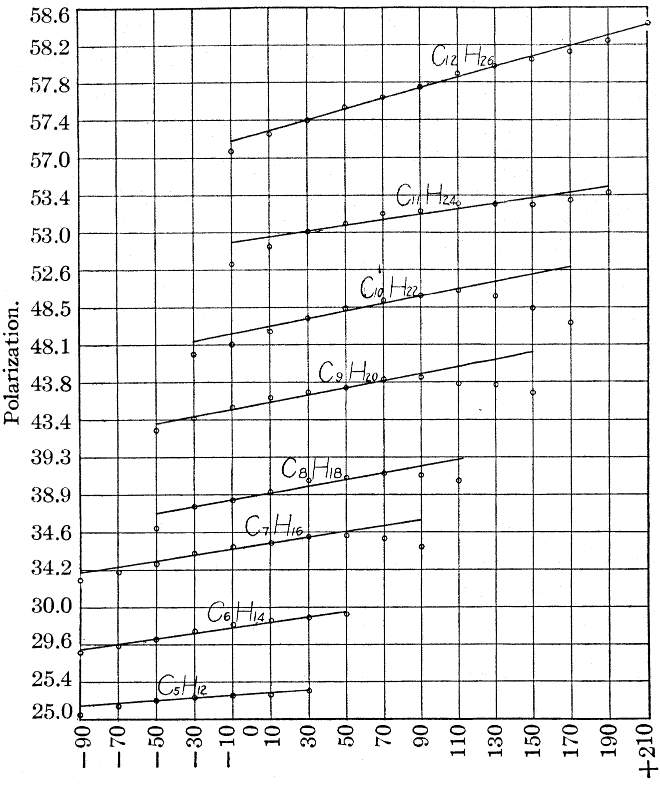

Fig. 1.—Variation of polarization with temperature.

---

[4] Smyth and Stoops, THIS JOURNAL, 51, 3312, 3330 (1929).

polarization. In these cases, the polarization, in spite of its reduction by intermolecular action, has been found to be considerably larger than the molar refraction, but the polarizations of these hydrocarbons at 20° are almost identical with the refractions for the sodium D line at this temperature. Only when the refraction is extrapolated to infinite wave length to obtain the values shown under P_E in Table III is the difference between P and P_E appreciable. The difference $P - P_E$ is smaller than the values commonly found for P_A,[5] which indicates a very small, if not zero, value for P_M as $P - P_E = P_A + P_M$. Moreover, the increase in $P - P_E$ in going up the series from pentane to dodecane is less than that commonly observed for P_A with increase in molecular weight, which indicates a negligible variation in any possibly existing moment. As the temperature variation of P also points to a small, if not zero, value for P_M, it may be concluded that the values of P_M and, hence, of the electric moments of the molecules, are indistinguishable from zero by the experimental method which has been employed. The difference $P - P_E$ is, therefore, set equal to P_A to obtain the values listed in Table III along with the dispersions and the values at 20° of the other constants which have been discussed.

TABLE III

PHYSICAL CONSTANTS AT 20°C.

		d	P	P_E	P_A	$MR_\gamma - MR_\alpha$	$n_\gamma - n_\alpha$

The value of P_A for heptane in Table III is smaller than that found by Smyth and Stoops by 0.11, which, in view of the lower value, 2.276, instead of 2.279, assigned to the dielectric constant of benzene used as standard in the calibration of the apparatus, may be regarded as excellent agreement. The values increase with increasing molecular weight in a manner to be expected from the increase in P and P_E. In view of the absence of moment, it is interesting to see whether the polarization resembles the refraction in being an additive property, as might be expected. For this purpose, the differences between the refractions and also the polarizations of successive members of the series are shown in Table IV, the difference in each case being the contribution of a CH_2 group.

The mean values of the refractions for the CH_2 group at different wave lengths agree well with those given in Landolt-Börnstein (5th ed.), which

are shown at the bottom of the table. In going down the columns of both the refractions and the polarizations there is a slight alternation in the values for the CH2 group, which suggests the possibility that the refraction and polarization of a molecule with an even number of carbon atoms in an unbranched chain may be proportionately a little lower than those of a molecule with an odd number of carbons in the chain. The range within which the values of P vary is slightly greater than that within which those for the more accurately measurable MK,, MR_β, MR_D and MR_α vary but no greater than the range of the value of P_E, in which the errors of measurement accumulate. As the values of P vary about the figure **4.60** without any trend upward or downward it is evident that the polarization of these hydrocarbons is an additive property, although a glance at the values of the dielectric constants in Table III shows that this quantity is decidedly not an additive property. The difference of the mean values of P and P_E for the CH2 group gives a value **0.07** for P_A for this group, which cannot, however, be regarded as of general significance.

The increase of polarization with temperature, about 1% per 100° in the absence of the depression noted for some substances as the boiling point is approached, is of the same magnitude as that found previously for *n*-heptane and two of its isomers. It was suggested in this work[4] that the force fields of adjacent molecules might reduce the mobilities of the bound electrons to a small extent, thereby reducing the polarization and refraction and that, as the molecular separation and motion increased with rising temperature, the effect of the force fields upon the electrons was decreased, the polarization and refraction thus being increased. However, subsequent investigations of the refractions of mixtures of heptane with strongly polar molecules,[6] including ethyl and butyl alcohol, have shown that the refraction of the mixture is a linear function of composition, deviations from linearity being of the magnitude of the experimental error, about **0.02** units. The very different force field around the heptane molecule when it is surrounded with alcohol molecules instead of with other heptane molecules

---

[6] **Smyth, Engel and** Wilson, THIS JOURNAL, 51,1736 (1929).

might be expected to bring about a considerable change in the refraction and polarization if the change of polarization with temperature observed in the present work were due to change in the effect of the molecular force fields. The absence of any such considerable change of refraction with concentration would, therefore, seem to argue strongly against the attribution of the increase of polarization with temperature to decreasing effect of the force fields. It was also suggested that a more important factor might be the increase in the number of degrees of freedom with increasing temperature, which should facilitate the displacement of charges in the molecule and, hence, increase the polarization. It must, however, be borne in mind that, in the derivation of the expression for refraction and polarization, factors have, of necessity, been neglected, the effects of which may be negligible in comparison to that of a large dipole moment, but which, in the absence of **a** moment, may easily become evident in the results of careful measurements.

The zero or exceedingly small moments of the molecules of these hydrocarbons, as in the case of the isomers of heptane, show the absence of any polarity in the bonds of alkyl radicals which may be detected through the electric moments arising from them, and, consequently, give no evidence of a difference in the electronegativities of the radicals.

Summary

The dielectric constants and densities of the normal paraffins from pentane to dodecane have been measured over almost the entire temperature range within which these substances are liquid at atmospheric pressure and the refractive indices and dispersions have been determined at 20°.

The polarizations calculated from the dielectric constants and densities increase about 1% per 100° rise in temperature. The molar refractions at different wave lengths obtained for the CH_2 group agree well with those in the literature and the constancy of the polarization of the CH_2 groups show that, in the absence of an electric moment, the polarization is an additive property, as would be expected.

The absence of any decrease of polarization with rising temperature and the small difference between the polarizations and the refractions show that the values of the electric moments of the molecules are indistinguishable from zero. The moments are, therefore, regarded as approximately zero and the conclusion is drawn that the bonds of alkyl radicals possess no polarity detectable through electric moments arising from them.

GERMANIUM. XXXV. GERMANIUM MONOXIDE. GERMANIUM MONOSULFIDE[1]

BY L. M. DENNIS AND R. E. HULSE

RECEIVED JUNE 9, 1930 PUBLISHED SEPTEMBER 5, 1930

Germanium Monoxide

Indications of the existence of this compound were observed by Winkler[2] but he was unable to purify the product for analysis. Consequently his statement that it is germanous oxide lacked experimental confirmation. Isolated details have since then appeared in the literature,[3] but none of the investigators made a systematic study of the compound. To extend our knowledge of this substance and possibly to open the way to the general study of the compounds of divalent germanium, about which comparatively little is known at present, this investigation was taken up.

Experimental

Preparation of Hydrous[4] Germanium Monoxide.—Germanium dioxide was dissolved in a slight excess of a 5 N solution of potassium hydroxide, hydrochloric acid was added in amount necessary to make the solution about 5 N in respect to HCl,[5] an excess of a 30% solution of hypophosphorous acid was then added, and the solution was held at 95° for two hours.

Since the hydrous germanium monoxide is quickly oxidized by air, it was necessary to precipitate and wash the compound in an inert atmosphere. This was accomplished with the apparatus shown in Fig. 1.

The reduced solution was placed in the cylinder A which was surrounded by a jacket through which hot water was kept circulating. Through the rubber stopper in the top of A were inserted a tube carrying a small separatory funnel and a branch M, a glass hand-stirrer B which passed loosely through a short piece of glass tubing, and a siphon tube D.

The air above the solution in A was displaced by hydrogen which entered through M and escaped around the glass rod B. This passage of hydrogen was continued throughout the operation.

Germanous hydroxide was now precipitated by adding dilute ammonium hydroxide through C. The contents of A was then held at about 90° for one hour by the hot water rising from the flask and filling the jacket around A. The precipitate was then allowed

[4] This term was introduced by Weiser to distinguish precipitated oxides that contain varying amounts of water, from hydrates in which water is chemically combined in definite stoichiometric proportions. See Weiser, "The Hydrous Oxides," 1926.

[5] When the solution is acidified, some germanium dioxide is precipitated, but this dissolves during the reduction.

to settle, the supernatant liquid was drawn off through D, hot water that had been boiled to free it from air was run in through C, and the mixture was stirred by moving B up and down and turning it. The precipitate was again allowed to settle, the supernatant liquid was drawn off, and the operations of washing were repeated until most of the soluble salts had been removed, which was shown by the tendency of the precipitate to become colloidal. Precipitate and liquid were then run into F by opening E and the precipitate was collected on a filter paper in the Biichner funnel G. Contact with the air was here avoided by surrounding G with the glass cylinder F which was closed at top and bottom with large rubber stoppers. The precipitate was washed until free from chloride, and was then quickly transferred to a boat of porcelain or alundum. This was inserted into a combustion tube and the precipitate was dried by heating it in a current of pure nitrogen to the desired temperature.

Freshly precipitated hydrous germanium monoxide varies in color from yellow to red, depending upon the conditions of precipitation. It is readily soluble in the halogen acids. Sulfuric acid, 6 N, changes its color to dark brown (partial dehydration) and slowly dissolves it. It is only slightly soluble in fixed alkalies, but forms red colloidal solutions.

When dried by heating in *vacuo*, water was steadily removed, and no evidence of the formation of definite hydrates was obtained. As the temperature of drying is raised, the oxide changes in color from red to brown to black, with decrease in solubility. Examination under the microscope showed that the particle size increases as the color becomes darker, which indicates that the color change is not due to tautomerism as Hantzsch supposed, but is dependent upon the size of the particles and the amount of water associated with the oxide.

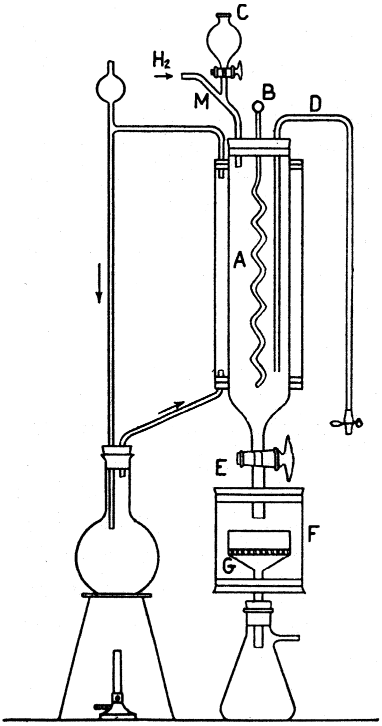

Fig. 1.

Anhydrous Germanium Monoxide.—Hydrous germanium monoxide is completely dehydrated when heated in nitrogen to 650°, and jet-black crystalline germanium monoxide, GeO, results. It was analyzed by oxidizing it with pure hydrogen peroxide, evaporating the solution to dryness, heating the residue to 800° and weighing the resulting GeO_2.

Anal. Subs., 0.1401, 0.1515. Calcd. for GeO: Ge, 0.1143, 0.1248 = 81.94%. Found: Ge, 0.1147 = 81.87%, 0.1240 = 81.81%.

Properties.—Anhydrous germanium monoxide is not acted upon by moisture or atmospheric oxygen at room temperature, is attacked very slightly, if at all, by hydrochloric or sulfuric acid or solutions of fixed alkali hydroxides, but is slowly oxidized by fuming nitric acid, potassium permanganate or chlorine water. It is rather readily oxidized by hydrogen peroxide in the presence of ammonium hydroxide. Oxidation in dry air begins at 550°. When heated in a closed apparatus in pure nitrogen, the oxide sublimes at 710°.

When heated in nitrogen in a boat of platinum or nickel to a temperature above 500°, germanium monoxide yields germanium dioxide and metallic germanium, the latter forming an alloy with the metal of the boat. When heated in boats of siliceous material the monoxide reacts above 800° to form yellow glazes.

Germanium monoxide is rapidly attacked by hydrogen chloride at about 175° with the formation of germanium chloroform and water. Chlorine attacks the oxide at 250°, forming $GeCl_4$ and GeO_2. No evidence of the formation of the oxychloride $GeOCl_2$, was obtained. The action of bromine is similar to that of chlorine.

Germanium Monosulfide

Germanium monosulfide was first described by Winkler,[2] and a study of its preparation by reduction of GeS_2 in hydrogen was made by Dennis and Joseph.[6] To obtain further information concerning the formation of GeS by precipitation of a solution of a germanous compound, and the properties of the resulting product, the present investigation was undertaken.

Experimental

Preparation of Germanium Monosulfide.—A solution of germanous chloride was prepared in the manner described under Germanium Monoxide. Hydrogen sulfide was passed into the hot solution and continued until the solution had cooled to room temperature. The precipitate under these conditions is dark red in color and granular. Precipitated from cold solution, the sulfide is light yellow and gelatinous. The red precipitate can readily be filtered and washed, and is quite stable toward oxygen at room temperature. Upon heating it to about 300° in pure nitrogen, all water was removed.

Analysis.—Germanium was determined by dissolving a sample in dilute ammonium hydroxide and 3% hydrogen peroxide that had been redistilled to free it from residue, evaporating the solution to dryness and carefully igniting the resultant GeO_2.

Sulfur was determined by the method of Popoff and Newman.[7]

Anal. Subs., 0.0970, 0.1340. Calcd. for GeS: Ge, 0.0673, 0.0930 = 69.37%. Found: Ge, 0.0671 = 69.22%; 0.0929 = 69.30%. Subs., 0.2236, 0.2571. Calcd. for GeS: S, 0.0685, 0.0788 = 30.63%. Found: S, 0.0684 = 30.59%; 0.0786 = 30.56%.

Properties.—Germanium monosulfide, thus prepared, is a dark red, amorphous substance; specific gravity, d_4^{20} 3.31. It is readily soluble in dilute hydrochloric acid, but is only slowly attacked by sulfuric, phosphoric or organic acids. It is rapidly oxidized by hot dilute nitric acid, and by aqueous solutions of hydrogen peroxide, potassium permanganate, chlorine or bromine.

---

[6] Dennis and Joseph, *J. Phys. Chem.*, *31*, 1716 (1927).

[7] Popoff and Newman, *Ind. Eng. Chem., Anal. Ed.*, **2**, 45 (1930).

The red sulfide is readily soluble in solutions of alkali hydroxides or sulfides, forming deep red solutions, from which the addition of alcohol causes the separation of red, viscous liquids. The sulfide is slowly oxidized in air at 350°, and rapidly at higher temperatures, forming GeO_2 and SO_2. When heated to about 150° in hydrogen chloride, germanium chloroform and hydrogen sulfide are formed. Chlorine attacks the sulfide at room temperature forming $GeCl_4$ and chlorides of sulfur.

Crystalline Germanium Monosulfide.—When red, amorphous germanium monosulfide is held at 450° in an atmosphere of nitrogen, it changes in a few hours to the black crystalline form described by Dennis and Joseph.[6] The substance is slowly oxidized by an ammoniacal solution of hydrogen peroxide and also by chlorine water or potassium permanganate. It begins to sublime in nitrogen at 430°, and melts at 625°. Its specific gravity is d_4^{20} 3.78.

Summary

This article describes the preparation and properties of hydrous and anhydrous germanium monoxide, and of amorphous and crystalline germanium monosulfide.

THE EFFECTS OF SUBSTITUENTS ON QUANTUM EFFICIENCY IN THE QUINONE-ALCOHOL REACTION

BY PHILIP A. LEIGHTON AND WILLIAM F. DRESIA

RECEIVED JUNE 9, 1930 PUBLISHED SEPTEMBER 5, 1930

The average of over twenty determinations[1] of quantum efficiency for the photochemical reaction between benzoquinone and ethyl alcohol in the wave length region λ4350–2537 Å. yields the figure 0.502. In other words, for every quinone molecule decomposed, two quanta are absorbed. The nearness of this ratio to one-half immediately raises interest as to its source.

Weigert and Brodmann[2] explained a quantum efficiency of one-half in the nitrobenzaldehyde photolysis as due to the different possible orientations of the absorbing molecules with respect to the electric vector of the incident light, by which statistically only one-half of the absorbed light could be effective in producing activation and subsequent chemical change.

By assuming a superoxide structure for quinone, the same explanation can be applied to the observed quantum efficiency in the quinone reaction. However, as was pointed out, the results can also be explained by assuming that every absorbed quantum is effective in producing activation, and that a 50% efficient secondary reaction is responsible for the observed yields.

---

[1] Leighton and Forbes, THIS JOURNAL, 51, 3549 (1929).

[2] Weigert and Brodmann, *Trans. Faraday Soc.*, 21, 453 (1925).

Changes in quinone concentration throw no light on this question, the alcohol being present in such excess that the reaction is pseudomonomolecular, and the quantum efficiency hence independent of concentration within measurable limits. Very low concentrations of alcohol and quinone in a neutral solvent might be used to gain evidence on this point, but a simpler method offers itself in the possibility of substituting heavy groups in the quinone molecule. If the quantum efficiency of one-half is inherent in the process of absorption and activation of molecules of the nitrobenzaldehyde and quinone type, substituents should not affect it; but if a secondary reaction, involving collisions with a low probability of effectiveness, is responsible, substituents should offer a steric hindrance to the reaction, with a resultant change in quantum yield.

We have investigated, therefore, the effects of substitution in a series of chloro and aliphatic substituted quinones.

Apparatus and Materials

The monochromator described earlier was used,' with the addition between the front slit and the collimating lens of a quartz–water cell to cut down infra-red radiation. In this cell could be placed Corning glass filter combinations, which were used to increase the purity of those mercury arc lines lying in the visible region. For example, the separation of λ5460 from λ5770, imperfect with the monochromator alone or with filters alone, is almost complete with the combination of monochromator and filters.

The experimental procedure and method of calculation employed were the same as described.' Some trouble was experienced with the analysis in the case of the alkyl substituted quinones, but this was overcome by using more concentrated hydrogen iodide solutions and by titrating dark and exposed samples simultaneously.

Monochloroquinone was prepared by the oxidation of monochlorohydroquinone with dichromic acid.[3]

Dichloroquinone was prepared by the oxidation of symmetrical trichlorophenol with chromic acid.[4]

Toluquinone was prepared by oxidizing o-toluidine with manganese dioxide under steam distillation.[5]

Chloranil and thymoquinone were obtained commercially. All the quinones were carefully purified by successive sublimation before use.

Experimental

Measurements of the amount of quinone disappearing during the exposure and of the number of ergs of monochromatic energy absorbed by the quinone itself were used in calculating quantum efficiencies. All experi-

ments were performed at 25°. Solutions were 0.005 *M* in absolute alcohol except that for chloranil an 0.0025 M solution was used. The solutions were kept under pure nitrogen at all times.

Alcoholic quinone solutions, especially those of the chloro-substituted quinones, decompose slowly in the dark, the average amount of decomposition being shown in Table I.

TABLE I

DARK REACTION (25°)

	Time, sec.	% Decomposed	Time. sec.	% Decomposed
Monochloroquinone	5660	1.0	10036	2.0
			15310	3.0
Dichloroquinone	4992	1.5	1926	1.0
Chloranil	6105	2.5		

The rate of the dark reaction apparently increases with amount of chlorine substitution.

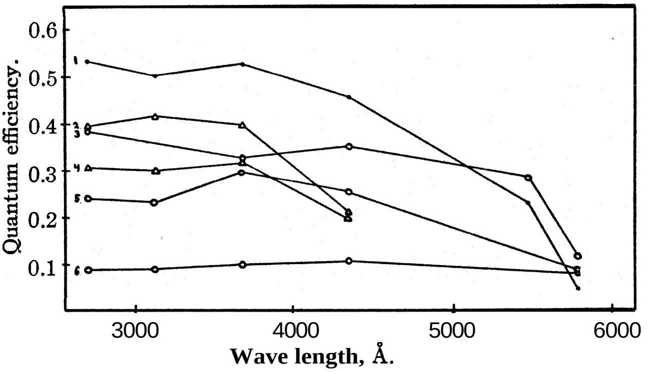

Fig. 1.—Relation between quantum efficiency and wave length. Circles represent chloroquinones; triangles, alkylquinones. 1, Benzoquinone; 2, toluquinone; 3, monochloroquinone; 4, thymoquinone; 5, dichloroquinone; 6, tetrachloroquinone.

Error from the dark reaction was avoided by always pipetting equal portions of solution into two similar cells, one being kept in the dark while the other was exposed, and both being analyzed simultaneously. Light reaction was then taken as the difference between dark reaction and total reaction.

In Table II, Q_m represents the fraction of the total incident energy of the entire exposure which was absorbed by the quinone alone,' and Φ represents the quantum efficiency, molecules/quanta. The individual values of Φ possess, in general, a probable error of ±10 to 15%.

Discussion

The quantum efficiencies are summarized in Table III, and compared on Graph 1.

Three points are to be observed. (1) For each quinone there is a region in which the efficiency of the reaction is, within limits of error, independent of the wave length. At longer wave lengths, however, for every quinone except chloranil there is a region in which the efficiency drops off rapidly. In other words, every quinone shows a threshold region below which the quantum efficiency is independent of wave length.

(2) This threshold region varies from one quinone to another—moving toward longer wave lengths with increasing chlorine substitution and toward shorter wave lengths with alkyl substitution. The oxidation potentials of the quinones are shifted in a similar manner, as shown by the following comparison.

Quinone	Oxidation potentials	Approximate threshold region, Å
Thymoquinone	0.5875	λ4000–4350
Toluquinone	.6454	40004350
Benzoquinone	.6990	4350–5000

Tetrachloro	246	.082	..	.106	.098	.089	.088	.095

The oxidation potential indicates an increase in the activity of the quinones as one goes from thymoquinone to the chloroquinones. The threshold region, in shifting toward longer wave lengths, indicates for the same progression a decrease in the amount of energy needed to activate the molecule. The two effects are entirely in accord—the more active quinones require less energy for activation.

(3) The value of the quantum efficiency below the threshold (in the region where it is independent of wave length) also varies from one quinone to another. Here, however, the effect appears to be independent of the chemical nature of the substituting groups. *It is a function only of their mass.* This is brought out by comparing the mean quantum efficiency in the constant region with the molecular weight of the quinone (graph 2).[7]

We believe this to be purely a space effect. The effect on the threshold region shows that substitution influences the energy needed to activate the molecule. Once activated, its fate is determined by the probability of a reaction-producing collision with an alcohol molecule. This may be represented by the reaction scheme

$$\text{Quinone} + h\nu \longrightarrow \text{Quinone}' \qquad (1)$$

$$\text{Quinone}' \longrightarrow \text{Quinone} + \text{energy} \qquad (2)$$

$$\text{Quinone}' + \text{alcohol} \longrightarrow \text{Hydroquinone} + \text{aldehyde} \qquad (3)$$

The quantum efficiency then is determined by the relative probabilities of Reactions 2 and 3. The larger and heavier the molecule, the smaller the probability of a suitable collision, or, the smaller the relative proba-

---

[7] It is to be noted that the alkyl quinones both deviate from the curve connecting the chloroquinones and benzoquinone. As this deviation lies just on the limits of experimental error, we cannot say that it is real.

bility of Reaction **3** compared with Reaction 2. The chemical nature of the substituting groups is without effect.

On this basis, the nearness of the quantum efficiency to one-half for benzoquinone can only be regarded as fortuitous, and the mechanism proposed by Weigert does not apply. Weight is added to this conclusion by the observation that in acid solutions the reaction rate is increased as much as 20%.

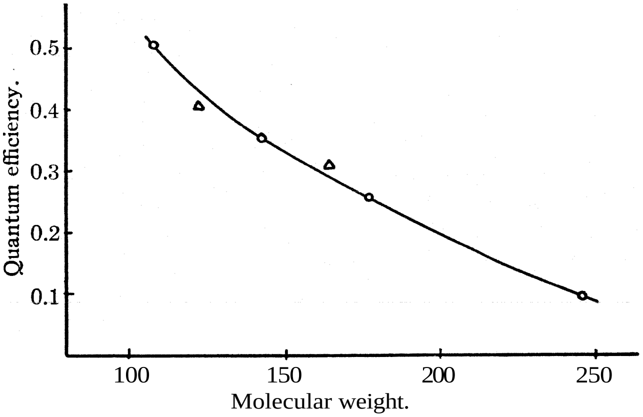

Fig. 2.—Showing relationship between quantum efficiency and the molecular weight of the quinone used. Circles are for chloro-substituted, triangles for alkyl-substituted, quinones.

Further measurements are in progress to determine whether the effects described here apply to other photochemical reactions. If found to be general, we believe these effects will give a valuable insight into the phenomenon of "steric hindrance" in chemical reactions. By the photochemical method of study it might be possible to separate pure space effects from those specific effects arising from the chemical nature of the substituents.

Summary

1. The quantum efficiencies of the photochemical decomposition of five chloro and alkyl substituted quinones in alcoholic solutions have been measured between A2700 and A5770 Å.

2. For each quinone, a threshold region, below which the efficiency is independent of the wave length, is observed.

3. Substituents which increase the oxidation potential of the quinone shift the threshold toward longer wave lengths and *vice versa.*

4. Substitution decreases the quantum efficiency as the mass of the molecule is increased, irrespective of the chemical nature of the substituents.

5. The specific effects on the threshold and the general effects on the efficiency are sharply differentiated. The first is ascribed to changes

produced by substitution on the energy of activation of quinone. The second is ascribed to a "steric hindrance" affecting the probability of reaction of the activated molecule.

THE SENSITIZED PHOTOSYNTHESIS OF CARBON DIOXIDE AT LOW CHLORINE PRESSURES

BY G. K. ROLLEFSON

RECEIVED JUNE 10, 1930 PUBLISHED SEPTEMBER 5, 1930

In studying the photosynthesis of phosgene, Chapman and Gee[1] found that oxygen had an inhibiting effect on the reaction. Later Bodenstein[2] showed that the concentration of the oxygen did not remain constant during the reaction, but decreased, due to the formation of carbon dioxide. Schumacher,[3] in a more extensive investigation, found that at high oxygen pressures the phosgene formation was so small that it could be neglected for chlorine pressures below 50 mm. In this case the oxygen and carbon monoxide reacted to form carbon dioxide, the rate law being

$$\frac{d(CO_2)}{dt} = kI_{\text{abs.}}^{0.71}\,(CO)^{1/2}$$

or for small absorption of light

$$\frac{d(CO_2)}{dt} = kI_0^{0.71}\,(Cl_2)^{0.71}\,(CO)^{1/2}$$

where I_0 is the intensity of the incident light. The exponent, 0.71, for the light absorbed suggests at once that the conditions were probably such that two parallel reactions were involved, one being proportional to the first power of the light absorbed, the other to the square root. A case of this type was shown to exist in the photosynthesis of hydrobromic acid.[4,5] That reaction followed the square root law at high pressures and the first power at low pressures. It seemed not unreasonable to think that in the sensitized formation of carbon dioxide a similar behavior should be found so that at high pressures of chlorine the square root of the light absorbed would appear in the rate law and at low pressures the first power. In both reactions the explanation of this behavior would be the same, *i. e.*, the destruction of the halogen atoms by first order reactions such as collisions with the walls of the reaction vessel or with impurities predominates at low pressures, whereas the recombination in the gas phase is of greater importance at high pressures.

Experimental

From Schumacher's results it seemed that the first power law must hold at pressures of chlorine below two centimeters of mercury; therefore the apparatus used in these experiments was designed for work in that range. The reaction vessel was made of pyrex, cylindrical in form with a plane window at one end and the inlet for the gases at the other. The length of the vessel was 18 cm. and the diameter 6 cm. Uniform illumination was obtained by rendering the light from a 500-watt tungsten filament lamp approximately parallel and passing it through a solution of quinine sulfate to remove rays of wave length less than 4050 Å. It is readily shown that under such conditions the change in intensity of the effective light in passing through the reaction vessel is never more than 10% if the pressure of chlorine is less than 2 cm. of mercury. Furthermore, the deviation from strict proportionality between the amount of light absorbed and the chlorine pressure is less than 5%.

The chlorine was prepared by heating anhydrous cupric chloride in a small side tube sealed onto the tube leading into the reaction vessel. The gas prepared in this manner has been tested previously and found thoroughly satisfactory.[6] The carbon monoxide was prepared by the decomposition of formic acid in sulfuric acid, washed with strong sodium hydroxide solution and finally dried with concentrated sulfuric acid. The gas was stored in a three-liter bulb from which it could be admitted to the reaction vessel as needed. The oxygen was prepared by the electrolysis of potassium hydroxide solution, was freed from hydrogen by passing over hot copper oxide, and was stored in a three-liter bulb containing some anhydrous calcium chloride which served as a drying agent.

The reaction was followed by observing the change in pressure with time. Due to the marked heating which occurs during the reaction, all readings were taken after turning off the light and allowing the system to stand until the pressure became constant. The manometer liquid was sulfuric acid of specific gravity 1.84. As the total pressure used in these experiments was of the order of half an atmosphere, a special form of manometer had to be devised in order to keep the length of the column to be measured within reasonable dimensions. The form finally adopted consisted of a vertical section of glass tubing, internal diameter 3 mm., the upper end of which was connected to the reaction vessel by means of a capillary tube and the lower end was ring-sealed into a flask of one-liter capacity in such a manner that the end dipped into thirty cubic centimeters of sulfuric acid in the bottom of the flask. Another tube leading out of the flask permitted either the simultaneous evacuation of both sides of the manometer or the admission of air into the flask to any desired pressure. Thus the manometer read the difference in pressure between the reaction vessel and the other side. For any one setting the range was approximately 50 cm. of sulfuric acid or 6.75 cm. of mercury. Pressure changes beyond this range were read by resetting the manometer as many times as necessary.

The procedure followed in making a run was to introduce chlorine into the reaction vessel up to a pressure 8–10 cm. of sulfuric acid above that to be used in sensitizing the carbon dioxide formation. Next the carbon monoxide was admitted from the reservoir bulb. These two gases were illuminated with resultant phosgene formation until the chlorine pressure had been reduced to the value desired for the run. This procedure was considered necessary by Schumacher in order to destroy inhibitors which would otherwise cause an induction period in the carbon dioxide formation. Some preliminary tests with the materials used in these experiments showed that frequently this procedure was unnecessary in order to obtain results free from an induction period but the number of

---

[6] Rollefson, THIS JOURNAL, 51, 770 (1929).

cases in which the induction period appeared was sufficient so that it was deemed expedient to carry out the reaction as recommended by Schumacher. After this preliminary formation of phosgene, the oxygen was admitted to a pressure 80–100 cm. of sulfuric acid in excess of the amount required for complete oxidaton of the carbon monoxide. A period of from one to three hours was allowed for the gases to mix before starting the reaction. In following the reaction readings were taken at intervals of from one-half to five minutes depending on the speed of the reaction.

Results

The data obtained are summarized in graphical form. Under the conditions of the experiments the amount of phosgene formed should be negligible and the rate independent of the oxygen pressure so that at a given chlorine pressure the observed law should be

$$-\frac{d(CO)}{dt} = k(CO)^{1/2}$$

Integrating this expression

$$(CO)^{1/2} = kt + a$$

where *a* is the constant of integration. Hence if we plot the square root of the carbon monoxide pressure against the time, the resulting curve should

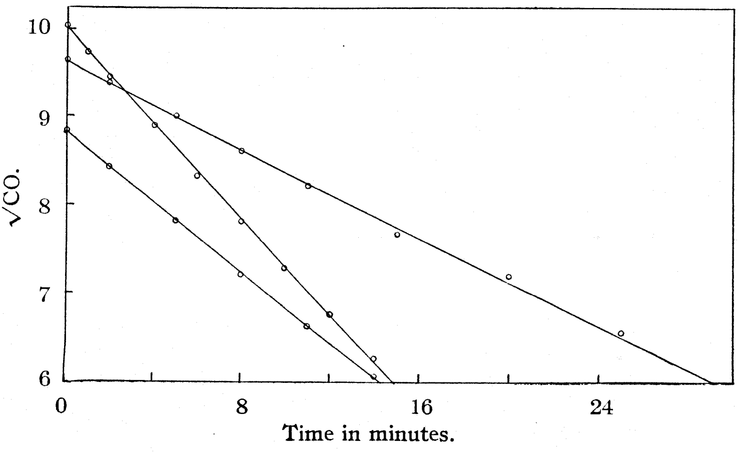

Fig. 1.

be a straight line. Pigure 1 shows the curves obtained at three different chlorine pressures. In each case the straightness of the line[7] shows that the assumptions of constancy of the chlorine pressure during the run and independence of the rate from the oxygen pressure are valid.

The effect on the rate of varying the chlorine pressure is obtained by plotting the values of k obtained above against the chlorine pressure raised to such a power that a straight line is obtained. Figure 2 shows the plot using the first power of the chlorine pressure and it is obvious that this law holds well within the limits of error of the experiments.

[7] In these plots the pressures have been left in terms of cm. of sulfuric acid.

It remains to show the effect of varying the intensity of the incident light. The procedure followed was to illuminate a given reaction mixture for three-minute intervals, using various screens to reduce the light intensity. The screens were of black cloth and had been calibrated with a thermopile and tested for neutrality. In Fig. 3 the observed rates are plotted against the light intensity, the intensity with no screen being taken as one. The circles were obtained with one reaction mixture and the crosses with another. The point on the abscissa axis represents the amount of reaction produced by light reflected from the walls of the room and surrounding objects. Another source of error which would be of consequence at low light intensities, but could not be corrected for, is the variation in light intensity due to imperfections in the filters. The graph shows that the rate of reaction is proportional to the first power of the light intensity.

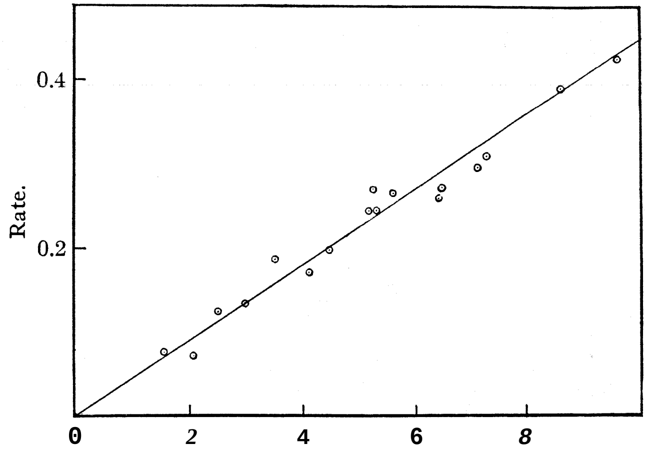

Fig. 2.

Discussion

From the data which have been presented, we see that at low pressures of chlorine the rate of formation of carbon dioxide is given by the expression

$$\frac{d(CO_2)}{dt} = kI_{abs.}(CO)^{1/2} = kI_0(Cl_2)(CO)^{1/2}$$

where the substitution of $I_0(Cl_2)$ for $I_{abs.}$ is justified by the fact that the total amount of light absorbed is small. This result confirms the view expressed at the beginning of this paper, to the effect that the exponent 0.71, found by Schumacher, is due to a mixture of reactions. The extension of the measurements to cover the pressure range studied by Schumacher has been delayed pending the construction of an apparatus which will permit the simultaneous observation of the carbon dioxide formation and the phosgene formation which is always present at high chlorine pressures. It may be that the deviation from the first power of the chlorine pressure at high pressures is due to the formation of phosgene, causing a break in the chain of reactions giving carbon dioxide, which would result in the observed yield being less than it would be if the phosgene formation remained negligible. This possibility is to be investigated.

Turning to a consideration of the possible mechanisms for the carbon dioxide formation, we find that the equations given by Bodenstein, Lenher and Wagner[8] and by Lenher and Rollefson[9] agree in that both have the carbon dioxide formed by the action of oxygen on an intermediate compound $COCl$. No detailed calculations concerning the formation of carbon dioxide were made in either paper as both were primarily concerned with the formation of phosgene. Some attempts have been made to calculate the rate law obtained in this paper from those mechanisms, but they have been unsuccessful, as the derived equations either showed a dependence of the rate on the oxygen pressure, or else gave the wrong exponents for the factors involved. These difficulties may be due to using the wrong chain-terminating reaction, although several different ones were tried. It is, however, possible to draw some conclusions concerning the nature of the

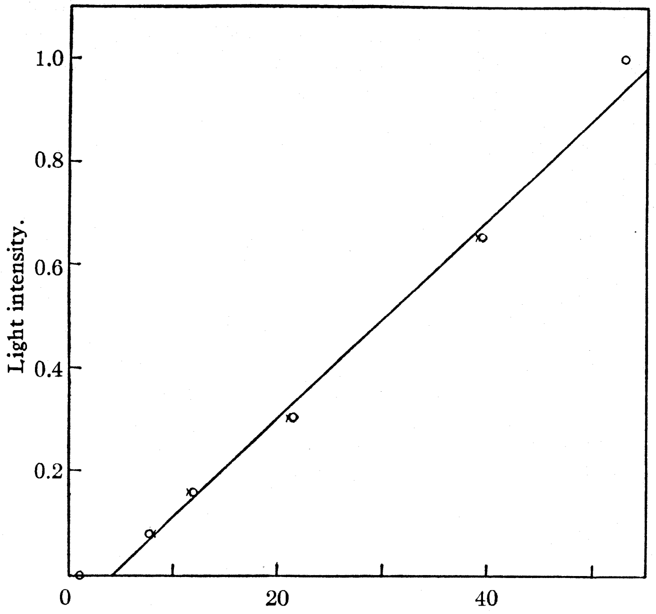

Fig. 3.

---

[8] Bodenstein, Lenher and Wagner, *Z. physik. Chem.*, B3, 459 (1929).

[9] Lenher and Rollefson, THIS JOURNAL, 52, 500 (1930).

reaction. In the first place the fact that the rate of the reaction is independent of the oxygen pressure at moderate pressures of oxygen, but not at lower pressures, indicates that in the higher range the step involving oxygen is too fast to be one of the rate-determining steps; therefore, on the basis of both the mechanisms referred to above, the rate of formation of carbon dioxide is essentially the rate of formation of COCl. Now it is an experimental fact that the rate of oxidation of carbon monoxide at a given chlorine pressure is comparable with the rate of formation of phosgene, at the same chlorine pressure, in the absence of oxygen. On the basis of the mechanism of Bodenstein, Lenher and Wagner, this would mean that their Reactions 2 and 4, namely

$$CO + Cl = COCl, \text{ and}$$
$$CO + Cl_2 + Cl = COCl_2 + Cl$$

have comparable rates. Such being the case, it is difficult to see how it would be possible for the phosgene formation to be negligible at any moderate pressure, as is found to be the case. This difficulty does not exist in the mechanism of Lenher and Rollefson, as COCl is a step in the formation of phosgene in that mechanism so that if the COCl is removed rapidly by oxygen, the rate of formation of phosgene will drop to a low value. At high temperatures the rate of dissociation of COCl becomes faster than the rate of reaction with oxygen, and therefore the carbon dioxide formation ceases at such temperatures. From this viewpoint the sensitized photosynthesis of carbon dioxide supports the views of Lenher and Rollefson concerning the formation of phosgene. Further discussion of this system will be postponed until more data are available.

Summary

The chlorine-sensitized photosynthesis of carbon dioxide has been studied for pressures of chlorine ranging from 2 to 13 mm. of mercury. In this range the rate law has been shown to be

$$\frac{d(CO_2)}{dt} = kI_0(Cl_2)(CO)^{1/2}$$

The results have been discussed briefly from the standpoint of the mechanisms which have been proposed by Bodenstein, Lenher and Wagner, and by Lenher and Rollefson.

THE USE OF CALCIUM HYDRIDE FOR THE DETERMINATION OF THE SOLUBILITY OF WATER IN BENZENE, CARBON TETRACHLORIDE AND TOLUENE

BY CHESTER K. ROSENBAUM[1] AND JAMES H. WALTON

RECEIVED JUNE 12, 1930 PUBLISHED SEPTEMBER 5, 1930

Introduction

For the determination of small amounts of water, 0.1% or less, a gasometric method has the advantage of giving a relatively large volume of gas from a small amount of water. Various reagents have been used to react with water to evolve a gas the volume of which was measured. Calcium carbide was used by Roberts and Frazer[2] and other investigators. Sodium[3] and the Grignard reagent[4] have also been used.

The energetic reaction of calcium hydride with water to evolve hydrogen suggested its use for the determination of water. The hydride offers two advantages over calcium carbide: (1) in most reagents the hydrogen evolved is not as soluble as acetylene and (2) the experimental accuracy is greater since, according to the following equations, twice the volume of gas is evolved:

$$CaH_2 + 2H_2O = Ca(OH)_2 + 2H_2$$
$$CaC_2 + 2H_2O = Ca(OH)_2 + C_2H_2$$

Calcium hydride has been used by Wirth[6] to determine water in ethyl alcohol using the reaction

$$CaH_2 + CO_2 + H_2O = CaCO_3 + 2H_2$$

His results, however, are of doubtful value because of the possible reaction of calcium hydride with the alcohol to evolve hydrogen.[6]

Since the completion of the work reported in this paper, an article has been published describing a method developed by Olav Notevarp,[7] who used calcium hydride to determine the water content of various solids and high-boiling liquids. The two methods, developed simultaneously and independently, are radically different since in Notevarp's method the hydride is suspended above the sample and does not mix with it. He found his apparatus to be impractical for determinations of water in low-boiling

organic solvents such as were used in the present investigation. Also, his analyses were concerned with various practical determinations in which larger percentages of water were present.

The present investigation was begun by studying the determination of water in benzene since the latter does not react[8] with the calcium hydride. The method developed was then extended to other solvents.

Experimental

Materials

The benzene was reagent grade, found free from thiophene, and had a boiling point 79.6° (corr.) and melting point 5.4° (corr.).

The carbon tetrachloride was found to be free from all impurities (boiling point 76.8° corr.).

The toluene was purified by standing over mercury, refluxing with phosphorus pentoxide and fractionating, the fraction distilling at 110.4–110.6° being used.

The calcium hydride was found to be about 97% pure. The chief impurity was about 2% calcium nitride as determined by acid titration of the ammonia evolved in the reaction with water. It contained about 0.2% of calcium carbide and possibly some metallic calcium and calcium oxide. None of these impurities interfered with the determinations, as will be shown later by the results in Table I.

Apparatus.—In the type of apparatus used by McNeil,[9] calcium carbide was dropped from a side arm into the sample contained in a flask connected with a gas buret. This gave inaccurate results when calcium hydride was used to determine water in benzene. The errors introduced by such an apparatus are as follows. (1) The largest error is due to adsorbed gases found present on the powdered calcium hydride. A considerable volume of gas was released when the hydride was heated in a tube or when the powder was dropped into a dry organic liquid. (2) A film of moisture remains on the reaction flask despite drying at 110° and is also adsorbed during the manipulations. (3) Any rubber present is attacked by the organic vapor with consequent leaks and introduction of impurities.

These errors are eliminated in the apparatus shown in Fig. 1, which is constructed as follows: a 150-cc. pyrex flask A is connected by the ground-glass stopcock B with the 50-cc. bulb C fitted with a ground-glass joint D. The ground-glass joint F is tightly held together by the rubber bands G stretched between wires encircling each half of the joint. The tube J is partly filled with calcium hydride to insure reaction of any water in the organic vapor with the hydride before it reaches the phosphorus pentoxide placed in the tube K. The rubber connection L is surrounded by a well of mercury M to prevent gas leakage. The 100-cc. gas buret N and the leveling tube P are filled with water. Constant temperature is maintained by pumping water at 30° from a thermostat through H, O, and the bath Q.

Method.—The apparatus was prepared for an actual water determination by the following preliminary treatment. About 5 g. of powdered calcium hydride was placed

in the flask A with about 15 cc. of the undried solvent being studied. The ground-glass joints were then lubricated by a special graphite paste made by mixing dry graphite powder (100 mesh) with just enough stopcock grease to give a thick paste. This special preparation was found necessary because the hot organic vapors dissolved the ordinary lubricants with consequent leakage. The flask **A** was then put in place as shown in Fig. 1 and was heated for several hours. This heating was conveniently accomplished by a small electric heating coil. After several hours the heating coil was removed from beneath A, the flask was allowed to cool and the thermostat Q was raised into place around A. After the system had come to equilibrium the gas volume was read. The barometric pressure was also recorded, since it was found that 1 mm. change in atmospheric pressure resulted in a change of 0.3 to 0.5 cc. in the gas volume (depending on the volume of gas present in the apparatus); this correction was always applied when any change in pressure occurred. The thermostat Q was then lowered and the heating of the flask continued for several hours. The heating coil was then removed from beneath **A,** Q was raised into place and a reading taken of gas volume and barometric pressure. The process of heating, cooling and taking readings was continued until no more hydrogen was evolved. This preliminary treatment served a three-fold purpose: (1) it checked the apparatus for leaks, (2) it removed any moisture in the apparatus, (3) it removed the adsorbed gases from the calcium hydride.

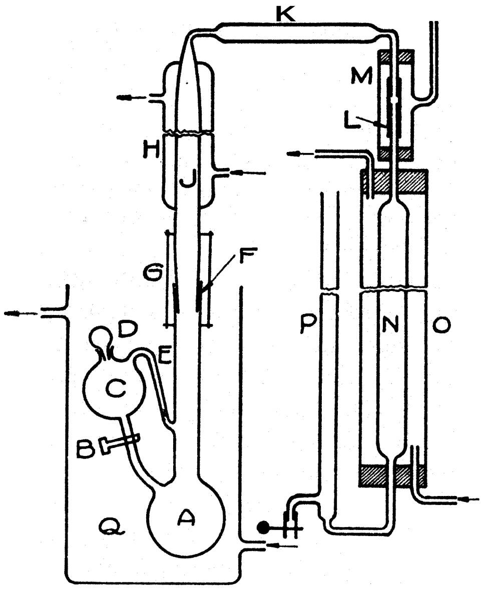

Fig. 1.—Apparatus for water determination.

After the above procedure the actual determination of water was carried out as follows. The organic solvent was first saturated by shaking with water in a flask at high temperature and then allowing the flask to cool in a thermostat to the desired temperature, with the resulting separation of excess water as shown by the turbidity. The solution was allowed to stand for a day or more to come to equilibrium before a sample was withdrawn for solubility measurements. The sample was then withdrawn with a 25-cc. pipet, the tip of which was guarded by a ground-glass cap and the upper end by a tube filled with calcium hydride to prevent absorption of moisture when not in use. The sample (**25** or 50 cc.) was introduced into the bulb C through D after B had been closed. The joint D was then closed and the bath Q raised around A. After the system had come to equilibrium, the initial gas reading and barometric pressure were recorded. The bath Q was then lowered and B was opened to allow the sample to react with the calcium hydride already present with the dry solvent in A. Hydrogen was evolved rapidly at first and after the evolution slowed down, the flask was heated to expedite the reaction. The process of heating, cooling and taking readings was continued until it was found that no more gas was being evolved. In some cases the reactions were allowed to continue for three days before the last traces of gas were evolved, although it was found that the reaction was about **95%** complete within the first ten hours.

After one determination was completed, another sample was added to the flask and successive analyses were carried out until the flask A was filled with the solvent.

Results.—The accuracy of the method was first established by adding a weighed amount of water from a weighing pipet to calcium hydride contained in benzene from which all water had been abstracted by boiling with the hydride until no more hydrogen was evolved. The results of these experiments are shown in Table I.

TABLE I

ACCURACY OF METHOD

Experiment	1	2	3

Hydrogen evolved (calcd. as water), g.	.0384	.0396	.0402

Solubility of Water in Benzene, Carbon Tetrachloride and Toluene.—The solubility of water in the above solvents was determined at various temperatures. The results are shown in Table II and are graphed in Fig. 2.

TABLE II

SOLUBILITY OF WATER IN BENZENE, CARBON TETRACHLORIDE AND TOLUENE

Temp., °C.	Grams of water per 100 g. of solvent Benzene	Carbon tetrachloride	Toluene
10	0.0451	0.00711	0.0335
20	,0573	.00844	.0450
30	.0746	.0109	.0600
40	.0953	.0152	.0733
50	.1271	.0237	.0953
60	.1637	....	....

(a) Solubility of Water in Benzene.—The values given in the table are an average of two to four determinations of the solubility at each temperature. A typical example of the accuracy of the individual determinations is illustrated by values of 0.0962, 0.0953 and 0.0944 (average 0.0953) for the solubility of water in benzene at 40°.

These results for the solubility of water in benzene are higher than those obtained by Clifford[10] by absorbing the moisture from the benzene with calcium chloride. They are somewhat lower than the results of Groschuff[11] determined by the turbidity method and also lower than the results of Hill[12] determined by measuring the solubility of silver perchlorate in benzene–water solutions.

As a practical application of this method of analysis, the drying of benzene by distilling off and discarding the first 10% was tested. This method is recommended for the removal of water from benzene.[13] Ordinary tech-

[13] "Organic Syntheses," John Wiley and Sons, Inc., New York, 1924, Vol. IV, p. 81.

nical benzene was used and in Table III the effect of distilling off 10% of Sample No. 1 was determined. Sample No. 2 was first saturated with water and 20% of the solution was distilled before the distillate came over unclouded, thus showing no more excess water.

TABLE III

THE REMOVAL OF WATER FROM BENZENE BY DISTILLATION

Sample No. 1. 10% distilled	Sample No. 2. 20% distilled
Original sample 0.025% H_2O	**Original sample 0.0746% H_2O**
Residue contained 0.0147% H_2O	**Residue contained 0.0156% H_2O**

(b) Solubility of Water in Carbon Tetrachloride.—The results given in Table II were obtained using 50-cc. samples and despite the very low solubility the method gave checks between individual determinations of 0.0004% H_2O. Clifford[10] using the calcium chloride method obtained values of 0.010% at 24° and 0.013% at 28.5°, the latter not agreeing with the present results.

The presence of carbon disulfide as an impurity in technical carbon tetrachloride was found to increase the solubility of water in the solvent by about 50%. As an example typical of several determinations, the solubility of water in carbon tetrachloride containing carbon disulfide was found to be 0.0170% instead of the value 0.0109% H_2O in pure carbon tetrachloride.

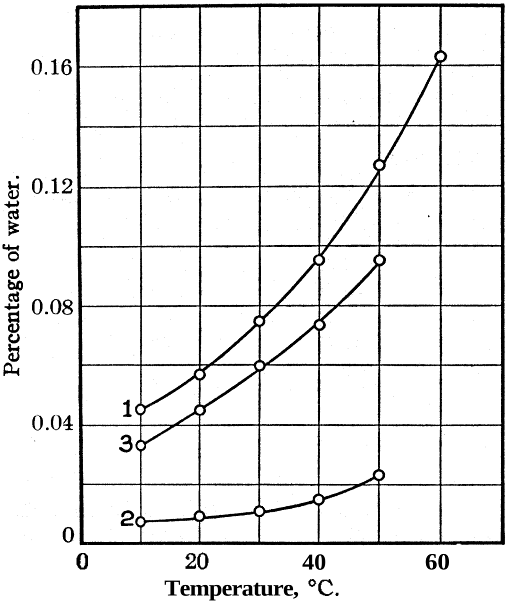

Fig. 2.—Solubility of water in organic solvents: Curve 1, benzene; Curve 2, carbon tetrachloride; Curve 3, toluene.

(c) Solubility of Water in Toluene.—The results given in Table II are average values obtained with 25- and 50-cc. samples of toluene.

Discussion

The principal value of the present method is its extreme accuracy. As shown by the results in Table I and the individual solubility determinations, the method is accurate to about 0.001% H_2O in determinations of less than 0.10% H_2O present in organic solvents.

A possible practical application of the method besides its use in solubility studies is as follows. A dry organic solvent such as benzene could be used to extract the water from a solid sample by leaching or refluxing and the water present in the solvent could subsequently be determined.

The two chief objections to the calcium hydride method are the following. First, the method is limited to solvents which do not react with calcium hydride or otherwise react so slowly that necessary corrections can be applied; second, the method is not rapid, since the analyses are of one to three days' duration, although they do not require much actual time or care. The time required can be shortened for practical determinations since the reaction is about 95% complete in ten hours and the percentage of total moisture could then be estimated.

Summary

1. A new improved apparatus and method have been developed for the gasometric determination of water in certain organic solvents.

2. Calcium hydride has been shown to be a good reagent for the quantitative determination of water, giving an accuracy of 0.001% H_2O in determinations of about 0.1% H_2O.

3. The solubility of water in benzene, in carbon tetrachloride, and in toluene has been determined at various temperatures.

4. Benzene can be dried to a water content of 0.015% by distilling and discarding the first 10 to 20% of the liquid.

A STUDY OF THE PRODUCTS OBTAINED BY THE REDUCING ACTION OF METALS UPON SALTS IN LIQUID AMMONIA SOLUTION. III. THE ACTION OF SODIUM UPON SILVER IODIDE AND SILVER CHLORIDE[1]

BY WAYLAND M. BURGESS AND EDWARD H. SMOKER

RECEIVED JUNE 18, 1930 PUBLISHED SEPTEMBER 5, 1930

Introduction

In the first paper of this series,[2] there was described a reaction in liquid ammonia between sodium and a salt, which resulted in the formation of a compound of sodium and the reduced metal. In the present paper a simpler case is presented where the reduced metal is obtained without further reaction.

Kraus and Kurtz[3] found that sodium reacted readily with silver cyanide

---

[1] This article is based upon the thesis presented to the Faculty of the Graduate School, University of Cincinnati, by Edward H. Smoker in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] Burgess and Rose, THIS JOURNAL, 51,2127 (1929).

[3] Kraus and Kurtz, *ibid.*, 47, 43 (1925).

or silver iodide in liquid ammonia, forming a metallic precipitate, inactive toward air and moisture. The reaction ratio of sodium to silver salt was given as 1.11 and 1.09. They concluded that no compound of sodium and silver was formed. A more accurate determination of this reaction ratio has been carried out, obtaining as an average value 1.00. The product of the reaction has been purified and shown by analysis to be metallic silver.

Experimental Method

Silver iodide (or silver chloride) was prepared by slowly mixing equal volumes of approximately 0.5 N solution of purified potassium iodide (or potassium chloride) and silver nitrate. The resulting precipitate was washed, filtered, dried at 110°, pulverized and kept in a brown bottle.

In carrying out the reaction, a small bent tube, containing a weighed amount of the silver salt, was placed in the side arm of a reaction tube, identical with the one used in the earlier work.[2] By gently tapping the tube, the powdered salt was slowly added to a liquid ammonia solution, containing a weighed amount of sodium, until the blue color just disappeared. The end-point of the reaction could be judged very accurately. From the weights of the silver salt and sodium used, the reaction ratio was calculated.

The precipitate formed by the reaction was washed according to the method previously described,[2] until the wash solution gave no test for soluble halides. The last trace of ammonia was allowed to evaporate against a slight pressure. Tests showed that the dried product did not gain weight in air, so it was removed from the reaction tube and weighed directly on a balance. The solid was then analyzed for silver by dissolving in concentrated nitric acid and precipitating as silver chloride. On a number of samples, determination of the loss in weight on heating to 100° and tests for iodides (or chlorides) and ammonia were made.

Experimental Data

In Tables I and II are summarized the experimental results for the reaction ratios and silver determinations.

L4	.2584	1.6118	.999	..

[a] Solution blue at end. [b] Those experiments marked I, carried out by Mr. Hooper Linford in this Laboratory.

Several samples showed a slight loss in weight on heating to 100° in an evacuated tube for several hours. The loss was of the magnitude of 0.1–0 . . In all cases, traces of iodides (or chlorides) were present in the product since the concentrated acid solution was always turbid. In a number of cases the dried precipitate was digested with water and the soluble iodides (or chlorides) determined. The values obtained varied from 0.1 to 0.8% of the total weight. Test made on the heated samples with Nessler's reagent showed that no ammonia was present. No gas was liberated during the reaction.

Discussion of Results

Both the reaction ratio and analysis of the product show that sodium reacts with silver iodide (or silver chloride) in liquid ammonia according to the following equation

$$Na + AgI \longrightarrow NaI + Ag$$

A product analyzing 100% silver could not be obtained because of the inability to wash the precipitate entirely free of adsorbed salts. That this was not due to inefficient washing was shown by digesting a dried sample with water before treatment with acid. Even then the acid solution was turbid, showing the presence of halogens.

The excellent agreement of the reaction ratio shows the high degree of accuracy with which the end-point of these reactions can be determined. It is suggested that free sodium in solution can be accurately determined by this method of adding a weighed quantity of silver chloride.

Summary

Sodium reacts with liquid ammonia solutions of silver iodide, or silver chloride, to form free silver and the corresponding sodium salt. No further reaction occurs.

THE REMOVAL OF GASES FROM LIQUIDS

BY ROGER K. TAYLOR

RECEIVED JUNE 24, 1930 PUBLISHED SEPTEMBER 5, 1930

The complete removal of gases from liquids is essential in some research problems, and is a matter presenting considerable difficulty. Although the distribution coefficient of many gases between the vapor and liquid phases of the solvent is of such magnitude as to indicate that practically all of the gas should be removable by sweeping off a comparatively small amount of the solvent, the establishment of equilibrium is usually very slow; the rate of liberation of dissolved gas is dependent on the extent, and particularly on the rate of renewal, of the liquid–vapor interface. Periodic removal of the vapor above a liquid standing in a bulb is a very tedious method of accomplishing gas removal, since diffusion of the gas to the liquid–vapor interface is slow. Stirring the liquid, especially if it can be spread out in a large thin film, accelerates the process considerably. This can be accomplished in an apparatus previously described.[1]

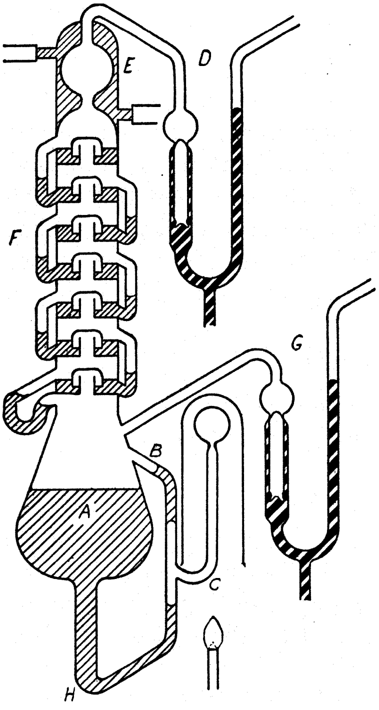

Fig. 1.

In another apparatus devised by the author, and shown in Fig. 1, the removal of air or other gas from any liquid of appreciable vapor pressure may be readily accomplished. The liquid is contained in **A**; most of the gas in the apparatus is pumped out through D. Then, with D closed, a small flame is placed under the side tube *C*, and cold water is circulated through the jacket E. The vaporization of the liquid in *C* carries a succession of slugs of the liquid up the tube B, splashing it against the opposite wall and permitting it to flow in a thin film down the wall, back to the bulk of the liquid. This action gives constant circulation and stirring of the liquid and active motion of the liquid–vapor interface.

C is sealed in somewhat above the center of B, so that even if B is for a moment completely filled with liquid, no opportunity is offered for vapor to push back to or past H. The liquid level in **A** must of course be somewhat above the junction of B and C. The constriction and bulb at the top of *C*, and jacket around *C*, are to keep this tube ever from filling completely with liquid, either by distillation or splashing; the heating of a nearly gas-free liquid at any considerable distance from a liquid–vapor interface leads to irregular, practically explosive, boiling and possibly disastrous bumping.

---

[1] Taylor, THIS JOURNAL, 50,2937 **(1928).**

When sufficient condensation has taken place in E to give overflow from all of the sections of the column F, the latter functions like any fractionating column. The mixture of gas and vapor passes up the column, bubbling through the liquid on each plate, and the only way for gas to pass from any given section to the one below is to return in solution in the overflow. The partial pressure of gas (and hence its solubility) is low; the volume of condensate, compared with that of the vapor forming it, is very small. Accordingly a state of equilibrium will finally be reached at which virtually all of the gas in the system is in the top of the column, since the ascending vapor in each section will be relatively richer in gas than the descending liquid; the slowly descending liquid is stripped of its gas content by meeting in counter-current the ascending practically gas-free vapor. It is evident that when equilibrium as to gas content is reached, the liquid in A will be nearly gas-free even when the partial pressure of gas at the top of the column is quite appreciable. Incidentally, a rough estimate of the amount of gas present may be made by comparing temperatures at A and at the top of F; for obvious reasons the presence of gas will lead to a higher temperature at **A,** while when the gas is nearly all gone the slight difference due to the head of liquid through which the vapor must bubble is not appreciable to the touch.

The gas is removed as it accumulates, together with some of the vapor, by opening periodically the trap D for an instant to a pump or to an evacuated space of some five or ten times the volume from the top plate to the trap. Active bubbling up the column, persisting for some time, follows this operation if gas has accumulated to any extent.

Trap G communicates with the apparatus in which the gas-free liquid is to be used; at the proper time the receiver is chilled, and when G is opened the liquid distils over. Or, of course, the unit itself may be employed as a reservoir for the gas-free liquid.

The advantages of this over the apparatus previously described[1] are that with the same amount of stirring the gas–vapor mixture need not be removed so frequently; if equilibrium is established before each removal, the same number of removals carries off a far larger fraction of the gas; hence, though the loss of liquid in complete degassing is small in either case, it is less with the present device; and the slight chance of carrying air in mechanically with the flowing mercury of the former apparatus is obviated with this one. Furthermore, even if there should be a minute leak admitting air into the system, it would still be possible to withdraw a practically air-free vapor through G, as the air would be carried out of A up the column as it leaked in.

On the other hand, the present apparatus cannot be used as well as the former if it is necessary to maintain the liquid at a constant temperature during the degasification.

A device of the present sort has a number of uses. (1) At this University it has served for the preparation of air-free water, benzene and toluene, used in several researches.

(2) The author has employed it in a study of the retention in *vacuo* of gases by soluble salts. In this instance air-free water was admitted, by breaking a septum with a magnetically operated hammer, to an evacuated tube sealed on at H containing the salt under investigation; after the salt had dissolved, the solution was degassed as described above; the gas liber-

ated, together with some water vapor, was pumped off at D for measurement and analysis.

(3) It could evidently be used to determine the solubility of gases in liquids, by admitting the saturated liquid into the evacuated apparatus and pumping off and measuring the gas liberated.

(4) Adsorption of gases by soluble materials could be determined by a method similar to that used in (2).

A modified Töpler pump, embodying the features of the McLeod gage, has been found convenient in handling small amounts of gases, as in (2). Such an apparatus as shown in Fig. 2 may well be used in any case, such as (2), (3) and (4), when the amount and nature of the gas evolved are of interest.

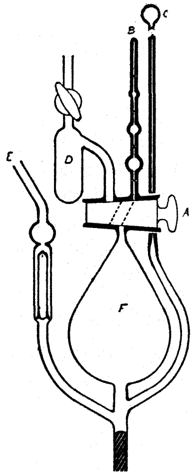

Fig. 2.

By raising the mercury, gas that has entered at E is compressed into the calibrated tube B up to one of the graduations, and the pressure is determined by comparing mercury levels in B and C. (Condensation of solvent vapor occurs in both B and C, so that vapor pressure is canceled in making this measurement.) If more than one stroke of the pump is to be made, condensation of vapor in F must be avoided, as otherwise re-vaporization on the down-stroke will leave practically no difference in pressure between E and F. This is easily accomplished by warming the mercury; most of the condensation then takes place in B instead of in F, and when A is closed the down stroke leaves a vacuum in F.

If a mixture of gases is present, it may be analyzed as follows. The total amount of gas is first determined as above; then by suitable manipulation of A and the mercury level, the gas is transferred to D, which is evacuated and contains an absorbent for one component of the mixture. When absorption is complete, the residual gas is pumped back into B and re-measured. D may then be opened, cleaned out, charged with another absorbent, and pumped out; the next constituent is then determined in a similar manner, and so on.

Summary

Description is given of apparatus and method for removal of gases from appreciably volatile liquids.

Some uses, actual and potential, for this device are listed.

Description is given of apparatus and method for pumping off, measuring and analyzing small amounts of gas, in absence or presence of condensable vapors.

CESIUM SULFATE AS A CONFIRMATORY REAGENT IN THE DETECTION OF ALUMINUM

BY HERMAN YAGODA AND H. M. PARTRIDGE

RECEIVED JUNE 25, 1930 PUBLISHED SEPTEMBER 5, 1930

Cesium salts, because of their unique properties, have long been used as reagents in micro-analytical work and with the increasing demand for salts of this element together with the opening of new ore deposits, it seems certain that much more general use of its interesting properties will result both in qualitative and quantitative analysis.

The familiar aluminum tests which depend on the formation of "Thenard's Blue" or "lakes" with organic dyes are not altogether satisfactory, especially for the average student in qualitative analysis. The formation of a relatively copious precipitate of the insoluble cesium alum, $Cs_2SO_4 \cdot Al_2(SO_4)_3 \cdot 24H_2O$, which contains only 4.75% by weight of aluminum, is on the other hand a simple and decisive test. Its sensitivity will be appreciated when it is recalled that a saturated solution of cesium alum at 0° is 0.00745 M with respect to aluminum ion, and that at 16° this value is but slightly greater, 0.0077 M. Concentrations of aluminum down to 0.1 mg. per cc. are easily and rapidly detected.

Procedure

The supposed aluminum hydroxide, separated in the usual manner from the other Group III metals, is dissolved in 1–5 cc. of hot 3 M sulfuric acid by repeatedly pouring the acid through the filter. (If the precipitate is large, it is more convenient to remove some of it and dissolve in an evaporating dish.) The resulting aluminum sulfate solution is cooled and 0.5–1 cc. of approximately 0.25 M cesium sulfate is added. On scratching the walls of the test-tube with a stirring rod, the dense white cesium alum separates and rapidly settles.

Time Required for Precipitation.—Due to the great tendency of cesium alum solutions to remain supersaturated, the following rough classification has been made

Concn. of Al ion in mg. per cc.	5 and greater	1–5	0.1–1
Time for precipitation	instantaneous	1 minute	3 minutes

Interfering Elements.—Although cesium has a great tendency to form double salts with many elements, only bismuth is likely to be troublesome. In practice this possibility of confusion may be eliminated by adding one drop of concd. hydrochloric acid to a portion of the white precipitate. Warm and add 1 cc. of hydrogen sulfide water. A brown precipitate of bismuth sulfide will indicate the presence of that element. Ferric and chromic alums are much more soluble than the aluminum alum. Beryllium and magnesium do not interfere. The elements lanthanum cerium, praseodymium, neodymium, erbium, yttrium, thorium, zirconium (and probably hafnium) form more soluble double cesium sulfates or form them much more slowly than aluminum.

The authors are indebted to the Maywood Chemical Works for their kind cooperation in this and other work which will be described later.

AN OXIDE OF IODINE, I_2O_2. AN INTERMEDIATE COMPOUND

BY WILLIAM C. BRAY

RECEIVED JULY 8, 1930 PUBLISHED SEPTEMBER 5, 1930

The recent experimental proof by Abel and Hilferding[1] that the reaction between iodate and iodide ions in acid solution, long known as a fifth order reaction,[2] is of the fourth order at a low iodide concentration, has led me to reexamine the series of investigations of Skrabal[3] on the rate of formation of iodate and iodide from iodine and hydroxide ion. Skrabal presented strong evidence that HI_3O and $I_3O_2^-$ exist as intermediate compounds in this reaction, and that HI_3O is a loose addition compound of iodine and hypoiodous acid. He also pictured $I_3O_2^-$ as a similar compound of iodine and iodite ion. The present analysis has led to the conclusion that $H_2I_2O_3$ and I_2O_2 also exist as intermediate compounds, and that $I_3O_2^-$ is really an addition compound of I_2O_2 and iodide ion.

Skrabal succeeded in demonstrating that the results of his rate measurements could be represented by three rate laws, A, B and C, and postulated the following mechanisms

	Relatively rapid equilibrium	$2IOH + I^- \rightleftharpoons I_3OH + OH^-$	(1a)
A	Rate-determining step	$I_3OH \longrightarrow$	(2)
	Main reaction	$3IOH + 3OH^- = 2I^- + IO_3^- + 3H_2O$	
	Relatively rapid equilibrium	$2I_3^- + OH^- \rightleftharpoons I_3OH + 3I^-$	(1b)
B	Rate-determining step	$I_3OH \longrightarrow$	(2)
	Main reaction	$3I_3^- + 6OH^- = IO_3^- + 8I^- + 3H_2O$	
	Relatively rapid equilibrium	$3I_3^- + 4OH^- \rightleftharpoons I_3O_2^- + 6I^- + 2H_2O$	(3b)
C	Rate-determining step	$I_3O_2^- \longrightarrow$	(4)
	4 + rapid steps	$I_3O_2^- + 2OH^- = IO_3^- + 2I^- + H_2O$	(5)
	Main reaction (Sum)	$3I_3^- + 6OH^- = IO_3^- + 8I^- + 3H_2O$	(6)

---

[3] Skrabal, (a) *Monatsh.*, **32**, 815–903 (1911); (b) *Oesterr. Chem.-Ztg*, No. 11 (1913); (a) is the fifth paper of a series of twelve, 1907–1916, on hypohalous acids and hypohalites, and (b) is a general discussion of the stoichiometric reactions of iodine isolated and studied in his investigations.

A and B have the same rate-determining step, (2), the disappearance of I_3OH in a first order reaction; they show differences in the rate laws, in the equilibria that precede the rate-determining step, and in the main reactions, merely because the initial concentrations of OH^-, HIO, I^-, I_3^- and I_2 differ in the two sets of experiments. C involves another rate-determining step, (4), the disappearance of $I_3O_2^-$, which is also a first order reaction. This reaction, termed by Skrabal the "slow" reaction, was detected in the presence of B; and, by suitable variation of the experimental conditions, was studied as a limiting reaction.

Additional evidence for this mechanism was presented by Xkrabal by means of rate measurements in the analogous bromine reactions at low concentrations of hydroxide ion.[4] The results furnish for the existence of HBr_3O a proof similar to that for the existence of HI_3O, and show that there is a second independent reaction resembling, but not identical with, that which involves $I_3O_2^-$. Measurements of the rate of formation of chlorate in solutions which contain hypochlorite and hypochlorous acid[5] have given no indication of the existence of either HCl_3O or $Cl_3O_2^-$. There is thus definite evidence that oxyhalogen compounds containing three halogen atoms per molecule exist as intermediate compounds, and that the tendency of such compounds to form decreases rapidly in the order iodine, bromine and chlorine. It will be recalled that the stability of the complex trihalide ions, as I_3^-, Br_3^- and Cl_3^-, decreases in the same order.

The relation of HI_3O and $I_3O_2^-$ to other substances and to each other are shown by the rapidly reversible reactions: 1a, 1b, 3b and the following

$$2I_2 + OH^- \rightleftharpoons HI_3O + I^- \qquad (1c)$$
$$I_2 + HIO \rightleftharpoons HI_3O \qquad (1d)$$
$$3HIO + OH^- \rightleftharpoons I_3O_2^- + 2H_2O \qquad (3a)$$
$$3I_2 + 4OH^- \rightleftharpoons I_3O_2^- + 3I^- + 2H_2O \qquad (3c)$$
$$HI_3O + HIO + 2OH^- \rightleftharpoons I_3O_2^- + I^- + 2H_2O \qquad (3d)$$

The valence (or polar number) of iodine in $I_3O_2^-$ is, on the average, the same as in hypoiodous acid, and that in HI_3O is lower. It is thus probable that in the spontaneous first order reactions, (2) and (4), at least one of the three atoms of iodine is changed to a higher, and one to a lower, valence stage than that of hypoiodite iodine.

Under the conditions of Skrabal's experiments there are two, and only two, paths which lead, through HI_3O and $I_3O_2^-$, respectively, to the formation of iodate and iodide. These two paths are to be regarded as independent, even though HI_3O and $I_3O_2^-$ are in equilibrium with each other as shown in 3d. Consideration of the equilibria, 1a–d, 3a–d and the hydrolysis of iodine

---

[4] Skrabal and Weberitsch, *Monatsh.*, 36, 237–256 (1915). This is the tenth paper of the series mentioned in the preceding reference.

[5] (a) Skrabal and Weberitsch, Ref. 4, p. 246; (b) Foerster and Dolch, *Z. Elektrochem.*, 23, 137 (1917).

$$I_2 + H_2O \rightleftharpoons HIO + H^+ + I^- \qquad (7)$$

leads to the conclusion that the rate of iodate formation must become extremely small in acid solutions which contain iodide, and this is in qualitative agreement with experimental results.[6] It is also to be expected that this spontaneous formation of iodate and iodide from HI_3O or $I_3O_2^-$ is impossible whenever the concentrations of IO_3^-, I^- and H^+ are high enough to enable these substances to react with each other. In this connection, Skrabal proved that the path from $I_3O_2^-$ to iodate and iodide is closely related to, if not identical with, that of the fifth order reaction[2] between IO_3^-, I^- and H^+; he proved this by calculating correctly[7] the value of the equilibrium constant of Reaction 6 from the rate laws and specific reaction rates of "C" and the fifth order reaction. Skrabal, however, did not outline a mechanism for either of the first order reactions, (4) and (2).

Several investigators had commented on the fact that all iodate–halide reactions in acid solution are of the fifth order, while the bromate and chlorate reactions are of the fourth order, and at least ones considered a transition to the lower order probable in the case of the IO_3^-–I^-–H^+ reaction. The recent investigation of Abel and Hilferding[1] has demonstrated that this transition is complete at a sufficiently low concentration of iodide ion, about 10^{-8} molal at 25°. They suggest for the mechanism the rate-determining step

$$HIO_3 + HI\ (\text{or } IO_3^- + I^- + 2H^+) \longrightarrow HIO + HIO_2 \qquad (8)$$

followed by the rapid reduction of HIO and HIO_2 to iodine; but they do not refer at all to the mechanism of the fifth order reaction, for which Abel and Stadler[2c] had written the rate-determining step

$$IO_3^- + 2I^- + 2H^+ \longrightarrow (IO_3{\cdot}2I{\cdot}2H)' \longrightarrow 2HIO + IO^- \qquad (9)$$

(where the middle term represents a Bronsted "critical complex"). Abel and Hilferding have thus left open the question as to a connection between the fourth and fifth order reactions.

On considering this question, Dr. Liebhafsky and I have concluded that Reaction 8 cannot be the first step in 9, that complete independence is improbable on account of the similarity and high orders of the two reactions, and that they can be brought into close relationship by assuming as an intermediate compound either $H_2I_2O_3$ or I_2O_2. I have now found this assumption to be consistent with Skrabal's reactions. In the following mechanisms, for reasons which will be explained later, both $H_2I_2O_3$ and I_2O_2 are assumed to exist.

Fourth order reaction at low concentration of iodide.

[7] Skrabal, Ref. 3a, pp. 878–881.

[8] Skrabal, Ref. 2b, p. 124 (1924); *Monatsh.*, 36, 230 (1915).

Relatively rapid equilibrium	$IO_3^- + I^- + 2H^+ \rightleftharpoons H_2I_2O_3$	(10a)
Rate-determining step	$H_2I_2O_3 \longrightarrow HIO_2 + HIO$	(11)
Main reaction	$IO_3^- + 5I^- + 6H^+ = 3I_2 + 3H_2O$	(12a)

Fifth order reaction, with excess iodide.

Relatively rapid equilibrium	$IO_3^- + I^- + 2H^+ \rightleftharpoons H_2I_2O_3 \rightleftharpoons I_2O_2 + H_2O$	(10b)
Rate-determining step	$I_2O_2 + I^- \longrightarrow I_3O_2^-$	(13)
Rapid follow reactions	$I_3O_2^- + 6I^- + 4H^+ = 3I_3^- + 2H_2O$	(14)
Main reaction	$IO_3^- + 8I^- + 6H^+ = 3I_3^- + 3H_2O$	(12b)

There is thus a "forking"[9] at the $H_2I_2O_3$ stage between a first order reaction (11) and a second order reaction which involves iodide ion (13). The rapid follow reactions, of course, take place in steps, which, in (14), are related to the reverse reactions of Nos. 3a–d. One of these, the reverse of **(3a)**

$$I_3O_2^- + H^+ + H_2O \longrightarrow 3HIO \qquad (14a)$$

is of especial interest, since it leads to three molecules of hypoiodite, as postulated in Reaction **9**. **A** consideration of these reactions leads to the conclusion that $I_3O_2^-$ is extremely unstable in an acid iodide solution.

The complete correspondence between the two series of reactions, **10b**–13–14 and **3b–4–5,** shows that, in this path, there is only one rate-determining step between iodine and iodate–iodide, and that Equation 4 may be completed by writing it as the reverse of (13). The assumption that these two rates are equal at equilibrium leads directly to an expression for the equilibrium constant of Reaction 6, closely related to that verified by Skrabal[7]

$$\frac{(IO_3^-)(I^-)^8}{(I_3^-)^3(OH^-)^6} = \frac{k_C}{3k_5k_w^2} \qquad (15)$$

where

$$-d(I_3^-)/dt = 3d(IO_3^-)/dt = k_C(OH^-)^4(I_3^-)^3/(I^-)^6 \qquad (16)$$
$$-d(IO_3^-)/dt = k_5(IO_3^-)(I^-)^2(H^+)^2, \text{ and } K_w = (H^+)(OH^-)$$

In Skrabal's other path from iodine to iodate–iodide there is a single rate-determining step (2), only at a distance from the final equilibrium; a second independent rate-determining step, presumably the reverse of (10), will manifest itself as equilibrium is approached; and the calculation of the equilibrium constant of Reaction 6 from the kinetic data is obviously impossible. The following reactions are suggested to complete (2), and to represent the subsequent relatively rapid steps in the alkaline solution

(Equation 2)	$HI_3O + H_2O \longrightarrow HIO_2 + 2I^- + 2H^+$	(17)
Rapid follow reactions	$2H^+ + 2OH^- = H_2O$	(17a)
	$I_3^- + OH^- = 2HIO + I^-$	(17b)
	$HIO_2 + HIO = H_2I_2O_3$	(17c)
	$H_2I_2O_3 + 2OH^- = IO_3^- + I^- + 2H_2O$	(17d)

---

[9] (a) This term was suggested by Luther; Bray, *Z. physik.* Chem., **54, 465** (1906); (b) Skrabal, Ref. 3a, p. 880.

It will be noted that the main reaction (6) is the sum of these reactions and (1b); and that (17c), the reverse of (11), appears as one of the rapid follow reactions. In the reverse case in acid solution, it is doubtful whether the rate-determining step (11) will always be followed by the reverse of (2), since this involves the assumption that HIO_2 cannot be reduced by iodide ion in acid solution by any other path than that through HI_3O. The above mechanism requires the presence of I_3^-, HIO_2 and OH^-, and therefore of I_2 and IO_2^- ion, and is thus at variance with the assumption that $I_3O_2^-$ can be formed rapidly from I_2 and IO_2^-.

It has already been mentioned that Skrabal[4] demonstrated two independent paths in the spontaneous formation of bromate and bromide from bromine in weakly alkaline solution, and concluded for one of them that the decomposition of HBr_3O is the rate-determining step. The reverse reaction between bromate and bromide ions in acid solution is well known to be the fourth order.[10] There is thus a complete analogy with the iodine path through HI_3O, and we may postulate a series of intermediate reactions which corresponds exactly with that presented in the preceding paragraph. The other path requires a more detailed consideration.

Skrabal's rate law[4]

$$-d(Br_3^-)/dt = 3d(BrO_3^-)/dt = k_2(OH^-)^4(Br_3^-)^3/(Br^-)^7 \qquad (18)$$

differs from Equation 16 only in the exponent of the halide term, 7 instead of 6. The rate law for the fourth order reaction is

$$-d(BrO_3^-)/dt = k_4(BrO_3^-)(Br^-)(H^+)^2 \qquad (19)$$

Skrabal demonstrated that the equilibrium constant, K, of the main reaction

$$3Br_3^- + 6OH^- = BrO_3^- + 8Br^- + 3H_2O \qquad (20)$$

can be calculated satisfactorily from an expression equivalent to

$$K = k_2/3k_4K_w^2 \qquad (21)$$

which is identical in form with Equation 15.

This evidence proves as conclusively as is possible that there is only one rate-determining reaction in this path, and that Equations 18 and 19 represent its rates in opposite directions far from equilibrium. The formulas of the bromine compounds involved in this rate-determining reaction are limited to the compositions Br_2O_2 and $H_2Br_2O_3$. We have chosen both of these substances, rather than two isomers of one of them. On this basis the mechanism of Skrabal's reaction, 20, by this path, is as follows

Relatively rapid equilibrium $3Br_3^- + 4OH^- \rightleftharpoons Br_2O_2 + 7Br^- + H_2O$ (22)
Rate-determining step $Br_2O_2 + H_2O \longrightarrow H_2Br_2O_3$ (23)
Rapid follow reaction $H_2Br_2O_3 + 2OH^- = BrO_3^- + Br^- + H_2O$ (24)

---

[10] (a) Judson and Walker, J. Chem. *Soc.*, 73, 410 (1898); (b) Skrabal and Weberitsch, *Monatsh.*, 36, 211–256 (1915); (c) Skrabal, *Z.* Elektrochem., 30, 109–124 (1924); (d) Bray and Davis, THIS JOURNAL, 52,1427–1435 (1930).

Similarly, the first stage in the fourth order reaction in acid solution is the relatively rapid equilibrium:

$$BrO_3^- + Br^- + 2H^+ \rightleftharpoons H_2Br_2O_3 \tag{25}$$

which is the reverse of (24) and corresponds exactly with the iodine reaction (10a). The rate-determining step in this path is the reverse of (23); but there is a forking at this stage, and some of the $H_2Br_2O_3$ changes to $HBrO_2 + HBrO$ (cf. the preceding paragraph and Reaction 11).

This close relationship with the corresponding iodine reactions is a striking result. The only difference is in the path with the single rate-determining step, and is shown, for example, by the presence of one more halide in Equilibrium 22 than in (3b). It seems justifiable to conclude that the same transitions $X_3O_2^- \overset{\alpha}{—} X_2O_2 \overset{\beta}{—} H_2X_2O_3$ actually occur in both cases. In the bromine reactions the β step *(23)* is the slower, and $Br_3O_2^-$ may be assumed to be included in (22); while in the iodine reactions the α step (13b) is the slower, and the equilibrium $I_2O_2 + H_2O \rightleftharpoons H_2I_2O_3$ may be assumed to be established relatively rapidly.

The rather complicated argument in favor of the existence of both $H_2I_2O_3$ and I_2O_2 may be restated as follows. Reasons were given for assuming an intermediate step in the fourth order iodate reaction. $H_2I_2O_3$ was chosen because it is directly related to both $HIO_3 + HI$ and $HIO_2 + HIO$. Reasoning by analogy, $H_2Br_2O_3$ was assumed in the exactly similar fourth order bromate reaction. The single rate-determining step in the path between bromate–bromide and bromine was shown to involve a second intermediate compound of similar composition, and Br_2O_2 was chosen. By analogy again, I_2O_2 was concluded to exist in the corresponding path between iodate–iodide and iodine. It is of interest to note that, even if $H_2I_2O_3$ and $H_2Br_2O_3$ are considered to be indefinite critical complexes, the reasoning is unchanged, and I_2O_2 and Br_2O_2 are still to be regarded as definite chemical compounds.

A molecule of I_2O_2 (or Br_2O_2) contains 26 valence electrons, and in the simplest electronic formula corresponding to IOOI or OIIO each of the four atoms has eight electrons associated with it. The formation of an addition compound with I^- or H_2O presents no more difficulty than the formation of I_3^- from I_2 and I^-; in all these cases at least one iodine atom must be associated with more than four pairs of valence electrons. $H_2I_2O_3$ is unsymmetrical, and is more closely related to $H^+ + IO_3^-$ and $H^+ + I^-$ than to HIO_2 and HIO (cf. the relative rates of Reactions 10a and 11). $I_3O_2^-$ undoubtedly reacts very rapidly in acid solution with H^+ and H_2O to form 3HIO (cf. 14a), and there seems to be no evidence that it is directly related to iodine and iodite ion.

The possibility that I_2O_2 might form an addition compound also with iodine was considered. As a result the following mechanism is suggested for the fifth order iodate reaction which is observed in the presence of tri-iodide:

Relatively rapid equilibrium $IO_3^- + I_3^- + 2H^+ \rightleftharpoons I_4O_2 + H_2O$ (26)

Rate-determining step $I_4O_2 + I^- \longrightarrow I_3O_2^- + I_2$ (27)

with rapid follow reactions as in (14). This mechanism is in agreement with the observation of Abel and Hilferding[1] that tri-iodide has no effect on their fourth order reaction (at low iodide concentration); but an additional assumption, that equilibrium in (27) is far to the right, seems necessary in order to explain why Skrabal found no trace of the reverse of (27) in his investigations.[11]

The value of any proposed mechanism must be judged by its usefulness, since a rigid proof is impossible. In the present instance Skrabal's proposals, with the extensions here presented, bring into close relationship the complicated reactions of iodine and of bromine with hydroxide ion and the reverse reactions in acid solution. It is hoped that the suggested or related intermediate compounds will prove useful in future work.

BERKELEY, CALIFORNIA

NOTE

The Atomic Weight of Chlorine. The Solubility of Silver Chloride.—We should like to call attention to the fact that Honigschmid and Chan,[1] in their recent work on the atomic weight of chlorine, have apparently neglected a rather important correction which affects the calculation of the Cl:AgCl ratio. Regarding the silver chloride lost in nephelometric tests, in determining the Cl:Ag ratio, the writers state: "Unter den Fällungsbedingungen enthält die klare eisgekühlte Analysenlösung bei 0° nur etwa 0.05 mg. AgCl pro Liter. Da für jede Nephelometerprobe etwa 50 cm.^{3}, also in ganzen hochstens 150 cm.^{3}, der Lösung entnommen wurden, konote der durch die Probenahme bedingte Verlust an AgCl kaum mehr als 0.01 mg. betragen, war also bei der folgenden Wägung des Chlorsilbers zu vernachlässigen."

Direct nephelometric measurements of the solubility of flocculent silver chloride in pure nitric acid show that the value accepted by Honigschmid and Chan as the solubility of silver chloride at 0° in the saturated analytical liquid at the *end-point* is entirely too low. Such measurements, made in this Laboratory in another connection, have yielded the following data.

Temp., °C.	Molarity of nitric acid	AgCl per liter, g.
0.5	0.00	0.00072
.5	.11	.00090
.5	.24	.00100
.5	.49	.00102
.5	.99	.00105

---

[11] Cf. Skrabal, Ref. 3a, p. 877.

[1] Hönigschmid and Chan, *Z. anorg. allgem. Chem.*, 163, 315 (1927).

Although Honigschmid and Chan do not state the concentrations of nitric acid in their analytical solutions, it seems reasonable to estimate that at least 0.001 g. of silver chloride per liter was withdrawn in the nephelometric test portions. It may be pointed out, moreover, that this is a minimum figure, because equilibrium is approached only slowly when these solutions are allowed to stand in an ice-bath. In our measurements, equilibrium was approached from the low-temperature side after completely freezing the solutions.

In order to estimate the error in the calculated atomic weight of chlorine resulting from the omission of the correction for silver chloride lost in nephelometric tests, we have recalculated the results of Honigschmid and Chan's final gravimetric series, assuming a correction of +0.00015 g. of silver chloride in each analysis. The corrected mean of the series, 35.456, differs only a little from the value 35.457 obtained by Honigschmid and Chan. However, since the correction affects only the gravimetric series, we can no longer regard the identical agreement of the gravimetric and nephelometric means, found by the above writers, as having any particular significance. Furthermore, the correction increases considerably the discrepancy in the results of the "complete synthesis" of the silver chloride. This can be seen from the total weights, in grams, corresponding to the eight completed experiments.

	Cl in vac.	Ag in vac.	Cl + Ag	AgCl in vac.	Difference
H. and C.	21.32439	64.88109	86.20548	86.20578	+0.00030
Recalcd.	21.32439	64.88109	86.20548	86.20698	+0.00150

It should be emphasized that the correction in question depends upon the number of nephelometric tests, which in the above case was unusually small. It seems particularly worth while to call attention to the correction because, as far as we are able to determine, it has been overlooked in other recent work from the Munich laboratory.

THE REACTION BETWEEN CITRONELLAL AND SOME ORGANOMAGNESIUM HALIDES

BY HENRY GILMAN AND W. F. SCHULZ

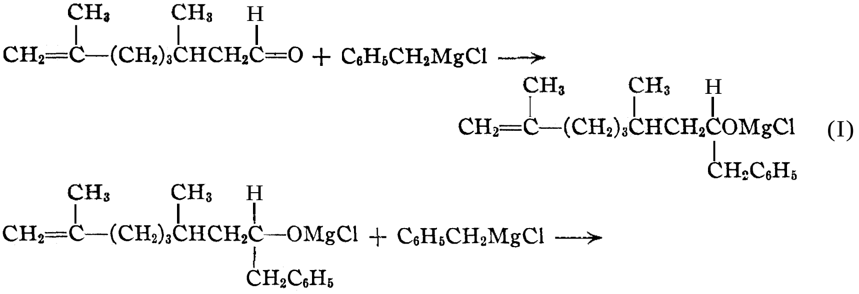
RECEIVED APRIL 28, 1930 PUBLISHED SEPTEMBER 5, 1930

Introduction

A very good case has been made for the non-addition, under usual experimental conditions, of organomagnesium halides to an ethylenic linkage.[1] There is, however, an apparent addition to such a linkage in compounds having the olefinic bond conjugated with another, and a different double bond, such as the carbonyl group in benzalacetophenone, $C_6H_5CH{=}CH\text{-}COC_6H_5$. Kohler and co-workers have demonstrated in an unequivocal manner that such conjugated systems can undergo 1,4-addition with the Grignard reagent. The enolic compound obtained subsequent to hydrolysis of the 1,4-addition intermediate then rearranges to give as an ultimate product a compound which might have been interpreted (and was interpreted incorrectly by earlier investigators) as involving direct addition to the ethylenic linkage.

The author of a recent book on organomagnesium halides,[2] in emphasizing the probability of direct addition to an ethylenic linkage, directs attention to a study by Rupe[3] on the purported addition of benzylmagnesium chloride to the ethylenic linkage in citronellal and makes the pointed observation that in this compound "1,4-addition is absolutely excluded."

The following reactions illustrate Rupe's interpretation of the mechanism of reaction.



$$\mathrm{CH_2{=}\overset{CH_3}{\overset{|}{C}}{-}(CH_2)_3\overset{CH_3}{\overset{|}{C}}HCH_2\overset{H}{\overset{|}{C}}{=}O + C_6H_5CH_2MgCl \longrightarrow}$$

$$\mathrm{CH_2{=}\overset{CH_3}{\overset{|}{C}}{-}(CH_2)_3\overset{CH_3}{\overset{|}{C}}HCH_2\underset{CH_2C_6H_5}{\underset{|}{\overset{H}{\overset{|}{C}}}}OMgCl} \qquad \text{(I)}$$

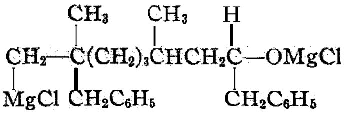
$$\mathrm{CH_2{=}\overset{CH_3}{\overset{|}{C}}{-}(CH_2)_3\overset{CH_3}{\overset{|}{C}}HCH_2\underset{CH_2C_6H_5}{\underset{|}{\overset{H}{\overset{|}{C}}}}{-}OMgCl + C_6H_5CH_2MgCl \longrightarrow}$$

---

[1] Gilman and Harris, *Rec. trav. chim.*, 49, June, (1930). References to earlier studies may be traced from this article.

[2] Courtot, "Le Magnésium en Chimie Organique," published in 1926 by the author at Nancy (see pages 317 and 324).

[3] Rupe, *Ann.*, 402, 161 (1914). The present controversy on the constitution of citronellal does not affect the discussion in our paper because neither the double bond in the methylene form nor the double bond in the isopropylidene form is conjugated with the carbonyl group.

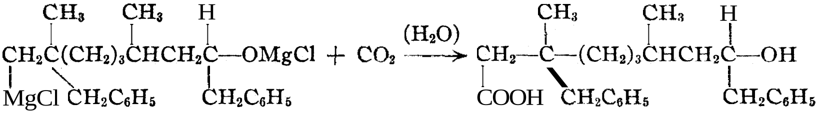


$$\underset{\mathrm{MgCl}}{\mathrm{CH_2}}\!-\!\overset{\mathrm{CH_3}}{\underset{\mathrm{CH_2C_6H_5}}{\mathrm{C}}}\mathrm{(CH_2)_3}\overset{\mathrm{CH_3}}{\mathrm{C}}\mathrm{HCH_2}\overset{\mathrm{H}}{\underset{\mathrm{CH_2C_6H_5}}{\mathrm{C}}}\!-\!\mathrm{OMgCl} \quad \text{(II)}$$

(A)

It appeared highly improbable from our earlier studies[1] that addition had occurred as postulated by Rupe in Reaction II. The results of this study show that there has been no addition to the ethylenic linkage. This has been established by indirect methods.

If addition had taken place in accordance with Reaction II, then a new Grignard reagent should result. This organomagnesium chloride having the terminal group $—CH_2MgCl$ would be expected to react essentially like other compounds having the $—CMgX$ group, and on carbonation, for example, should give the corresponding carboxylic acid.



$$\underset{\mathrm{MgCl}}{\mathrm{CH_2}}\overset{\mathrm{CH_3}}{\underset{\mathrm{CH_2C_6H_5}}{\mathrm{C}}}\mathrm{(CH_2)_3}\overset{\mathrm{CH_3}}{\mathrm{C}}\mathrm{HCH_2}\overset{\mathrm{H}}{\underset{\mathrm{CH_2C_6H_5}}{\mathrm{C}}}\!-\!\mathrm{OMgCl} + \mathrm{CO_2} \xrightarrow{\mathrm{(H_2O)}} \underset{\mathrm{COOH}}{\mathrm{CH_2}}\!-\!\overset{\mathrm{CH_3}}{\underset{\mathrm{CH_2C_6H_5}}{\mathrm{C}}}\!-\!\mathrm{(CH_2)_3}\overset{\mathrm{CH_3}}{\mathrm{C}}\mathrm{HCH_2}\overset{\mathrm{H}}{\underset{\mathrm{CH_2C_6H_5}}{\mathrm{C}}}\!-\!\mathrm{OH} \quad \text{(III)}$$

(B)

The absence of this carboxylic acid was established in a reaction involving citronellal and three equivalents of benzylmagnesium chloride. This excess of Grignard reagent left one equivalent of benzylmagnesium chloride over and above that required by Reactions I and II. On carbonating the entire reaction mixture, the excess of benzylmagnesium chloride should be converted to the corresponding phenylacetic acid, $C_6H_5CH_2COOH$. If Reaction II took place, then subsequent to carbonation, hydrolysis and extraction with alkali a mixture of acid (B) (from Reaction III) and phenylacetic acid should result. The only acid obtained, however, was pure phenylacetic acid. The purity of the acid was established by determinations of melting point, mixed melting point and neutralization equivalent. We also showed, in like manner, that phenylmagnesium bromide and n-butylmagnesium bromide did not add to the ethylenic linkage, although it should be stated that of the Grignard reagents studied by Rupe only benzylmagnesium chloride was said to have added to the ethylenic linkage.[4]

Objections can be raised against this indirect proof. First, addition may have occurred at the ethylenic linkage, prior to addition to the carbonyl group, and the aldehydo-Grignard reagent formed in this manner might then have undergone intramolecular reaction to give a cyclic *sec*ondary alcohol. This is altogether unreasonable when one considers that aldehydes react almost instantly with Grignard reagents,[5] and that there is

---

[4] Rupe (Ref. 3, footnote on p. 161) has remarked that "benzylmagnesium chloride has a great tendency to 1,2-addition to a double bond." No such tendency was noted in a comprehensive study by Gilman and McGlumphy, *Rec. trav. chim.*, 47, 418 (1928).

[5] Gilman, Heck and St. John, *ibid.*, 49, 212 (1930). Obviously aldehydes with high

not, up to the present time, any case of even a slow addition of RMgX compounds to a non-conjugated ethylenic linkage.[6] Second, the acid (B) might actually have been formed in accordance with Reactions II and III and yet not revealed itself in the alkali extraction because of intramolecular esterification to give a ten-membered lactone. This also is highly unlikely per se, and particularly under our experimental conditions, because the lactone even though formed quantitatively should have been hydrolyzed in part, at least, by the alkali treatment to give the acid (B). This acid might subsequently have been converted to lactone, in part. Either or both of these products should have revealed themselves as impurities in the phenylacetic acid, but the high purity of this acid belied admixture, in any significant quantity, of contaminating lactone or acid.

Experimental Part

A solution of 23.1 g. (0.15 mole) of citronellal in 50 cc. of ether was added dropwise to a well-stirred solution containing 0.45 mole of benzylmagnesium chloride in 250 cc. of ether. Stirring and gentle refluxing were continued for fifteen minutes after addition of the aldehyde. The reaction mixture was then carbonated in a customary manner,[7] poured into iced dilute sulfuric acid, and the ether layer separated, washed with water and extracted with 10% sodium hydroxide. The alkaline extract was washed with ether, acidified with hydrochloric acid, and the precipitate so obtained filtered, washed with a minimum of water and dried in the air. Its melting point and mixed melting point with phenylacetic acid were identical with that of phenylacetic acid. The neutralization equivalent was 137.1, and the calculated value for phenylacetic acid is 136.1.

The reaction undoubtedly proceeded in accordance with that carried out by Rupe[3] because we also obtained the oil described by him (the product from hydrolysis of compound (A) in Reaction II) and its boiling point (244°/9 mm.) agreed with that determined by him. We have not investigated the constitution of this compound.

In a corresponding experiment with phenylmagnesium bromide the benzoic acid obtained melted at the correct melting point for this acid and showed no depression in a mixed melting point determination with an authentic specimen. The neutralization equivalent was 121.2, and the calculated equivalent for benzoic acid is 122.

The n-valeric acid obtained from a similar reaction between citronellal and an excess of n-butylmagnesium bromide had the following constants: b. p. 186°; d^{20}_{20} 0.9362; n^{20}_{α}, 1.404; and its neutralization equivalent was 108.8 (calcd. 102.1).

Summary

Contrary to the interpretations of others, benzylmagnesium chloride does not add to the ethylenic linkage in citronellal.

AMES, IOWA

steric hindrance about the carbonyl group will react more slowly than aldehydes without such steric hindrance.

[6] An interesting case of 1,4-addition to a conjugated system that is part aliphatic and part aromatic has been described recently by Gilman, Ruby and Kinney, THIS JOURNAL, 51, 2252 (1929). There is a somewhat remote possibility that even though there is no formal conjugated system in citronellal, there still might be addition to a conjugated system resulting from the spatial contiguity of the aldehyde and ethylenic groups.

CHEMICAL STUDIES ON POLLEN AND POLLEN EXTRACTS
I. DISTRIBUTION OF NITROGEN EXTRACTED BY VARIOUS SOLVENTS

BY EDMOND E. MOORE AND MARJORIE B. MOORE

RECEIVED APRIL 30, 1930 PUBLISHED SEPTEMBER 5, 1930

Whether one is inclined to accept or to reject the theory that pollen sensitization or allergy is an anaphylactic phenomenon due to one or more specific proteins of the pollen, it is evident that a careful chemical study of different pollens is desirable as a basis for further research which may lead to the isolation of the actual causative agent or agents.

The literature yields only very limited information on the subject of pollen composition. As proteins are usually considered to be the offending agents in cases of allergy, it seemed desirable to begin such a study by determining the nitrogen extractable by various solvents.

Heyl,[1,2] Caulfeild, Cohen and Eadie,[3] Koessler[4] and Csonka, Bernton and Jones[5] have contributed valuable information on this subject. However, because of the varying methods of attack the results of the different investigators do not agree.

Certain definitions which have been made to fit the animal proteins cannot be applied to vegetable proteins. This fact must be kept in mind by anyone who works with the proteins of pollen. In this work the purpose was to extract the pollen with different solvents in such a manner as to cause the least possible denaturation. No heat or concentrated solutions of electrolytes were used. The development by Koch and McMeekin[6] of a satisfactory direct colorimetric micro-analysis for nitrogen has made it possible to determine nitrogen in pollen and pollen fractions with greater ease and accuracy than could be secured by any macro method.

For this work four pollens have been chosen; two representative of the type causing spring hay fever, timothy (*Phleum pratense* L.) and orchard grass (*Dactylis glomerata* L.) and two of the type causing autumnal hay fever, short ragweed (*Ambrosia elatior* L.) and giant ragweed (*Ambrosia trifida* L.).

Small samples (*i. e.*, two to four grams) of pollen were used. This obviated the necessity of handling large volumes of solutions when exhaustive extraction was attempted. The nitrogen determination by the modified micro-Kjeldahl method of Koch and McMeekin[6] permitted accurate estimation of the nitrogen in these solutions.

Extractions were made of at least four samples of each pollen studied. Preliminary work had shown the amount of solvent necessary for practically complete extraction with each extracting menstruum.

All water used was redistilled from alkaline permanganate and tested for ammonia.

Method

An accurately weighed sample of *dry* pollen, usually two or four grams, was placed in a dry beaker. A suitable portion of ether was then added and mixed with the pollen sample. The mixture was filtered by suction through a hardened paper in a **4.5-cm.** Biichner funnel. The residue was washed with a little ether and again carefully transferred to the beaker to be re-extracted. Previous work had shown that it was possible to determine the completeness of extraction by the color imparted by the residue to the fresh ether. The ragweed pollens required a greater number of ether extractions than did the grass pollens, the total volume of ether solution being for the ragweeds **100** cc. and for the grasses **50** cc.

The same method was used in carrying out the other extractions upon the ether-extracted samples, the residue from filtration being transferred back to the beaker for mixing with fresh portions of the solvent. The volumes of each extract obtained, using four-gram samples, were: water, **250** cc.; salt solution (**10%** sodium chloride at **60°**), usually **100** cc.; alcohol solution (75%), **100** cc.; alkaline solution (**0.2%** sodium hydroxide), usually **100** cc.

Nitrogen was determined on 5- or **10-cc.** aliquots of each of these extracts and on weighed samples (preferably **20** to **30** mg.) of the original dry pollen and of the residue which had been thoroughly washed with water to remove alkali and dried in air and over sulfuric acid. In the case of the grass pollens, enormous swelling took place in the alkaline solution and the residue finally obtained, even after repeated washings with

water, formed a hard cake on drying, probably due to incomplete removal of the alkali. The ragweed pollens gave residues which were easily powdered.

Aliquots of 100 and 50 cc., respectively, of the water and of the salt extracts were used for dialysis. They were electrodialyzed under toluene in gold beaters' sacs at about 2° for approximately a week. The distilled water outside the sacs was frequently changed. Carbon electrodes with a potential difference of 110 volts were used. In the case of the salt extract a preliminary dialysis was necessary in order to remove the excess sodium chloride before electrodialysis

Precipitates were formed by electrodialysis of both water and salt extracts. These were separated from the solutions by centrifugation. Nitrogen was determined on these precipitates and on aliquots of the solutions.

Table I and the figures give the results obtained. The values for nitrogen are all calculated on the basis of the original dry pollen.

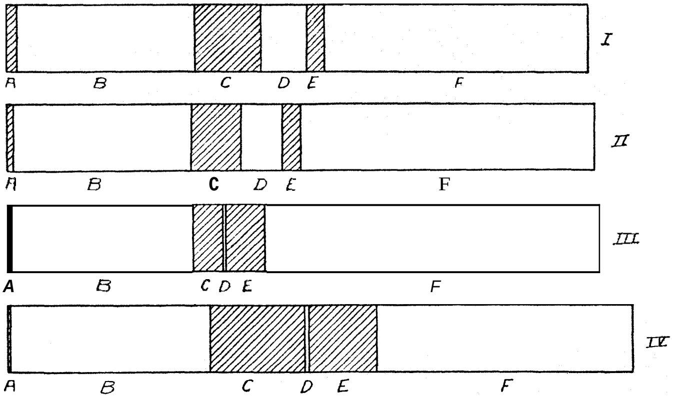

Fig. 1.—Nitrogen extracted. I, Giant ragweed; II, short ragweed; III, orchard grass; IV, timothy. A, by ether; B, by water; C, by sodium chloride solution; D, by ethyl alcohol solution; E, by sodium hydroxide solution; F, in residue.

Discussion

Only a very small amount of nitrogen was extracted by ether, and this is probably non-protein in nature. However, recent work by Milford[7] indicates that this fraction may be of allergic importance. Although by far the largest part of the nitrogen extractable by the solvents used appeared in the water solution, only a small percentage of this was non-dialyzable under the conditions of these experiments. This may be taken to mean that most of the nitrogen thus extracted is not protein nitrogen. It has been suggested that much of the nitrogen present in the pollen may occur in the form of water-soluble diffusible bases such as betaines. It is also conceivable that enzymes contained in the pollen may have been able to hydrolyze the proteins and change their nitrogen into a dialyzable form

---

[7] Edgar L. Milford, "Specific Studies in Allergy. I. The Specific Activity of Pollen Oil," J. *Allergy,* 1, 331–333 (1930).

during the prolonged dialysis. The former theory is supported by the results of Heyl,[2] who found the total coagulable protein plus material precipitated by saturation with zinc sulfate to represent only a small portion of the nitrogen extractable by water. It might be assumed that the action of enzymes mould be greatly retarded by the low temperature and the toluene used in the dialysis. However, because of the large number of enzymes found in pollen (Paton[8]) and because of the small amount of investigation that has been done on them, it would seem unwise to make any assumptions as to their action.

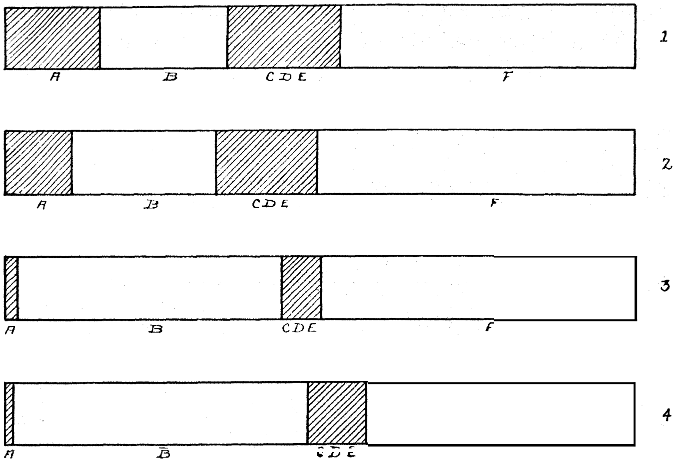

Fig. 2.—Total solids extracted. 1, Giant ragweed; 2, short ragweed; 3, orchard grass; 4, timothy. A, By ether; B, by water; CDE, by sodium chloride, ethyl alcohol and sodium hydroxide; F, in residue.

It is of interest to note that in every case about one-half of the non-dialyzable nitrogen of the water extract is precipitated by dialysis. This behavior would not be expected if the water extract contains only albumin and proteose, as is generally assumed. On the basis of Osborne's[9] definition, this precipitable material should be classified as a globulin. It might be postulated that the albumin has been denatured by continued contact with pure water, but it seems more logical in the present state of our knowledge to assume that most of the globulin present can be extracted by redistilled water with the aid of salts present in the pollen itself.

The nitrogen extracted by salt solution (10% NaCl) is small in amount and a considerable portion of it is dialyzable. The same argument as to

---

[9] Thos. B. Osborne, "The Vegetable Proteins," Longmans, Green and Company, New York, 1924, p. 18.

whether or not this is due to enzyme action applies here as in the water extract. The precipitate may be safely classified as globulin. The fractions soluble in water and diluted salt solutions are generally conceded to be the most important ones as causative agents in allergic conditions.

The alcohol solution (75% EtOH) extracts a small amount of nitrogen. No further work was done on this fraction to determine whether this nitrogen is protein in nature. Clinical studies by various investigators have shown some allergic activity in the alcohol-soluble material from pollens.

A further small amount of nitrogen is extracted by dilute alkali (0.2% NaOH) of which approximately half is precipitated by acidification of the extract. This precipitated material is probably a glutelin, and its importance as a factor in allergy is doubtful.

Approximately half of the nitrogen originally present in the pollen remains in the residue after extraction with all the above solvents. Its nature is not known but as it appears highly probable that the toxic agent in allergic conditions is one easily extracted by body fluids, it may be assumed that this nitrogen is not of clinical importance.

The allergic properties of the various fractions are being studied. No significant difference was found in the amount of nitrogen extracted from different pollens by the solvents used.

A difference between the ragweed arid grass pollens is shown in the quantities of material extracted by ether and by water. Table II shows the total solids extracted by ether and by water, and the weight of material left after extraction by all of the solvents mentioned above. These percentages are calculated on the basis of the original dry pollen.

TABLE II

TOTAL SOLIDS

	Giant ragweed	Short ragweed	Orchsrd grass	Timothy
Ether-soluble	**15.4**	**11.1**	**1 9**	**1 6**
Water-soluble	**20.7**	**22.9**	**42.5**	**47.0**
Residual	**46.3**	**49.8**	**49 6**	**42.7**
Soluble in 10% NaCl, 75% EtOH and 0.2% NaOH (by difference)	17.6	16.2	6.0	8.7

Summary

Pollens of giant ragweed (*Ambrosia trifida* L.), short ragweed (*Ambrosia elatior* L.), timothy (*Phleum pratense* L.) and orchard grass (*Dactylis glomerata* L.) were exhaustively extracted with ether, water, salt solution, alcohol and alkali in the order named. Nitrogen was determined on each of these extracts and on the original pollen and the residue.

The water and salt solution extracts were dialyzed. In both dialyses a precipitate was thrown down. Nitrogen was determined in the precipitate and in the filtrate which remained in the dialyzing sac.

The total materials extracted by the ether and by the water were determined as well as the amount of residue remaining. The quantity of material extracted by the combined salt, alcohol and alkali extractions was calculated by difference.

The similarity between the two grass pollens and between the two ragweed pollens is very marked. The grass pollens swelled greatly in alkali while the ragweed pollens did not. The ragweed pollens contain much more ether-soluble material, but only approximately half as much material extractable by water.

The differences in nitrogen content in the similar fractions of the different pollens do not appear to be significant. About half of the nitrogen was not extractable by the solvents used.

The results on the water extracts indicate that most of the nitrogen extracted by this solvent is non-protein. It also appears that the water extract contains globulin.

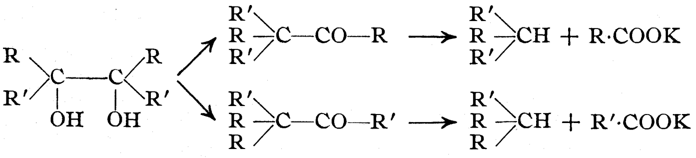
THE EFFECT OF SUBSTITUENTS UPON THE REARRANGEMENT OF BENZOPINACOL

BY JOHN C. BAILAR, JR.

RECEIVED APRIL 30, 1930 PUBLISHED SEPTEMBER 5, 1930

The relative migratory tendencies of organic radicals have often been determined by means of molecular rearrangements. Any rearrangement in which two groups occupy identical positions and are equally free to move might theoretically be used for this purpose, but if the two groups are nearly equal in migratory tendency, each will migrate to some extent, and a mixture of two isomeric products will be formed. The separation of these, or a determination of the relative amounts in which they are present, is often difficult. In the case of the pinacol rearrangement, however, each of the two pinacolones which are formed may be split by the action of alcoholic potassium hydroxide into a hydrocarbon and the potassium salt of an acid. These acids are often readily separated.



Thus Montagne has determined the relative migratory tendencies of the *p*-chlorophenyl and phenyl groups[1] and the *p*-bromophenyl and

---

[1] Montagne, *Rec. trav. chim.*, **26**, 253 (1907).

phenyl groups,[2] separating the substituted and unsubstituted acids by the difference in their solubilities. In like manner Gomberg and Bachmann[3] compared the *p*-biphenyl and phenyl groups, and Gomberg and Bailar[4] have compared the *p*-biphenyl group with the *m*- and *p*-bromophenyl groups, separating the acids by the difference in the solubility of the barium salts.

But in many cases a quantitative separation of the acids or their salts is a long and tedious process. The comparisons reported in this article have been made possible by the use of a method which depends upon the determination of the equivalent weight of the mixture of the acids formed from the pinacolones. Knowing this, and the equivalent weight of the two acids which might possibly be present, it is easy to calculate the percentage composition of the mixture, and from this the relative migratory tendencies of the two groups. The equivalent weight of the mixture is determined by titration of a weighed sample with a standard base. The method is not an extremely accurate one, but repeated and careful experiments have shown that the composition of the mixture can be calculated within 5%, even when the two acids are as similar as benzoic and toluic acids.

Experimental

During the course of this investigation ten symmetrically substituted benzopinacols have been subjected to rearrangement. None of these pinacols has been described in the literature. Table I gives the formulas, melting points and analytical data for these, and also ratios indicating the comparative migratory tendencies of the various groups.

The 4,4′-dimethoxy-di-α-naphthyl pinacol was prepared by the action of α-naphthylmagnesium bromide upon anisil; the *sym.*-2,2′- and 3,3′-dimethoxybenzopinacols by reduction of the corresponding ketones by zinc and acetic acid. In the course of preparation of 3-methoxybenzophenone two compounds not previously described were obtained. 3-Methoxybenzoic acid was converted through the chloride into the amide, and thus into the cyanide. This, by treatment with phenylmagnesium bromide, gave the ketone in good yield.

Amide.—White crystals melting at 130°. Anal. Calcd. for $C_8H_9O_2N$: C, 63.54; H, 6.00. Found: C, 63.79; H, 6.11.

Cyanide.—Colorless liquid boiling at 140° at 34 mm. pressure. Anal. Calcd. for C_8H_7ON: C, 72.14; H, 5.30. Found: C, 71.97; H, 5.15.

All of the other pinacols were prepared from the corresponding ketones by the method of Gomberg and Bachmann.[3] In every case the yield of crude pinacol was practically quantitative; in some cases large losses were incurred during the process of purification. Bachmann and Shankland have previously encountered this difficulty.[5]

Two of the ketones used were not known previously. 4-Isopropylbenzophenone

was obtained by the reaction of benzoyl chloride and isopropylbenzene; yield, 75%. The best yield is obtained when a large excess of isopropylbenzene is used. The ketone is a colorless liquid which does not crystallize at −10°; b. p. 197° at 10 mm.

Anal. Calcd. for $C_{16}H_{16}O$: C, 85.66; H, 7.19. Found: C, 85.44; H, 7.15.

4-Methyl-4'-ethylbenzophenone resulted from the reaction of toluyl chloride and ethylbenzene; yield, 70%. The ketone did not crystallize; b. p. 215° at 10 mm.

Anal. Calcd. for $C_{16}H_{16}O$: C, 85.66; H, 7.19. Found: C, 85.49; H, 7.05.

The determination of the migratory tendencies was made as follows. A 3-g. sample of pure pinacol was subjected to rearrangement by boiling with 30 cc. of glacial acetic acid and a small crystal of iodine for one hour. The solution was poured into 400 cc. of water containing a pinch of sodium bisulfite to remove the iodine. The white precipitate of pinacolone was separated from the liquid by filtration, washed with water and allowed to dry, after which it was boiled with 1 g. of potassium hydroxide in 50 cc. of absolute alcohol for twelve hours. (Two or three hours' boiling suffices to split some pinacolones, but not all of them.) Sometimes the solution turned brown during this boiling; in such cases, the results of the experiments were never concordant, and were discarded. The alcoholic solution was poured into water and evaporated until the precipitate had coagulated. This was then filtered off and the filtrate, which contained the potassium salts of the acids, was extracted with ether in order to remove any remaining traces of foreign organic matter. Upon acidification of the solution, the acids precipitated, and were extracted with ether. The extract was dried over anhydrous sodium sulfate, filtered and allowed to evaporate. The residue was weighed and after being dissolved in alcohol, was titrated with standard sodium hydroxide. The results obtained in the three experiments which were carried out with 4,4′-di-isopropylbenzopinacol are shown in Table II. The average of the three values obtained for the ratio of the migratory tendencies of the substituted and unsubstituted groups is 8.9:1. In Table I this is recorded as 9:1; similarly in other cases, realizing that the method is not one of extreme accuracy, we have taken approximate, simple ratios. The approximation did not require as great a change in any other cases as in this one.

TABLE II

EXPERIMENTAL DATA

	Weight of mixed acids	Cc. of 0.1852 *N* NaOH	Equivalent weight of mixture	Weight percentage of benzoic acid	Mole percentage of benzoic acid	Migratory tendency
1	0.6024	25.22	128.99	87.75	90.34	9.3:1
2	.5948	25.16	127.64	86.67	89.74	8.7:1
3	.4590	19.42	127.64	86.67	89.74	8.7:1

In the case of 4,4′-di-isopropylbenzopinacol one of the pinacolones was formed in so much greater quantity than the other that separation of the two was easy. Three recrystallizations from glacial acetic acid gave pure benzoyl-4,4′-di-isopropyltriphenylmethane; m. p. 140°.

Anal. Calcd. for $C_{32}H_{32}O$: C, 88.52; H, 7.67. Pound: C, 88.72; H, 7.47.

This pinacolone, heated with alcoholic potassium hydroxide, gave a quantitative yield of 4,4′-di-isopropyltriphenylmethane. This hydrocarbon resisted all attempts at crystallization. In an ice–salt mixture it solidified to a glassy mass.

Anal. Calcd. for $C_{25}H_{28}$: C, 91.40; H, 8.60. Found: C, 91.61; H, 8.77.

Two of the pinacols—those in which the methyl and methoxy groups occupy the ortho-positions—did not rearrange upon boiling for one hour with glacial acetic acid and iodine. Even four hours' boiling had no effect. Heating for two hours with glacial acetic acid and acetyl chloride (a method often used to effect the rearrangement of pinacols) produced no change—longer heating decomposed the pinacols to a sticky mass of unidentifiable products.

Discussion

Thorner and Acree[6] have reported that in the rearrangement of *sym.*-4,4′-dimethylbenzopinacol only the substituted group moves. This indicates that the *p*-tolyl group has such a large migratory tendency in comparison with that of the phenyl group that no definite comparison can be made between the two. It should be possible to assign a definite value to the migratory tendency of the p-tolyl group by comparing it with some other group of large, but known, migratory tendency. Such is the p-biphenyl group, which Gomberg and Bachmann[3] have shown to have a migratory tendency 12.5 times as great as that of the phenyl group. The rearrangement of symmetrical 4,4′,4″,4‴-dimethyldiphenylbenzopinacol shows the p-tolyl and *p*-biphenyl groups to have approximately equal migratory tendencies (Table I). In making this determination we not only determined the equivalent weight of the mixed acids, as outlined above, but we separated the two acids by dissolving the toluic acid out of the mixture with boiling water, in which *p*-phenylbenzoic acid is insoluble. The two methods gave the same result. The relation between the migratory tendencies of the p-tolyl group and the phenyl group has been confirmed by another indirect comparison. The substitution of an ethyl group increases the migratory tendency of the phenyl group five-fold; the rearrangement of symmetrical 4,4′,4″,4‴-dimethyldiethylbenzopinacol shows that a methyl group in the para-position has three times the effect of an ethyl group. Prom this it may be inferred that the p-tolyl radical has a migratory tendency approximately fifteen times as great as the phenyl. A direct comparison of the two is difficult because of the great similarity in their properties and equivalent weights.

The substitution of a methyl radical in the meta-position decreases the migratory tendency of the phenyl radical somewhat; if the substitution is made in the ortho-position, the migratory tendency becomes very small indeed. Not only does the substituted group fail to migrate—it prevents the migration of the unsubstituted group as well. Such a result was not wholly unexpected—Koopal[7] has reported that benzopinacol in which a chlorine or bromine atom has been substituted in the ortho-position rearranges only very slowly—when rearrangement does take place, it is due entirely to the migration of the unsubstituted group. According to Lagrave[8] this inhibition of the rearrangement can be ex-

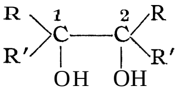
[7] Koopal, *Rec. trav. chim.*, *34*, 134 (1915).

[8] Lagrave, Ann. *chim.*, [10] 8,363 (1927).

plained in the following way. Upon rearrangement of a pinacol, one or the other of the radicals attached to one of the central carbon atoms (C 2) migrates to the other central carbon atom (C 1), but if C 1 is already holding groups of large affinity capacity, it will be unable to accept another group. Such is the case here; the o-tolyl group absorbs so much of the energy of C 1 that very little is left to attract another group from C 2. Hence no rearrangement takes place.



Tiffeneau and Orekhoff[9] have shown that the *p*-anisyl radical migrates exclusively in the rearrangement of 4,4′-dimethoxybenzopinacol. As is shown in Table I, the m-anisyl radical has but one-fifth of the migratory tendency of the unsubstituted phenyl group, and the presence of the methoxy group in the ortho position prevents any rearrangement. The p-anisyl group has twice the migratory tendency of the a-naphthyl group, which in turn is somewhat larger than that of the *p*-tolyl group. The ratio of the migratory tendencies of the *p*-anisyl and phenyl groups is, therefore, in the neighborhood of 40:1.

It will be noticed that the p-anisyl group has a much greater tendency to migrate than the m-anisyl, which, however, is still more prone to migrate than the o-anisyl. The same is true, though less marked, if the substituent is the methyl radical instead of the methoxy. It is apparently true also when the substituent is either a chlorine or a bromine atom.[1,7]

The p-isopropylphenyl group has nine times the migratory tendency of the unsubstituted phenyl radical. Thus the effect of the *p*-isopropyl group is not as large as that of the *p*-methyl, but is much larger than that of the p-ethyl. Whether this peculiarity be due to the branching of the chain, or to some other factor, cannot be stated without further experimentation.

From the results of this investigation and those of previous workers, the migratory tendencies of various aromatic radicals may be arranged in the following series: (the migratory tendency of the phenyl radical has been chosen as unity) p-anisyl, about 40; a-naphthyl, about 18; *p*-tolyl, 12–15; *p*-biphenyl,[2] 12.5; p-isopropylphenyl, 9; *p*-ethylphenyl, 5; *p*-fluorophenyl,[7] 1.86; *p*-iodophenyl,[7] 1; phenyl, 1; *p*-bromophenyl,[1] 0.75; *p*-chlorophenyl,[1] 0.66; m-tolyl, 0.6; m-anisyl, 0.2; o- and *m*-bromophenyl, o- and *m*-chlorophenyl[7]; o-tolyl, o-anisyl, very small. It is known also that the β-naphthyl group has a much larger migratory tendency than the phenyl group,[5] but just how much larger has not been determined.

Summary

1. Ten aromatic pinacols have been subjected to rearrangement, and the relative effect of various substituents in the phenyl group has been noted.

---

[9] Tiffeneau and Orekhoff, *Bull. soc. chim.*, **37, 430** (1925).

2. The various groups have been arranged in order of their migratory tendencies. Definite values have been assigned when possible.

3. *m*-Methoxy cyanobenzene, m-methoxybenzamide, benzoyl-4,4'-di-isopropyltriphenylmethane, and 4,4'-di-isopropyltriphenylmethane have been described, in addition to the ten pinacols, none of which has previously been reported in the literature.

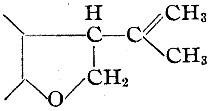
ROTENONE. VIII. ISOMERIC HYDROXY ACIDS AND THEIR RELATION TO DEHYDROROTENONE

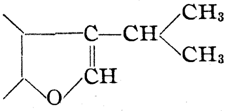
BY F. B. LAFORGE AND L. E. SMITH

RECEIVED MAY 14, 1930 PUBLISHED SEPTEMBER 5, 1930

Rotenone is converted by a number of oxidizing agents into dehydrorotenone, with the loss of two hydrogen atoms. In a recent article, Butenandt has shown that a double bond is formed in this process.[1] Although this new double bond cannot be reduced by catalytic hydrogenation, its presence in dehydrorotenone can be demonstrated by the reaction of Diels,[2] which involves a condensation of a conjugated system with maleic anhydride. It has also been demonstrated that the optically active tubaic acid obtained by cleavage of rotenone with alcoholic potassium hydroxide is converted into inactive rotenic acid under the same conditions by which rotenone is converted into isorotenone and that isorotenone yields rotenic acid by cleavage with alcoholic potassium hydroxide.[1,3] It follows from these facts with a fair degree of certainty that the isomerism between rotenone and isorotenone is due to the same cause as the isomerism between tubaic and rotenic acids. The change involved may be illustrated by the tentative formulas I and II. In these formulas the positions of attachment of the side chain, as well as that of the hydroxyl and carboxyl groups not shown in the figures are as yet undetermined.[4]



I. Tubaic acid



II. Rotenic acid

Since an asymmetric center disappears in this process and since isorotenone is optically active, Butenandt infers that this compound still contains one or more asymmetric carbon atoms in the other half of the molecule, about which little was known to him at the time.

[4] Haller and LaForge, *ibid.*, 52, 3207 (1930).

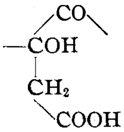
Cehydroisorotenone described by Butenandt and by us[6] is optically inactive whether prepared from isorotenone by the action of iodine and potassium acetate or by the conversion of dehydrorotenone into its isomer by sulfuric acid. It follows from this, as Butenandt has pointed out, that an asymmetric center has disappeared in the formation of the dehydro derivatives.

This theory seemed to be in agreement with the principal facts observed by us regarding the mechanism of the formation of the dehydro compound~.~

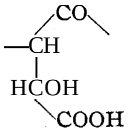
We have described an intermediary product, rotenolone, isolated from the reaction mixture obtained when iodine and potassium acetate react on rotenone.[5] Rotenolone is an hydroxy rotenone and is easily converted into dehydrorotenone by elimination of water.

Dehydrorotenone is converted into a dihydroxy monobasic acid by the action of alcoholic potassium hydroxide, a reaction which is assumed to involve the addition of one molecule of water to the new double bond characteristic of the dehydro derivatives and another molecule of water to the lactone group ta form the acid radical.

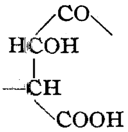
The resulting acid most likely contains one of the following groupings



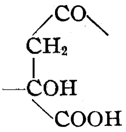
III



IV



V



VI

Dehydrorotenone is converted by catalytic hydrogenation into dehydrodihydrorotenonic acid, which in turn is converted into an hydroxy acid which also contains the same grouping as the acid just referred to.[6] Both give derric acid on oxidation.

In a previous article we have shown that this oxidation product, which represents the part of the rotenone molecule containing the methoxyl groups, in all probability is of the nature of a dimethoxy phenyl malic acid and would therefore contain one of the groupings given above.[7] Rut since the carbonyl group in these groupings becomes a carboxyl group in derric acid, the possibilities are then limited to two combinations, since III and VI and IV and V become identical.

We have just pointed out the fact that the dehydro derivatives are formed from hydroxy derivatives of the rotenolone type by elimination

---

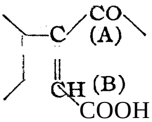
[5] LaForge and Smith, THIS JOURNAL, 52, 1094 (1930).

[6] We have designated acids of this type as dehydro hydroxy acids in previous articles because they were obtained from dehydro compounds, but since it is now fairly certain that they correspond to rotenonic acid, the prefix "dehydro" has been discontinued.

[7] LaForge and Smith, THIS JOURNAL, 52, 2878 (1930).

of water. This reaction is easily brought about by boiling the hydroxyl derivative or the corresponding acetyl compounds with alcoholic sulfuric acid. This reaction does not take place in the case of denic acid or either of the hydroxy acids from which it is obtained. For this reason the position of the hydroxyl group in rotenolone cannot be the same as in these acids.

If we assume that the hydroxy acids are formed by the addition of water to dehydrodihydrorotenonic acid of possible formula indicated, it will be apparent that there are a number of possibilities, depending on whether the hydroxyl is added at position A or B. If it is added at A, one asymmetric carbon atom arises, if at B, two are formed, and the number of possible compounds is multiplied by two, because the part of the molecule not involved in these changes already contains an asymmetric carbon atom. Because of the fact that derric acid and the two hydroxy acids which had' been prepared did not revert to dehydro compounds when treated with alcoholic sulfuric acid, we were inclined to another theory regarding the nature of the dehydro compounds.[7]



We have, however, lately prepared two dihydrohydroxyrotenonic acids, isomeric with the one obtained by the action of alcoholic potassium hydroxide on dehydrodihydrorotenonic acid. These new acids are readily dehydrated by alcoholic sulfuric acid and give dehydrodihydrorotenonic acid. Because of these new facts it is now possible to bring our views into harmony with the theory of Butenandt. It is not possible to assign the position of the hydroxyl in any of the acids concerned but for convenience we will designate those compounds which are easily dehydrated as belonging to the alpha, and those which cannot be dehydrated to the beta series.

One of the two new alpha acids was prepared in two ways: by reducing rotenolone with hydrogen and platinum catalyst which yielded dihydrorotenolonic acid together with dihydrorotenolone, or by catalytic reduction of acetylrotenolone to dihydro-acetylrotenolone and dihydro-acetylrotenolonic acid. The latter is easily saponified to the hydroxy acid.

The second acid was obtained by oxidation of rotenonic acid with hydrogen peroxide in alkaline solution. The products obtained were an hydroxyrotenonic acid of formula $C_{23}H_{24}O_7$ together with some of the corresponding dehydro acid of formula $C_{23}H_{22}O_6$. The hydroxy acid is easily reduced by catalytic hydrogenation to the dihydro acid. Both of these isomeric dihydrohydroxy acids readily give dehydrodihydrorotenonic acid when treated with alcoholic sulfuric acid. From the acid ($C_{23}H_{24}O_7$) obtained directly from rotenonic acid, dehydrorotenonic acid was obtained for the first time, for it had not been possible to reduce the lactone ring in dehydrorotenone without reduction of the double bond so that dehydrodihydrorotenonic acid was always obtained. Dehydrorotenonic acid is readily hydrogenated to the dihydro derivative.

We have also made some alkaline peroxide oxidations on two other rotenone derivatives with rather unexpected results. The acid of formula $C_{23}H_{22}O_8$ (dihydrodehydrohydroxyrotenononic acid), described by us in a previous communication, obtained by the action of strong alcoholic potassium hydroxide on dihydrorotenonone yielded no derric acid or corresponding methoxyl-containing compound but dihydrotubaic acid as the only crystalline reaction product.

This fact is an additional proof that the reaction leading to the compounds of the rotenonone type do not take place in the part of the rotenone represented by tubaic acid, but in the other half of the molecule.

We have expressed the view in a previous article[5] that dihydrodehydrohydroxyrotenononic acid was formed by the opening of a lactone ring and not as Butenandt believed by a benzilic acid rearrangement. We have been able to prove our theory to be correct by the fact that the acid easily reverts to dihydrodehydrorotenonone by boiling in acetic acid solution.

Dehydrodihydrorotenonic acid did not yield derric acid on oxidation with hydrogen peroxide but gave the acid of formula[7] $C_{11}H_{12}O_7$ which we obtained from derric acid by permanganate oxidation.

We have made numerous attempts to separate derric acid into its optically active components. Its brucine salt crystallizes well, but after four recrystallizations the derric acid from it was still inactive. No other suitable alkaloid salts were obtained.

β-Dihydrohydroxyrotenonic Acid.—One and eight-tenths grams of dehydrodihydrorotenonic acid5 was refluxed for four and one-half hours with 18 cc. of 15% potassium hydroxide, 54 cc. of ethyl alcohol and 3.6 g. of zinc powder. After removal of the zinc by filtration, the solution was acidified with dilute hydrochloric acid, and water was added until it became turbid. The white crystalline compound so obtained was recrystallized from dilute ethyl alcohol. The yield was 1.5 g. The compound begins to darken at 192° and melts at 198°.

Anal. Subs., 0.0727: CO_2, 0.1779; H_2O, 0.0425. Calcd. for $C_{23}H_{26}O_7$: C, 66.67; H, 6.27. Found: C, 66.73; H, 6.49.

Oxidation of p-Dihydrohydroxyrotenonic Acid to Derric Acid.—One and a half grams of the acid was dissolved in 18 cc. of 5% potassium hydroxide and to the hot solution 5 cc. of 30% hydrogen peroxide was added in small portions. A small amount of tarry matter which formed was removed mechanically. After being boiled to remove the excess of hydrogen peroxide the solution was cooled and acidified with dilute hydrochloric acid and extracted with ether. The ether solution dried over sodium sulfate gave on evaporation derric acid in a yield of 0.25 g. It was recrystallized from ethyl acetate–n-butyl ether, and melted at 170°. Mixed with derric acid it melted at 170".

Acetyl a-Dihydrorotenolonic Acid (Acetyl a-Dihydrohydroxyrotenonic Acid).—Three grams of acetylrotenolone was reduced in ethyl acetate solution with 0.2 g. of platinum oxide catalyst. In about thirty minutes 252 cc. of hydrogen had been absorbed, and the reaction stopped. The theoretical quantity of hydrogen corresponding to two molecules is calculated as 295 cc. The solution was diluted with ether and extracted with ice cold 2% aqueous potassium hydroxide solution The material insoluble in alkali was isolated by evaporation of the dried ether–ethyl acetate solution. It was recrystallized from methyl alcohol and melted at 189°. It was identical with acetyldihydrorotenolone obtained from dihydrorotenone by the iodine potassium acetate method. The yield was 0.5 g. The aqueous alkaline extract yielded 2 g. of acetyldihydrorotenolonic acid melting between 210 and 214° with decomposition.

Anal. Subs., 0.0687: CO_2, 0.1668; H_2O, 0 0390. Calcd. for $C_{25}H_{28}O_8$: C, 65.79; H, 6.14. Found: C, 66 21; H, 6 31.

Dihydrorotenolonic Acid **(a-Dihydrohydroxyrotenonic** Acid).—This acid may be obtained either by saponification of acetyldihydrorotenolonic acid or by direct hydrogenation of rotenolone, and separation of the reaction mixture into neutral and acid fractions. By the last-mentioned method the yield of acid is small and hence the first procedure is to be preferred. Two grams of acetyldihydrorotenolonic acid was boiled for two hours with slightly more than the calculated quantity of half normal potassium hydroxide. The solution was acidified and the precipitated acid dissolved in ether. After drying and removal of the ether, a sirup was obtained which crystallized completely after seeding with crystals obtained by hydrogenation of rotenolone. The compound is extremely soluble in all reagents except water and petroleum ether. We have not succeeded in recrystallizing it.

Acetyldihydrorotenolonic acid readily gives dehydrodihydrorotenonic acid when boiled for about an hour with 10 parts of 10% alcoholic sulfuric acid and an equal volume of hot water is added to it. Dehydrodihydrorotenonic acid was identified by its melting point, mixed melting point and an optical examination of the crystals. The crude dihydrorotenolonic acid, treated in the same manner, gives the same compound.

Oxidation of Rotenonic Acid with Hydrogen Peroxide.—Two grams of rotenonic[8] acid is dissolved in 25 cc. of 5% potassium hydroxide and to the warm solution 30% hydrogen peroxide is added in small portions until a precipitate is produced. About 8 cc. is usually required. The reaction mixture is boiled for a few minutes and then cooled and saturated with carbon dioxide. A heavy precipitate is formed which is extracted with ether and the solution dried over sodium sulfate.[9] The ether residue contains two compounds. It is dissolved in methyl alcohol from which a small quantity of a yellow compound crystallized on cooling. It melted at 225°. The analysis agrees for dehydrorotenonic acid.

Anal. Subs., 0.0608: CO_2, 0.1551; H_2O, 0.0308. Calcd. for $C_{23}H_{22}O_6$: C, 70.05; H, 5.59. Found: C, 69.57; H, 5.61.

When the methyl alcoholic mother liquor is diluted with water the second crystalline compound is obtained which is recrystallized from dilute methyl alcohol. It melts at 137°, and the yield is 0.25 g. The analysis shows it to be an hydroxyrotenonic acid. The compound was dried to constant weight at 110° for analysis.

Anal. Subs., 0.0681, 0.0741: CO_2, 0.1671, 0.1817; H_2O, 0.0367, 0.0394. Subs., 0.0187: AgI, 0.0215. Calcd. for $C_{23}H_{24}O_7$: C, 66.99; H, 5.82; 2OCH_3, 15.04. Found: C, 66.9, 66.87; H, 5.99, 5.90; OCH_3, 15.17. Subs., 0.0146: 0.375 cc. of $N/10$ KOH; mol. wt. calcd. 412; found, 390.

Isomeric **a-Dihydrohydroxyrotenonic** Acid.—One-half gram of α-hydroxyrotenonic acid was reduced in ethyl acetate solution with 0.1 g. of platinum catalyst. The theoretical volume of hydrogen for 1 molecule, 27 cc., was absorbed in a few minutes. The

---

[8] LaForge and Smith, THIS JOURNAL, 51, 2578 (1929).

[9] Most acids of the type of rotenolonic acid are insoluble in carbonates and are precipitated from alkaline solution by carbon dioxide.

solution was decanted from the platinum, evaporated to dryness and the substance recrystallized from dilute ethyl alcohol. The compound sinters somewhat, probably due to water or alcohol of crystallization, and melts at 132°. For analysis it was dried to constant weight at *110°*.

Anal. Subs., *0.0608:* CO_2, *0.1474;* H_2O, *0.0342.* Calcd. for $C_{23}H_{26}O_7$: C, *66.66;* H, 6.28. Found: C, 66.11; H, 6.25.

Dehydrorotenonic Acid.—One gram of the hydroxyrotenonic acid was boiled for one and one-half hours with *10* cc. of 10% alcoholic sulfuric acid. When *3* cc. of water was slowly added to the boiling solution, a small quantity of a compound crystallized out at once. The solution was refluxed for fifteen minutes, cooled and the precipitate was filtered off and recrystallized from benzene. It melts at 275°. The yield was *0.13* g.

This compound is stable to alkali. Further study is being made on this substance. The alcoholic mother liquors were diluted with water, and a yellow crystalline compound was obtained which was recrystallized from methyl alcohol. It melted at 225–227°. When mixed with dehydrorotenonic acid obtained directly by the oxidation of rotenonic acid with hydrogen peroxide, the melting point showed no depression.

Dehydrodiiydrorotenonic Acid from Dehydrorotenonic Acid.—Dehydrorotenonic acid was reduced in acetone solution with hydrogen with platinum catalyst in the usual manner. The theoretical amount of hydrogen for the *0.35* g. used, *20* cc., was absorbed in a few minutes. The solution was evaporated to dryness and the compound recrystallized from dilute ethyl alcohol. It melted at 221°. Mixed with dehydrodihydrorotenonic acid it melted at *221°*. The two substances were compared optically by George L. Keenan of the Food, Drug and Insecticide Administration of the Department of Agriculture, and found to be identical.

"In ordinary light this material is of a sulfur-yellow color and consists of very fine needles. In parallel polarized light, crossed nicols, the extinction is straight and the sign of elongation negative. Nothing significant is shown in convergent polarized light with crossed nicols. The refractive indices are: $-n_\alpha = 1.470$ (commonly shown lengthwise); $n_\beta = 1.690$; $n_\gamma = 1.737$ (commonly shown crosswise); all ±0.003."

Oxidation of Dihydrodihydroxyrotenononic Acid[6] with Hydrogen Peroxide.—Two grams of the acid was dissolved in *30* cc. of 5% potassium hydroxide, and 8 cc. of 30% hydrogen peroxide was added in small portions. After boiling for a few minutes the solution was cooled and made acid with dilute hydrochloric acid. A light yellow material crystallized out, which was recrystallized from dilute methyl alcohol. It melted at *167"*. The yield was *0.3* g. The compound contains no methoxyl group. When mixed with dihydrotubaic acid of melting point 167°, the melting point showed no depression.

Oxidation of Dehydrodihydrorotenonic Acid with Hydrogen Peroxide.—One and three-tenths grams of acid was dissolved in *17* cc. of 5% potassium hydroxide solution, and *5* cc. of 30% hydrogen peroxide was added in small portions. After boiling for a few minutes the solution was filtered from a small precipitate and cooled. On acidifying with dilute hydrochloric acid, a crystalline material was obtained which was recrystallized from *95%* ethyl alcohol. It melted at 262° with decomposition. The yield was *0.2* g.

Anal. Subs., *0.0658:* CO_2, *0.1247;* H_2O, *0.0272.* Calcd. for $C_{11}H_{12}O_7$: C, *51.56; H, 4.68.* Found: C, *51.68;* H, *4.59.* Subs., *0.0187: 1.55* cc. of $N/10$ KOH; mol. wt. calcd., *256;* found, *241.*

The compound is identical with the acid obtained by the oxidation of derric acid.

Dihydrorotenonone from Dehydrodihydrorotenononic Acid.—When dehydrodihydrorotenononic acid is boiled with glacial acetic acid for a few minutes the solution becomes very dark and on cooling, a yellow compound crystallizes out, melting at *288"*.

The yield is about 25% of the theoretical. Mr. Keenan has found the compound to be optically identical with dihydrorotenonone.

Anal. Subs., 0.0647: CO_2, 0.1605; H_2O, 0.0286. Calcd. for $C_{23}H_{20}O_7$: C, 67.61; H, 4.93. Found: C, 67.66; H, 4.89.

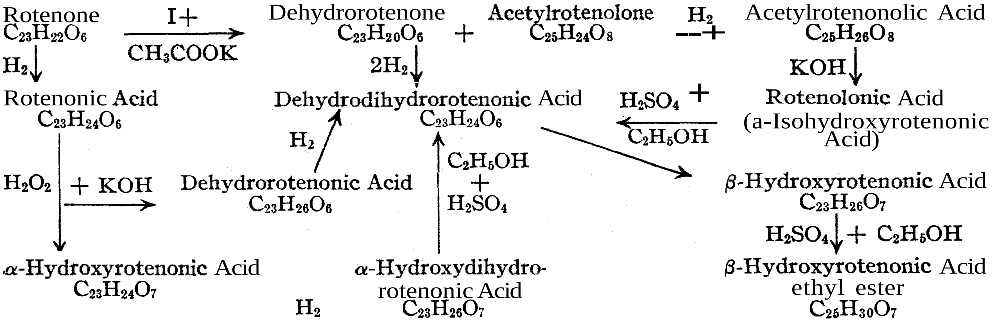
Summary

Dehydrodihydrorotenonic acid is formed by catalytic reduction of dehydrorotenone. It is also produced by dehydration of α-hydroxyrotenonic acids by alcoholic sulfuric acid. Two isomeric alpha acids were prepared.

Dehydrodihydrorotenone adds water when boiled with alcoholic potassium hydroxide to form β-hydroxyrotenonic acid which cannot be dehydrated but yields an ester when treated with alcoholic sulfuric acid. β-Hydroxyrotenonic acid yields derric acid on peroxide oxidation.

Dehydrodihydrorotenonic acid yielded no derric acid but its oxidation product of formula $C_{11}H_{12}O_7$. By the same treatment dihydrodehydrohydroxyrotenononic acid gave dihydrotubaic acid.

Attempts to separate derric acid into optical isomers were unsuccessful. The reactions involved are illustrated in the table.



WASHINGTON, D. C.

[CONTRIBUTION FROM THE EXPERIMENTAL RESEARCH LABORATORIES, BURROUGHS WELLCOME AND COMPANY]

1,2-DIHYDROPAPAVERINE AND MODIFIED SYNTHESES OF PAPAVERINE AND PAPAVERALDINE (XANTHALINE)

BY JOHANNES S. BUCK

RECEIVED MAY 17, 1930 PUBLISHED SEPTEMBER 5, 1930

A number of investigations have been carried out on the reduction products of papaverine, but 1,2-dihydropapaverine or 6,7,3′,4′-tetramethoxy-1,2-dihydroprotopapaverine[1] (IV) has not been previously isolated. Pyman[2] described a compound of the same empirical formula, which he supposed to have the structure of the 1,2-derivative. Later[3] he modified this view on the basis of exhaustive methylation experiments, and assigned to it the structure (VIII), naming it Pavine.

The writer has obtained 1.2-dihydropapaverine by a rigid method and has established the structure. Homoveratroyl-w-amino-acetoveratrone (I), prepared from homoveratroyl chloride and o-amino-acetoveratrone, was cyclized by means of phosphorus oxychloride, yielding 6,7,3′,4′-tetramethoxy-4-keto-3,4-dihydroprotopapaverine (II). This compound on reduction gave 6,7,3′,4′-tetramethoxy-4-hydroxy-1,2,3,4-tetrahydroprotopapaverine (111), which on appropriate treatment lost the elements of water, 1,2-dihydropapaverine being formed (IV). The structure was established by its smooth reduction (catalytic) to the known tetrahydropapaverine[2] (VII), by its dehydrogenation to papaverine (IX) and by its oxidation to 6,7,3′,4′-tetramethoxy-9-keto-1,2-dihydroprotopapaverine (V), which in turn is readily converted into papaveraldine (VI) or 6,7,3′,4′-tetramethoxy-9-keto-protopapaverine. Papaveraldine is identical with the naturally-occurring alkaloid xanthaline.[4]

The dehydration of (III) to 1,2-dihydropapaverine was carried out by means of phosphorus pentachloride in cold chloroform solution. When heating with phosphorus pentoxide or oxychloride in toluene was employed, only the oxidized product (V) was isolated. The same product was also formed by air oxidation of solutions of 1,2-dihydropapaverine exactly as with 6,7,3′,4′-tetramethoxy-3,4-dihydroprotopapaverine.[5] The parallel is even closer, as 1,2-dihydropapaverine behaves exactly like the latter compound (3,4-dihydropapaverine) when heated with methyl alcoholic potash, both giving papaveraldine (VI).

It was hoped to obtain interesting derivatives from the compounds (II)

---

[1] The nomenclature of Buck, Perkin and Stevens, *J. Chem. Soc.*, 127, 1462 (1925). is used except where well-established names exist.

[2] Pyman, *zbzd.*, 95, 1610 (1909).

[3] Pyman and Reynolds, *ibid.*, 97, 1320 (1910); Pyman, *zbzd.*, 107, 176 (1915).

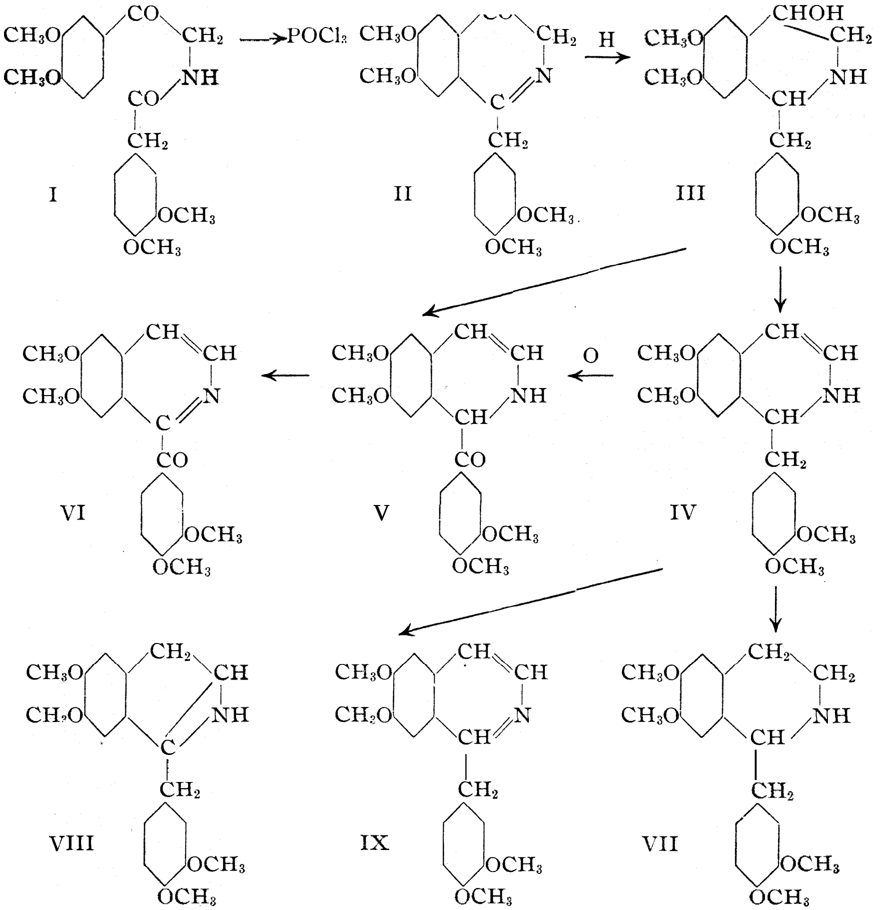
[4] Dobson and Perkin, *ibid.*, 99, 135 (1911).

[5] Buck, Haworth and Perkin, *ibid.*, 125, 2176 (1924).

and (III) but they proved to be disappointingly inert. No derivatives of the carbonyl or hydroxyl groups were isolated, and the basic properties are so suppressed that the bases form no well-defined salts. Indeed (III) may be recrystallized unchanged from fairly strong hydrochloric acid.

1,2-Dihydropapaverine is conspicuous by its ready oxidizability in air, when in solution, and by its very insoluble perchlorate. But for this salt it is doubtful whether 1,2-dihydropapaverine could have been isolated in the pure state.

It will be seen that the isolation of papaverine and papaveraldine (xanthaline) in the above series of reactions constitutes new syntheses of these substances.



Experimental

Homoveratroyl-ω-amino-acetoveratrone (I) was prepared from homoveratroyl chloride and ω-amino-acetoveratrone and was found to be identical with the product of

Pictet and Gams.[6] In preparing homoveratric acid[7] it is advantageous to carry out the oxidation of dimethoxyphenylpyruvic acid with 10% or stronger hydrogen peroxide in the presence of ice, and to recrystallize the acid from benzene.

6,7,3′,4′-Tetramethoxy-4-keto-3,4-dihydroprotopapaverine (II).—Twenty grams of homoveratroyl-w-amino-acetoveratrone, 40 cc. of phosphorus oxychloride and 100 cc. of toluene were boiled for forty-five minutes, cooled and petroleum ether added until no more oil separated. The supernatant liquor was decanted, the oil dissolved in alcohol and sodium hydroxide solution added until the mixture was strongly alkaline. The product separated as an oil and soon solidified; yield almost theoretical. Recrystallized from alcohol the compound forms a white felted mass of slender needles, slightly soluble in cold alcohol and moderately soluble in hot. It is insoluble in water, but readily soluble in cold benzene; m. p. 116–117° (uncorr.). The solution in hydrochloric acid is pale yellow and the solution in chloroform has a marked bluish fluorescence.

With cold concentrated sulfuric acid the solid turns bright blue and gives a blue solution which becomes intensely violet on heating. A crystal of potassium nitrate added to the cold solution gives a deep claret color, changing to crimson. Luchini's reagent gives an orange-brown color, changing to greenish-black, Wenzell's reagent. transient violet, becoming golden: Erdmann's reagent, intense red; Mandelin's reagent, golden brown, greenish on heating: Fröhde's reagent, violet, blue on heating.

It was difficult to obtain concordant analyses on this compound, micro-analyses being usually high and macro-analyses usually low.

Anal. Calcd. for $C_{20}H_{21}O_5N$: C, 67.54; H, 5.67; N, 3.94; mol. wt., 355. Found: C, 67.45; H, 5.99; N, 3.84; mol. wt., 335, 343.

Methiodide.—This was prepared by heating with benzene and methyl iodide in a sealed tube at 100° for two hours. It forms faintly yellow thin square plates, m. p. 202° (uncorr.) with frothing.

Anal. Calcd. for $C_{21}H_{24}O_5NI$: C, 50.7; H, 4.8. Found: C, 50.5; H, 4.8.

6,7,3,′4′-Tetramethoxy-4-hydroxy-1,2,3,4-tetrahydroprotopapaverine (III).—It was not found possible to reduce the compound (II) successfully with the usual reagents, such as zinc and sulfuric acid, etc Ultimately a very active catalyst (platinic chloride in hydrochloric acid with the addition of platinum oxide and Skita catalyst) was prepared. This readily caused the absorption of four atoms of hydrogen (acetic acid with hydrochloric acid as solvent). No stage corresponding to two atoms of hydrogen was isolated. After the catalyst had flocculated, the solution was evaporated under reduced pressure, the residue dissolved in methyl alcohol and treated with ammonia. The product crystallizes out on standing. Recrystallized from alcohol, the compound forms white, bulky aggregates of crystals (thin rectangular plates) melting at 123° (uncorr.). It is slightly soluble in hot water, readily soluble in hot alcohol and moderately soluble in hot toluene.

With cold concentrated sulfuric acid the compound gives a colorless solution, becoming pale amethyst on warming. Addition of a crystal of potassium nitrate to the cold acid solution produces an orange-brown color. Luchini's reagent gives a pale gold color; Wenzell's reagent, violet changing to gold; Erdmann's reagent, light golden; Mandelin's reagent, greenish-gold; Frohde's reagent, green, changing to deep brown.

Anal. Calcd. for $C_{20}H_{25}O_5N$: C, 66.85; H, 6.96. Found: C, 66.72; H, 7.21.

1,2-Dihydropapaverine (IV).—One gram of compound (III) dissolved in 10 cc. of chloroform was treated with 3 g. of phosphorus pentachloride and allowed to stand for forty-eight hours in the cold. The yellow magma which formed was added to crushed ice,

---

the chloroform layer separated, washed with water and sodium bicarbonate solution and evaporated under reduced pressure. The residual gum was taken up in acetic acid and 20% perchloric acid added. The sparingly soluble perchlorate was filtered off, washed, dried, suspended in benzene and a stream of dry ammonia passed in. After filtration and the addition of petroleum ether, a crop of crystals separated on standing in a refrigerator and was filtered off. The liquor slowly deposits the oxidized compound (V) (below). For this reason, any prolonged operations should be carried out in an atmosphere of inert gas. For analysis, the compound was recrystallized several times from dilute methyl alcohol, after it had been warmed with methyl alcoholic potash to remove impurities. 1,2-Dihydropapaverine forms a bulky white mass of crystals (narrow hexagonal plates) melting at 97–98" (uncorr.). It is easily oxidized in solution by air, or by strong hydrogen peroxide in acetone solution, to the compound (V). It is readily soluble in the usual solvents, sparingly soluble in petroleum ether and practically insoluble in water.

With cold concentrated sulfuric acid it gives a yellow-brown solution which becomes intensely bluish-violet on heating. A crystal of potassium nitrate added to the cold acid solution gives an intense golden-brown color. Boiling acetic anhydride slowly develops a light emerald-green color (see compound V). Luchini's reagent gives a deep red color; Wenzell's reagent, deep violet; Erdmann's reagent, orange-red; Mandelin's reagent, blood-red, golden on heating; Frohde's reagent, yellow-green, becoming deep green, then violet on heating.

Anal. Calcd. for $C_{20}H_{23}O_4N$: C, 70.38; H, 6.74. Found: C, 69.98; H, 6.99.

On catalytic reduction in hydrochloric–acetic acid solution, tetrahydropapaverine is produced. It was isolated and identified by means of the characteristic hydriodide, which was compared with an authentic specimen prepared by Pyman's method. A mixed melting point determination showed no depression.

The dehydrogenation of 1,2-dihydropapaverine went very smoothly when 0.4 g. was heated with 0.2 g. of palladium black[8] in an inert atmosphere for thirty minutes at 170–180°. The melt was extracted with 10% hydrochloric acid and the papaverine precipitated as iodide by the addition of potassium iodide. The iodide was recrystallized from alcohol and identified (properties and mixed melting point determination) by comparison with an authentic specimen, and was then converted into the base and similarly identified as papaverine

1,2-Dihydropapaverine is very similar to 3,4-dihydropapaverine[5,6] and is best distinguished by means of its oxidation product (V), which shows considerable differences from that derived from the 3,4-compound.

Perchlorate.—This was prepared from the purified base and forms a sphaerocrystalline white powder, melting with blackening at 238° (uncorr.) after sintering. It is very sparingly soluble except in strongly acid solutions.

Anal. Calcd. for $C_{20}H_{23}O_4N \cdot HClO_4$: C, 54.36; H, 5.44. Found: C, 54.31; H, 5.74.

Picrate.—Prepared from the purified base, the picrate forms a lemon-yellow sphaerocrystalline powder, melting at 151° (uncorr.).

Anal. Calcd. for $C_{20}H_{23}O_4N \cdot C_6H_3N_3O_7$: C, 54.74; H, 4.56. Found: C, 54.39; H, 4.72.

6,7,3,'4'-Tetramethoxy-9-keto-1,2-dihydroprotopapaverine.—As already mentioned, this compound is produced by air-oxidation of 1,2-dihydropapaverine or by oxidation by strong hydrogen peroxide in acetone solution. When phosphorus pentoxide or oxychloride is used to remove water from (111), this compound is usually obtained. It

forms a compact mass of thick, irregular prisms from alcohol, melting at 187° (uncorr.). It is moderately soluble in alcohol, soluble in chloroform, somewhat soluble in hot benzene and very sparingly soluble in ether. With cold concentrated sulfuric acid it forms a golden solution, which becomes intensely red on adding a crystal of potassium nitrate. It dissolves in hydrochloric acid with a golden color and in hot acetic anhydride with an intense deep-green color. Luchini's reagent gives a red color; Wenzell's reagent, transient violet; Erdmann's reagent, orange red; Mandelin's reagent, blood red, becoming golden on heating; Frohde's reagent, brownish, blood-red when heated.

Anal. Calcd. for $C_{20}H_{21}O_5N$: C, 67.54; H, 5.67. Found: C, 67.22; H, 5.94.

When warmed on the steam-bath with methyl alcoholic potash, the compound rapidly changes into papaveraldine, identified by comparison and mixed melting point determinations with the authentic compound and with the alkaloid xanthaline.

Summary

1,2-Dihydropapaverine, hitherto unknown, has been synthesized and its structure established. In the course of the work, papaverine and papaveraldine have been obtained by a new series of reactions.

AN IODIMETRIC METHOD FOR DETERMINING OXIDASE ACTIVITY[1]

BY JOHN D. GUTHRIE

RECEIVED MAY 17, 1930 PUBLISHED SEPTEMBER 5, 1930

The usual methods for estimating oxidase activity depend on either the production of a colored substance,[2] or the measurement of the volume of oxygen absorbed.[3] Recently an electrometric method has been suggested.[4] Colorimetric methods are often inapplicable on account of pigments or turbidity in the extracts to be tested. Methods measuring the oxygen uptake require special apparatus. The method to be described here requires no unusual equipment, is easy to use and reasonably accurate. With it as many as sixteen determinations have been made at the same time.

In a previous paper,[5] it was noted that potato juice contains a substance or substances that may be titrated with iodine in acid solution (trichloroacetic acid) and that this titration decreases on exposure to air. Ordinarily five cc. of juice reduces about 0.5 cc. of $N/100$ iodine. However, juice from one lot of potatoes was found to reduce 2.0 cc. of $N/100$ iodine. It was thought that this might be due to a low content of oxidase, the substance responsible for the iodine reaction not being oxidized in the

process of extraction for this reason. In order to test this point, juice of this lot of potatoes was boiled and filtered. It still reduced 2.0 cc. of $N/100$ iodine. To 50-cc. portions of this boiled, filtered juice, 1 cc. of fresh juice from the same lot of potatoes and also 1 cc. from a lot giving the usual iodine titration were added. On exposing these mixtures to air in a thin layer, the iodine titration of the one containing the juice suspected of being low in oxidase had decreased 0.8 cc. after forty-five minutes, while the titration of the one containing juice of the other lot had decreased 1.4 cc. A water blank decreased 0.2 *cc.*

These results suggested that if a substance could be found that would reduce iodine in acid solution and which would also be oxidized by the air in the presence of potato juice, a convenient method would be available for determining oxidase. Cysteine was first tried. Its oxidation is catalyzed by potato juice, but the reaction proved to be autocatalytic and therefore unsuitable for the purpose. The autocatalytic nature of the oxidation of cysteine has been previously noted.[6]

Szent Gyorgyi[7] has noted the iodine reaction of plant juices and has isolated a substance that reduces iodine in acid solution from the adrenal cortex, orange and cabbage. He finds it to be a hexuronic acid. For this reason glucose that had been warmed with dilute sodium hydroxide was tried, since this product is known to contain a great variety of carbohydrate derivatives and it was thought that some of these might reduce iodine in acid solution. It was found that the iodine titration was quite large. Tests showed that it decreased on exposure to air and that this oxidation was catalyzed by potato juice.

Preliminary Work.—During the first part of the work, the reaction was carried out in liter beakers, 25 cc. of the reacting mixture being exposed in a thin layer in the bottom. At intervals, 5-cc. aliquots were drawn, 10 cc. of 10% trichloro-acetic acid was added and titrated with $N/100$ iodine, using starch as an indicator. The first difficulty encountered was a high blank, but it was found that clearing the substrate with decolorizing charcoal obviated this. It was also found that the conditions for aeration were unsatisfactory, since the rate of oxidation ceased to be directly proportional to the concentration of enzyme when more than 1 cc. of potato juice was used. Carrying out the reaction in aeration tubes corrected this difficulty. This improvement necessitated the use of a foam breaker. Capryl alcohol was tried, but all samples available interfered with the end-point, probably due to some impurity. It also had a slight retarding effect. Amyl alcohol, while not affecting the end-point, was decidedly injurious to the enzyme. Paraffin oil, although not so efficient a foam breaker as the higher alcohols, was finally chosen. In

[7] Szent Gyorgyi, *Biochem. J., 22,* 1387–1409 (1928).

order to test the effect of foaming, the addition of digitonin was tried. It greatly increased foaming but did not affect the results. As an additional improvement it was found that more accurate results could be obtained by adding a known quantity of iodine, allowing to stand and then titrating the excess with thiosulfate.

Preparation of Substrate.—Dissolve 40 g. of glucose in 400 cc. of N sodium hydroxide, place it in a 500-cc. Florence flask and immerse in a water-bath at 80° for fifteen minutes. Remove and neutralize at once by adding 10 cc. of 85% phosphoric acid. Add 25 g. of decolorizing charcoal (Norit A was used) and allow to stand overnight. Filter and add 25 g. of decolorizing charcoal to the filtrate. Allow to stand for fifteen minutes and filter. Dilute a small portion of the filtrate about one to five and determine the PH value. If it is not close to PH 6.5, adjust to this PH with N sodium hydroxide or N hydrochloric acid. The addition of 2 cc. of either to 100 cc. of the filtrate shifts the acidity about 0.1 *PH*. The iodine value for 25 cc. should be equal to about 60 cc. of *N*/50. Before using, dilute the filtrate with an equal volume of water.

The Method.—Pipet 25-cc. portions of the diluted substrate into Van Slyke–Cullen[8] aeration tubes. Add 2 cc. of the juice or extract containing the enzyme. For each determination run a blank, using 2 cc. of the boiled, filtered juice or extract. Add five drops of paraffin oil to each tube and aerate for one hour. Wash into 300-cc. Erlenmeyer flasks containing 25 cc. of 10% trichloro-acetic acid, adding in all about 50 cc. of water. Add 50 cc. of *N*/50 iodine in *N*/10 potassium iodide and allow to stand for thirty minutes. Titrate with *N*/100 sodium thiosulfate, using 1 cc. of 1% starch paste as an indicator. Titrate the blank first and the determination immediately afterward. The difference between these titrations is a measure of the oxidase activity of the sample.

Accuracy of the Method.—In order to test how nearly results could be duplicated, twelve determinations were made on the same lot of potato juice. The average value was 6.15 cc. with an average error of ±0.15 cc. To see how nearly the substrate could be duplicated, four batches were prepared and used with the same potato juice. The average value was 6.50 cc. with an average error of ±0.2 cc. This was repeated with four other batches of substrate and other potato juice. The average value was 6.8 cc. with an average error of ±0.15 cc.

Choice of PH Value.—Acidity of the reacting medium greatly affects the activity of enzymes. Therefore, a series of determinations was made at various PH values. These were obtained by the addition of N sodium hydroxide or N hydrochloric acid to the substrate. The quinhydrone electrode was used. Some difficulty was experienced, probably due to the interference of reducing substances. On the concentrated substrate values that were too alkaline were obtained. More acid values, which are believed to represent nearly the true PH, were obtained by diluting with about five volumes of water and using a large amount of quinhydrone. This effect is probably brought about by diluting the interfering substances and thereby minimizing their effect. Several experiments were made to determine the effect of the PH value of the substrate. A curve showing one of these, which is typical of the others, is shown in Fig. 1. Between PH 6.0 and PH 7.0 the oxidase activity is not greatly affected. Therefore, PH 6.5 was chosen as the best for carrying out the determinations. Bunzell[9] has investigated the effect of hydrogen-ion concentration on oxidase activity and recommends approximate neutrality for making the determinations. His data, however, are insufficient to show the exact form of the PH–oxidase curve, especially between PH 6.0 and 7.0.

[9] H. H. Bunzell, *ibid.*, 28, 315–333 (1916).

Effect of Concentration of Enzyme and **Time** of Aeration.—In order to test the effect of the concentration of enzyme and decide on the time of aeration, experiments were made using one, two, three and four cc. of potato juice and aerating for different periods. In the first experiments which were aerated for two hours the oxidase activity was not linear with the concentration, but curved upward. This tendency was negligible

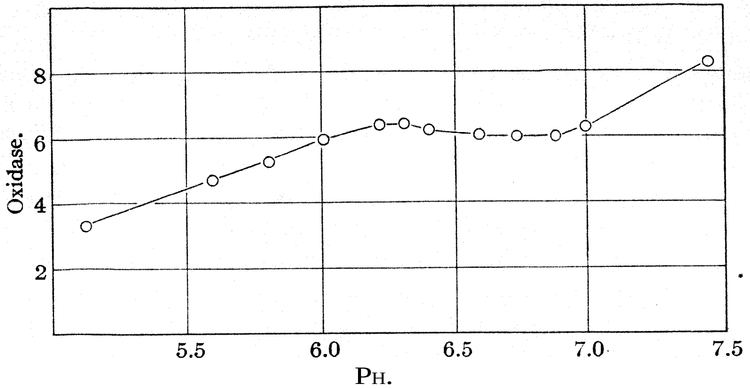

Fig. 1.—Showing the effect of hydrogen-ion concentration on the oxidase activity of potato juice. Aerated for one hour; two cc. of juice used.

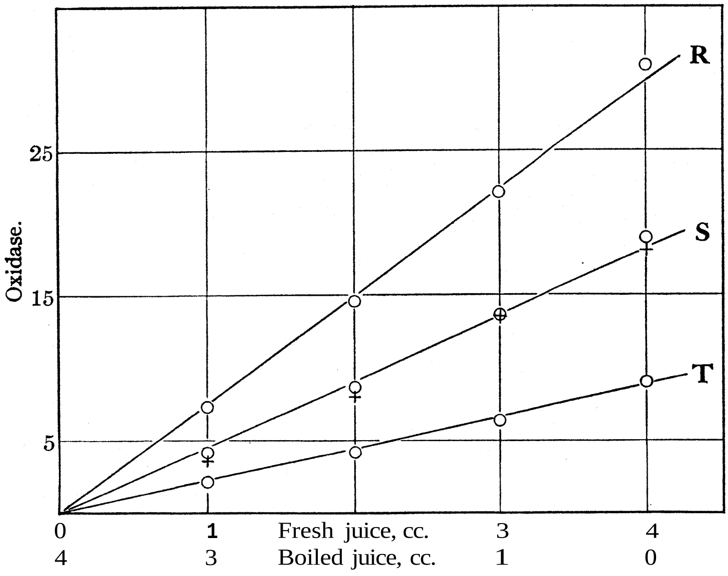

R, 120 minutes; S, 60 minutes; T, 30 minutes.

Fig. 2.—Showing the effect of enzyme concentration and time of aeration. Circles determined with usual substrate concentration, crosses with half this concentration.

when the aeration was only for one hour. It was found that the reason for this was the protective action of the juice, the enzyme in the tubes containing the larger amounts of juice being better protected. This protective action is present in the boiled, filtered juice. Therefore, an experiment was made in which the tube with 1 cc. of fresh juice contained also **3** cc. of boiled juice, the tube with 2 cc. of fresh juice, 2 cc. of boiled juice, and so on. Thus each tube contained 4 cc. of juice, but different amounts of enzyme in each. The results are shown in Fig. 2. It will be seen that the oxidase activity is almost linear with the concentration of enzyme even with two hours' aerating. Up to one hour the reaction is linear with time. In the second hour the reaction goes more slowly, showing that some enzyme is being destroyed. Therefore, one hour has been chosen for the time of aeration. Points are also given for the one-hour aeration curve in which half the usual concentration of substrate was used. Very little difference is noted, showing that in this range substrate concentration is not an important factor.

Results with Other Plants.—In order to see if the methods could be used on other materials besides potato juice, several other plant juices were tried. The results are shown in Table I. Qualitative tests were also made with the indophenol reagent.[10] The quantitative results correlate well with the qualitative.

TABLE I

APPLICATION OF METHOD TO VARIOUS PLANTS. TWO CC. OF JUICE USED UNLESS OTHERWISE NOTED

Plant	Iodimetric oxidase		Indophenol oxidase
Onion (bulb)	**0.6**	**0.4**	
Turnip (root)	**0.3**	**0 3**	−

Tobacco (mosaic leaves) 0.5 **cc.**	**12.8**		+++++

Summary

An iodimetric method is given for the estimation of oxidase activity. Oxidase activity as measured by the method is a linear function of the enzyme concentration. The effect of hydrogen-ion concentration on potato oxidase has been studied. The method is applicable to a variety of plants.

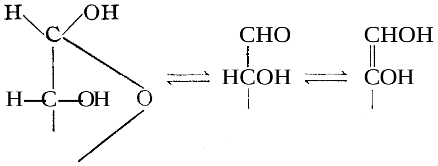
ALDEHYDO-I-ARABINOSE TETRA-ACETATE[1]

BY M. L. WOLFROM AND MILDRED R. NEWLIN

RECEIVED MAY 21, 1930 PUBLISHED SEPTEMBER 5, 1930

In continuation of the studies being made in this Laboratory on the open-chain forms of the sugar acetates, we wish to report in this paper the synthesis of the crystalline free aldehyde form of *l*-arabinose tetra-acetate. Although the ring formulas for the monosaccharides meet the requirements imposed by experimental data in most cases, there are nevertheless many reactions which are best explained by the assumption of an open-chain form in equilibrium with the ring or lactal structures. This is particularly true of the reactivity of the sugars in alkaline media. The changes that I-arabinose undergoes in alkaline solutions have been studied by Nef[2] and by Evans and Conaway.[3] These changes are best explained on the basis of enolic equilibria, which then require an intermediate open-chain formula, as follows



This paper presents evidence that the free aldehyde form of *l*-arabinose is capable of stable existence in the form of its crystalline acetate, $CH_2OAc-(CHOAc)_3-CHO$.

The methods used were similar to those reported in the case of glucose[4] and of galactose.[5] Arabinose ethyl mercaptal was acetylated and the thioethoxy groups replaced by an oxygen atom through reaction with mercuric chloride[6] and water under controlled conditions. The modifications introduced to obtain the arabinose compound consisted in the use of less water in the reaction and a slightly different method of isolation.

The free aldehyde form of *l*-arabinose acetate or aldehydo[5]-*l*-arabinose tetra-acetate crystallizes in prismatic needles and has widely differing constants from the two known lactal acetates of this sugar. Chavanne[7] first obtained crystals of the a-form of arabinose tetra-acetate, but in too

small amount to analyze. Hudson and Dale[8] have synthesized and characterized a- and β-*l*-arabinose tetra-acetates. The properties of the three forms are listed in Table I.

TABLE I

PROPERTIES OF THE THREE TETRA-ACETATES OF *l*-ARABINOSE

Form	M. p. °C.	$[\alpha]_D$, Chloroform
α	97	+ 42.5"
β	86	+147.2°
Aldehydo	114	− 65"

The rotation of aldehydo-*l*-arabinose tetra-acetate was stable in acetylene tetrachloride ($[\alpha]_D^{26}$ −58°) solution and in alcohol-free chloroform but underwent a slow change in the dextro direction in methyl alcohol and U. S. P. chloroform. In the former solvent the initial specific rotation was −46°, changing to −29° in five days. That this is due to combination with the alcohol is made probable by the isolation of well-characterized compounds of this type in the case of galactose.[5] The substance readily gave the Schiff aldehyde test and reduced Fehling's solution. A crystalline semicarbazone was formed without loss of an acetyl group. This semicarbazone showed a normal molecular weight by the Rast[9] method. The aldehydo forms of glucose and galactose acetates showed low specific rotations, being −5 and −25° in chloroform, respectively. This was thought to be probably characteristic of the open-chain forms. However, the value −65° obtained for the arabinose acetate, shows that the carbonyl group may produce a relatively high rotation, in spite of the absence of rings.

Further work on the synthesis and reactivity of the free aldehyde forms of sugar acetates is in progress in this Laboratory.

Experimental

***l*-Arabinose-ethylmercaptal Tetra-acetate.**—Three grams of *l*-arabinose ethyl mercaptal[10] (m. p. 124–126°) was dissolved in 12 cc. of dry pyridine at room temperature and the solution cooled in ice water. To this was added, gradually, 24 cc. of acetic anhydride. Some of the solute precipitated, but redissolved after a short time on standing at 0° with occasional shaking. The solution was then allowed to stand overnight at room temperature. At the end of this period it was poured slowly with stirring into 600 cc. of ice and water. A heavy oil separated which crystallized readily. Recrystallization was effected by dissolving the filtered crude material in methyl alcohol at room temperature, adding water and allowing the mixture to crystallize in the ice box. The yield of the pure product was 4.5 g. or 91%.

The substance crystallizes in prisms and after one recrystallization melted at 79–80". After another recrystallization the melting point was the same and the specific rotation in chloroform was −30.8° at 27° (0.4005 g. subs. in 10.06 cc. U. S. P. chlorcform

---

[8] C. S. Hudson and J. K. Dale, THIS JOURNAL, 40, 992 (1918).

[10] E. Fischer, *ibid.*, 27, 673 (1894).

soln., 1.1-dm. tube, LYD = –1.35°). After four recrystallizations the melting point was 79–80° and the specific rotation in the same solvent was –29.9° at 26° (0.4008 g. subs. in 10.06 cc. U. S. P. chloroform soln., 1.1-dm. tube, α_D = –1.31'). The substance is practically insoluble in cold water, slightly soluble hot, somewhat soluble in ethyl alcohol and petroleum ether, and very soluble in ether, acetone and chloroform.

Anal. Subs., 0.2002: 19.01 cc. 0.1 *N* NaOH. Subs., 0.2001: 19.01 cc. 0.1 *N* NaOH. Calcd. for 100 mg. of $C_5H_6O_4(CH_3CO)_4(SC_2H_5)_2$: cc. 0.1 *N* NaOH, 9.43. *Found:* 9.49, 9.50.

Aldehydo-*l*-arabinose Tetra-acetate.—An amount of 25 g. of *l*-arabinose-ethyl mercaptal tetra-acetate (m. p. 79–80') was dissolved in 90 cc. of pure acetone, and 15 cc. of water added. To this was added with mechanical stirring, an excess, 40 to 50 g., of finely powdered alkali-free cadmium carbonate, then a solution of 59 g. of mercuric chloride in 75 cc. of acetone. Stirring was maintained at room temperature for twelve hours, with occasional additions of fresh cadmium carbonate. The mixture was then held for fifteen minutes in a 50° bath, vigorous stirring being maintained. Finally, the solution was refluxed for fifteen minutes. The solution was cooled and filtered, cadmium carbonate being placed in the suction flask before filtering. The filtrate was then concentrated under reduced pressure at 30–35° in the presence of an excess of cadmium carbonate and dried several times by adding fresh acetone and evaporating under reduced pressure. The residue was extracted with warm chloroform and the extract dried *a* short time with sodium sulfate, adding some norite at the same time. After filtration, the solution was evaporated to dryness at room temperature in a vacuum desiccator. The last traces of chloroform were removed by several treatments with petroleum ether. A partially crystalline mass was thus obtained, from which the crystals were isolated by treatment with alcohol-free, dry ether, which dissolved the sirup. The ether solution was filtered and the crystalline residue washed with ether. The amount of this material was 5 g. and an additional crop of 2 g. was obtained from the ethereal filtrate on standing overnight in the ice box.

For purification, the material was dissolved in the minimum amount of warm acetone, and half the volume of anhydrous and alcohol-free ether added. Petroleum ether was then carefully added, crystallization being effected readily. By this procedure 5 g. of the crude material from the ether treatment gave 3.7 g. of product with m. p. 112–114° (corr.) and showing a specific rotation in acetylene tetrachloride soln. of –57.8° at 26° (0.4008 g. subs. in 10.06 cc. acetylene tetrachloride soln., 1.0-dm. tube, α_D = –2.30"). After three recrystallizations the melting point was 113–115° (corr.) and the specific rotation in the same solvent was –58.0° at 26° (0.4002 g. subs. in 10.06 cc. acetylene tetrachloride soln., 1.0-dm. tube, α_D = –2.31°). After five recrystallizations the melting point remained at 113–115" (corr.).

The substance crystallizes in clusters of prismatic needles. It is slightly soluble in cold water and ethyl alcohol, and readily soluble in these solvents when warmed. It is slightly soluble in warm ether and is practically insoluble in petroleum ether. It dissolves readily in methyl alcohol and with extreme ease in chloroform and acetone. The initial specific rotation of the pure substance in U. S. P. chloroform at 31° was –65.2" (0.4014 g. subs. in 10.06 cc. U. S. P. chloroform soln., 1.0-dm. tube, α_D = –2.60°). This value changed slowly in the dextro direction, being –63.3° after thirty minutes. In alcohol-free chloroform solution the specific rotation at 27" of the pure substance was –65.4° (0.4013 g. subs. in 10.06 cc. chloroform soln., 1.0-dm. tube, α_D = –2.61°). Another determination at the same temperature gave the value –65.6" (0.4017 g. subs in 10.06 cc. chloroform soln., 1.0-dm. tube, α_D = –2.62"). The change in these values in twenty-four hours was negligible. The alcohol-free chloroform was prepared from the U. S. P. grade by washing with water, drying overnight with sodium and calcium chloride and redistilling. In methyl alcohol solution an initial specific rotation of −46° was obtained, changing slowly in the dextro direction. This change is tabulated in Table II.

Anal. Subs., 0.1000: 12.56 cc. 0.1 N NaOH. Subs., 0.1000: 12.76 cc. 0.1 N NaOH. Subs., 0.2196: CO_2, 0.3939; H_2O, 0.1176. Calcd. for $C_5H_6O_5(CH_3CO)_4$: C, 49.04; H, 5.69; cc. 0.1 N NaOH per 100 mg., 12.6. Found: C, 48.92; H, 5.99; cc. 0.1 N NaOH, 12.6, 12.8; S, absent.

Aldehydo-*l*-arabinose-semicarbazone Tetra-acetate.—An amount of 4 g. (1 mole) of aldehydo-*l*-arabinose tetra-acetate (m. p. 113–115°) was dissolved in 40 cc. of warm water and cooled rapidly to room temperature. A mixture of 2 g. (1.3 moles) of semicarbazide hydrochloride and 2.5 g. (2 moles) of potassium acetate was added and the solution shaken vigorously. The crystalline semicarbazone began to separate rapidly after three to four minutes in the form of glittering four-sided plates. After one recrystallization from methyl alcohol the melting point was 184–187° (corr.) and this value was unchanged on a second recrystallization from hot water. The substance is moderately soluble in chloroform and acetone, soluble in warm water and warm alcohol, and is practically insoluble in ether and petroleum ether.

Molecular weight (Rast). 0.0106 g. subs. in 0.1017 g. of camphor depressed the m. p. 10.5°. Mol. wt. calcd. for $C_{14}H_{21}O_9N_3$: 375. Found: 396.

Anal. Subs., 0.2007: N_2, 19.50 (742.2 mm., 20°). Subs., 0.1000: cc. 0.1 N NaOH, 10.8, 10.7. Calcd. for $C_6H_9O_5N_3(CH_3CO)_4$: N, 11.20, cc. 0.1 N NaOH per 100 mg., 10.7. Found: N, 10.96, cc. 0.1 N NaOH, 10.8, 10.7.

Summary

1. A new form of *l*-arabinose tetra-acetate has been synthesized in pure crystalline condition.

2. Evidence is presented that this substance possesses the free aldehyde structure.
3. The crystalline semicarbazone of this aldehyde has been prepared in pure form.

THE CHEMISTRY OF DIARYL SULFIDES. III. THE SYNTHESIS OF THIOTHYRONINE[1]

BY GEORGE H. LAW AND TREAT B. JOHNSON

RECEIVED MAY 22, 1930 PUBLISHED SEPTEMBER 5, 1930

In two previous papers from this Laboratory,[2] attention has been directed to the remarkable effect of diaryl-sulfide groupings in organic compounds which have been shown to have therapeutic value as germicides or antiseptics. The outstanding derivative thus far studied is p-hydroxy-diphenyl-sulfide which was found to possess a germicidal activity equivalent to a phenol coefficient of 115. As a result of the discovery of this unexpected increase in germicidal power, and on account of the growing interest in the biochemistry of organic sulfur groupings in general, we have now extended further our researches in this field, and have begun a study of practical methods for synthesizing sulfur-ether-a-amino acid combinations corresponding in structure to the naturally occurring protein acids, phenyl-alanine and tyrosine, and also the sulfur analog of the hormone—*thyroxine.* In this paper we describe methods of synthesizing the two new α-aminoacids—*p*-methyl-*p'*-diphenylsulfide-β-alanine and p-hydroxy-*p'*-diphenylsulfide-β-alanine or *thiothyronine* (desiodo-thyroxine), which are expressed by formulas I and II, respectively. The amino acid II is the sulfur analog of thyronine III already described by Harington,[3] and is the first aromatic sulfur-ether derivative of the amino acid thiotyrosine IV to be described. A method for preparing *thiotyrosine* IV was first described in a paper from the Yale laboratory by Johnson and Brautlecht[4] in 1912, and so far as the authors are aware no attention has been paid to

$CH_3C_6H_4SC_6H_4CH_2CH(NH_2)COOH$

its chemistry since that date. The further study of this interesting acid and its derivatives is now in progress.

The approach to α-amino acid derivatives of diaryl sulfides has been accomplished as a result of the successful introduction of aldehyde groups into sulfide-ether constructions. Previous to our work no aldehyde derivatives of an aromatic sulfide have been described in the chemical literature. Of the various procedures previously employed for introducing the aldehyde group into the aromatic nucleus,[5] the method of Stephen,[6] involving conversion of a nitrile to an imide by reduction, and the latter to an aldehyde by hydrolysis, was the only one considered at all practical for accomplishing our purpose. This was also the method utilized by Harington and Barger[7] in their original work leading to the final synthesis of thyroxine. There is a serious objection to the application of any oxidation process for aldehyde synthesis in this series of compounds, as we are dealing with sulfur constructions which are easily altered by application of such experimental technique. The sulfides represent the lowest valency state of sulfur **and** all reactions must be avoided which would tend to convert the respective sulfide to a sulfoxide or a sulfone. It now seems probable from the work already done in this Laboratory that the Stephen reaction will be found of quite general application for aldehyde synthesis in the aromatic sulfide series.

The starting points for our two amino acid syntheses were *p*-methyl-*p*′-cyandiphenyl-sulfide and *p*-ethoxy-*p*′-cyandiphenyl-sulfide expressed by formulas V and VI, respectively. These were transformed into the corresponding aldehydes, VII and VIII, by application of Stephen's reaction

$$\underset{\text{V}}{CH_3C_6H_4SC_6H_4CN} \qquad \underset{\text{VI}}{C_2H_5OC_6H_4SC_6H_4CN}$$

$$\underset{\text{VII}}{CH_3C_6H_4SC_6H_4CHO} \qquad \underset{\text{VIII}}{C_2H_5OC_6H_4SC_6H_4CHO}$$

and then condensed with hydantoin according to the method of Wheeler.[8] After reducing the resulting aldehyde condensation products, and then destroying the resulting hydantoin derivatives by alkaline hydrolysis, the corresponding a-amino acids were easily obtained in good yield. Dealkylation of *p*-ethoxy-*p*′-diphenylsulfide-β-alanine by heating with hydrobromic acid gave the sulfur analog of thyronine represented by formula II. Description of the products formed in the different stages of the two syntheses

are given in the experimental part of this paper. Further work dealing with the preparation and study of halogen derivatives of aromatic sulfide amino acids is now in progress.

Experimental Part

p-Ethoxythiophenol, $C_2H_5OC_6H_4SH$.—This thiophenol has previously been prepared by Lagai[9] and also Gattermann.[10] By application of the technique of Leuckart[11] we succeeded in preparing the same compound in good yield (77%) from *p*-phenetidine. Ninety-six grams of the amine is productive of 83–85 g. of the thiophenol distilling between 238–241".

p-Ethoxy-p^1-nitrodiphenyl-sulfide, $C_2H_5OC_6H_4SC_6H_4NO_2$.—This is formed by digesting in alcoholic solution the sodium salt of p-ethoxythiophenol with *p*-nitrochlorobenzene. The sulfide is easily obtained in a yield of 93% of the theoretical and crystallizes from alcohol in needles melting at 96". It is insoluble in water but soluble in all common organic solvents except petroleum ether.

Anal. Calcd. for $C_{14}H_{13}NSO_3$: N, 5.09; S, 11.63 Found: N, 4.90; S, 11.49.

p-Methyl-p'-nitrodiphenyl-sulfide, $CH_3C_6H_4SC_6H_4NO_2$, is obtained from *p*-thiocresol and p-nitrochlorobenzene in a yield of 95% of the theoretical. It crystallizes from alcohol in yellow needles melting at 81.5".

Anal. Calcd. for $C_{13}H_{11}O_2NS$: N, 5.71; S, 12 06. Found: N, 5.63; S, 13.12.

Reduction of these two nitro compounds with stannous chloride in dilute alcohol solution acidified with hydrochloric acid leads to the formation of the corresponding amino derivatives.

***p*-Ethoxy-*p'*-aminodiphenyl-sulfide,** melting at 53° from alcohol. The hydrochloride melts at 184–185°.

Anal. Calcd. for $C_{14}H_{15}ONS$: N, 5.71; S, 13.06 Found: N, 5.47; S, 13.01.

***p*-Methyl-*p'*-aminodiphenyl-sulfide,** melting at 73.5° from alcohol. The hydrochloride melts at 183–184° and is obtained in a yield of 84% of the theoretical.

Anal. Calcd. for $C_{13}H_{13}NS$: N, 6.51; S, 14.88. Found: N, 6.39; S, 15.01.

p-Ethoxy-p^1-cyandiphenyl-sulfide. **VI.**—From the corresponding amine by application of Sandmeyer's reaction. This was purified by distillation under diminished pressure and finally by crystallization from dilute acetic acid. It separated in colorless prisms melting at 95–96°. The nitrile is insoluble in water, but soluble in all the common organic solvents.

Anal. Calcd. for $C_{15}H_{13}ONS$: N, 5.49; S, 12.55. Found: N, 5.45; S, 12 39.

***p*-Methyl-*p'*-cyandiphenyl-sulfide. V.**—This was prepared from *p*-aminobenzonitrile[12] and *p*-thiocresol according to Ziegler's technique,[13] and also from *p*-methyl-*p'*-aminodiphenylsulfide by application of Sandmeyer's reaction. The yield by either method is about 45% of the theoretical. This nitrile is easily purified by crystallization from dilute acetic acid and crystallizes in plates melting at 102–103°.

Anal. Calcd. for $C_{14}H_{11}NS$: N, 6.22; S, 14.22. Found: N, 6.14; S, 14.08.

p-Ethoxy-diphenyl-sulfide-p^1-carboxylic acid, melts at 201–202° (calcd.: S, 11.68. Found: S, 11.75).

_p_-Methyl-diphenyl-sulfide-_p_'-carboxylic acid, melts at 197–198° (calcd.: S, 13.12. Found: S, 13.21).

_p_-Ethoxy-_p_'-aldehyde-diphenyl-sulfide. VIII.—Thirty grams of anhydrous stannous chloride is added to 900 cc. of dry ether and the solvent saturated at low temperature with hydrochloric acid gas. Eight grams of *p*-ethoxy-*p*'-cyandiphenyl-sulfide dissolved in 30 cc. of chloroform is then added and after thorough mixing the solution is allowed to stand in an ice chest for several hours. Saturation with hydrochloric acid gas is then repeated and the mixture again allowed to stand for eight to ten hours. The imide hydrochloride is then separated by filtration and immediately converted to the aldehyde by warming with very dilute hydrochloric acid solution. The aldehyde crystallizes from dilute acetic acid in plates which melt at 83°. It is insoluble in water, but soluble in all the common organic solvents.

Anal. Calcd. for $C_{15}H_{14}O_2S$: S, 12.41. Found: S, 12.42.

Its phenylhydrazone, $C_{21}H_{20}ON_2S$, crystallizes from alcohol in yellow needles melting at 126–127° (calcd.: N, 8.04. Found: N, 7.82).

_p_-Methyl-_p_'-aldehyde-diphenyl-sulfide. VII.—This is obtained from *p*-methyl-*p*'-cyandiphenyl-sulfide by application of Stephen's reaction in a yield of 81% of the theoretical. The aldehyde is purified by crystallization from dilute acetic acid and separates in plates melting at 69°.

Anal. Calcd. for $C_{14}H_{12}OS$: S, 14.04. Found: S, 14.17.

Its phenylhydrazone, $C_{20}H_{18}N_2S$, crystallizes from alcohol in yellow plates melting at 149–150° (calcd.: N, 8.80. Found: N, 8.61).

_p_-Methyl-diphenylsulfide-_p_'-aldal-hydantoin, $CH_3C_6H_4SC_6H_4CH{=}\overline{CCONHCONH}$.—This is formed in a yield of 71% of the theoretical by interaction of *p*-methyl-*p*'-aldehydodiphenyl-sulfide (15.5 g.) with hydantoin (6.9 g.) and sodium acetate (26 g.) in a mixture of glacial acetic and acetic anhydride heated at its boiling point for eight hours. On pouring into cold water the hydantoin separates and is purified by crystallization from dilute alcohol. It melts at 239–240° and is insoluble in water and ether and only sparingly soluble in alcohol and acetic acid.

Anal. Calcd. for $C_{17}H_{14}O_2N_2S$: N, 9.03; S, 10.32. Found: N, 8.83; S, 10.19.

_p_-Ethoxy-diphenyl-sulfide-_p_'-aldal-hydantoin, $C_2H_5OC_6H_4SC_6H_4CH{=}\overline{CCONHCONH}$.—This hydantoin crystallizes from dilute alcohol in needles which melt at 254° with decomposition. The hydantoin is insoluble in water and ether and only sparingly soluble in alcohol and acetic acid.

Anal. Calcd. for $C_{18}H_{16}O_3N_2S$: N, 8.24; S, 9.41. Found: N, 8.16; S, 9.22.

Reduction of **the** Unsaturated **Hydantoins.**—This was accomplished by dissolving the respective hydantoin in warm alcohol and then reducing it at the double bond by slow addition of 2.5% sodium amalgam to the solution. When the reduction was complete the solution was acidified with hydrochloric acid and the reduced hydantoin precipitated by addition of water. The yield of crude hydantoin is about 85–90% of the theoretical.

_p_-Methyl-diphenyl-sulfide-_p_'-aldyl-hydantoin, $CH_3C_6H_4SC_6H_4CH_2\overline{CHCONHCONH}$, crystallizes from dilute alcohol in plates which melt at 187–189°. It is insoluble in water and ether, and soluble in acetic acids.

Anal. Calcd. for $C_{17}H_{16}O_2N_2S$: N, 8.97; S, 10.25. Found: N, 8.82; S, 10.09.

_p_-Ethoxy-diphenyl-sulfide-_p_'-aldyl-hydantoin, $C_2H_5OC_6H_4SC_6H_4CH_2\overline{CHCONHCONH}$, crystallizes from dilute alcohol in needles which melt at 184–185°. It is insoluble in water and ether, but soluble in the common organic solvents.

Anal. Calcd. for $C_{18}H_{18}O_3N_2S$: N, **8.18**; S, 9.36. Found: **N, 8.09; S, 9.45.**

p-Methyl-p′-diphenyl-sulfide-β-alanine. I.—This a-amino acid is formed by heating its hydantoin (above] in strong aqueous barium hydroxide at the boiling point of the solution for several hours (forty-eight). On acidifying the alkaline solution with hydrochloric acid and cooling, the hydrochloride of the amino acid separated as clusters of colorless prismatic crystals. The yield was **81% of** the theoretical and the salt melted at 205–207° with decomposition. The free amino acid was precipitated from an aqueous solution of its hydrochloride by addition of sodium acetate. This proved to be a very insoluble substance, and was purified by repeatedly dissolving in alkaline solution and precipitating with acetic acid. The sodium salt was found to crystallize from dilute sodium hydroxide solution as needles. The acid gives the normal ninhydrin test characteristic of a-amino acids. The acid melts at 198–200° with great decomposition.

Anal. Calcd. for $C_{16}H_{17}O_2NS$: N, **4.88**; S, **11.15.** Found: N, **4.80**; S, **11.74.**

p-Ethoxy-p′-diphenyl-sulfide-β-alanine, $C_2H_5OC_6H_4SC_6H_4CH_2CH(NH_2)COOH$.—This is formed by hydrolysis of its corresponding hydantoin (above) with barium hydroxide (heating at **100°** for forty-eight hours). The yield of hydrochloride was 82% of the theoretical, and it melted at 218–220° with decomposition. The free amino acid melts at 208–210° with intense decomposition and is slightly soluble in dilute solutions of mineral acids and alkali and insoluble in water. It responds to the ninhydrin test for α-amino acids.

Anal. Calcd. for $C_{17}H_{19}O_3NS$: N, 4.41; S, **10.09.** Found: N, 4.38; **S. 10.21.**

p-Hydroxy-p′-diphenyl-sulfide-β-alanine or **Thiothyronine. 11.—This** amino acid is formed by heating the corresponding ethyl ether with a mixture of 48% hydrobromic acid and acetic anhydride at 90° for several hours (forty-eight). The reaction mixture was then diluted with water and the hydrobromic acid neutralized by addition of sodium acetate using alizarine as an indicator. The amino acid separated at once and was further purified by dissolving in sodium hydroxide solution and precipitating with acetic acid. Further purification was effected by dissolving the amino acid in hydrochloric acid and reprecipitating by adding to the solution sodium acetate. This amino acid crystallizes in the form of colorless spherical crystals which darken when heated at **230"** and melt with decomposition at 240–242°. It is insoluble in cold water, very slightly soluble in hot water, and also sparingly soluble in dilute acid and alkaline solutions. It gives a positive ninhydrin test but does not give as distinct and decisive a Millon's test as tyrosine. This later color change is undoubtedly influenced by the presence of sulfur in the sulfide molecule.

Anal. Calcd. for $C_{15}H_{15}O_3NS$: C, **62.2**; H, **5.19**; N, **4.84.** Found: C, **62.0**; H, **5.26**; **N, 5.00.**

Summary

1. The Stephen reaction for preparing aldehydes from cyanides has been applied with success in the diaryl-sulfide series.

2. The two aldehydes $CH_3C_6H_4SC_6H_4CHO$ and $C_2H_5OC_6H_4SC_6H_4CHO$ condense smoothly with hydantoin, giving condensation products which can be transformed into characteristic a-amino acids.

3. Three new α-amino acids have been described, including thiothyronine, the sulfur analog of thyronine or desiodo-thyroxine.

4. The study of these amino acids and their halogen substitution products is being continued.

ISOMERIC ALPHA,BETA-DIPHENYL-DELTA-KETONIC ACIDS. I[1]

BY S. AVERY AND G. C. JORGENSEN

RECEIVED MAY 23, 1930 PUBLISHED SEPTEMBER 6, 1930

Introduction

α,β-Diphenylglutaric acids, the isomerism of which has been explained by Avery and Maclay,[2] have, in so far as their asymmetric carbon atoms are concerned, a structure similar to α,β-diphenyl-δ-ketonic acids, as the following comparison shows.

Glutaric acids $CO(OH)CH_2CH(C_6H_5)CH(C_6H_5)CO_2H$
Ketonic acids $CO(R)CH_2CH(C_6H_5)CH(C_6H_5)CO_2H$

It is to be anticipated, therefore, that a careful study of isomeric δ-ketonic acids will disclose many points of similarity between these compounds and the corresponding 8-carboxylic or glutaric acids. By analogy it should be possible to synthesize two optically inactive stereoisomers in the case of each ketonic acid. These acids should form two definite series of isomeric derivatives, as nitriles and esters. The preparation of such compounds would add convincing evidence of the correctness of the explanation of stereoisomerism in the glutaric series. Finally, as in the glutaric series, it should be possible to resolve each inactive acid into its optical isomers. The present paper, however, deals with inactive isomers only.

The study just outlined would naturally begin with isomeric α,β-diphenyl-y-acetylbutyric acids, but inasmuch as efforts to prepare acids of this composition were unsuccessful, owing to the active hydrogen atoms of the acetyl group, attention was turned to other derivatives.

By combining benzyl cyanide or an ester of phenylacetic acid with benzalpinacolone, one might expect to synthesize derivatives of isomeric α,β-diphenyl-γ-trimethylacetylbutyric acids. The experimental part of the paper will show that such compounds were easily formed in so far as the higher-melting series is concerned. Lower-melting isomers, however, were formed in small quantities. It was, moreover, not found possible to secure them free from isomeric admixture. The higher-melting series is as follows

$$\begin{tikzcd}
\text{Methyl ester } 175° \arrow[rd, shift left] & \\
& \text{Acid } 235\text{–}236° \arrow[lu, shift left] \\
\text{Nitrile } 86° \arrow[ru] &
\end{tikzcd}$$

The lower-melting series will be discussed in the experimental part of this paper.

---

[1] Read at the Atlanta meeting, Organic Section, American Chemical Society, April 8, 1930.

[2] Avery and Maclay, THIS JOURNAL, 51,2833 (1929).

Owing to the poor yield and the doubtful purity of the lower-melting isomers, the authors of this paper decided to turn their attention to the corresponding benzoyl derivatives, which had already found a place in chemical literature.

The Isomeric α,β-Diphenyl-γ-benzoylbutyric Acids.—Borsche,[3] by combining ethyl phenylacetate with benzalacetophenone, obtained an ethyl ester of this series melting at 153–154° which hydrolyzed in alkaline solution to the salt of an acid melting at about 240°. He designated it as α,β-diphenyl-γ-benzoylbutyric acid.

By the oxidation of α,β,δ-triphenyl-δ-hydroxyvaleric acid, Meerwein[4] obtained an acid of the same composition melting at 186–187°. By combining methyl phenylacetate with benzalacetophenone, he obtained a mixture of isomeric esters. The esters yielded two acids, one melting at 186–187°, identical with the oxidation product previously obtained, and an isomer melting at 260–261°. These formed methyl esters melting at 157–158° and 177–178°, respectively. Meerwein's work indicates that the 240° acid of Borsche was a mixture of isomers.

By combining benzyl cyanide with benzalacetophenone, Kohler and Allen[5] obtained a nitrile melting at 118° and an isomer melting at 109'. The higher-melting nitrile gave a methyl ester melting at 150°, the lower nitrile a methyl ester melting at 139'. Both esters gave on saponification an acid melting at 239'. This acid on esterification with methanol and hydrogen chloride gave a product melting at 150°, identical with the ester (150") obtained directly from the higher-melting nitrile.

Owing to the lack of close agreement in certain parts of the work of previous investigators, the authors of this paper have attempted to clarify the subject by repeating (with some modifications) and extending the work of their predecessors. They have made free from isomeric admixture the ethyl ester (156° corr.) of Borsche, (1) by direct synthesis, (2) by esterification of the 260–261° acid of Meerwein and (3) by treating the 118° nitrile of Kohler and Allen with ethanol and hydrogen chloride. The methyl ester 177–178° of Meerwein has been prepared (1) by direct synthesis, (2) by treating the 118° nitrile with methanol and hydrogen chloride, and (3) by esterification of the 260–261° acid. The 260–261° acid of Meerwein has been prepared (1) by hydrolyzing the 156° ethyl ester, also the 177–178° methyl ester, (2) by hydrolyzing the 118° nitrile, and (3) by hydrolyzing a lactone not found in the literature of the subject.

The 186–187° acid of Meerwein has been prepared (1) by fractional crystallization from a mixture of the acids resulting from the hydrolysis of the mixed esters or of the mixed nitriles, (2) by hydrolysis of the pure

---

[3] **Borsche,** *Ber.*, 42,4497 (1909).

[4] **Meerwein,** J. *prakt. Chem.*, 97,272 (1918).

[5] **Kohler** and **Allen,** THIS JOURNAL, 46, 1522 (1924).

esters (ethyl 100–101°, methyl 155°), and (3) by the hydrolysis of a lactone. The following list shows the members of both series that the authors of the present paper have prepared free from any isomeric admixture.

The higher-melting series

Methyl ester	177–178°	⇄	Acid 260–261°
Ethyl ester	156°	⇄	
Lactone	220–222°	⇄	
Nitrile	118°	→	

The lower-melting series

Methyl ester	155°	⇄	Acid 186–187°
Ethyl ester	100–101°	⇄	
Lactone	136°	⇄	

The ready formation of distinct lactones from both acids and the hydrolysis of these lactones into the original acids is evidence against the assumption of a "*trans*" or "fumaroid form for the 260–261° acid and the "cis" or "maleinoid" form for the 186–187° acid.

Experimental Part

The Trimethylacetyl Derivatives

The Nitrile of α,β-Diphenyl-γ-trimethylacetylbutyric Acid.—Benzalpinacolone condenses with benzyl cyanide readily under a variety of conditions. The details of the procedure employed will be given under the description of the condensation of benzyl cyanide with benzalacetophenone. No trimolecular body is formed. On recrystallizing from light gasoline, crystals superficially reminding one of quartz are obtained, melting point 86° (corr.), yield about 90% of the theoretical.

Anal. Calcd. for $C_{21}H_{23}NO$: C, 82.57; H, 7.60; N, 4.62. Found: C, 82.57; H, 7.84; N, 4.50.

The 86° nitrile hydrolyzed (in acid solution) to an acid melting at 236°, while a less pure sample, of slightly lower and less definite melting point, not only gave the 236° acid but also a small percentage of an acid melting between 189 and 190°.

The Methyl Ester of α,β-Diphenyl-γ-trimethylacetylbutyric Acid.—A crystalline mass is formed by the reaction of benzalpinacolone with methyl phenylacetate in the presence of sodium methylate. The yield of the impure ester was nearly quantitative. Repeated recrystallizations from methanol gave a product forming long slender needles melting at 175°, soluble in chloroform and benzene.

Anal. Calcd. for $C_{22}H_{26}O_3$: C, 78.06; H, 7.75. Found: C, 77.97; H, 7.78.

The ester saponified (in acid solution) to an acid identical with the 236° acid obtained from the nitrile. The 236" acid with methanol and hydrogen chloride again formed the 175° ester.

The filtrates from the above were condensed and again recrystallized from methanol. By repeated fractional crystallizations a small amount of a product forming long, slender rods, m. p. 110–115°, was obtained. It was found impossible to obtain a product with a sharp melting point.

Anal. Calcd. for $C_{22}H_{26}O_3$: C, 78.06; H, 7.75. Found: C, 77.64; H, 7.70.

This 110–115° ester saponified in acid solution to a 189–190° melting acid.

The α,β-Diphenyl-γ-trimethylacetylbutyric Acid.—As previously stated, a sharply melting acid may be prepared from the 86° nitrile or the 175° methyl ester by hydrolysis in acid solution. This 236° acid crystallizes from 95% ethyl alcohol in flattened needles or long plates.

Titration. 0.3211 g. required 19.72 cc. of $N/10$ NaOH. Calcd.: 19.82 cc. ***Anal.*** Calcd. for $C_{21}H_{24}O_3$: C, 77.73; H, 7.46. Found: C, 77.76; H, 7.43.

The evidently impure 110–115° ester saponified to an acid melting at 189–190°. A sharp melting point could not be obtained after repeated recrystallizations of the small amount available. It appeared to be identical with the acid obtained from the fraction of the nitrile melting below 86°.

Titration. 0.3904 g. required 24.16 cc. of $N/20$ NaOH. Calcd.: 24.10 cc. ***Anal.*** Calcd. for $C_{21}H_{24}O_3$: C, 77.73; H, 7.46. Found: C, 77.63; H, 7.46

In spite of the analytical data, the presence of the lower-melting isomers is not definitely established. The quantities were minute in comparison with the well-defined bodies of a higher-melting series. Sharp melting points and clearly defined crystal forms are lacking. The most probable conclusion is that the 110–115° ester and the 189–190° acid, though members of a lower-melting series, contain also a small admixture of the higher isomers and possible traces of some unidentified compound.

The above view is further strengthened by the fact that when the pure 175° ester is saponified in alkaline solution, the salts of mired acids are formed. From this mixture the pure 236° acid, and an acid or acid mixture melting at 189–190° can be separated by fractional crystallization. The change from the pure ester to a mixture of isomeric acid salts by hydrolysis in alkaline solution will be dealt with later in this paper.

An attempt was made to obtain the lower-melting acid in pure condition by proceeding in the following manner. Phenylacetaldehyde was united to benzalpinacolone in the presence of sodium methylate. A product melting sharply at 158°, of very definite crystalline character was obtained. The composition is that of a direct addition product, $C_{21}H_{24}O_2$. This substance proved to be highly stable, thus differing in behavior from the α,β,δ-triphenylvalerolactone of Meerwein.

The Benzoyl Derivatives

Preparation of the 118° Nitrile of α,β-Diphenyl-γ-benzoylbutyric Acid.—A yield of nearly 90% of this compound (melting at 116–118°) was obtained by slightly modifying the procedure of Kohler and Allen. On the basis of the benzalacetophenone employed, about a 10% excess of benzyl cyanide was used and less than one mole of sodium methylate in a methanol solution. The mixture was stirred for half an hour at the temperature of the ice-bath, then at room temperature. After seeding with nitrile previously prepared, a crystalline mass separated out which soon became too thick to stir conveniently. Ligroin was then added and stirring continued. After two hours of vigorous stirring, glacial acetic acid in slight excess in proportion to the sodium methylate was added and the mass filtered off, washed with ligroin, dried and recrystallized. Made in this way it is nearly free from the trimolecular body and from the lower-melting nitrile of Kohler and Allen. This last named compound, thoroughly investigated by these authors, was prepared in this Laboratory in quantity and purity sufficient only to show its relation to the 186–187° acid.

Hydrolysis of the Nitriles.—The nitrile is dissolved in boiling acetic acid in a flask fitted with a return flow condenser. To the boiling solution, drop by drop, a mixture of equal volumes of sulfuric acid and water is added. Separation of oily drops of the unchanged nitrile indicates that the strong aqueous sulfuric acid solution is being added too rapidly. After some time crystals begin to appear in the boiling solution. During a period of about six hours, the original acetic acid solution is diluted to about two volumes with the sulfuric acid solution.

The content of the flask is now poured into cold water and filtered. The crystalline substance retained by the filter is treated in a large beaker with potassium carbonate, in slight excess, dissolved in enough boiling water to hold in solution the difficultly soluble potassium salt formed. The undissolved portion is unchanged nitrile and a small amount of an unidentified cleavage product. This is filtered off and rejected. The filtrate contains the acid sought in the form of the potassium salt, which being difficultly soluble in water may partially separate out on cooling. The filtrate is acidified, the precipitated acid filtered off, dried and recrystallized using methods described under the next sub-heading.

Hydrolyzed in the above manner, the 118" nitrile yields the 260–261° acid. The lower-melting nitrile gives the 186–187° acid. Hydrolyzing in acid solution is of importance inasmuch as many nitriles cannot be successfully saponified by sodium or potassium hydroxides and, further, as previously pointed out by Avery and Maclay for the glutaric series, hydrolyzing in an acid medium at moderate temperature does not effect a transformation of the lower $\rightleftarrows$ higher series, while the sodium or potassium hydroxides often cause such transformation.

Preparation of the Mixed (260–261° and 186–187°) α,β-Diphenyl-γ-benzoylbutyric Acids.—Ten and four-tenths grams of benzalacetophenone and 7.5 g. of methyl phenylacetate were dissolved in 25 cc. of absolute methanol. To the solution, cooled in an ice-bath, 1.15 g. of sodium dissolved in absolute methanol was added. The mixture was stirred for half an hour in the ice-bath and then at room temperature until it was too thick to stir well. Ligroin was added as a diluent and stirring continued for several hours; 5 cc. of glacial acetic acid was added and the stirring continued for half an hour. The crystalline mass was filtered, washed with ligroin and dried. The mixed esters were then hydrolyzed in acid solution and the mixed acids separated as follows. The 260–261° acid separated out on cooling from a hot glacial acetic solution of the two acids and is obtained in a pure condition by further recrystallization from this solvent. The acetic acid filtrates are brought together, heated and water added until a crystallizing precipitate forms at the boiling temperature. On cooling, nearly all of the 186–187" acid separates out. By fractional recrystallization from hot benzene, rejecting the small portion of the 260–261° acid that first separates out on cooling, the acid is obtained in a nearly pure condition. Recrystallization again from benzene gives the pure 186–187° acid. This is an adaptation of the procedure of Borsche and of Meerwein.

The Ethyl Ester of the 186–187° Acid.—To complete the series of methyl and ethyl esters (for both isomers) the ethyl ester of the lower-melting acid was prepared with ethyl alcohol and hydrochloric acid. It is readily soluble in the usual organic solvents, crystallizes in long, slender plates or needles and melts at 100.5°.

The Lactones of the α,β-Diphenyl-γ-benzoylbutyric Acids.—The 186–187° acid dissolves readily in acetyl chloride at the temperature of the steam-bath. The concentrated solution is treated with ligroin and the precipitate formed recrystallized from tertiary amyl alcohol. It separates from this solvent as needles or long prisms, soluble in acetic acid, chloroform and benzene, m. p. 136°. On heating the solution in acetic acid to boiling, adding 50% sulfuric acid and continuing the boiling for a few minutes, the 186–187" acid is regenerated.

The 260–261° acid is less readily soluble in acetyl chloride. The lactone begins to separate out before the acid is completely dissolved. After protracted boiling, ligroin is added to the flask containing the products of the reaction and the mass is filtered off and recrystallized out of a mixture of tertiary amyl alcohol and chloroform. It forms needles or rods, more difficultly soluble in the ordinary solvents than its isomer, m. p. 220–222°. It hydrolyzes to the 260–261° acid.

Anal. Calcd. for $C_{23}H_{18}O_2$: C, 84.62; H, 5.56. Found for the 136° lactone: C, 84.30; H, 5.60. Found for the 220–222° lactone: C, 84.48; H, 5.64,

Transformation: The Higher Series ⇄ the Lower.—Saponification by alcoholic potassium or sodium hydroxide of the esters of either series leads to the corresponding acid, mixed, however, with a certain amount of the isomer. The action appears to explain why in some previous investigations an acid melting at 239–240° was obtained.

Summary

The points of analogy between the corresponding 8-ketonic and δ-carboxylic acids are considered.

α,β-Diphenyl-γ-trimethylacetylbutyric acid has been synthesized and possible isomeric forms are discussed.

The work of previous investigators on α,β-diphenyl-γ-benzoylbutyric acid is reviewed. Discrepancies in the literature are found to have resulted mainly from the hydrolysis of pure esters by sodium or potassium hydroxide, thus forming isomeric mixtures. Through the preparation of new compounds, both series of the isomeric benzoyl derivatives are now fairly complete. Resolution of both isomeric acids into optical isomers may be anticipated.

ACTION OF METALLIC SODIUM ON DIPHENYL- AND DITOLYLTRICHLORO-ETHANES[1]

BY ELWIN E. HARRIS

RECEIVED MAY 23, 1930 PUBLISHED SEPTEMBER 5, 1930

In a former report[2] the author stated that when diphenetyltrichloroethane was treated wuth sodium in benzene a good yield of *p,p'*-diethoxystilbene was obtained. He was unable at the time to account for the mechanism of the reaction although similar products had been reported from the reaction of the same compound with zinc.[3] This investigation was undertaken to determine the course of the reaction and the nature of the products formed.

It was found that the presence of moisture is essential to the reaction in benzene, as in its absence no *p,p'*-diethoxystilbene could be isolated and most of the starting product was recovered unchanged. The reaction apparently takes the course

$$(C_2H_5OC_6H_4)_2CHCCl_3 + 4Na + H_2O \longrightarrow C_2H_5OC_6H_4CH{=}CHC_6H_4OC_2H_5 + 3NaCl + NaOH$$

Fritsch[4] found that heating the compound with sodium alcoholate in a

sealed tube for six hours gave a good yield of the stilbene. To keep the sodium melted and to raise the temperature, toluene was substituted for the benzene. Precautions were taken to prevent moisture from entering the apparatus and all the chemicals were carefully dried. A very violent reaction took place which in a few cases was uncontrollable and a fire resulted. The mixture became deep greenish-brown in color. The reaction was so complex and so many-products were formed that further work was postponed on diphenetyltrichloro-ethane and ditolyltrichloro-ethane was substituted in the study. The same kind of reaction resulted except that it was much less violent. About 50% of the starting product could be accounted for as *p,p*-dimethylstilbene and about 45% as pip-dimethyltolane. The equation is

$$2(CH_3C_6H_4)_2CHCCl_3 + 3Na \longrightarrow CH_3C_6H_4CH{=}CHC_6H_4CH_3 + CH_3C_6H_4C{\equiv}CC_6H_4CH_3 + 3NaCl$$

It is obvious that rearrangement and intramolecular oxidation have taken place. Other studies on this interesting reaction are now in progress.

Experimental Part

Apparatus and Materials.—The apparatus used was a round-bottomed flask fitted with a dropping funnel, a mercury-sealed stirrer and a reflux condenser. To give plenty of room for possible frothing, the Bask had a capacity ten times the volume of the contents. The dropping funnel and the condenser were fitted with drying tubes.

The toluene was treated first with a small amount of sulfuric acid, washed with water and 10% sodium hydroxide, then dried over calcium chloride and finally allowed to stand over sodium powder for a week or more. It was then distilled from fresh sodium with a distilling tube. Only that portion boiling from 110 to 112° was used, and this was caught in the flask to be used for the experiment. The sodium was the commercial purified form. The crust was removed under toluene and the sodium transferred quickly to the reaction flask. The diphenyl- and the ditolyltrichloro-ethanes were prepared according to the method formerly described by the author.[2] These were recrystallized from toluene just before the experiment.

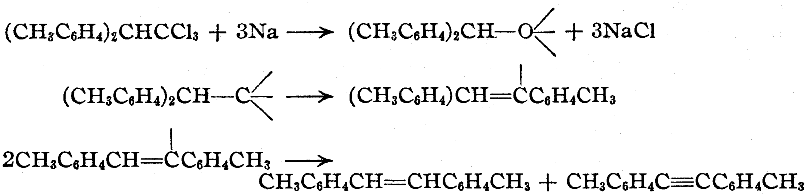
Observations

The Action of Sodium on **β,β,-Ditolyl-α,α,α-trichloro-ethane** in Boiling Toluene.—Thirty-one grams of ditolyltrichloro-ethane was dissolved in 150 cc. of the purified toluene and placed in the dropping funnel, which was kept warm with a hot cloth, and allowed to drop onto 14 g. of melted sodium in boiling toluene. It was stirred with an electric stirrer to keep the sodium whipped to a very fine powder. A violent reaction began almost immediately and lasted for about twenty minutes. The mixture turned green. It was then heated for an hour with continuous stirring. The sodium was allowed to settle and the toluene solution was decanted off. The sodium was extracted several times with more hot toluene and finally treated with alcohol. No organic product was found in the alcoholic solution from the sodium. The toluene solution was concentrated and cooled. *p,p'*-Dimethylstilbene crystallized out in large plates. These were filtered off and recrystallized from benzene, melting point 177°; dibromide, melting point 214°. The filtrate was again concentrated and another crop of the substituted stilbene separated. The combined portions represented over 45% yield from the starting product. Alcohol was then added to the filtrate from the stilbene and there separated *p,p'*-dimethyltolane and a yellow compound which did not melt sharply; m. p. 85 to 90°. It was very soluble in benzene, and more soluble in alcohol than the stilbene or the tolane. Each crystallization of this yellow compound gave a small amount of *p,p'*-dimethyltolane melting at 135°; dibromide, 204°. The addition of a small amount of hydrochloric acid to the alcohol from which it was crystallized caused all of the yellow compound to change to the tolane. One sample of the yellow compound stood in a tube for four years and was found to have changed over to the tolane, melting at 135°. These combined portions of the tolane brought the yield to about 45%, accounting for 90 to 95% of the starting material.

The Action of Sodium on **β,β-Diphenyl-α,α,α-trichloro-ethane.**—The reaction described above was performed with diphenyltrichloro-ethane. In all respects it seemed to be much the same as that above, but it has been very difficult to isolate the products formed. Some of each of the following were found, and converted into their dibromide for identification: normal stilbene melting at 124° (dibromide, 236°); isostilbene, an oil (dibromide, 109°) and tolane, melting point 60° (tolane dibromide, 208°). Although it was impossible to obtain very large portions of the above compounds from the reaction. no other products were found; therefore one would be led to believe that the mechanism of the reaction was the same as in the first case.

Attempts to Isolate Intermediate Sodium Compounds.—The above reactions were also run in an atmosphere of nitrogen to eliminate the effect of air on the reaction, which may decompose any sodium organic complex. Carbon dioxide was then passed into the mixture but there was no indication of a reaction to form the acid derivative of tolane or stilbene.

Mechanism of the Reaction.—The formation of an intermediate sodium compound would be a simpler method of accounting for the reaction, but since none could be found, it should not be used in interpreting the reaction. The mechanism given below is similar to one given by Wooster.[5]



$$(CH_3C_6H_4)_2CHCCl_3 + 3Na \longrightarrow (CH_3C_6H_4)_2CH-O\lt + 3NaCl \qquad (1)$$

$$(CH_3C_6H_4)_2CH-C\lt \longrightarrow (CH_3C_6H_4)CH=\overset{|}{C}C_6H_4CH_3 \qquad (2)$$

$$2CH_3C_6H_4CH=\overset{|}{C}C_6H_4CH_3 \longrightarrow CH_3C_6H_4CH=CHC_6H_4CH_3 + CH_3C_6H_4C\equiv CC_6H_4CH_3 \qquad (3)$$

The second equation should easily form a dimolecular compound. If such a dimolecular compound was formed, it must have split immediately, with rearrangement to form stilbene and tolanes. This wandering of groups is similar to that shown by Lachman,[6] also by Stieglitz[7] and Tiffeneau.[8] This reaction is not preceded by the elimination of hydrogen chloride, as was suggested in the reaction by Wooster,[5] for this would give rise to compounds in which the ethane hydrogen is absent. A study of a reaction in which the hydrogen chloride is first removed is to be the subject of another report.

Summary

1. The action of sodium on ditolyltrichloro-ethane in boiling toluene results in the formation of *p,p'*-dimethylstilbene and *p,p'*-dimethyltolane.

2. A similar reaction takes place when sodium acts on diphenyltrichloro-ethane.

3. A possible interpretation of the reaction is given, involving the formation of monovalent carbon followed by the rearrangement of the phenyl groups within the molecule and the redistribution of the hydrogens between the molecules.

THE POLYHYDRIC ALCOHOL–POLYBASIC ACID REACTION.

II. ETHYLENE GLYCOL–PHTHALIC ANHYDRIDE

BY R. H. KIENLE AND A. G. HOVEY

RECEIVED MAY 24, 1930 PUBLISHED SEPTEMBER 5, 1930

Introduction

In the first paper of this series[1] the reaction between glycerol and phthalic anhydride was described. The changes in properties were shown to be gradual and continuous. The conclusion was drawn that although the reaction proceeded by esterification, it did not necessarily take place with the formation of definite mono-, di- or triglycerides, but that a heterogeneous complexity of esters resulted.

It is interesting to compare the reaction of ethylene glycol and phthalic anhydride with the reaction of glycerol and the same acid, for ethylene glycol is a smaller and simpler molecule than glycerol. Any differences in properties of the resinous products of the reactions should therefore be due to the difference in size and structure of the alcohols.

Historical.—The reaction of ethylene glycol with phthalic anhydride was known to M. J. Callahan[2] in 1914, but the resin did not receive commercial application as soon as that formed from the glycerol–phthalic anhydride reaction, because ethylene glycol has not been available in considerable quantities until within the last five or six years. Much additional work was done by J. G. E. Wright and co-workers, the authors, and others, with the result that certain modifications of the reaction have been effected and several novel resins of commercial value have been produced. Recently, R. H. Kienle and C. S. Ferguson[3] described the product of the ethylene glycol–phthalic anhydride reaction as belonging to a "heat-

non-convertible" type of film-forming resins. Carothers and Arvin[4] gave a description of methods of preparing glycol phthalate esters and obtained their molecular weights.

Materials.—C. P. phthalic anhydride (Monsanto Chemical Co.) having a melting point of 131.1°, and ethylene glycol of the best grade furnished by Carbide and Carbon Chemicals Corporation, having a specific gravity of 1.069 and boiling point of 194°, were used.

Experimental Part

I. A Study of the Products of the Reaction.—In the first paper of this series[1] the products of the glycerol–phthalic anhydride reaction were studied and found to be nothing more than water and resin. It was concluded that the only reaction involved was that of esterification. A similar result was obtained for the glycol–phthalic anhydride reaction.

Using an apparatus as described in our previous paper, the reaction mixture was heated in a tared Erlenmeyer flask on a sand-bath. To prevent oxidation, a stream of nitrogen carried the vapors evolved through Traps A, B and C where solid, liquid and gas were collected, respectively, and then finally through Trap D which contained a solution of rosaniline and sulfurous acid to detect any volatile aldehyde or reducing compounds which might not condense in the liquid-air trap if blown through too rapidly.

Stoichiometrical proportions (186 g. of ethylene glycol and 444 g. of phthalic anhydride) were gradually heated from room temperature to 230°. At this temperature the mix was maintained for three and one-quarter hours, when it seemed that a final equilibrium had been reached. Unlike the resinous product of the glycerol–phthalic anhydride reaction, no gelation takes place, so there is no way of knowing how far the reaction has gone except by taking out some of the reaction mixture and testing it. After cooling, the reaction mixture was found to consist of a clear, transparent, brittle resin (yield 568 g.) having the following characteristics: flow point, 69°; acid number, 22.8; saponification number, 582.8; (calcd.) percentage of esterification, 96.5%.

The traps A, B and C were disconnected and weighed. The total amount of material collected was 62.0 g., which agreed with the loss in weight of the reaction mixture. The amount of phthalic anhydride in each trap was found by titration with standard potassium hydroxide solution using phenolphthalein as an indicator. The samples were then made acid and tested for the presence of aldehydes using a standard rosaniline–sulfurous acid solution,[5] shaking and allowing to stand overnight.

Table I shows the results obtained upon examining the products collected in the various traps. As in the case of the glycerol reaction, the amount of phthalic anhydride evolved is far less than would be expected from watching the reaction take place. Most of the material in each trap was a clear transparent liquid with melting point approximately zero. Making due allowance for the effect of varying quantities of dissolved phthalic anhydride on the melting points of the liquids, nothing but phthalic anhydride, glycol and water were found. A determination of the amount of glycol distilled over was not made.

The tests for aldehyde were so weak that it is very doubtful whether any

Table I

Results of Experiments

Trap no.	A	B	C	D	Total
Material coll., g.	52.1	3.8	6.1	...	62.0
0.0874 N KOH, cc.	149.42	1.78	14.36	...	166.56
Equiv. wt. of phthalic anhyd., g.	0.968	0.012	0.094	...	1.074
Obs. m. p., °C.	......	0.2	Almost exactly zero		......
Aldehyde test	Very doubtful	None	Very weak test only at very last stage of the reaction	None	No aldehyde found in the reaction mixture itself
Odor	Burnt sugar	Burnt sugar	Burnt glycerol	...	
Remarks	Detn. of amt. of glycol distilled not made	Diff. in m. p. from product in Trap C thought to be due to glycol	Phthalic anhydride present both as crystals and in solution	...,	Inferred that water and resin are only products. Some phthalic anhydride and glycol distilled over

reducing substances were present at all. Judging by the amount of coloration when a known amount of acrolein was added to the rosaniline solution, there could not have been a total of 0.1 g. of aldehyde present in all three traps. No volatile aldehyde was found escaping the liquid-air trap C. No aldehyde was detected in the reaction mixture itself.

Since aldehyde, if present at all, is in so small a proportion that it can scarcely be detected, it is very doubtful whether the mechanism by which resins are formed from glycol and phthalic anhydride is through the formation of an intermediate aldehyde. The only products of the reaction seem to be water and resinous esters, and since the reacting molecules are those of an alcohol and of an acid, it is highly probable that the reaction is that of esterification.

II. Kinetic Isothermal Studies with Time.—As in the case of the reaction of glycerol with phthalic anhydride, this reaction was followed by determining the change of the free acid and of the combined acid with time.

Preparation of Samples.—The reaction was allowed to proceed at atmospheric pressure, keeping the conditions as nearly isothermal as possible, while **124** g. of the ethylene glycol was weighed out into the reaction vessel and heated up to its boiling point, phthalic anhydride was heated in an Erlenmeyer flask slightly above the temperature at which the reaction was to take place to allow for the cooling effect of pouring. When ready to start the reaction, **396** g. of the molten phthalic anhydride was weighed out into the reaction vessel and stirred up with the glycol. Because of the rapid progress of the reaction at the start, so much heat is evolved in a short time that the temperature of the reaction mixture rapidly rises about 40° above the temperature that it had at the instant of mixing. Since the boiling point of glycol is 197.5°, it was necessary to depend upon this quick rise in temperature when mixing the alcohol and acid in order to attain the isothermal conditions for the higher temperature runs.

If it was desired to run the reaction at lower temperatures, it was necessary to cool as rapidly as possible with a jet of compressed air until the right temperature was obtained. In either case, as soon as the desired temperature was reached, the reaction vessel was lowered into a constant temperature oil-bath and the reaction allowed to proceed to completion with the necessary amount of heat supplied to maintain isothermal conditions.

Samples of the reaction mixture were pipetted out from time to time and allowed to cool rapidly, thus freezing the equilibrium at that point. This was done oftener in the earlier stages than in the later stages, because the reaction was proceeding so much more rapidly. The viscosity of the liquid reaction mixture kept increasing as in the case of the glycerol–phthalic anhydride, but finally reached a maximum with no gelation taking place. Since gelation did not take place, it was possible to carry the reaction practically to completion.

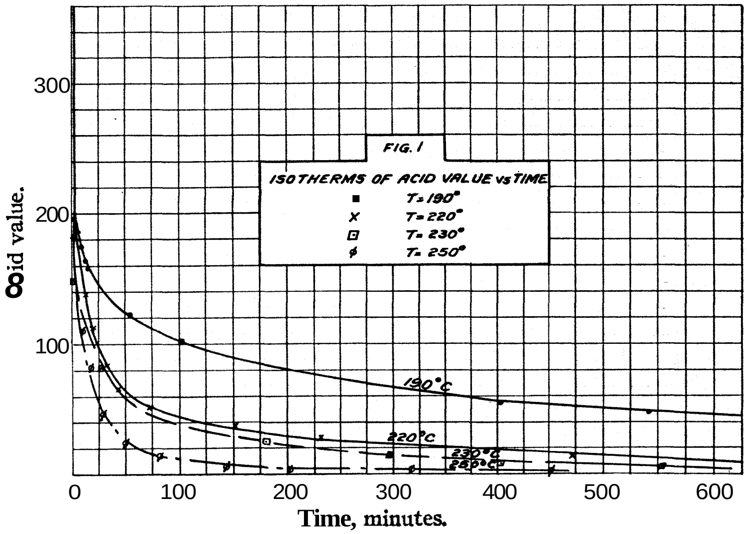

Fig. 1.

(a) Free Acidity.—The change in free acidity with time was determined and reported both as acid number and as percentage of free phthalic anhydride. Samples weighing 1 g. each were dissolved in 25 cc of C. P. acetone and titrated with 0.1 *N* potassium hydroxide solution using phenolphthalein as indicator.

As in the case of the glycerol–phthalic anhydride reaction, the free acidity is reduced to at least one-half within the first minute after mixing the hot liquids, after which it proceeds to completion at a greatly diminished rate. The graphical representation of the change in free acidity with time is shown in Fig. 1.

(b) Saponification Number.—The method of determining the saponification number differed from the procedure which was used in the first paper[1] in that the samples, after titration for free acidity, were used for the determination of ester number. The samples were refluxed for one hour with 50 cc. of normal alcoholic potassium hydroxide solution. Upon cooling, titration was effected with 0.5 N hydrochloric acid until the pink color of the phenolphthalein disappeared; then 0.5 N potassium hydroxide solution was run in until the pink color reappeared. The calculation of ester number was made from this titration, which added to the acid number gave the saponification number. Although the saponification number for zero time was calculated as 534.5, actually a lower value was obtained for the earliest time at which the reaction mixture could be sampled. Then as the reaction proceeded, the saponification number increased, finally reaching a more or less constant value. The observed variation in saponification number was probably due to the presence of water, and its subsequent evolution.

(c) Degree of **Esterification.**—The ratio of the amount of combined acid to the total amount of acid give's the degree of esterification—a measure of the completeness of the reaction. The change of this value with time is given in Fig. 2, which shows the rapid increase in esterification at the start of the reaction and the falling off in the rate of increase as the reaction approaches completion.

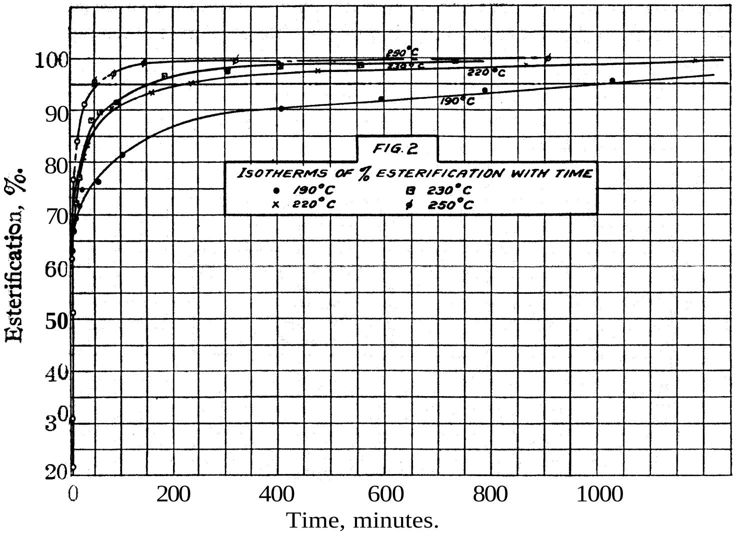

Fig 2.

(d) Variation of Other Properties with Time. 1. Flow Point.—The flow point[1] gradually increases as the reaction proceeds, as is shown in Fig. 3, and reaches a maximum of about 80° when the reaction is complete. Since no gelation takes place upon further heating, the flow point can always be taken, but has not been found to increase appreciably.

2. Viscosity.—The viscosity of the hot liquid reaction mixture increases, but when the esterification is complete, the viscosity appears to have reached a final value.

3. Density.—The density at 25.0–25.0° was determined using a pycnometer with specially distilled mineral spirits (sp. gr. 0.7779) as an inert liquid. The results are included in Table **II.** The variation of density with time is found to be quite irregular, although there is a definite upward trend throughout the reaction. The same type of variation has also been found, by careful check, to exist in the case of the resinous product of the reaction of phthalic anhydride and glycerol.[6]

4. Color.—The color change is even less than that of the glycerol–phthalic anhydride reaction. The resin is clear, colorless and transparent at the start and remains so up to the end, when it resembles glass.

An error has been found in our previous paper [THIS JOURNAL, 51, 509 (1929)]. In Table IIb the density data should read: time 3420 sec., d, 1.376; 3980 sec., d, 1.390; 5740 sec., d, 1.420; 9720 sec., d, 1.400.

5. Refractive Index.—The refractive index of the resinous product was found to be within the limits of 1.560 and 1.570.

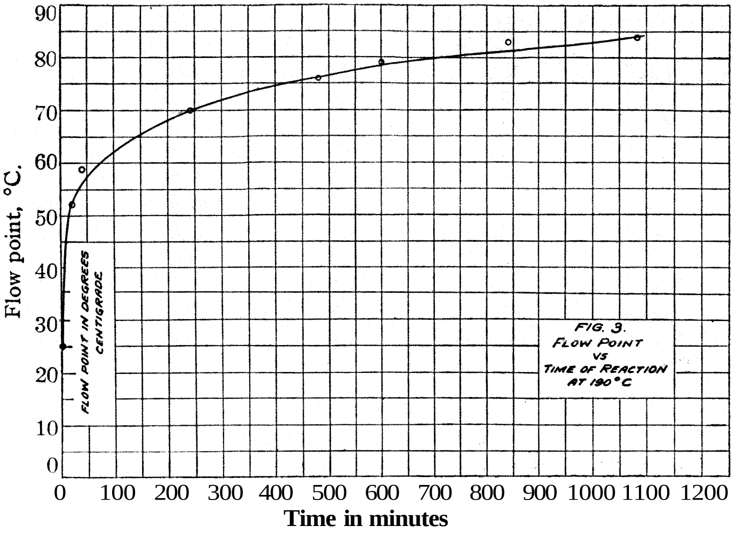

Fig 3

Table II shows a comparison of the variations of different properties of a set of standard samples taken from time to time with the temperature at 190°.

III. The Effect of Temperature.—The reaction of ethylene glycol and phthalic anhydride was studied not only at 190°, but also by making runs as nearly isothermal as possible at 220, 230 and 250°; the results are given in Tables III, IV and V, respectively. The isotherms of free acidity are plotted in Fig. 1 and show that the effect of carrying out the reaction at a higher temperature is to reduce the amount of free acid more rapidly than at a lower temperature. The isotherms of the percentage of esterification given in Fig. 2 show the effect of increasing the speed of the reaction by increasing the temperature.

The resinous product of the reaction is completely volatilized at 400°.

In the case of the glycerol-phthalic anhydride reaction, it was shown[1] that plotting on semi-log paper the time to attain gelation against the reciprocal of absolute temperature resulted in a straight line. Since no gelation occurs in the ethylene glycol–phthalic anhydride reaction, it is not possible to use this transition point as a measure of a particular stage in the reaction. However, any definite percentage of esterification furnishes a suitable measure of the extent to which the reaction has taken place. Thus, taking 95% esterification, although other percentage esterifications may be taken equally well, it is possible by referring to Pig. 2 to set up a relationship between temperature and the time necessary to reach a definite percentage of esterification. The interpolated values of time necessary to produce 95% esterification at each temperature are given in Table VI.

TABLE VI

INTERPOLATED TIMES

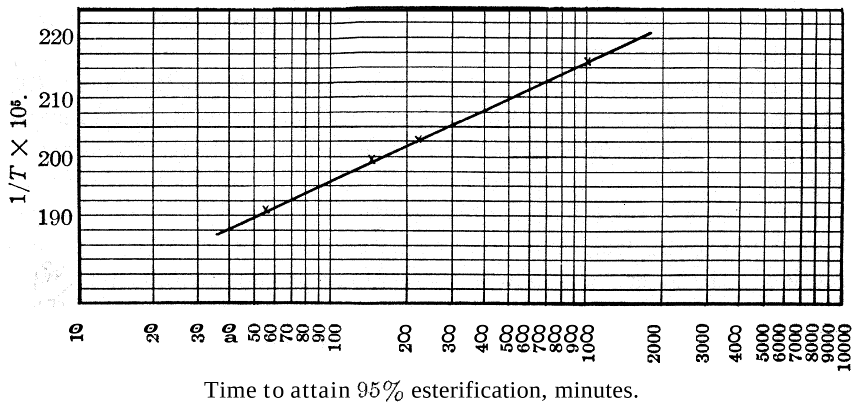
Temp., °C.	Temp., °Abs.	$1/T \times 10$	Time at which esterification = 95% (obtained from Fig. 2), min.
190	463	216	1000
220	493	203	220
230	503	199	145
250	523	191	55

Plotting these data in Fig. 4 again shows a linear relationship for the log time vs. the reciprocal of the absolute temperature.

Discussion

The data of the ethylene glycol–phthalic anhydride reaction again show that in the formation of polyhydric alcohol–polybasic acid esters, the principal reaction is that of esterification, no intermediate aldehyde formation occurring. The change in all the properties is progressive and continuous, making it plausible that the esterification takes place according to the chance meeting of the individual alcohol and acid radicals, resulting in a mixture of esters instead of the formation of simple mono- or di-esters.

The ethylene glycol–phthalic anhydride reaction differs from that of glycerol–phthalic anhydride in that the reaction can be carried practically to completion without gelation, although the kinetic data of the two reactions give similarly shaped curves. This marked change in physical properties of the resinous product by simply substituting a dihydric alcohol for a trihydric alcohol is significant in theories of resin formation. The importance of the number of reacting groups on the inter-reacting molecules is clearly shown.



Pig. 4.—Relationship of time to attain definite percentage esterification *vs.* reciprocal of absolute temperature.

Linear relationship between the reciprocal of the absolute temperature and the log of the time necessary to reach a definite percentage of esterification points out how these poly-ester reactions obey Arrhenius' equation[7] relating to the effect of temperature on chemical reactions

$$\log_e \frac{k_1}{k_2} = \frac{Q}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

Since the reaction at each temperature has been carried to the same end-point

$$k_1 \infty \frac{1}{t_1} \text{ and } k_2 \infty \frac{1}{t_2}$$

therefore

$$\log_e \frac{t_2}{t_1} = \frac{Q}{R}\left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

Applying this equation to the data given in Table VI, it is possible to calculate the heat of activation for the reaction, the order of magnitude of which is characteristic of many chemical reactions, *viz.*, 22,600 calories.

Summary

1. The glycol–phthalic anhydride reaction is similar to the glycerol–phthalic anhydride reaction in that: (a) the reaction proceeds by esterifica-

---

[7] Taylor, "Treatise on Physical Chemistry," D. Van Nostrand Company, New York, Vol. II, p. 900,

tion, since water and resin are the only products. No intermediate aldehyde is formed. (b) The reaction, when carried on at a temperature at which both reactants are liquid, goes very rapidly at the start, evolving heat and is apparently about one-half complete within one minute of mixing. (c) As the reaction proceeds under isothermal conditions, the free acidity decreases, and the percentage esterification and the flow point increase. (d) The properties and appearance of the resinous products are similar except that the phenomenon of gelation possessed by the product of the glycerol–phthalic anhydride reaction is not possessed by the product of the ethylene glycol–phthalic anhydride reaction.

2. The glycol–phthalic anhydride reaction is dissimilar to the glycerol–phthalic anhydride reaction in that: (a) gelation of the resinous product does not take place at any temperature at which the reaction is carried out. The product remains fusible and soluble. (b) The reaction may be carried practically to completion, because gelation does not interfere with its normal course

SOME NEW DERIVATIVES OF DIPHENYLCARBAMINE CHLORIDE

BY THEODORE W. EVANS[1] AND WILLIAM M. DEHN

RECEIVED MAY 26, 1930 PUBLISHED SEPTEMBER 5, 1930

Recently the probable –OM rather than the –NM linking in salts of cyclic imides was shown. Since the reactions of metallic sodium on aniline and acetanilide are remarkably different, it was thought that the constitution of sodium acetanilide is $C_6H_5{-}N{=}CONaCH_3$, rather than $C_6H_5{-}N{-}NaCOCH_3$. When this salt is treated with RI, etc., the R or other group is known to be linked to nitrogen; however, this linking can result from either of the two forms of the salt, from the –NNa form by direct substitution and from the –ONa form by initial addition, followed by a splitting off of sodium chloride, as indicated in the equation

$$C_6H_5N{=}CONaCH_3 + RI \longrightarrow C_6H_5NRICONaCH_3 \longrightarrow C_6H_5NRCOCH_3 + NaI$$

Since diphenylcarbamine chloride[2] reacted with many bases to yield additive compounds, it was anticipated that it would react with this salt to give some indication of addition. This was found to be the case.

When the sodium salt of acetanilide is suspended in toluene, treated with its equivalent of diphenylcarbamine chloride dissolved in toluene,

---

[2] Platt and Dehn, THIS JOURNAL, 37, 2122 (1915).

and the mixture is heated gently, a clear solution is obtained.[3] Since the original salt is insoluble in toluene, this clear solution must contain a solute other than the original salt or sodium chloride, which latter is precipitated from the clear solution by boiling or by merely permitting it to stand. After filtering, etc., the acetyltriphenylurea was obtained.

Similar evidence of the formation of an intermediate additive compound was obtained with the sodium salt of acetyl-*p*-phenetidine and diphenylcarbamine chloride in toluene solution.

Other condensations were studied. Whereas piperidine reacts exothermically with diphenylcarbamine chloride, pyrrole could be condensed with the latter only by employing its potassium salt. The diphenylthiocarbamic esters, Ph_2NCOSR, formed from the mercaptans, constitute a new type of compound.

Experimental

The methods studied to produce condensation products were three. **(A)** Equivalents of the compound studied and diphenylcarbamine chloride

---

[3] For a somewhat similar case involving acetoacetic ester see Michael, *Ber.*, 38, 3217 (1905); this was claimed to be due to colloidal sodium chloride by Paal, *ibid.*, 39, 1436 (1906). Our case seems to be essentially different from Michael's in that the sodium chloride is much more readily precipitated, and when once precipitated it does not redissolve; also, similar solutions are not obtained with metallic salts where addition should not be expected, *e. g.*, with the sodium salts of the mercaptans.

were melted together. (B) They were boiled for several hours in toluene. (C) The sodium salt of the compound to be condensed was heated with with diphenylcarbamine chloride in toluene solution. Upon filtering and evaporation of the toluene solution, the product usually crystallized out; otherwise, ether was added and the solution cooled with ice. The products were purified by recrystallization.

Diphenyl-p-phenetylacetylurea was prepared by method (C) and also by direct acetylation of diphenyl-*p*-phenetylurea.

Summary

1. Diphenylcarbamine chloride reacts with the sodium salt of acetanilide to give first an additive compound. This indicates that the salt possesses the enol structure.

2. A number of new derivatives of diphenylcarbamine chloride have been prepared.

ORGANIC OXIDATIONS BY IODIC ACID

BY THEODORE W. EVANS[1] AND WILLIAM M. DEHN

RECEIVED MAY 26, 1930 PUBLISHED SEPTEMBER 5, 1930

This acid has been used only rarely, exclusively in acid solutions and almost entirely for producing color effects.[2]

We have found that iodic acid can be applied in neutral solution, as, for example, its characteristic effect on amidol; in acid solutions, with most amines and phenols; in alkaline solutions, with mercaptans, thioureas and benzoin. Because it has no effect on alcohols, most alkaloids,[3] gluco-

---

[1] The material presented in this paper is from part of a thesis submitted by Theodore W. Evans, du Pont fellow for **1929–1930,** in partial fulfilment of the requirements for the degree of Doctor of Philosophy, **1930.**

[3] Warneke, *Arch. Pharm.,* **226, 281** (1888), oxidized wrightine to oxywrightine by iodic acid; this product by means of other oxidizing agents has been attempted in vain.

sides, carbohydrates, etc., it is concluded that it is very selective in its action. Symmetrical diaryl thioureas give the corresponding ureas, but asymmetrical diaryl thioureas, all tri- and tetra-substituted thioureas are without action, as also are the mustard oils, and disulfides, sulfoxides, etc.

Through the use of iodic acid we have been able to develop improved methods of preparation of the disulfides, aryl cyanamides, symmetrical diaryl ureas, purpurogallin and benzilic acid.

Experimental

A large number of amino and phenolic compounds, alkaloids and glucosides were tested for the oxidizing effect of iodic acid. The method employed was to place in a beaker some aqueous iodate solution, a few milligrams of the substance to be tested, a few drops of acetic acid and pieces of silk and cotton cloth. The mixture was boiled until the dye was fixed on the fabrics. With the different amino and phenolic compounds every imaginable shade of brown was obtained on the silk. In most cases no dye was fixed on the cotton; whenever fixed, light browns, buffs and ochers were obtained. The diamine and alkylated anilines, especially, gave beautiful shades of brown. Some of these amino and phenolic compounds will be investigated.

Color Tests on Silk.—Phenol, light brown; catechol, guaiacol, resorcinol, diresorcinol, deep brown. The naphthols, yellow-brown, eugenol, gold-brown. Quinol, brown. Procaine, butyn, anesthesine, *p*-aminobenzoic acid, light brown. Aminophenol and amidol, red-brown; *p*-aminophenol, dark brown. Phloroglucinol, blood-red. After hydrolysis with hydrochloric acid, phoridzin, through yellow to blood red. This is the only glucoside that gave a positive test. Apomorphine, beautiful light green, through chrome green to green-black on silk; greenish-gray on cotton. Boldine and apocodeine, brown.

Action on Mercaptans.—A mixture of 3 g. of *p*-thiocresol, 6 g. of sodium iodate, 6 g. of sodium hydroxide and 90 cc. of water was heated on the water-bath for an hour. When cooled and neutralized, the di-p-tolyldisulfide precipitated. After recrystallization from alcohol it melted at 46°.

In an analogous manner dibenzyldisulfide, melting at 71°, was prepared.

Action on Thioureas.—Equal weights of thiocarbanilide, sodium iodate and sodium hydroxide in 100 cc. of water were heated to boiling until a plastic mass in the water was obtained. If this is filtered hot and washed with water, pure diphenylurea is obtained.

In a similar manner, 3,3'-dinitrothiocarbanilide yielded 3,3'-dinitrodiphenylurea, melting at 233°; phenyl-*p*-tolylthiourea gave phenyl-p-tolylurea melting at 212".

Ethyl-N,N'-diphenylthiourea, N,N-methylphenylthiourea and N,N'-diphenylbenzylthiourea failed to react with iodate.

Preparation of Aryl Cyanamides.—When a mixture of equal weights of phenylthiourea, sodium iodate, sodium hydroxide and a double mass of water was heated to boiling for ten minutes, then cooled, filtered[3] and neutralized with acetic acid, a plastic

---

[3] In the preparation of these aryl cyanamides, small quantities of the corresponding diarylureas always were formed—these constitute the precipitates found at this point.

mass precipitated. After decanting, washing with water and letting stand, it solidified. Its identity was established by heating with aniline, thus forming diphenylguanidine, melting at 147°.

In a similar manner o-tolylcyanamide and *p*-tolylcyanamide were prepared.

The Preparation of Purpurogallin.—When 100 cc. of a cold aqueous solution containing 8 g. of sodium iodate is slowly added with constant stirring to 10 g. of pyrogallol[4] dissolved in a little cold water, the reaction proceeds smoothly with a precipitation of 7.6 g. of purpurogallin. Assuming the reaction to be

$$2C_6H_6O_3 + NaIO_3 = C_{11}H_8O_5 + CO_2 + NaI + H_2O$$

this is equivalent to a 92% yield.

In order to test the validity of this equation, the carbon dioxide evolved was determined by absorbing it in a potash bulb. In two determinations each starting with 10 g. of pyrogallol and 8 g. of iodate, 1.2902 and 1.2899 g. of carbon dioxide were obtained. In each case the yield of purpurogallin was 6.5 g. These figures represent a 78% yield of purpurogallin and a 74% yield of carbon dioxide. This would seem to indicate that for each molecule of purpurogallin formed a corresponding molecule of carbon dioxide is liberated.

The Preparation of Benzilic Acid.—Benzoin is directly convertible into benzilic acid by the action of sodium iodate in concentrated sodium hydroxide. When it is added to a hot concentrated solution of these, the reaction proceeds spontaneously, and substantially a quantitative yield of benzilic acid is obtained, in accordance with the reaction

$$3C_6H_5CHOHCOC_6H_5 + NaIO_3 + 3NaOH = 3(C_6H_5)_2COHCOONa + 3H_2O + NaI$$

From Pure Benzoin.—To a beaker containing 20 g. of sodium hydroxide and 7 g. of sodium iodate, sufficient water is added to make a boiling hot solution; then 20 g. of benzoin is put in and stirred with a rod. The purplish colored mixture is then heated and stirred. Finally, when the purple color is entirely discharged, sufficient water is added to dissolve the solids to a clear solution. Concentrated hydrochloric acid is gradually added and the iodine and traces of benzoic acid are expelled by boiling. On cooling, filtering and drying, about 20 g. of crude benzilic acid is obtained. This is dissolved in boiling benzene, filtered and cooled rapidly, when about 18 g. of pure benzilic acid is obtained. From the benzene filtrate 2 g. of impure benzilic acid may be recovered. The crude benzoin obtained from benzaldehyde may be used directly in this preparation, but a lessened yield is obtained.

Summary

Iodic acid has been shown to be a very selective oxidant. By its use various improved preparations have been developed.

SEATTLE, WASHINGTON

---

[4] Various oxidizing reagents have been used to prepare purpurogallin from pyrogallol. These were compared by Perkin and Stevens, who contributed what they considered the best reagent, namely sodium nitrite and acetic acid. Their best yields were 30–40% [*J. Chem. Soc.*, 83,194 (1903)].

THE MOLECULAR WEIGHT OF LACTALBUMIN

BY BERTIL SJÖGREN AND THE SVEDBERG

RECEIVED MAY 27, 1930 PUBLISHED SEPTEMBER 6, 1930

A first attempt to study the dispersity of the proteins of milk by means of ultracentrifugal methods was made by Fåhraeus and one of the present writers in 1924.[1] Cows' milk was submitted to the action of a centrifugal field about 1500 times the force of gravity and exposures were taken at intervals of one hour. From the rate of sedimentation and the spreading of the boundary it was concluded that the natural casein—or calcium casein compound—of milk is a polydisperse colloid of comparatively low degree of dispersity, containing particles of radius ranging from about 10 to 70$\mu\mu$. The behavior of purified casein in centrifugal fields up to 100,000 times the force of gravity was studied by Carpenter.[2] The latter investigation showed that casein is a very unstable protein and that the molecular weight and degree of homogeneity of the product depend on the method of preparation which has been used. The sedimentation constant for casein isolated by the method of Van Slyke indicates a molecular weight around 100,000 for the bulk of this protein material—a value which is in the neighborhood of the molecular weight of serum globulin. Heating to 40° for one hour caused an increase in molecular weight to about double, and treatment with acidified 70% alcohol at 40° after the manner of Linderström-Lang gave a product which possessed a molecular weight nearly four times that of the original casein.

Besides the casein the chief protein constituent of cows' milk is the lactalbumin. It occurs to about 10% of the amount of casein. In view of the complicated behavior of casein it was thought to be of interest to collect some data concerning the dispersity of lactalbumin in order to see whether the very marked instability observed for casein also occurs in the lactalbumin and, therefore, is to be considered as a characteristic of the milk proteins.

Preparation of Lactalbumin.—Seven thousand cc. of fresh cows' milk of P_H 6.7 and containing some toluene was run through a separator to remove the fat. Saturated ammonium sulfate solution was added to 50% saturation and the P_H of the mixture brought to 5.2 by means of acetic acid. After standing for twenty-four hours in the ice box the precipitate of casein and globulin was centrifuged off and saturated ammonium sulfate solution added to 80% saturation. After twenty-four hours in the ice box the albumin precipitate was centrifuged off and washed with a weak solution of ammonium sulfate. The precipitate was dissolved in water and brought to crystalliza-

[2] T. Svedberg, L. M. Carpenter and D. C. Carpenter, THIS JOURNAL, 52, 241, 701 (1930).

tion at room temperature by the addition of ammonium sulfate and sulfuric acid.[3] The crystals were dissolved in water, dialyzed against toluene-saturated water at 5° until the sulfate reaction was negative and finally electrodialyzed with a current density of 0.6 milliampere per sq. cm. for thirty hours. No precipitation occurred during the electrodialysis; volume of solution 175 cc.; concentration 0.74% (Material I).

Another sample of lactalbumin was made up from an equal quantity of milk proceeding as described above but omitting the crystallization process. The volume of the final solution was 200 cc. and the concentration 3.14% (Material II).

Specific Volume, Isoelectric Point and Light Absorption of Lactalbumin.—The partial specific volume was measured pycnometrically at 20°. Material II was used and determinations were carried out in electrolyte-free solutions at 3.14 and 2.04%. The values agreed within experimental error and gave V = 0.750.

The isoelectric point of Material II was determined by means of the photographic cataphoresis method worked out in this Laboratory by A. Tiselius.[4] The protein was found to be electrochemically inhomogeneous and to possess an isoelectric point of approximately Pa 5.2.

The light absorption was measured on Material II by means of the Judd-Lewis spectrophotometer. The solution was electrolyte-free, of concentration 0.1% and thickness of layer of 2.0 cm. The specific extinction coefficient $\epsilon/c = 1/cd \times \log I_0/I$ (where c is the concentration, d the thickness of the solution, I_0 the intensity of the light beam after passing through the solvent and I the intensity after passing through the same thickness of solution) had a maximum value of 10.6 at a wave length of 279μμ and a minimum value of 3.6 at 255μμ. In Fig. 1 the absorption curve is given.

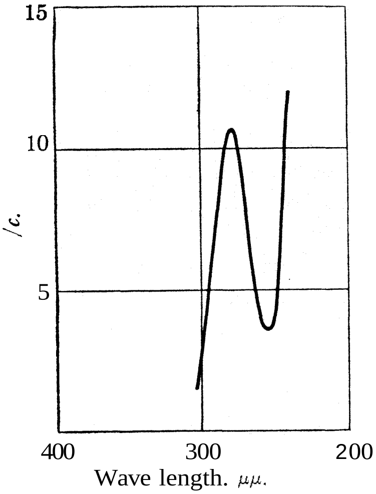

Fig. 1.

Molecular Weight and Sedimentation Constant of Lactalbumin.—A sedimentation equilibrium measurement was carried out on the crystallized Material I at a speed of 11,200 r. p. m. The protein concentration was 0.10% at the start and the solution 0.025 M in KH_2PO_4 and 0.025 M in Na_2HPO_4, giving a PH of 6.8. The molecular weight was calculated from the relation

$$M = \frac{2\,RT\ln\,(c_2/c_1)}{(1 - V\rho)\,\omega^2(x_2^2 - x_1^2)}$$

where R is the gas constant, T the absolute temperature, V the partial specific volume of the solute, p the density of the solvent, *w* the angular velocity and c_2 and c_1 are the concentrations at the distances x_2 and x_1 from the center of rotation.

The values of the molecular weight were not independent of the distance

[4] A. Tiselius, "Dissertation," Upsala, 1930.

from the center of rotation but varied from 12,000 at a distance of 5.50 cm. to 25,000 at a distance of 5.90 cm.

In Table I are given the results of two sedimentation velocity runs made on Materials I and II.

TABLE I

LACTALBUMIN SEDIMENTATION VELOCITY RUNS

Material	Solvent		*Pa* of	Concn. of		Remarks
	KH_2PO_4, M	Na_2HPO_4, M	soln.	protein, %	$S_{20°} \times 10^{13}$	
I	0.019	0.001	5.5	0.27	2.22	a
II	.025	.025	6.8	.63	2.95	b

[a] Strong drift in diffusion constant; trace of non-centrifugible material.

[b] Drift in diffusion constant; no non-centrifugible material.

Material II was again tested after having been left for three months in the ice box. The sedimentation constant was approximately the same but about 15% of the protein was broken up into a non-centrifugible substance.

The drift in the values of the molecular weight with distance from the center of rotation as well as the drift observed in the apparent diffusion constant shows that lactalbumin is not homogeneous with regard to molecular weight. In this respect therefore it resembles casein.

Direct Ultracentrifugal Analysis of Milk and of Lactalbumin at Different Stages of Purification.—The fact brought out by the above measurements that lactalbumin is not homogeneous with regard to molecular weight made it desirable to study the dispersity of this protein at different stages during the process of purification in order to ascertain whether the inhomogeneity is caused by the procedure of isolation.

Sedimentation velocity runs at high speed (centrifugal force about 100,000 times the force of gravity) during three to four hours at a temperature of 20–23° were used for testing the material.

Fresh milk (PH 6.8) was first centrifuged without any treatment at all. At the high speed used the casein is thrown down in a few minutes. After that period only a very slight sedimentation occurred (Fig. 2A, time between exposures, one hour). The bulk of the light-absorbing material (65–80%) was non-centrifugible. Addition of acetic acid until a molarity of 0.02 was reached with a PH of 5.8 had no effect on the sedimentation. The PH of the milk was then raised to 10.3 by the addition of sodium hydroxide until the molarity was 0.02. The sedimentation remained the same. Dilution of the milk with water or with a 2% solution of ammonium sulfate to two-ninths of the original concentration slightly increased the sedimentation.

In order to eliminate the influence of viscosity caused by the presence of the lactose, a sample of milk containing toluene was dialyzed against water for three days in the ice box. Only a slight increase in sedimentation occurred. Addition of 5% ammonium sulfate to the dialyzed milk had no effect.

These experiments show that untreated milk and milk the P_H of which has been lowered to 5.8 or raised to 10.3 and milk treated with ammoniuni sulfate up to 5%, or milk which has been freed from lactose and salts by dialysis contain but a small quantity of lactalbumin of the degree of dispersity observed in the product isolated by the usual method. In the milk the lactalbumin is present in a very much higher degree of dispersity than in the finished laboratory product.

A lowering of the P_H of the milk to 4.1 either by the addition of hydrochloric acid or acetic acid raised the sedimentation constant slightly above 2×10^{-13} and converted part of the non-centrifugible material into centrifugible substance.

A sample of milk was half saturated with ammonium sulfate, the casein–globulin precipitate removed and the solution dialyzed against water in the ice box for two days. The sedimentation constant was identical with that for lactalbumin as determined above. The non-centrifugible material had decreased considerably and now only amounted to about 20% (Fig. 2 B, time between exposures one-half hour).

A similar experiment was performed with milk from which the casein had been removed by precipitation with acetic acid. The product showed the same properties as the one just described.

To another sample of milk was added ammonium sulfate to saturation. After standing for twenty-four hours in the ice box the precipitate was dialyzed against water until the sulfate reaction was negative (five days). The casein–globulin precipitate was removed and the solution tested in the ultracentrifuge; the sedimentation constant and amount of non-centrifugible material were as before.

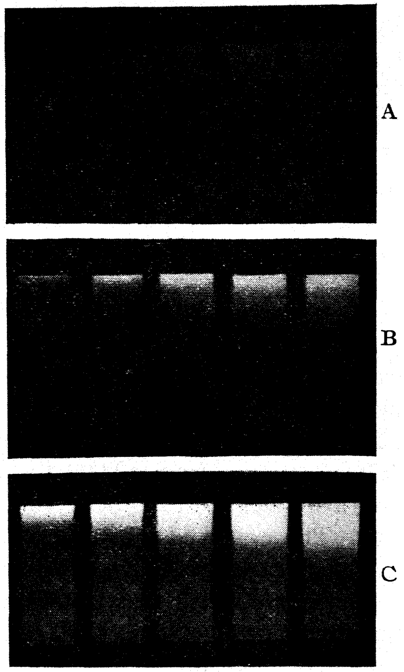

Fig. 2.

The treatment to which the milk was subjected in the last three experiments is identical with the chief processes of isolation used for the preparation of lactalbumin. As a matter of fact this treatment brought about a considerable change in the properties of the original albumin of the milk toward the properties found in the "purified" lactalbumin. The sedimentation constant was practically the same but the material still contained about 20% of non-centrifugible substance.

For the sake of comparison a picture of the sedimentation of the purified lactalbumin (Material II) is given in Fig. 2 C (time between exposures forty min.).

From the above experiments it is obvious that the lactalbumin is an artificial product built up during the process of "purification" from some material of low molecular weight present in the milk. The degree of dispersity or molecular weight of this non-centrifugible material we have not as yet made any attempt to determine. We have ascertained that it is almost completely precipitated by saturation with ammonium sulfate and that it does not diffuse through collodion bags. From the centrifuging tests it follows that the molecular weight cannot be higher than about 1000. The molecular weight of the "purified" lactalbumin was found to range from 12,000 to 25,000, which shows that the molecular weight of the original lactalbumin of the milk has been raised many times in the "purification" process.

The expenses connected with these experiments have been defrayed by a grant from the foundation "Therese och Johan Anderssons Minne."

Summary

1. The molecular weight and sedimentation constant of lactalbumin prepared from cows' milk were determined by means of the ultracentrifugal methods.

2. Lactalbumin is not homogeneous with regard to molecular weight. Values ranging from 12,000 to 25,000 were observed. The mean sedimentation constant lies between 2 and 3 times 10^{-13}.

3. The observed inhomogeneity of lactalbumin suggested ultracentrifugal tests at different stages during the process of purification.

4. It was found that lactalbumin with the properties observed in the "purified" product does not exist in the milk, but is formed during the process of "purification," especially by the action of ammonium sulfate of high concentration.

5. The bulk of the material from which the lactalbumin is formed has a low molecular weight not exceeding 1000. The comparatively high molecular weight of the final product is a result of gradual aggregation of the material of low molecular weight originally present in the milk.

6. The pronounced instability of casein with regard to molecular weight as found by Carpenter also occurs in lactalbumin and this property is, therefore, probably a characteristic of the milk proteins and may be of considerable physiological importance in nutrition.

REDUCTION REACTIONS WITH CALCIUM HYDRIDE. II. DETERMINATION OF SULFUR IN SULFUR OILS AND RUBBER[1]

BY WILLIAM E. CALDWELL WITH FRANCIS C. KRAUSKOPF

RECEIVED MAY 31, 1930 PUBLISHED SEPTEMBER 5, 1930

Oxidative methods used at present for the determination of sulfur in sulfur-containing oils and rubber are time-consuming and painstaking. Having obtained satisfactory results by the reductive method for determining the sulfur content of sulfates, using a preliminary heating with calcium hydride, it seemed desirable to apply this method to the sulfur analysis of other substances.

When volatile sulfur-containing compounds are to be dealt with, as in rubbers or oils, we would no longer be able to carry on open heatings with calcium hydride as in a sulfate analysis. The volatile sulfur-containing compound must be mixed with the powdered hydride in a bomb and the whole heated to around 750°. The residue from such heatings should contain all the sulfur as calcium sulfide, which as a water-soluble sulfide may be iodimetrically determined.

Materials.—In order to test this new method as to its applicability in sulfur determinations on oils and rubbers, many samples of varying sulfur content were obtained. Definite sulfur percentages on these oils as determined by oxidative and reductive methods are given in Table I. Eight sulfur-bearing oils, used in industry as cutting and lubricating oils, were analyzed.

Ten different rubber samples obtained from rubber companies were also ground to a finely divided state, sampled and analyzed. The variance in the nature of these rubber samples, with results of analyses upon them, are to be noted in Table II.

It was found difficult to prepare finely divided samples of these rubbers such that an intimate mixture could be made with the powdered hydride. Some of the rubbers could be cut into shreds with scissors and then into small cubes. This is laborious and one still does not have the rubber finely divided. The best method was to use an emery wheel, which quite readily ground the rubber into a finely divided condition. This was especially true of the hard and semi-hard rubbers, and on grinding them a suitable powder was obtained which with calcium hydride gives an intimate mixture. The softer rubbers and gums on being ground would yield

---

[1] This paper is prepared from the latter part of a dissertation on reduction reactions with calcium hydride, presented by William E. Caldwell in partial fulfilment of the requirements for the degree of Ph.D. The first part was published in THIS JOURNAL, 51,2936 (1929).

particles which would again agglomerate. An intimate heating mixture was impossible in their case and our later results show that we had a correspondingly low result in sulfur percentage due to incomplete action with the calcium hydride.

Bombs.—Small bombs of about three-fourths of a cubic inch capacity were used. In the course of the work bombs of different design were used in endeavoring to hold all the gas formed within the bomb. The requirements for a bomb for this work are quite stringent. Because the mass within must be heated to about 800°, the bomb must withstand that temperature and a copper gasket must be used. An attempt was made to estimate the pressure that would be reached in the bombs.

Assuming that a 1-g. sample of an oil with an average molecular weight of 224 is taken, and that the gas capacity of the one-half filled bomb is about 10 cc.

224 g. of oil would yield 22,400 cc. of gas at 0° and 760 mm.

1 g. of oil would yield 100 cc. of gas at 0° and 760 mm.

P, 1 atm.; V, 10 cc. air + 100 cc. (potential volume of oil vapor); T, 273°K.; P', x; V', 10 cc.; T', 1073°K.

$$\frac{PV}{T} = \frac{P'V'}{T'}$$

$$P' = 43.2 \text{ atm.}$$

$$43.2 \times 14.7 = 625 \text{ pounds per sq. inch}$$

Considering these assumptions, a pressure of six hundred and twenty-five pounds per square inch may be built up in the bomb. The pressure could be more if cracking of the oil to smaller molecules occurred or if an oil of a smaller average molecular weight were taken. Pressure might also be developed by decomposition of the hydride to calcium and hydrogen vapors. However, the pressure may be considerably less in that much calcium carbide is formed and organic matter thus combined in the solid state.

Accordingly a bomb must be made of materials of such thickness as to withstand these pressures and temperatures. On the other hand, a bomb of as little weight as possible is desired so that heating and cooling may be rapid.

It is admitted that we have not developed a wholly satisfactory bomb for use in this work. Bombs have allowed gas to leak by the gaskets and through the threads. This is considered then to be the source of low results in the determination of sulfur in very volatile oils containing low molecular weight mercaptans, disulfides, etc.

Solutions and Calcium Hydride.—Carefully standardized 0.1 N iodine and sodium thiosulfate solutions were used as in previous work for determining the water-soluble sulfide in the residue after the heating of sulfate compounds with hydride. A calcium hydride powder of less than sixty mesh was used in intimate contact with the oil and rubber in a manner similar to that in the work on insoluble sulfates.

Experimental

Sulfur Content of Oils. —Weighed amounts of the oils are poured into the bombs containing about 7 g. of the powdered calcium hydride. The oil is quite readily mixed with the hydride by means of a small glass rod. A gram or two more of the hydride is pressed into the bomb over the oil–powder mixture. The bomb is tightly sealed and quickly heated to redness in a muffle furnace or over a Méker burner. After the bomb has been at a bright red heat for ten minutes it is allowed to cool. The contents are readily removed from the bomb and placed in a 500-cc. Erlenmeyer flask. The residue is moistened with about 20 cc. of dry alcohol. This is to prevent dusting, which would occur if water were immediately dropped upon the hydride. Water is now slowly added to the moistened fusion mass from a dropping funnel which is above a reflux condenser at the bottom of which is placed the Erlenmeyer flask. After the excess hydride and the carbide formed have been decomposed, additional water is added to make a solution of about 400 cc. It is well to add some ice in place of a portion of the water so that the solutions will be cool for a better end-point in ensuing titrations.

Before iodine titration, the mass is placed in a liter beaker and an excess of concentrated hydrochloric acid added with a minimum of stirring. The large volume of water is necessary to dissolve and hold the hydrogen sulfide obtained on acidifying the calcium sulfide solution.

The resulting hydrogen sulfide solution is titrated for sulfur content with the 0.1 N iodine solution, one cubic centimeter of the iodine solution being equal to 0.0016 g. of sulfur.

Sulfur **Content** of Rubber.—Rubber samples are treated in a manner similar to that for oils except that the powdered rubber is intimately stirred into the finely divided hydride.

Sample weights of the oils and rubbers are taken so that one can expect a 10–50 cc. iodine titration. For substances expected to contain less than 3% sulfur, a sample up to 1.5 g. is taken. For a hard rubber of around 20% sulfur, a 0.25-g. sample should suffice.

Table I gives the results of sulfur analysis on oils by Eschka's oxidative method compared with percentage sulfur as determined by the above outlined reductive method. Samples 1–8 are on cutting and lubricating oils, the sulfur having been incorporated into these products by heat and pressure. The sulfur compounds so formed are not volatile at low temperature.

Three samples of petroleum oil were analyzed both by Eschka's and our methods. Neither method gave check results or indicated the total sulfur in these oils. Such an oil of low sulfur percentage and containing very volatile sulfur compounds must be treated by some digestion and oxidative method.

Table II lists results of sulfur analyses on rubbers by oxidative and reductive methods. Some other rubbers were tried with discouraging results. These rubbers were mainly of a sticky nature such that an intimate mixture of their macerated form could not be made with the powdered calcium hydride.

8	2.75	2.68	Black rubber plate
9	1.63 1.58	1.58	Rubber casting
10	29 6	29.3 29.8	Ground fountain pen casing

Miscellaneous Sulfur Determinations.—Two 0.05-g. samples of free sulfur were heated in bombs with 5 g. of calcium hydride. The cooled residue on analysis for water-soluble sulfide gave results corresponding to 0.0512 and 0.0496 g. of sulfur. Thus free sulfur may be determined within a 2% error even on such small samples.

Samples of sodium thiosulfate were similarly treated to determine their sulfur content. Considering the sample to be $Na_2S_2O_3 \cdot 5H_2O$ it would contain 25.8% of sulfur. An average of our analyses showed it to contain 25.34%.

Discussion of Results

It is evident from a consideration of results obtained that the method here presented of determining sulfur in insoluble sulfates may be extended to the determination of sulfur in oils and rubbers when one uses a gas-tight bomb instead of the open crucible. All of the sulfur in the organic material is converted to calcium sulfide when heated to 700° in contact with calcium hydride. The water-soluble sulfide thus formed may be determined by iodimetry. The method lends itself most readily to determinations in rubbers and oils of high sulfur content, and presents itself as a rapid method for the determination of sulfur in this type of material.

Summary

1. Sulfur may be determined in sulfurated oils by fusion of the oils with calcium hydride, followed by an iodine titration on an acidified solution of the fusion residue.
2. A method of determining the percentage of sulfur in some rubbers is presented.
3. By this method it is possible to determine the percentage of sulfur in free sulfur, sodium thiosulfate and similar sulfur-containing compounds.

AGRICULTURAL CHEMISTRY, UNIVERSITY OF WISCONSIN]

COMPOSITION OF THE GUM PRODUCED BY ROOT NODULE BACTERIA

BY E. W. HOPKINS, W. H. PETERSON AND E. B. FRED

RECEIVED MAY 31, 1930 PUBLISHED SEPTEMBER 5, 1930

One of the most striking characteristics of the root nodule bacteria is the gummy or viscous nature of the colonies or streak cultures. The mucinous appearance of the cultures has been reported by many investigators[1] and has been attributed to the formation of dense capsules by the organisms. What function the gum performs in the metabolism of the bacteria or in their relation to the host plant is not known. Grieg-Smith[2] suggests that the gum is used by the plant and built into nitrogenous compounds, while Mazé[3] is of the opinion that the gum itself is the nitrogenous compound supplied the plant by the bacteria. That the latter assumption is

[1] (a) M. W. Beijerinck, *Bot. Ztg.*, 46, 754 (1888); (b) G. F. Atkinson, *Bot. Gaz.*, 18, 157 (1893); (c) L. Hiltner, *Centr. Bakt.*, II Abt., 6, 273 (1900); (d) M. Dawson, Phil. *Trans. Roy. Soc.*, B193, 51 (1900).

[2] R. Grieg-Smith, *Centr. Bakt.*, II Abt., 30, 552 (1911).

[3] M. Mazé, *Ann. de l' Inst. Pasteur*, 12, 1 (1898).

incorrect was shown by Buchanan[4] and Fred,[5] who found that the purified gum contained no nitrogen.

The properties and composition of the gum have not been thoroughly investigated. Much of the work has been of a qualitative nature, and in no case have the hydrolysis products been conclusively identified.

The nitrogen-free gums of clover[6] and of bean[4] root nodule bacteria were found to give on hydrolysis reducing sugar which was assumed to be glucose. According to Beijerinck,[7] the slime producing strains of B. *radicicola* form a "cellulan" a type of gum which, contrasted with the dextrans and levulans, is not fermentable by *Granulobacter saccharobutyricum*. Grieg-Smith[8] prepared gum from cultures of lupine and pea nodule bacteria which had specific rotations of +29.7 and 31.7°, respectively. These gums contained small amounts of nitrogen and on hydrolysis gave a sugar which from its reducing power and optical rotation appeared to be almost entirely glucose. A phenylosazone, separated into two fractions with melting points 205 and 193°, thus similar to those of glucose and galactose, was reported, but the author gives no information as to how these were obtained or analyses of their composition. Owing to the lack of particulars, it is impossible to decide whether the author had an osazone of galactose or merely a slightly impure glucosazone. It is well known that a slight impurity markedly lowers the melting point of an osazone. In a later paper by the same author,[2] the gum of bean root nodule bacteria was reported as consisting of glucose and galactose, and the specific rotation of the gums of bean, pea and lupine root nodule bacteria is given as +29°. Kramár[9] hydroyzed B. *radicicola* gum, and prepared a phenylosazone which was apparently glucosazone. Its melting point was 205°. As far as present knowledge goes, the gum of the root nodule bacteria presumably contains glucose, but there has as yet been no conclusive proof of the presence of this sugar. As to the question of the existence of galactose as a constituent of the gum, the evidence is much less convincing than that for glucose. In our own work the gum has been found on hydrolysis to give glucose and a uronic acid, but no fructose, mannose, galactose or pentoses have been found among the hydrolysis products.

Experimental

Preparation of Samples.—The gums studied in this work were produced from cultures of root nodule bacteria of three different cross-inoculation groups. The strains used were *Rhizobium meliloti* 100 (alfalfa), three

The general procedure for preparing the samples was first to test the purity of the cultures at the end of fermentation by inoculating sterile litmus milk and potato slants. All contaminated cultures were discarded. In the case of the agar cultures, the surface growth was washed from the agar and filtered through a thick layer of absorbent cotton to remove any pieces of agar. The liquid cultures were so viscous that dilution was usually desirable. The gum solution and bacterial suspension was then run through a Sharples supercentrifuge rotating at a speed of about 42,000 r. p. m. This treatment removed most of the bacteria from suspension, while the gum remained dissolved in the liquid. Concentration of the gum solution was effected in a vacuum pan at 60° and the gum precipitated by adding two volumes of acetone. This precipitate was redissolved in warm water and again precipitated, and a second resolution and precipitation conducted in the same manner for further purification of the gum. The stringy coagulum, when dried, gave a grayish-yellow cake, which was ground to an impalpable powder and dried to constant weight.

It was observed that when calcium carbonate was used in the medium, the gum precipitated as a stringy mass, while in the other media, it came down as flocculent particles. Better precipitation of the gum was found to take place in all cases when calcium chloride was added to the gum solution. This procedure was then followed to insure a maximum yield of the gum. This improved precipitation may be due to a chemical union of calcium with the gum—later work showed that the gum molecule contains a sugar acid.

Analytical Methods.—The ash was determined by ignition of 50-mg. samples. *Uronic acid anhydride* determinations were made by the procedure of Dickson, Otterson and Link.[10] The term "uronic" acid is here applied to glucuronic and galacturonic acids. Decarboxylation of the uronic acids is effected by means of hydrochloric acid and the carbon dioxide driven off estimated by absorption in alkali. For *pentosan* determinations, the Youngburg[11] micro-method of distillation with phosphoric acid was used. *Sugars* were determined by the micro-method of Stiles, Peterson and Fred.[12]

Composition of Gum.—In Table II are given the analytical results. The ash content of the samples is not consistent. Gum from agar cultures contained less ash than that from liquid cultures inasmuch as the separation from the salts of the medium was more easily accomplished in the former cases.

TABLE II

ANALYTICAL DATA ON THE DRY GUM PRODUCED BY THE ROOT NODULE BACTERIA

[a] In Sample 1, calcium carbonate in medium but no calcium chloride was added to the gum solution. In Samples 2 and 3, no calcium carbonate in medium and no calcium chloride was added to the gum solution. In Samples 4 and 5, calcium carbonate was present in the medium and calcium chloride was added to the gum solution. In Samples 6, 7, 8 and 9, no calcium carbonate in medium, but calcium chloride was added to the gum solution. [b] (Total furfural – furfural from uronic acid) X 1.71.

The uronic acid content of the gums shows great variation. Pea and red clover nodule bacteria gums contain between 19.3 and 25% of the acid anhydride, while the gum of alfalfa nodule bacteria contains only about one-fourth as much anhydride.

In the calculations of the pentosan figures given in Table II, the furfural obtained by the Youngburg method of analysis was multiplied by 1.71, the average figure given in Kröber's tables[13] for a like calculation. The

general trend of the figures is toward high values when the uronic acid content is high, and low figures for the samples which contain less uronic acid.

The sixth column in Table II is headed "Pentosans (actual)." Both uronic acids and pentoses will yield furfural when heated with phosphoric acid, If the amount theoretically obtainable from the uronic acid is subtracted from the total furfural a small difference is left. This remainder was calculated to pentosans, and the values are given under the column headed "Pentosans (actual)." The figures vary from 2.2 to 9.2%.

The last column of Table II gives the percentage (ash-free basis) of reducing sugar calculated as glucose which was yielded on hydrolysis of the gums. The amount of reducing substance obtained ranged from 52.8 to 82.2% of the ash-free gum. Although the reducing effect was calculated as glucose, the reduction is not necessarily due to this sugar alone, since other substances such as furfural or uronic acid would likewise reduce Fehling's solution. Our results are not in agreement with those of Grieg-Smith,[8] who reported that the gums of pea and lupine nodule bacteria were hydrolyzed quantitatively to reducing sugar.

Hydrolysis of Gums, and Identification of Sugars by Chemical Means

Tests were made on Preparation 1 (alfalfa nodule bacteria) to ascertain what conditions of hydrolysis gave the maximum yield of sugars. Five per cent. (by weight) sulfuric acid was used as the hydrolytic agent. Although refluxing the acid solution of the gum for ten hours produced the maximum yield of reducing sugar (72.9), autoclaving for two hours at 15 pounds' steam pressure was a more convenient method of hydrolysis and gave only a slightly lower yield of sugar (68.4%). The latter method was therefore adopted as the general procedure. The acid was neutralized with barium carbonate, the barium sulfate filtered off, washed free of reducing sugars and the filtrate evaporated to about 50 cc. At this point decolorization was effected with bone charcoal and the filtrate again evaporated to a small volume. On pouring this sugar solution into four volumes of 95% alcohol, a flocculent precipitate formed at once. This precipitate was probably uronic acid. Ehrlich and von Sommerfeld[14] obtained barium galacturonate from the hydrolysis of pectins at this point. The precipitate gave a strong naphthoresorcinol test for uronic acid. A mucic acid test was negative, *so* that the acid seems to be *glucuronic*. All of the preparations of which the hydrolysis products were studied (Numbers 1, 6, 7, 8) gave strong naphthoresorcinol tests. Work is now in progress to identify this acid by the preparation of its characteristic derivatives.

Hydrolysis **of** Preparation 1.[15] (Alfalfa Nodule Bacteria Gum.)—The carbon content of this preparation was found to be 40.6% when analyzed by the micro-method of Lochte.[16] Analysis for total nitrogen by the Kjeldahl method gave no nitrogen beyond the experimental error.

The gum was hydrolyzed by the procedure already given and glacial acetic acid was added to the concentrated sugar solution. Crystallization took place after several days. The crystals were filtered off, washed with glacial acetic acid, redissolved in a minimum

[15] The work on the preliminary hydrolyses, the crystallization and identification of glucose was performed by Mr. W. B. Sarles.

[16] H. L. Lochte, THIS JOURNAL, 48,1301 (1926).

quantity of water and again recrystallized after the addition of glacial acetic acid. After filtering and washing, the crystals were dried to constant weight in a vacuum desiccator. The weight of sugar obtained was 0.3158 g. This sugar was dissolved in 25 cc. of water, a drop of ammonia was added to bring about constant rotation and readings were made in a 200-mm. tube at 20°: reading, +7.75° Ventzke scale, $[\alpha]_D^{20}$ +53.2°; $[\alpha]_D^{20}$ for d-glucose, +52.8°.

Hydrolysis of Preparation 7. (Red Clover Nodule Bacteria Gum.)—The sugar was used for qualitative tests, and osazone preparations. Qualitative tests: aniline hydrochloride and phloroglucinol tests for furfural were positive. A uronic acid, as well as a pentose, would yield furfural under the conditions of these tests. Grieg-Smith[8,2] reports that the gums which he examined gave furfural on hydrolysis.

To the sugar in solution, phenylhydrazine hydrochloride and sodium acetate were added in amounts such that the ratio of the three compounds was 1, 2, 3. Yellow crystals formed after seventeen minutes heating in a boiling water-bath. The crystals were filtered off, recrystallized twice from a mixture of pyridine and 50% alcohol and twice from pyridine alone. The crystals occurred in fan-shaped aggregates of yellow needles. The melting point was 204°.

The osazone of glucose was prepared in the same way and recrystallized four time.; from pyridine. The preparation melted at 204°. Browne[13] gives the melting point of phenylglucosazone as 204–205°.

Hydrolysis of Preparation 6.—The phenylosazone of the reducing sugar was prepared as previously indicated and purified by six recrystallizations from pyridine. Its melting point was 204°.

Qualitative tests for mannose (hydrazone test) and fructose (Seliwanoff test) were made on the sugar solution after hydrolysis of the gum with negative results in both tests. When mannose and fructose equivalent to 5% of the total reducing sugar present were added to the hydrolysis product, positive tests were obtained. It is probable, therefore, that if these sugars are contained in the gum molecule, they constitute only a small percentage of the total sugar.

Hydrolysis of Preparation 8. (Pea Nodule Bacteria Gum.)—The phenylosazone of the sugar was prepared, and recrystallized seven times from pyridine. The melting point was 204°. Qualitative tests were made for mannose and fructose as under the hydrolysis of Preparation **6,** and both tests were negative.

Identification of Sugar by Fermentation Tests

The above evidence shows that glucose is a constituent of the gum, but that fructose and mannose are absent. The work of Grieg-Smith[8,2] indicates the possibility of the presence of galactose. Pentoses may also be present, as was suggested by the furfural figures (Table II). The chemical determination of such a mixture of sugars would be difficult, if not impossible. It should be possible, however, by means of fermentation tests to prove the presence or absence of these sugars. This method of sugar determination has been suggested and used in various ways. Kluyver[17] used yeast alone for the sugar determination, while Sherrard and Blanco[18] used yeast fermentation followed by fermentation with bacteria. By means of galactose and non-galactose fermenting yeast, the presence or absence of this sugar could be demonstrated. Likewise, the use of twa

strains of bacteria, one fermenting xylose but not arabinose, the other using arabinose and not xylose, might be used in the determination and identification of any pentoses present. The organisms selected for this purpose were the following: *Schizosaccharomyces pombe*, *Saccharomyces cerevisiae*, yeast, Honey B and lactic acid-producing organisms Nos. 19 and 36. The *Saccharomyces cerevisiae* yeast was obtained from a single cell isolation. The yeast called "Honey B" was isolated from fermenting honey. *Schizosaccharomyces pombe* and Honey *B* ferment glucose but not galactose, while the *Saccharomyces cerevisiae* ferments both glucose and galactose. Culture No. 36 ferments xylose, but leaves arabinose untouched, while Culture 19 ferments arabinose, but not xylose. Analysis of a mixture of known sugars by means of these organisms was first made to determine whether the method would give satisfactory results. The sugar solutions were added to a 10% extract of fresh starch-free yeast and the PH adjusted to 5.2; 10-cc. samples of this solution were pipetted into test-tubes, the tubes plugged with cotton and sterilized. Inoculations of the tubes were made as indicated in Table III, and after eight days' incubation at 28° the remaining sugar was determined in 1 cc. drawn from each culture tube. The remaining liquid was resterilized, sterile calcium carbonate added and inoculated with the pentose-fermenting bacteria. Sugar analyses were made on the cultures after ten days' incubation at 37°. Table III gives the results of the experiment, and indicates that satisfactory checks can be obtained by this method. The slight decrease in sugar in the uninoculated controls (Tubes 7 and *8)* is probably due to loss on sterilization.

TABLE III

ANALYSIS OR KNOWN MIXTURES OR SUGAR BY MEANS OF YEASTS AND BACTERIA

	Tubes 1 and 2		Tubes 3 and 4		Tubes 5 and 6		Tubes 7 and 8	
	Yeast fermentation

Should be present, mg.	24.2	24.2	49.0	49.0	49.0	49.0	101.5	101.5
	Bacterial fermentation							
Bacteria	No. 36	No. 19	No. 36	No. 19	No. 36	No. 19	Uninoculated	
Type of sugar fermented	Xylose	Arabinose	Xylose	Arabinose	Xylose	Arabinose		
Before, mg.	27.3	26.6	499	49.2	48.7	47.8	99.7	99.7
After, mg.	11.8	13.6	12.4	12.4	13.4	12.5	94.3	95.4
Should be present, mg.	11.4	12.8	11.4	12.8	11.4	12.8	101.5	101.5

The sugar solution in each tube contained the following amounts of sugar: glucose, 52.5 mg.; galactose. 24.8 mg.; xylose, 12.8 mg.; arabinose, 11.4 mg.; total, 101.5 mg.

The fermentation test just described was applied to the hydrolyzed solution of Preparations 6 and 8.

Fermentation Test on Preparation 6. (Red Clover Nodule Bacteria Gum.)--0.532 g. of sugar in solution was taken for the fermentation test. This solution was concentrated, yeast water added and the P_H adjusted to 5.2; 10-cc. portions of this solution were then pipetted into each of four test-tubes and the tubes sterilized. Three of the tubes were inoculated with yeast which would ferment only glucose, Honey B and *Schizosaccharomyces pombe*, and the other one with the yeast which would ferment both glucose and galactose, *Saccharomyces cerevisiae*. The tubes were incubated at 28°. Eight days after inoculation the cultures were made up to 10 cc., and 1 cc. was removed. This was then made up to 5 cc., and 1 cc. of this last dilution taken for micro sugar analysis.

As has been indicated, the presence of pentoses was suggested by the furfural data (Table II). The pentoses present would be most likely to be arabinose and xylose, it being more probable that there would be only one of these in the molecule. In order to decide this question, the solutions fermented by the yeast were submitted to bacteria fermentations. Yeasts do not normally attack pentoses, especially in the presence of a hexose, so that the pentose, if present, should still be in solution. The control fermentation of the mixture of known sugars showed that the pentoses were not attacked by the yeast. The remaining sugar solution after the yeast fermentation was again sterilized in tubes and sterile calcium carbonate added. Pure cultures of the lactic acid bacteria were inoculated into the tubes of sugar solution, and incubated at 38° for twelve days. At the end of that time the contents of each tube were made up to 10 cc., and 1 cc. of this solution was taken for micro sugar analysis.

The results of the two fermentations are given in Table IV. The yeast fermentation gave results which showed that the hexose was glucose, or that if galactose was also present, it was so in insignificantly small amounts. The difference between the amount of sugar fermented by the two bacterial cultures was so slight as not to permit the conclusion that pentoses were present. Typical fermentation data are given in detail in Table IV. The extent of recovery of galactose when added to the gum sugar solution was tested in later experiments: 98–100% was destroyed by the galactose-fermenting yeast and 3.8% fermented by the non-galactose fermenting yeast.

TABLE IV

FERMENTATION OF SUGARS FROM PREPARATION 6 (RED CLOVER ROOT NODULE BACTERIA GUM)

	Tube 1	Tube 2	Tube 3	Tube 4
	Yeast fermentation

After, mg.	26.6	24.7	22.3	26.6
Sugar fermented, mg.	240.4	242.3	244.7	240.4
	Bacterial Fermentation			
Bacteria	No. 36	No. 19	No. 36	No. 19
Type of sugar fermented	Xylose	Arabinose	Xylose	Arabinose
Before, mg.	26.6	24.7	22.3	26.6
After, mg.	16.0	16.6	15.6	16.8
Sugar fermented, mg.	10.6	8.1	6.7	9.8

A second fermentation experiment (data not given) was conducted in the same manner as the one above. *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe* were the yeasts used in this experiment, since Honey B grew more slowly and gave no additional information. The percentage of sugar fermented by the yeasts was higher in this experiment than in the first. The reducing substance remaining after the yeast fermentation is probably uronic acid, which is generally believed to be unfermentable by yeasts. The controls of known sugars show that the yeast fermentation is complete to the extent of nearly one hundred per cent. In the gum sugar solutions the bacteria do not, then, ferment only the portion of the hexose left by the yeast, but also a part of some other reducing substance still in solution. It may be possible that they are able to ferment the uronic acid. At the same time this fermentation does not indicate the presence of a pentose. The difference in percentage of fermentation of the sugar by the yeast between the first and second fermentations may be explained by the fact that in the first fermentation calcium carbonate had been used to neutralize the acid after hydrolysis of the gum, while in the second fermentation, barium carbonate was used. Since barium salts are generally less soluble than calcium salts, there was probably more complete removal of the uronic acid when barium carbonate was used. The reducing material left after the yeast fermentation appears to be the uronic acid, or its salts.

In the second bacterial fermentation of the sugars produced by hydrolysis of Preparation 6, the sugar contents of only two of the six tubes used in the fermentation could be determined. The other four tubes contained some material which prevented the appearance of the usual iodine end-point. In these cases, after titration to the end-point, the blue color reappeared.

Fermentation Test on Preparation 8. (Pea Root Nodule Bacteria Gum.)—The fermentation test was conducted in the same manner as was given under the fermentation of Preparation 6, two complete sets of fermentations being made in this case as in the one above. In Table V it will be seen that the extent of fermentation of the sugar by yeast is not as great as it was on the sugars from Preparation **6.** The presence of galactose is not indicated by the results obtained.

The percentage of hexose fermented by the yeast in the second fermentation (Prepn. 8) was larger than it was in the first. This is probably due, as seemed to be the case with the fermentation of sugars from Preparation 6, to the use of barium carbonate instead of calcium carbonate as the neutralizing agent of the hydrolysate in the second fermentation.

The bacterial fermentation in the second fermentation gave results which did not indicate the presence of a pentose.

Table V gives a summary of the results of the fermentations on the hydrolyzed gum of Preparations 6 and 8. The figures given under each preparation are the average of two complete fermentation tests like that represented in Table IV. **A** comparison of the percentages of sugar fermented by the galactose and non-galactose fermenting yeast indicates that if galactose is present at all, it is so in amounts of 1% or less. Likewise, the bacterial fermentations demonstrated that there is less than 1% of **a** pentose present, and it is likely that no pentose is present at all. The small differences between these fermentations cannot safely be attributed to any other cause than the biological variation inherent in such a method. The results of the yeast fermentation tests show that the hexose obtained on hydrolysis of the gum of both red clover and pea root nodule bacteria gum was glucose. The bacterial fermentations do not give evidence of the presence of a pentose sugar.

TABLE V

THE COMPOSITION, AS SHOWN BY FERMENTATION TESTS, OF THE GUM SUGAR OBTAINED FROM HYDROLYSIS OF PREPARATIONS 6 AND 8

		Preparation 6 Percentage of total sugar		Preparation 8 Percentage of total sugar	
Yeast	**Glucose fermenting**	92.6	93.1	82.9	83.2
	Galactose and glucose fermenting	93.6		83.6	
Bacteria	**Xylose fermenting**	3.2	3.0	5.6	5.2
	Arabinose fermenting	2.8		4.7	
Unfermented reducing substance			4.3		11.6
			100.4		100.0

Conclusions

Root nodule bacteria of three cross-inoculation groups were grown in pure culture on synthetic media, and the gum produced was precipitated with acetone. The gum of the root nodule bacteria of alfalfa, *Rhizobium meliloti* 100, was nitrogen-free, The carbon content of this gum was variable, being 40.6% in one sample, and 36.4% in another. Glucose was crystallized from the gum solution after hydrolysis, and identified by its specific rotation (+53.2°).

Glucosazone was prepared from hydrolyzed gum produced by pure cultures of red clover root nodule bacteria, *Rhizobium trifolii* 205 and 201, and pea root nodule bacteria, *Rhizobium leguminosarum* 311. Fermentation tests of the sugar from these two gums by pure cultures of known yeasts also indicated that the sugar was glucose. Fermentation tests by pure cultures of pentose-fermenting lactic acid bacteria showed the absence of a pentose sugar.

The gums of *Rhizobium meliloti* 100, *Rhizobium trifolii* 205 and 201, and *Rhizobium leguminosarum* 311 contain uronic acid in amounts varying between 4.1 and 25.3% ash-free basis.

All of the results up to the present time indicate that these gums of the root nodule bacteria are complexes of glucose and a uronic acid, probably glucuronic acid.

THE VISCOSITIES OF GLYCEROL TRINITRATE AND CERTAIN RELATED GLYCOL NITRIC ESTERS[1]

BY J. MERRIAM PETERSON

RECEIVED JUNE 3, 1930 PUBLISHED SEPTEMBER 5, 1930

Introduction

During a general study of glycerol trinitrate and certain glycol dinitrates need arose for data on the viscosities of these substances. A search of the literature revealed only a small amount of data and the values which were reported covered a very limited temperature range. It was then necessary to undertake the task of determining these viscosities and determinations were made at five-degree intervals over the temperature range 10 to 60°, inclusive, on highly purified samples of the following esters: propylene glycol dinitrate, ethylene glycol dinitrate, trimethylene glycol dinitrate, diethylene glycol dinitrate and glycerol trinitrate.

Naoúm[2] tabulates viscosities at 20° for four of the esters included in the present investigation. The data are given in seconds required to run 5 cc. out of a 10-cc. pipet, as follows: propylene glycol dinitrate, 5.0 seconds; ethylene glycol dinitrate, 5.0 seconds; trimethylene glycol dinitrate, 5.5 seconds, and glycerol trinitrate, 12.5 seconds. A calibration of the pipet with water required 4.5 seconds for the time of flow. The results indicate that the viscosities of the esters are only slightly greater than the viscosity of water, with the exception of glycerol trinitrate, which appears to be about 2.5 times as viscous. More reliable values were determined by Rinkenbach[3] for glycerol trinitrate and diethylene glycol dinitrate between 15 and 27°. In an earlier communication[4] he gives values for the viscosities of ethylene glycol dinitrate and glycerol trinitrate at 23.6°. These values are included for comparative purposes in the tables of viscosities for the present work.

Materials.—The nitric esters were prepared from the corresponding glycols by nitration with a mixture of nitric and sulfuric acids as described by Crater.[5] After neutralization, washing and thorough drying, determinations of the specific gravity and nitrogen content were made for each compound. The results given in Table I indicate compounds of a high degree of purity.

[a] Naoúm. [b] Rinkenbach.

Method.—A Bingham and Jackson[6] viscometer was used to determine the viscosities of the esters. While this instrument is of the pipet type, it eliminates most of the objections so common to many of the pipet methods and is capable of giving absolute values for viscosity in c. g. s. units. **A** correction may be applied when necessary for the kinetic energy of the liquid measured, a correction which is too often overlooked or neglected in viscosity determinations.

The method consists essentially in measuring the time of flow of a given volume of liquid (about 4 cc.) at a specified temperature and under a known constant pressure, through a capillary tube which has been previously calibrated. Details of the instrument and method may be found by referring to the original paper.

Temperature was held automatically to ±0.1° of that desired by means of a large, well-stirred water thermostat controlled by a mercury regulator in conjunction with a relay and knife type lagless heater. Pressure was supplied from a tank filled to any desired pressure directly from the compressed air line and was measured by an open-end mercury manometer. Corrections were made to reduce the manometer readings to mm. of mercury at 0°. The tank was of sufficient size so that there was no perceptible drop in pressure resulting from the small quantity of air removed during a determination. Time measurements were made with a stop watch accurate to 0.2 second.

Calibration and Calculations.—The viscosities were calculated by the formula

$$\eta = Cpt - \frac{C'\rho}{t} \qquad (1)$$

where η is viscosity of the substance in c. g. s. units (poises), C and C are constants of the individual instrument, t is time in seconds, p is pressure in grams per square centimeter and p is density of sample in grams per cubic centimeter.

The second term of the right-hand member of the above equation is the

---

[6] Bingham and Jackson, Sci. Papers of the Bureau of Standards, No. 298 (1917)

kinetic energy correction, which is kept small by keeping *t* comparatively large. For this reason C' and p need not be known with great accuracy. The density of the ester used in this correction was calculated from the specific gravity values given in Table I.

The value of the constant C' was determined from the dimensions of the instrument as outlined by Bingham.[7] The value of the constant C was obtained by filling the viscometer with freshly distilled, dust-free water and determining the time of flow at 20°. The value used for the viscosity of water at 20° was **1.005** centipoises. Table II lists the constants of the two instruments used.

TABLE II

CONSTANTS OF VISCOMETERS

Viscometer	Capillary length. mm.	Radius, mm.	Volume of bulb, cc. (20°)	C	C'
Instrument 1	121.0	0.169	4.08	6.416×10^{-7}	0.01504
Instrument 2	120.0	0.244	4.02	2.851×10^{-6}	0.01494

Data.—In Tables III, IV, V, VI and VII are tabulated summaries of the viscosity data obtained. Four to six determinations were made at each temperature for each substance; the number in each case is given in the first column of each table. The temperature of the liquid **at** the time of the determination is given in Col. 2, the average of the values for the separate viscosity determinations is tabulated in Col. **3 and** the maximum deviation of the individual determinations from the average viscosity is recorded in Col. 4. The fluidity in rhes (reciprocal viscosity in poises) was calculated and is given in Col. 5. The values for the viscosities of the esters at the corresponding temperatures as reported by previous investigators, Rinkenbach (indicated by R) and Naoúm (indicated by N),

4	60	.0680	.0000	14.7		

are given in the last column. Naoúm's values were converted to c. g. s units, for comparative purposes, by the equation

$$\eta = \eta_0 \frac{\rho t}{\rho_0 t_0} \qquad (2)$$

where η, ρ and t represent the viscosity, density and time of flow, respectively, for the unknown and η_0, ρ_0 and t_0 represent similar quantities for the standard substance (water). η_0 was taken as 0.0100 poises at 20° and ρ_0 was taken as 1.0.

Discussion of Results

Pressure measurements ranged from 10.04 to 163.23 cm. of mercury. The maximum error was probably not greater than 0.2 mm., which would result in an error of not more than 0.2% in the calculated viscosities even at the lower pressures. The times of flow varied from 490.6 to 45.6 seconds. Except in the case of ethylene glycol dinitrate, however, the times of flow were over 200 seconds. An error of 0.2 second in the time measurements would cause an error of not more than 0.1% in the calculated values, except with ethylene glycol dinitrate, where the error may reach 0.4%. By using an accurately controlled thermostat and waiting several minutes for temperature equilibrium of the sample to be reached after each change in the thermostat temperature, the error from this source was negligible. The total error in the final results is thought to be not greater than 0.25% for the individual determinations and this appears to be justified by an examination of the maxium deviation from the mean as given in the tables.

The average viscosities when plotted against temperatures give smooth curves, as shown in Fig. 1. Considering the fact that the plotted viscosities are the mean of four to six closely agreeing, duplicate values, the resulting curves should be in error by not more than 0.1%. This is within the limitations associated with the purification of the compounds studied.

It is interesting to note that the values are almost the same for propylene glycol dinitrate and ethylene glycol dinitrate, while the values for the two isomers, propylene glycol dinitrate and trimethylene glycol dinitrate differ considerably. Such a marked increase in the viscosity of glycerol trinitrate might not have been expected. Because of its large coefficient of viscosity with temperature in this temperature range, the upper part of the viscosity curve, Fig. 1, was cut off. The unplotted values, however, fall upon as smooth a curve as do the plotted values.

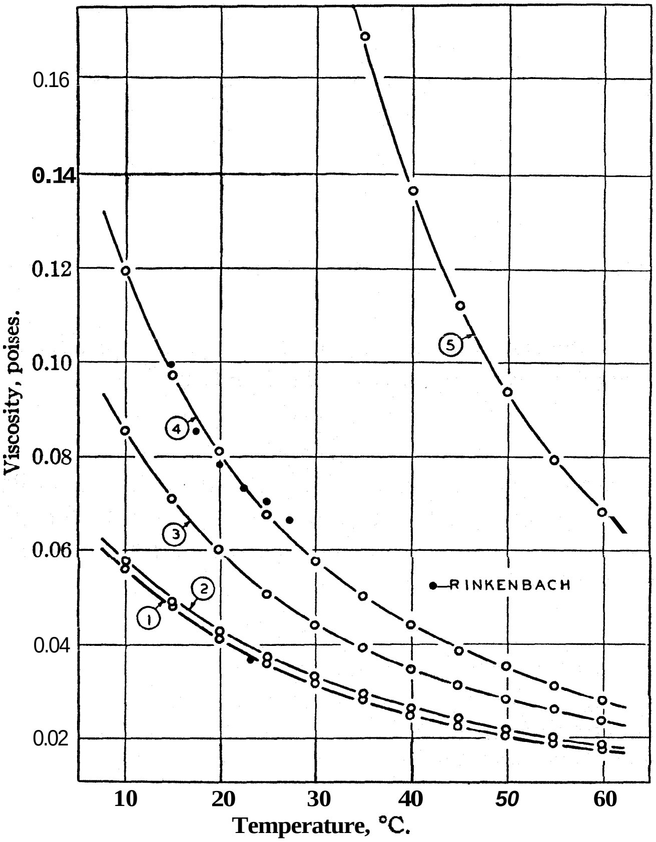

Fig. 1.—viscosity-temperature curves of esters: 1, propylene glycol dinitrate; 2, ethylene glycol dinitrate; 3, trimethylene glycol dinitrate; 4, diethylene glycol dinitrate; 5, glycerol trinitrate.

The results herein reported agree quite satisfactorily with those reported by Rinkenbach. The values given by Naoúm are worthy of special attention. They are quite typical of many values reported in the literature obtained by arbitrary methods where the viscometer used is calibrated by a substance which differs greatly from the unknown substance, and no kinetic energy corrections are made for rapid rates of flow. While such results are usually intended only for relative values, they are often decidedly misleading. In the present case it would be assumed from the times of flow that glycerol trinitrate is approximately 2.5 times as viscous as water at 20°, or four times as viscous if the viscosity is calculated by Equation 2. The results obtained during this investigation show the ratio to be about 36 to 1.

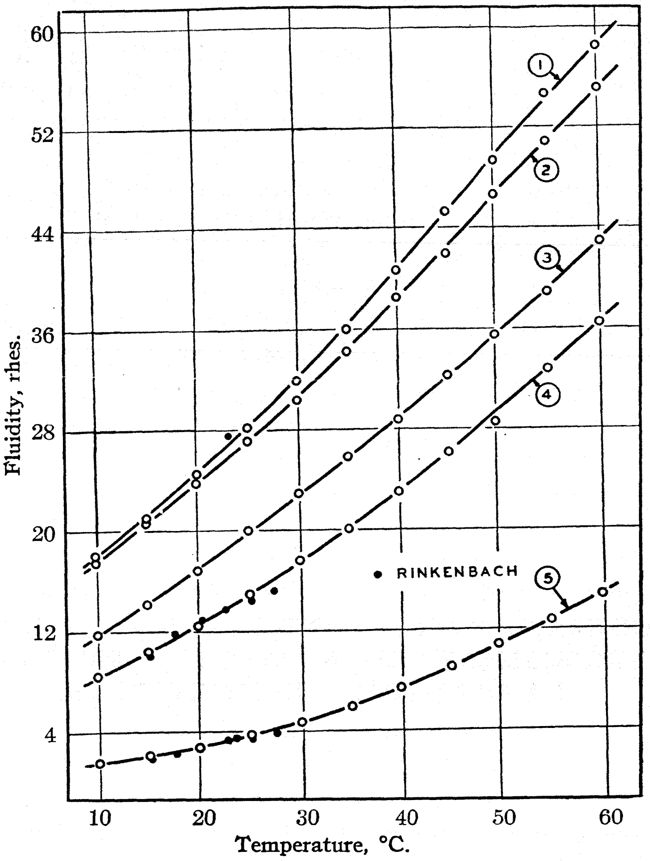

Fig. 2.—Fluidity–temperature curves of esters: 1, propylene glycol dinitrate; 2, ethylene glycol dinitrate; 3, trimethylene glycol dinitrate; 4, diethylene glycol dinitrate; 5, glycerol trinitrate.

Since fluidities (reciprocal viscosities) are more convenient to use in certain cases than viscosities, they are included in the tables and are plotted in Fig. 2. The resulting curves deviate somewhat from straight lines, a slight sag being noted in each case.

Plotting log viscosities against temperatures resulted in curves which deviated from straight lines to about the same extent as did the fluidity curves.

The fluidity curves, however, approach straight lines nearly enough so that they may be easily extended to temperatures beyond those actually determined, at least to those temperatures of importance in the commercial application of the esters.

Acknowledgment.—The author wishes to express his appreciation of the assistance of W. deC. Crater, who kindly prepared the samples used in this investigation.

Summary

The viscosities of highly purified samples of propylene glycol dinitrate, ethylene glycol dinitrate, trimethylene glycol dinitrate, diethylene glycol dinitrate and glycerol trinitrate were measured in c. g. s. units (poises) at five-degree intervals over the temperature range 10 to 60°, inclusive, and the results compared with previously reported values. The corresponding fluidities were calculated and reported.

RESEARCHES ON HYDANTOINS. XLIX. A NEW REARRANGEMENT LEADING TO THE FORMATION OF 4-AMINOHYDANTOIN DERIVATIVES

BY R. M. HERBST[1] AND T. B. JOHNSON

RECEIVED JUNE 5, 1930 PUBLISHED SEPTEMBER 5, 1930

In the course of an investigation dealing with the synthesis of 5,5-dialkylated hydantoins from ketones, the authors had occasion to study the applicability of a series of reactions suggested for the preparation of 1,5,5-trialkyl-hydantoins. Tiemann and Piest[2] first showed that the Strecker synthesis of a-amino acids could be modified to include N-alkylamino acids if an amine is used in place of ammonia in the reaction with aldehyde or ketone cyanhydrins. Biltz and Slotta[3] applied this phase of the Strecker–Tiemann reaction to the synthesis of 1-alkyl-hydantoins. We have now employed the same series of reactions described by Biltz and Slotta under modified experimental conditions for the preparation of 1,5,5-trialkyl-

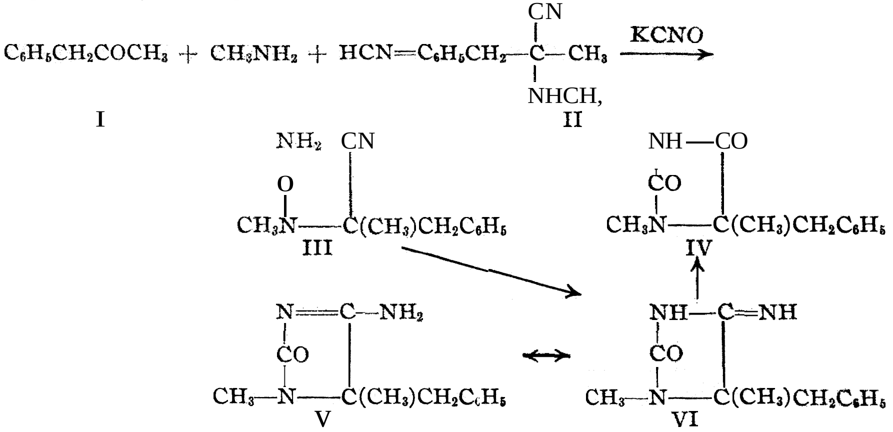
hydantoins. The method of operating is illustrated by the synthesis of 1,5-dimethyl-5-benzylhydantoin from methyl benzyl ketone which is expressed by the equations



$$\underset{I}{C_6H_5CH_2COCH_3} + CH_3NH_2 + HCN = \underset{II}{C_6H_5CH_2-\underset{NHCH_3}{\overset{CN}{C}}-CH_3} \xrightarrow{KCNO}$$

A careful study of these reaction changes has now revealed a mechanism of ring formation which has not been observed, hitherto, in the hydantoin series. The a-methylureido-a-methyl-/3-phenylpropionitrile (III), prepared as an intermediate in this synthesis, undergoes a molecular rearrangement on boiling in water solution to form 1,5-dimethyl-5-benzyl-4-aminohydantoin (V or VI). The transformation is perfectly analogous to that which was observed by Pschorr,[4] who encountered a similar reaction in the synthesis of α-aminoquinolines from o-aminocinnamylcyanides. Traube[5] and Conrad[6] have described analogous rearrangements leading to the formation of ring compounds in the synthesis of barbituric acid and derivatives.

Jongkees[7] has prepared 4-iminohydantoin-1-acetamide, in which the imino group is easily replaced by oxygen by warming with dilute hydrochloric acid. His technique involved cyclization in ammoniacal solution. Our compound shows a much greater stability than Jongkees' hydantoin, and is not affected by boiling even with fairly strong hydrochloric acid. The amino group can be replaced with oxygen, however, by treatment with nitrous acid, analogous to the conversion of cytosine into uracil studied by Kossel and Steudel[8] and later by Wheeler and Johnson.[9] These facts favor the amino V, in preference to the imino structure VI, for the cyclic compound.

This rearrangement suggests a possible reaction mechanism for the conversion of ureido-nitriles into hydantoins by means of aqueous hydrochloric acid. Generally this transformation is expressed as one involving, first, hydrolysis of the nitrile to the corresponding hydantoic acid, and then a molecular condensation to form the hydantoin. According to the new conception the change to ring structure first involves a formation of the intermediate imino compound VI, which is unstable in the presence of strong hydrochloric acid and is decomposed immediately, giving the normal hydantoin. On the other hand, in the absence of hydrochloric acid, or under conditions where we have a low hydrogen-ion concentration, the imino compound may undergo tautomerization to form the isomeric and more stable aminohydantoin V, which is not attacked by acids. In the above rearrangement we have an excellent example apparently of this tautomeric change, and it is a molecular transformation which possesses considerable biochemical interest. This tautomerization is undoubtedly influenced by the character of the groups substituted in the hydantoin ring on nitrogen and carbon.

The rapidity with which hydantoins are formed from ureido-nitriles, the reaction being almost instantaneous, lends support to the belief that something other than the hydrolysis of a cyanide group to carboxyl is involved in this reaction. The unique behavior of the ureido-nitrile suggests a mechanism of reaction which is far more general than we have hitherto realized.

Experimental

α-Methylamino-α-methyl-β-phenylpropionitrile, II.—Seven and nine-tenths cc. (0.2 mole) of anhydrous hydrocyanic acid and 6.2 g. (0.2 mole) of dry methylamine are dissolved in a thoroughly cooled solution of 26.8 g. (0.2 mole) of methyl benzyl ketone in 25 cc. of absolute ethyl alcohol. After the solution has stood at room temperature in a well-stoppered bottle for twenty-four hours, it is taken up in 200 cc. of ether, washed with cold water and dried over sodium sulfate. The hydrochloride of α-methylamino-α-methyl-β-phenylpropionitrile is then precipitated by passing dry hydrogen chloride into the ethereal solution. It separates first as an oil, which on continued treatment with hydrogen chloride changes to a colorless, crystalline solid, melting at 106–108°[10] with decomposition, after sintering at 102°. The yield of hydrochloride is 35 g. (85%). The hydrochloride decomposes slowly on standing, and cannot be kept over long periods. Heating in non-anhydrous solvents causes methylamine hydrochloride and hydrocyanic acid to split off with regeneration of the ketone.

Anal. Calcd. for $C_{11}H_{15}N_2Cl$: N, 13.30. Found: N, 13.14, 13.09

The free methylamino-nitrile, obtained by evaporating the solvent from an ethereal solution at room temperature under reduced pressure, decomposes easily on heating, and cannot be distilled even in vacuo without serious decomposition.

α-Methylureido-α-methyl-β-phenylpropionitrile, III.—During the course of an hour 25 g. of finely ground potassium cyanate is added to a cold suspension of 35 g. of α-methylamino-α-methyl-β-phenylpropionitrile hydrochloride in 100 cc. of glacial acetic acid. After standing in a cool place for fifteen hours, the reaction mixture is poured into

---

[10] All melting points are corrected.

500 cc. of ice water. On standing in the refrigerator, **α-methyl-ureido-α-methyl-β-phenylpropionitrile** separates as a flocculent white solid, which is filtered off through a Biichner funnel, washed with water and air-dried. The yield of crude material is 28 g. (77.5%). It crystallizes from 50% alcohol in colorless needles, melting at 130–131°.

Anal. Calcd. for $C_{12}H_{15}ON_3$: N, 19.35. Found: N, 18.91, 18.93.

1,5-Dimethyl-5-benzylhydantoin, IV.—Twenty-eight grams of crude a-methyl-ureido-α-methyl-β-phenylpropionitrile is suspended in 100 cc. of 20% hydrochloric acid. On warming the methylureido-nitrile dissolves and the hydantoin begins to precipitate almost immediately. After heating for one hour on the steam-bath, the suspension is cooled, filtered through a Biichner funnel and the residue washed with cold water. The yield of crude hydantoin is 23 g. (82%). Recrystallization from 50% alcohol. decolorizing with norite if necessary, yields a product melting at 134–135°.

Anal. Calcd. for $C_{12}H_{14}O_2N_2$: N, 12.84. Found: N, 12.92, 12.81.

An attempt to decompose the hydantoin to the corresponding methylamino acid was unsuccessful. After refluxing 5 g. of the hydantoin for one hundred hours with saturated barium hydroxide solution, 4.5 g. of the unchanged hydantoin was recovered.

A crystalline sodium salt is formed when a mixture of a small amount of the hydantoin with an equivalent amount of a 5% solution of sodium hydroxide in 95% alcohol is evaporated in a vacuum desiccator. Solutions of mercuric chloride, calcium chloride and magnesium sulfate precipitate the corresponding salts when added to aqueous solutions of the sodium salt of the hydantoin, The mercury salt precipitates as a flocculent white solid, whereas the calcium and magnesium salts separate as colorless needles.

1,5-Dimethyl-5-benzyl-4-aminohydantoin.—When a solution of or-methylamino-α-methyl-β-phenylpropionitrile in hot water is boiled momentarily, 1'5-dimethyl-5-benzyl-4-aminohydantoin crystallizes out on cooling in a practically quantitative yield, in the form of small, colorless needles, melting at 267–268° with charring.

Anal. Calcd. for $C_{12}H_{15}ON_3$: N, 19.35. Found: N, 19.32, 19.27.

The aminohydantoin is readily soluble in dilute mineral acids, but insoluble in alkalies, which precipitate it unaltered from its solutions in acids. Boiling with acids or alkalies does not affect the aminohydantoin. It forms a characteristic mono-hydrc-chloride and picrate.

On treating with nitrous add, as described by Kossel and Steudel[8] for the ton-version of cytosine to uracil, an acidic compound is obtained, crystallizing from 50% alcohol in plates and melting at 134–135°. Mixed with 1,5-dimethyl-5-benzyl-hydantoin the melting point is unchanged

The hydrochloride of **1,5-dimethyl-5-benzyl-4-aminohydantoin** is prepared by pouring a solution of the aminohydantoin in 95% alcohol saturated with hydrogen chloride into dry ether. On standing the hydrochloride precipitates as a colorless crystalline solid, melting at 218–223° with decomposition.

Anal. Calcd. for $C_{12}H_{16}ON_3Cl$: N, 16.57; Cl, 14.00. Found: N, 16.65; Cl, 13.93.

The picrate of **1,5-dimethyl-5-benzyl-4-aminohydantoin** crystallizes as yellow needles when a solution of equal amounts of the aminohydantoin and picric acid in a slight excess of boiling water is cooled. After recrystallization from 50% alcohol it melts at 226–227° with decomposition.

Anal. (Kjeldahl–Gunning). Calcd. for $C_{18}H_{18}O_8N_6$: N, 18.83. Found: N, 18.97.

Summary

1. 1,5-Dimethyl-5-benzylhydantoin and its 4-amino derivative have been prepared.

2. A new rearrangement leading to hydantoin derivatives substituted in the 4-position with an amino group has been described.

THE MECHANISM OF CARBOHYDRATE OXIDATION. XII. THE ACTION OF POTASSIUM HYDROXIDE ON *l*-ARABINOSE AND d-XYLOSE

BY WM. LLOYD EVANS AND ROLLIN FRANCIS CONAWAY

RECEIVED JUNE 6, 1930 PUBLISHED SEPTEMBER 5, 1930

When the hexose sugars, glucose, mannose, fructose and galactose are treated with aqueous solutions of potassium hydroxide, it is found that the amounts of certain reaction products are definitely dependent upon the normality of the solutions used and also upon the temperature employed. In a recent report, Shaffer and Friedman[1] have shown that the concentration of the sugar is also an important factor in the reaction of the hexose sugar under these conditions.

Since it is conceivable that pentose sugars may be formed as intermediate compounds in reactions involving the decomposition of hexose sugars in alkaline solutions, it becomes of much interest to know whether the products formed in a similar decomposition of the pentoses will show the same general relationship to the experimental conditions used as the hexose sugars do under similar circumstances. To obtain data with reference to this point was the principal objective in these experiments. For our experimental purposes we used the two easily accessible five-carbon atom sugars, *l*-arabinose and d-xylose. A similar study concerning the theoretically possible intermediate trioses has been made in this Laboratory previously.[2]

Experimental

(a) Materials.—All materials used in these experiments were examined for their purity by well-known laboratory methods.

(b) Manipulation. Lactic, Acetic and Formic Acids.—A 100-cc. round-bottomed pyrex flask containing 25 cc. of potassium hydroxide of the desired normality was attached to a mechanical agitator placed in a thermostat. After sufficient time had elapsed for the flask and its contents to come to the desired temperature (25, 50 or 75°), 1.875 g. (0.5*M*) of the crystalline *l*-arabinose or d-xylose was added through a large funnel whose stem had been shortened. Usually ten samples, including different normalities and duplicates, were started within the period of an hour. As in all the previous studies in this series, the agitation of these solutions was continued for forty-eight hours. Owing to the difficulties arising from the deposition of moisture during the preparation of the reacting systems at 75°, it was found more convenient to place the sugar in the flask first and then add the standard alkali solution. The general procedure from this

[1] Shaffer and Friedman, *J. Biol. Chem.*, 86, 345 (1930).

[2] (a) Evans and Hass, THIS JOURNAL, 48, 2703 (1926); (b) Evans and Cornthwaite, *ibid.*, 50,486 (1928).

point on for the determination of lactic, acetic and formic acids has been described previously. It was found that the difficulties attending the determination of zinc lactate due to the presence of large amounts of gum (probably a mixture of the zinc salts of saccharinic acids) could in some measure be overcome by boiling the aqueous solution with a little norite before removing the insoluble zinc carbonate. Obviously, this also introduces a possible error for zinc lactate.

In the determination of formic acid it was found best to attach a Kjeldahl bulb to the distilling column in order to prevent any of the solution from bumping over into the distillate. The receiver, a 250-cc. distilling flask, was completely immersed in a freezing mixture of salt and ice. A piece of glass tubing was sealed to the end of the condenser, in order that the condenser tube might extend down into the bulb part of the receiver. This was done for the purpose of diminishing, as far as possible, the loss of vapors from the receiver.

The distillations were carried to dryness, after which about 10 cc. of distilled water was added to the dry salt residue and the distillation again carried to dryness. It was found that much better results could be obtained in the formic acid determination by thus distilling the residues to dryness three or four times.

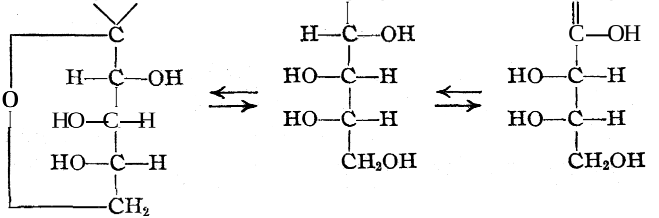
After the distillation was complete, the stem of the Kjeldahl bulb which extended into the flask was rinsed into the salt residue, while the remainder of the bulb and the condenser was rinsed with distilled water into the distillate. The distillate was then carefully transferred to a 100-cc. calibrated flask. After the temperature of the distillate had adjusted itself to that of the room, enough distilled water was added to make a volume of 100 cc.

Pyruvic Aldehyde Osazone.—In this determination, 25 cc. of the standard potassium hydroxide solution was placed in a 100-cc. round-bottomed flask, together with 17.5 cc. of 95% ethyl alcohol and 1.875 g. of the pentose sugars. After being agitated for forty-eight hours at the desired temperature, the pyruvic aldehyde osazone was determined as previously described.

Theoretical Discussion and Summary

When the behavior of I-arabinose and d-xylose in alkaline solutions is examined from the standpoint of their ability to form enediols in the same manner as has been repeatedly discussed for the hexose sugars, then it is possible to predict that the pentose sugars will form certain compounds which are also formed in the alkaline decomposition of the hexose sugars. Nef[3] made an exhaustive study of the behavior of these two pentose sugars in 8 N potassium hydroxide solution, and in an earlier report he gave an account of the behavior of I-arabinose in an alkaline cupric hydroxide system.

***l*-Arabinose 1,2-Enediol.**—The behavior of *l*-arabinose under our experimental conditions is shown in the equations

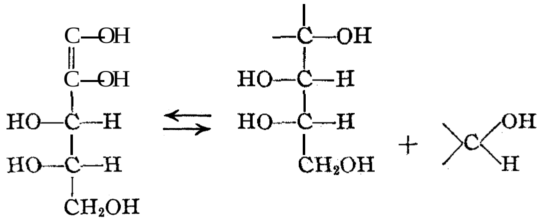


l-Arabinose *l*-**Arabinose,** aldehyde form *l*-**Arabinose 1,2-enediol**

---

[3] **Nef,** (a) *Ann.*, **376,** 1 (1910); (b) 357,214 (1907).

If the *l*-arabinose 1,2-enediol should undergo cleavage at the double bond, erythrose and formaldehyde would be formed according to the reaction

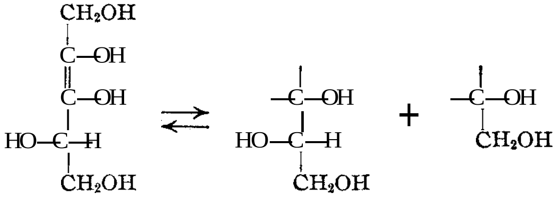


l-Arabinose 1,2-enediol — Erythrose, active form — Formaldehyde, active form

In these experiments the formaldehyde may be regarded as one of the sources of formic acid. Nef[3a] found that 8 N alkaline solutions of glycol aldehyde gave traces only of formic acid and no lactic acid. It has been shown in this Laboratory[4] that alkaline solutions of glycol aldehyde extending over 0.1–10 N give no trace of lactic acid under the experimental conditions which are employed in these experiments. However, such solutions gave rise principally to C_4 saccharins, which must have arisen from the tetroses formed.[5]

Therefore it follows that the lactic acid found in our experiments must have arisen through some other possible decomposition of the pentose sugars than through the intermediate formation of a tetrose sugar. Obviously, the same general structural relations and conclusions are equally true for d-xylose.

***l*-Arabinose 2,3-Enediol.**—As the concentration of the alkali is increased, the pentose sugars should give rise in each case to 2,3-enediols, which in turn may undergo a cleavage at the double bond, thus giving rise to glyceric aldehyde and glycol aldehyde. These changes are shown in the equation



I-Arabinose 2,3-enediol — Glyceric aldehyde active form — Glycol aldehyde active form

(a) Lactic Acid.—In the absence of an oxidizing agent, glyceric aldehyde becomes the source of lactic acid, through the intermediate formation of pyruvic aldehyde. If the alkaline solutions of these pentose sugars contain equilibrated systems,[6] similar to those which have been thought to

exist in alkaline solutions of the hexose sugars under the same conditions, then it would follow that the quantity of lactic acid formed should increase

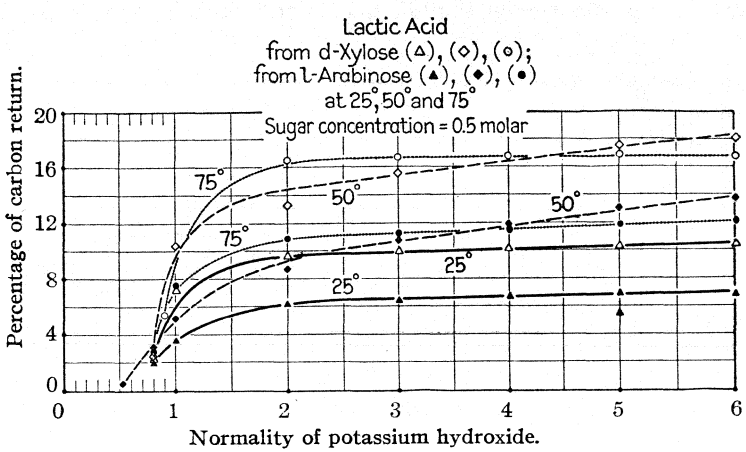

Fig. 1.

with an increase in the alkali normality. That this general relationship holds true may be seen in Fig. 1. Thus we see that the same general temperature relationships are also found to exist in the formation of lactic

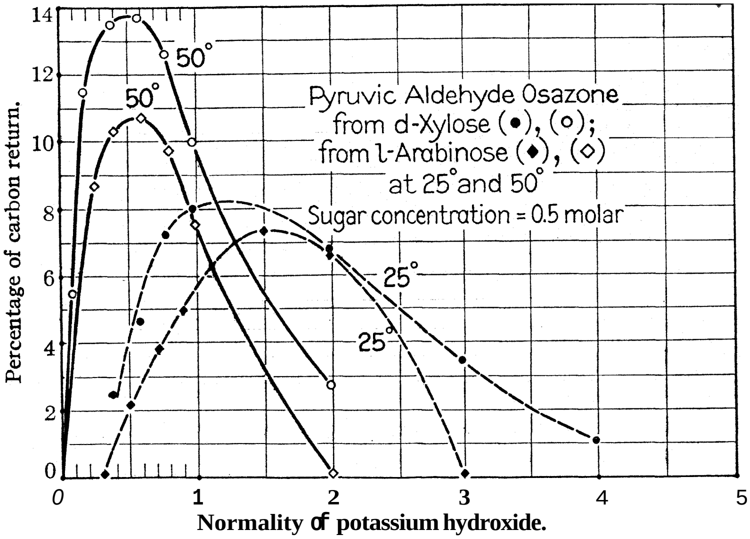

Fig. 2.

acid from the alkaline pentoses as were observed in the solutions of the hexoses. As the temperature rises, it is seen that the rate of formation of lactic acid at 75° becomes less than that at 50°. This same observation has also been made previously with mannose,[7] glucose,[7] fructose[8] and the trioses.[2] Although the cause of this difference has not been systematically investigated, yet this change may be due to an increasing rate of formation

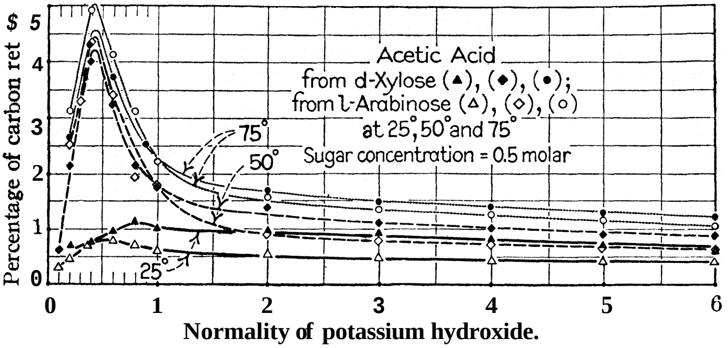

Fig. 3.

of the saccharinic acids arising from an increasing temperature, a condition which obviously would result in a corresponding decrease of the alkali normality of the reacting system due to neutralization. In time this would tend to diminish the pentose 2,3-enediol formation.

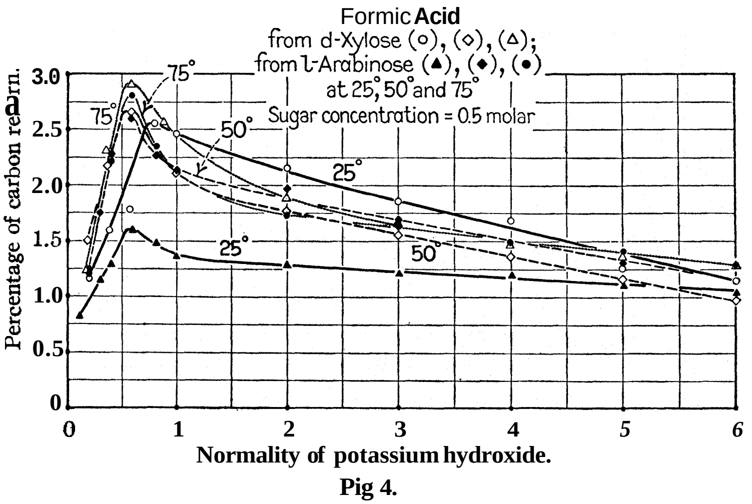

Fig. 4.

(b) **Pyruvic Aldehyde.**—It is generally accepted that pyruvic aldehyde formation is the forerunner of lactic acid in the alkaline decomposition of the sugars. Since this acid was found in these reactions with the pentoses an examination was made for the presence of pyruvic aldehyde.

---

[8] Evans and Hutchman, *ibid.*, 50, 1497 (1928).

Our results are shown in Fig. 2. The temperature and alkali effects are practically the same as those which have been observed in this Laboratory with the trioses,[2] certain hexoses[7,8] and maltose.[9]

(c) Acetic and Formic Acids.—Previously it has been thought that the presence of acetic acid in these reactions might be due to a decomposition of pyruvic aldehyde into acetaldehyde and carbon monoxide, which, in turn, would yield acetic and formic acids, respectively. If this were true, then these acids should also show maximum yields, because the tendency of the pyruvic aldehyde toward a minimum after the maximum, has been thought to be due to the increasing rate of lactic acid formation with the increasing normality of the alkali. That these general considerations are also true in the alkaline decomposition of the pentoses may be seen in Figs. 3 and 4. It is also conceivable that the glycol aldehyde which is formed in the decomposition of the 2,3-pentose enediols as well as the 1,2-triose and 2,3-hexose enediols may also give rise to acetic acid formation.[10]

From the data presented in this report it is clear that any pentoses which might possibly form in the alkaline decomposition of the hexose sugars are to be considered as possible sources of pyruvic aldehyde, lactic, acetic and formic acids.

A MODIFICATION OF THE SKRAUP SYNTHESIS OF QUINOLINE

BY ESSIE WHITE COHN

RECEIVED JUNE 7, 1930 PUBLISHED SEPTEMBER 5, 1930

The Skraup synthesis is widely used as a method for the preparation of quinoline and its derivatives. The synthesis, when performed in the manner advocated by Skraup, is often accompanied by a violent reaction. In addition, the yields obtained are variable and often low. To overcome the disadvantages of the original Skraup method, various improvements have been published from time to time.

To date the most important of the improvemerits made have been the ferrous sulfate modification of Clarke and Davis,[1] the acetic acid modification of Cohn and Gustavson[2] and a thorium–vanadium oxide method of Darzens, Delaby and Hiron.[3] The ferrous sulfate modification gives a very much better yield than does the original Skraup method. The re-

[3] Darzens, Delaby and Hiron, Bull. *soc. chim.,* 47,227 (1930).

action, however, is sometimes violent. The acetic acid modification accomplishes a complete removal of all traces of violence. The yields obtained by this method are smaller than those of the ferrous sulfate modification. The modification which has been named the thorium–vanadium oxide modification gives good yields. The violence of reaction has been avoided by adding sulfuric acid in three stages, controlling the temperature at which the reaction mixture is refluxed and by stirring.

Since each of these methods leaves something to be desired from the standpoint of smoothness in the first method, of yield in the second and of convenience in the third, the present paper presents a method which moderates the violence of the reaction and produces yields comparable with those obtained by other methods. This method will be termed a boric acid modification.

Experimental

The boric acid modification of the ferrous sulfate modification method for preparing quinoline may be carried out as follows. The reagents are placed in a liter flask in the order given: 14 g. of ferrous sulfate, **38** g. of aniline, **29.5** g. of mononitrobenzene. Twenty-five grams of boric acid is dissolved in **150** g. of glycerol, heat being used to effect solution of the boric acid. The boric acid–glycerol mixture when cooled is added to the contents in the liter flask and the whole mixed. Finally, **69.8** cc. of **95%** sulfuric acid is added, the contents mixed well, connected with a reflux condenser and heated over a free flame until the boiling point is reached. The mixture in the flask is kept simmering for a period of refluxing from nine to twenty hours, depending upon the yield desired. It is then cooled and diluted with water. The flask is connected with steam distillation apparatus and steam is passed in until the distillate is clear. The contents of the flask are cooled and made alkaline with about **250** cc. of a **60%** sodium hydroxide solution. The sodium hydroxide is added cautiously with frequent cooling of the flask. The contents of the flask are again distilled with steam. The current of steam is discontinued when the distillate is clear. The distillate is dissolved in sulfuric acid **(25.7** cc. of 95% sulfuric acid diluted with an equal volume of water). The mixture is cooled, sodium nitrite added until a drop of the solution causes a starch–potassium iodide spot to turn blue and the material is allowed to stand for about an hour. The contents of the flask are again made alkaline and steam distilled until the distillate is clear. The distillate is extracted with ether, the ether evaporated and the resulting product of quinoline weighed. Comparisons are based on the weight of quinoline obtained at this stage, although further purification is effected by distillation.

The following table shows a comparison of yields obtained by three methods of preparing quinoline for a five-hour period of refluxing. The yields are based on the same quantity of aniline and approximately the same quantities of materials with the exception of ferrous sulfate, acetic acid and boric acid.

Method	Time of heating, hours	Average yield, *g.*
Ferrous sulfate modification...............	5	30
Acetic acid modification..................	5	25
Boric acid modification....................	5	38

Figure 1 shows the yield obtained in the boric acid modification method as the time of refluxing was varied. For a fifteen-hour refluxing, the yield of quinoline is 90% of the theoretical based upon the amount of aniline originally added.

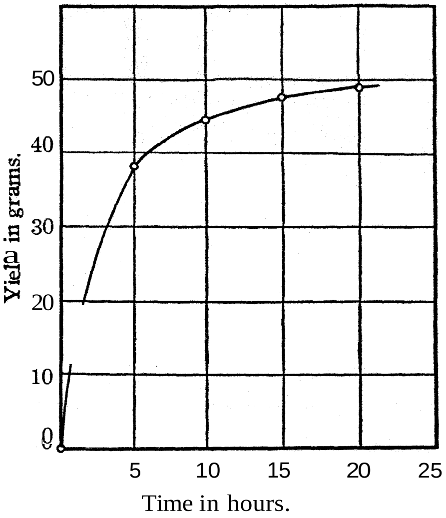

Fig. 1.—Yield of quinoline with time of refluxing.

The theory for the action of boric acid is believed to be similar to that of the acetic acid modification of Cohn and Gustavson,[2] namely, that an intermediate semi-stable glycerol borate is formed which hydrolyzes, gradually liberating glycerol.

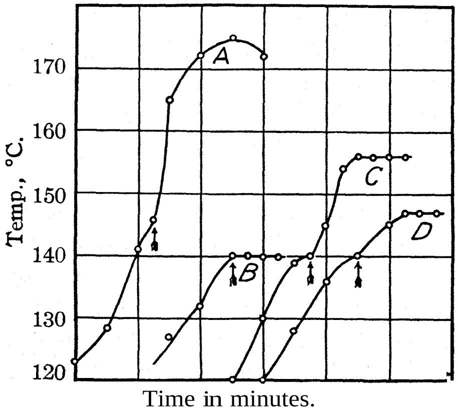

Fig. 2.—Comparative initial rise of temperature with time of heating.

A Measure of the Vigor of the Initial Reaction.—To obtain a more definite measure of the violence of the various reaction mixtures used in the synthesis of quinoline, the rate of rise of temperature under uniform heating conditions was obtained for each. The method used was to place in an 8-inch pyrex test-tube a fixed volume of the mixture to be tested. The tube was placed in an electrically heated vertical tube furnace of small heat capacity constructed for this experiment. The furnace was started in all cases at a temperature of 20° and was heated by a current of 1.80 amperes with constant stirring of the mixture. The increase in temperature with time was noted. Figure 2 shows typical curves obtained. These curves represent in a graphic manner the relative vigor of the reactions encountered in each case. The temperature at which bubbles began to escape is marked with an arrow. This point may not represent the boiling point of the mixture as a whole. Curve **A** represents the temperature–time curve above 120° for the original Skraup mixture. The temperature at which bubbles escape from the solution is approximately 146°. It will be noted that the temperature rise above this point is extremely rapid, reaching within the next minute about 175°. The rapid change in temperature is apparently related to the violence of the reaction. Curve B indicates the entire lack of violence found in the acetic acid modification. In Curve C, representing the curve obtained in the ferrous sulfate modification, the rise of temperature after the evolution of bubbles can be seen to approximate 15° within one-half minute. In Curve D, which represents the data from the boric acid modification, the rise of temperature is approximately one-half of that found in Curve C and, as will be noted by the slopes of the two curves, the rise is more gradual.

Summary

1. It has been found possible to decrease the violence of the reaction of the ferrous sulfate modification of the Skraup quinoline synthesis by the addition of boric acid.

2. The yield of quinoline has been increased by the addition of the boric acid.

3. A comparison of the vigor of the reactions has been obtained.

THE STEROLS OF ERGOT. II. THE OCCURRENCE OF DIHYDRO-ERGOSTEROL

BY FREDERICK W. HEYL AND ORLO F. SWOAP[1]

RECEIVED JUNE 9, 1930 PUBLISHED SEPTEMBER 5, 1930

Recently[2] we briefly described the preliminary fractionation of "ergosterol" from ergot fat. Crude ergosterol was prepared from an ether solution of the unsaponifiable fraction by precipitation with petroleum ether. We have now studied this ether–petroleum ether filtrate. Originally our expectation was that fungisterol might be found there in such proportion that its isolation would be somewhat more readily accomplished. In this study we have incidentally isolated pure α-dihydro-ergosterol, which was first described by Windaus and Brunken.[3] They report a specific rotation of $-19.3°$, and a melting point of 173–174°. The acetate melts at 180–181° and for $[\alpha]_D$ they found $-21.0°$ Heilbron, Johnstone and Spring[4] report that the melting point of a-dihydro-ergosterol acetate varies from 179–180 to 173°, depending upon the duration of the acetylation process. The rotation, $[a]_{5461}^{21}$, varied from -25.3 to $-30.3°$.

a-Dihydro-ergosterol, isolated from ergot fat, melted at 172.5–175°, gave an acetate melting at 176–177° and for $[\alpha]_D^{26}$ we found − 20.6". The benzoate melted at 153–155° and the color tests agreed with those known for this substance.

This result is what one might expect since Anderson has repeatedly shown that sitosterol is accompanied by dihydrositosterol in corn oil,[5] wheat embryo,[6] and rice bran.[7] Consequently a mixture of very closely related alcohols in various stages of saturation might be anticipated in the unsaponifiable matter of ergot fat.

Experimental

A quantity of petroleum ether-ether filtrates from ergosterol had separated a quantity of crystalline material upon long standing. This was filtered off and lightly washed with petroleum ether. A quantity (74 g.) was fractionally crystallized from ethyl acetate. The top fraction melted at 158.5–160°; intermediate fractions showed a series of melting points of about 121–125°, and the bottom fractions melted below 100°. A further quantity (312 g.) of the crude material was fractionally crystallized in the same way and separated into 33 fractions after an elaborate system of recrystallizations.

Fractions 6, 7 and 8, aggregating about 5 g., showed rotations of —22.5, —22.5 and —19.1°, respectively, and from these, by further elaborate fractional crystallization from alcohol, α-dihydro-ergosterol was isolated. For example, the fractionation of fraction 8 (2.3 g.) yielded the following fractions:

Fraction no.	Weight, g.	M. p., °C.	$[\alpha]_D$
8A	0.45	165–167	−25.0
8B	.14	159–164	−25.4
8C	.24	161–164	−22.66
8D	.08	156–159	−12.4
8E	.15	137–150	− 9.5

Of these, A, B and C were acetylated separately:

Fraction no.	Weight, g.	M. p., °C.	$[\alpha]_D$
Acetate 8A	0.26	171–173	−19.75
8B	.10	169–173	−19.0
8C	.20	167–173	−18.1

8A, 8B and 8C were combined with acetate fraction 7C (m. p. 167–170°; $[\alpha]_D$ −17.0). The acetate was recrystallized several times from ethyl alcohol, when it melted at 176–177°.

Anal. Calcd. for $C_{27}H_{43}OCOCH_3$: C, 81.60; H, 10.87. Found: C, 82.02; H, 10.60.

The above acetate was saponified with 3% methyl alcoholic potash and the recovered alcohol was crystallized three times from methyl alcohol. Pure a-dihydro-ergosterol as leafy needles melting at 172.5–175° and $[\alpha]_D^{26}$ − 20.6 was isolated.

Anal. Calcd. for $C_{27}H_{43}OH$: C, 84.30; H, 11.54. Found: C, 84.52; H, 11.54.

Color Tests of α-Dihydro-ergosterol.—With the Rosenheim trichloro-acetic acid, a

---

[5] Anderson, This Journal, **46**, 1450 (1924).

[6] Anderson and Nabenhauer, ***ibid.***, **46**, 1717 (1924).

[7] Nabenhauer and Anderson, ***ibid.***, **48**, 2972 (1926)

completely negative test resulted. With Salkowski test, the chloroform was colorless and the sulfuric acid layer orange-yellow. With the Liebermann-Burchard test the color transitions were as follows: very slight pink, transitory lavender, deep blue, slowly to green.

α-Dihydro-ergosterol Benzoate.—The alcohol (0.1 g.) was dissolved in pyridine (2 cc.) and 2 drops of benzoyl chloride added. The benzoate precipitated and after long standing was filtered off and recrystallized from alcohol. It melted at 153–155°.

Anal. Calcd. for $C_{27}H_{43}OCOC_6H_5$: C, 83.55; H, 9.90. Found: C, 83.10; H, 10.33.

The benzoate gave the same color reactions described above and in addition gave a positive reaction to the Heilbron and Spring[8] modification of the Tortelli–Jaffe reaction.

Reduction to α-Ergostenol.—Three-tenths of a gram of the acetate was reduced with Adams' platinum oxide catalyst as previously described[9] and a top fraction of α-ergostenol acetate melting at 110–111° was obtained. Upon saponification with 3% methyl alcoholic potash, α-ergostenol melting at 133° was obtained.

Summary

From the unsaponifiable fraction of ergot fat, α-dihydro-ergosterol has been isolated. The alcohol itself melted at 172.5–175° and gave $[\alpha]_D^{26}$ −20.6°. The acetate of α-dihydro-ergosterol melted at 176–177° and the benzoate at 153–155°. The color reactions agree exactly with those described by Windaus and Brunken, and by Heilbron and Spring.

STUDIES RELATING TO ORGANIC GERMANIUM DERIVATIVES. III. DIPHENYL GERMANIUM DIHALIDES AND DIPHENYL GERMANIUM IMINE

BY CHARLES A. KRAUS AND CECIL L. BROWN

RECEIVED JUNE 12, 1930 PUBLISHED SEPTEMBER 5, 1930

I. Introduction

The present is one of a series of papers relating to the chemistry of the typical amphoteric elements. It may be considered that all the elements from the first to the seventh groups inclusive, which have a deficiency of from seven to one electrons with respect to the rare gas type, are amphoteric. The elements that have a deficiency of only one or two electrons are strongly electronegative and their amphoteric tendencies are not marked. On the other hand, those elements that have a deficiency of five, six or seven electrons usually act electropositively and their electronegative characteristics are not pronounced. Amphoteric properties are most marked in the elements of the fourth group, which have a deficiency of four electrons. In the case of carbon, this property is well illustrated by triphenylmethyl. The triphenylmethyl group combines, on the one hand, with negative

---

[8] Heilbron and Spring, *Biochem. J.*, 24, 133 (1930).

[9] Hart, Speer and Heyl, THIS JOURNAL, 52, 2017 (1930).

elements or groups to form compounds that, under certain conditions, exhibit electrolytic properties. On the other hand, the same group combines with the alkali metals to form relatively stable compounds which are typical salts and in which the triphenylmethyl group acts as anion. Triphenylmethyl also exists in the neutral state. In other words, triphenylmethyl exists in three states of oxidation: as a positive group, as a neutral group, and as a negative ion.

While in certain respects carbon is the ideal amphoteric element, in other respects other elements of the fourth group exhibit amphoteric properties more commonly. Previous investigations have shown that the tertiary organic derivatives of tin, whether alkyl or aryl, are uniformly amphoteric.[1] And not only may we obtain univalent amphoteric groups in the case of tin; we may also obtain divalent groups. Thus Kraus and Greer[2] have shown that dimethyl tin acts electropositively toward the halogens, while it also combines with sodium to form a divalent anion. Similar properties have been found in the case of the diphenyl tin group.''

Our knowledge of corresponding groups of germanium and silicon is very limited. In general, the study of these groups is rendered difficult because of the ease with which their halogen derivatives are ammonolyzed. Kraus and Foster,[3] however, have investigated the triphenyl germanium group. Investigations relating to silicon, germanium and boron have been under way in this Laboratory for some years and the results will be published from time to time. The present investigation is specifically directed toward the isolation of diphenyl germanium and the preparation and properties of some of its derivatives. It was found that the diphenyl germanium group lends itself to study less readily than do corresponding derivatives of tin. Furthermore, our knowledge of organic germanium derivatives generally is very limited so that it was found necessary to study many problems relating to source materials.

Among the earlier investigations relating to phenyl germanium derivatives may be mentioned those of Morgan and Drew,[4] who prepared tetraphenyl germanium and some other phenyl derivatives, and Tabern, Orndorff and Dennis: who prepared tetraphenyl germanium as well as other quaternary alkyl and aryl germanium compounds. The work of Kraus and Foster, in this connection, has already been referred to.

In the present investigation, diphenyl germanium dihalides were first prepared and characterized. The action of ammonia and ethylamine on diphenyl germanium dihalides was also studied and, finally, diphenyl

germanium was prepared in the free condition. Its physical properties and chemical reactions were investigated; disodium diphenyl germanide was prepared and octaphenyl germanopropane was synthesized. The two last-named compounds will be described in a succeeding paper.

11. Diphenyl Germanium Dihalides

Method of **Preparation.—Tetraphenyl** germanium served as source material for the preparation of the dihalides. This compound was prepared according to the method of Kraus and Foster[3] and preparative details need not be described here. It was recrystallized from trichloro-ethylene and melted at 230–231° (corr.).

According to Kraus and Foster, tetraphenyl germanium is brominated with considerable difficulty, although they were able to prepare the monobromide by boiling a mixture of the compound with the theoretical amount of bromine in carbon tetrachloride for a considerable period of time. The second phenyl group is substituted even less readily than the first. Preliminary experiments confirmed the observations of Kraus and Foster, but on further study it was found that the rate of bromination is greatly dependent upon the concentration of bromine. On boiling a mixture of **37** g. of tetraphenyl germanium and 15 cc. of bromine in 70 cc. of carbon tetrachloride for ten hours, a fairly satisfactory yield of diphenyl germanium dibromide was obtained. The product, however, was impure, containing some of the monobromide and a smaller proportion of the tribromide. Since completing the present investigation, Tabern, Orndorff and Dennis[5] have shown that tetraphenyl germanium is more readily brominated in ethylene dibromide.

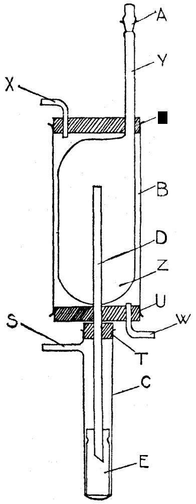

Fig. 1.

In brominating tetraphenyl germanium, a mixture of bromides is in general obtained and separation becomes necessary. An attempt to fractionally distil the bromides did not prove particularly successful. Diphenyl germanium dibromide is not very volatile at 100°, even at a pressure as low as 0.005 mm. Accordingly, it was found more convenient to convert the mixture of bromides to chlorides. The original mixture was separated from residual impurities by vacuum distillation at 150°. The distillate was placed in an evaporating dish, a little alcohol was added and then strong ammonium hydroxide to complete the hydrolysis. The mixture was boiled for some time, in which process most of the phenyl bromide was carried off with the steam. On cooling, a mixture of oxides solidified. The solid mass was separated from the aqueous solution, washed and dried. These oxides were then converted to chlorides by heating with concentrated hydrochloric acid. The desired product settled to the bottom as a heavy liquid which was extracted with benzene. After removal of most of the solvent, the product was introduced into a special still and fractionated under reduced pressure.

The distillation apparatus consisted of a pyrex tube **Z**, which was provided with a steam jacket B, the tubes X and W serving as inlet and outlet tubes, respectively. The liquid to be distilled was introduced through the tube Y, which was provided with a ground stopper **A.** The vapors from the liquid passed down through the re-entrant tube D. The condensate was collected in a small bottle E, which was contained in a wide test-tube C. This tube was attached to the distillation apparatus by means of a rubber stopper T. The side tube S, attached to the test-tube, was connected to a vacuum pump, a McLeod gage being connected in the exhaust line.

Diphenyl germanium dichloride distils readily at 100° under a pressure of 0.005 mm. The yield of dichloride, based on the weight of original tetraphenyl germanium used, ranged from 40 to 60%. The purity was tested by analysis.

Diphenyl Germanium Dichloride.—Diphenyl germanium dichloride is a colorless liquid. According to Sherman[6] it freezes at lower temperatures and melts at 9°. Its density is greater than that of water. It is readily soluble in ordinary organic solvents. It is slightly hydrolyzed in moist air, more rapidly in water and alcohol, and still more rapidly in alkaline solution.

The compound was analyzed for both germanium and chlorine. For the halogen determinations, from 0.2- to 0.3-g. samples were treated with dilute ammonium hydroxide, the mixture being stirred until the oxide was reduced to fine powder. It was then thrown onto a filter and the oxide was thoroughly washed. The ammoniacal filtrate was acidified with nitric acid and the chlorine was precipitated with silver nitrate and weighed as silver chloride.

Anal. Subs., 0.1836, 0.2460, 0.2721: AgCl, 0.1758, 0.2375, 0.2639. Calcd. for $(C_6H_5)_2GeCl_2$: Cl, 23.83. Found: Cl, 23.68, 23.88, 23.99, mean, 23.85.

The germanium was determined by a modification of the Krause method.[7] Samples of the dichloride were introduced into a pyrex tube (22 × 2.5 cm.) which had been heated to constant weight. About 5 cc. of fuming sulfuric acid was added with shaking, followed by 5 cc. of fuming nitric acid, which was added slowly. The mixture was then boiled for about twenty hours. Whenever the nitric acid content became low, as was indicated by the color of the fumes, more was added to the cooled solution. When oxidation was thought to be complete, the acids were boiled off. If the organic material was incompletely oxidized, a black deposit was formed on the walls of the tube as the residue dried up. In that case, more nitric acid was added and the sample was boiled for some hours longer. Kemoval of the acids was facilitated by drawing a gentle current of air through a glass tube, the end of which was located midway along the axis of the analysis tube. Certain of the phenyl germanium derivatives are oxidized with extreme difficulty. The method here described is effective in all cases provided that the process is continued for a sufficient length of time. After removing the acid, the oxide was ignited at a dull red heat until constant weight was reached.

Anal. Subs., 0.3068, 0.3161, 0.1940: GeO_2, 0.1085, 0.1115, 0.0677. Calcd. for $(C_6H_5)_2GeCl_2$: Ge, 24.39. Pound: Ge, 24.54, 24.48, 24.22; mean, 24.40.

Diphenyl Germanium Dibromide.—Diphenyl germanium dichloride of known purity was hydrolyzed and the resulting oxide was converted to the dibromide by heating with strong hydrobromic acid. The oily liquid was extracted with benzene, the solvent was removed and the dibromide distilled in *vacuo* at 120° under a pressure of 0.007 mm. The properties of the dibromide correspond closely to those of the dichloride except that it is markedly less volatile.

The bromine content of the compound was determined by hydrolyzing a known sample of the compound with a weak solution of sodium hydroxide, separating the sodium bromide solution from the solid diphenyl germanium dibromide and precipitating the bromine as silver bromide. The germanium content was determined by the method already described in connection with the analysis of the dichloride.

Anal. Subs., 0.3542, 0.4068: AgBr, 0.3434, 0.3940. Calcd. for $(C_6H_5)_2GeBr_2$: Br, 41.35. Pound: Br, 41.26, 41.22; mean, 41.24. Subs., 0.2275, 0.2117; GeO_2, 0.0620, 0.0572. Calcd.: Ge, 18.78. Pound: Ge, 18.91, 18.75; mean, 18.83.

---

[6] Unpublished observations by C. S. Sherman in this Laboratory.

[7] Krause, *Ber.*, 55, 896 (1922); Kraus and Bullard, THIS JOURNAL, 51, 3606 (1929).

Diphenyl Germanium Difluoride.—The difluoride was prepared by treating diphenyl germanium oxide (resulting from hydrolysis of the chloride) with hydrofluoric acid. Most of the excess acid was evaporated and the difluoride was extracted with benzene. After removal of the solvent, the fluoride was distilled in *vacuo* at 100° at a pressure of 0.007 mm. The germanium content of the difluoride was determined by the method already described.

Anal. Subs., 0.1490, 0.1471: GeO_2, 0.0585, 0.0576. Calcd. for $(C_6H_5)_2GeF_2$: Ge, 27.43. Found: Ge, 27.25, 27.18; mean, 27.22.

The fluorine was determined by the method of Starck.[8] The difluoride was hydrolyzed with sodium hydroxide and the solution separated from the resulting oxide by filtration. To the filtrate was added sixteen drops of concentrated hydrochloric acid, the solution being warmed to 40°. Methyl orange was then added and the solution acidified with nitric acid, allowing three drops in excess. Ten drops of glacial acetic acid and 25 cc. of a filtered solution (10%) of lead acetate containing 1% of acetic acid were added under stirring. Fluorine was precipitated as lead chlorofluoride. The precipitate was allowed to stand overnight, when it was filtered and weighed in a Gooch crucible.

Anal. Subs., 0.2983, 0.2944: PbClF, 0.5273, 0.5731. Calcd. for $(C_6H_5)_2GeF_2$: F, 14.36. Pound: F, 13.93, 14.04; mean, 13.98.

Diphenyl germanium difluoride is a colorless liquid which is decidedly more volatile than the corresponding chloride. Of the three dihalides studied, it is the most sensitive toward moisture. On standing in the air but a short time, a film of oxide is formed on the surface of the liquid. This layer protects the remainder of the liquid against further hydrolysis. It is readily soluble in the common organic solvents.

III. Diphenyl Germanium Oxide

Morgan and Drew[4] have prepared diphenyl germanium oxide by hydrolyzing mixtures of bromides containing dibromide. From this mixture they separated a partially dehydrated hydroxide and a complex oxide that melted at 149 and 218°, respectively. It seemed worth while to examine the oxide obtained on hydrolyzing a pure dihalide. Accordingly, a quantity of the dichloride was hydrolyzed by the method already described. After drying, it was analyzed for germanium.

Anal. Subs., 0.1121, 0.1709: GeO_2, 0.0483, 0.0735. Calcd. for $(C_6H_5)_2GeO$: Ge, 29.92. Found: Ge, 29.90, 29.85; mean, 29.88.

Properties.—The oxide is a white powder which is practically insoluble in organic liquids. Of various samples tested, none was found to have a definite melting point. By extracting with boiling benzene, a minute quantity of oxide was obtained which melted between 133 and 150". By means of boiling alcohol, small quantities were obtained that melted between 140 and 185° and 149 and 300°. The variation of the melting point indicates that, when the dihalides are hydrolyzed, a mixture of complex oxides is produced. It is doubtful whether the simple oxide $(C_6H_5)_2GeO$ can be obtained. A similar mixture of oxides is obtained by hydrolysis of diphenyl germanium imine.

IV. Action of Ammonia on Diphenyl Germanium Dichloride

Kraus and Wooster[9] have shown that triphenyl germanium halides are ammonolyzed by potassium amide in liquid ammonia. It was anticipated that the diphenyl germanium dihalides would be ammonolyzed by liquid ammonia. In preliminary ex-

[9] Kraus and Wooster, THIS JOURNAL, 52, 372 (1930).

periments, weighed samples of diphenyl germanium dichloride were sealed in fragile glass capsules which were introduced into one leg of a weighed two-legged reaction tube. This tube was provided with a stopcock through which it was evacuated prior to weighing, and through which ammonia could be introduced as desired. After evacuation, the bulb was broken, the tube was immersed in boiling ammonia and ammonia was condensed upon the dichloride. The reaction mixture was allowed to stand for several hours, after which the solvent was allowed to evaporate. The tube was then again exhausted and weighed. The increase in weight of the tube gave approximately the amount of ammonia added on ammonolysis. The results were as follows: wt. of $(C_6H_5)_2GeCl_2$, 0.2269, 0.2460, 0.2810; gain in wt. as NH_3, 0.0375, 0.0429, 0.0483; moles of NH_3 per mole of dichloride, 2.90, 3.05, 3.00; mean, 2.98. These data indicate that ammonolysis occurs according to the equation

$$(C_6H_5)_2GeCl_2 + 3NH_3 = (C_6H_5)_2GeNH + 2NH_4Cl \qquad (1)$$

In order to separate the organic material from the ammonium chloride, dry benzene was condensed on the product of reaction and the solution was decanted into the second leg of the reaction tube. By repeated distillation and decantation, complete separation of the ammonium chloride was effected. Most of the benzene was then removed by means of an aspirator pump and the last traces by means of a high vacuum pump. Dry nitrogen was introduced and the two legs were separated by sealing off the connecting tube with a blowpipe. The ammonium chloride left behind in the first leg of the reaction tube was analyzed for chlorine. The tube containing the salt was opened, the material was dissolved in water and the halogen determined as silver chloride in the usual way. The results follow, the percentages of chlorine being based on the weight of diphenyl germanium dichloride originally taken.

Anal. Subs., 0.2269, 0.2460, 0.2810: AgCl, 0.2202, 0.2375, 0.2371. Calcd. for $(C_6H_5)_2GeCl_2$: Cl, 23.83. Found: Cl, 24.00, 23.88, 24.04; mean, 23.94.

These results show that the ammonolysis of the dichloride was complete and in accord with Equation 1. Since the weight of the original products of the reaction indicated that three moles of ammonia were involved, the third molecule must have been combined with germanium as an imine group.

Diphenyl Germanium Imine.—The leg containing the soluble product of the reaction was evacuated and freshly distilled water was introduced. A white deposit gradually replaced the colorless viscous liquid in the tube. After standing for twenty-four hours, the stopcock of the tube was connected with a condenser and the liquid contents were distilled and collected in a flask. The distillate was titrated against standard acid.

Anal. $(C_6H_5)_2GeCl_2$, 0.2460, 0.2810: calcd. wt. of imine, 0.1998, 0.2282: cc. of 0.03043 N HCl used, 27.6, 30.7; N, 0.01176, 0.01309. Calcd. for $(C_6H_5)_2GeNH$: N, 5.80. Found: N, 5.89, 5.73; mean, 5.81.

The analyses show that one mole of ammonia is formed on hydrolysis of the imine. The white solid resulting on the hydrolysis of the imine was shown by analysis to be diphenyl germanium oxide.

Anal. Subs., 0.1709, 0.1121: GeO_2, 0.0735, 0.0483. Calcd. for $(C_6H_5)_2GeO$: Ge, 29.92. Found: Ge, 29.85, 29.90; mean, 29.88.

The imine is a colorless liquid which is extremely viscous at ordinary temperatures but becomes markedly more fluid at higher temperatures. It is readily soluble in ordinary organic solvents and is hydrolyzed with extreme ease.

Summary

Diphenyl germanium dibromide was prepared by the direct bromination of tetraphenyl germanium in boiling carbon tetrachloride. The mixture of

bromides so obtained was converted to oxides and in turn converted to the corresponding chlorides. The dichloride was obtained from this mixture by fractional distillation. Pure dibromide and difluoride were prepared by converting pure dichloride to its oxide and treating with hydrobromic or hydrofluoric acid.

The three dihalides are liquids at ordinary temperatures and are readily soluble in the common organic solvents. They may be distilled under pressures below 0.01 mm. at temperatures between 100 and 150". The fluoride is markedly sensitive to moisture.

Diphenyl germanium imine was prepared by the action of liquid ammonia on diphenyl germanium dichloride. It is a highly viscous liquid at ordinary temperatures. It is readily soluble in the common organic solvents and is hydrolyzed with extreme ease.

QUINAZOLINES. I. THE INTERACTION OF 2,4-DICHLOROQUINAZOLINE WITH SODIUM ALCOHOLATES AND SODIUM PHENATES WITH THE REPLACEMENT OF ONE HALOGEN TO FORM HALOGEN-OXYGEN ETHERS

BY N. A. LANGE, W. E. ROUSH AND H. J. ASBECK

RECEIVED JUNE 13, 1930 PUBLISHED SEPTEMBER 5, 1930

Since evodiamine and rutaecarpine, the alkaloids of *Evodia rutaecarpa*, have been shown to be derivatives of quinazolone[1] and since the quaternary salts of a few quinazolines have been found to have a lowering effect on the blood pressure,[2] it appears likely that other compounds of the quinazoline group might possess some desirable medicinal properties. It was during the course of a research now in progress in this Laboratory, the purpose of which was the preparation of a series of quinazoline derivatives for subsequent pharmacological testing,[3] that several anomalous compounds were obtained and a further investigation of these compounds was made because the quinazolines have an intrinsic interest of their own.

When 2,4-dichloroquinazoline (I) in alcohol is treated with sodium ethylate both halogens are replaced by ethoxy groups with the formation of 2,4-diethoxyquinazoline (V).[4] In attempting to prepare a similar ether of quinazoline with the phenolate of resorcinol in alcohol, several compounds were isolated from the reaction product which were found to differ from the expected ether. When phenol was substituted for resorcinol, it

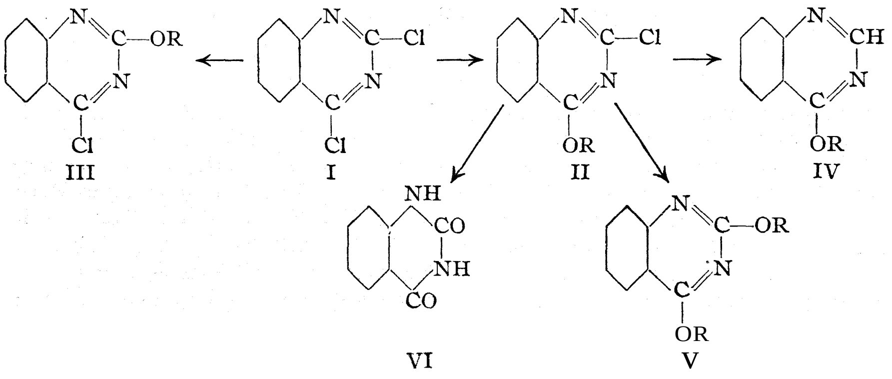
[3] The writers are indebted to Professor Marston Taylor Rogert for his suggestion that members of this group of compounds be prepared with this idea in mind.

[4] Aht, J. *prakt. Chem.*, [2] 39, 149 (1889).

was found that one of the reaction products was identical with one obtained when resorcinol was used. On further investigation by chemical analysis, molecular weight determination and chemical properties, the compound was found to be the monochloro-ethoxy derivative of quinazoline (II or III). That a compound with the formula II or III is formed is also shown by the fact that when it is treated with sodium ethylate in ethyl alcohol it yields the diethoxy derivative of quinazoline mentioned above. From this it is evident that one of the two chlorine atoms in dichloroquinazoline is more labile than the other. To establish the position of the unreacted halogen and thus decide whether the structural formula for the compound is best expressed by II or by III, an attempt was made to hydrolyze off the remaining chlorine atom by gently heating the chloro-ethoxy derivative with water. These attempts were not successful as either no hydrolysis took place after a short time or after continued heating both the chlorine atom and the ethoxy group were removed yielding benzoylene urea. The replacement of the halogen by hydrogen by treatment of the Grignard reagent with water was not successful, inasmuch as it was found impossible to bring about the formation of an RMgCl compound with the chloro-ethoxyquinazoline and magnesium. Nearly all of the original chloro-ethoxy derivative was recovered unchanged when the attempted reduction was carried out with (a) sodium amalgam and ether saturated with water, (b) sodium and ethyl alcohol, (c) sodium and ether saturated with water, (d) sodium and amyl alcohol, or (e) zinc, sodium hydroxide and ethyl alcohol; however, when reduced with (f) sodium and methyl alcohol in ether or (g) with zinc and acetic acid in ethyl alcohol, it yielded a product which was found to be identical with the 4-ethoxyquinazoline (IV) previously prepared by Bogert and May.[5] From this it is evident that the structure of the chloro-ethoxy derivative is best expressed by formula II and that the chlorine atom on postion 4 is more reactive than



In compound II, $R = CH_3, C_2H_5, C_6H_5$ or $m\text{-}C_6H_4OH$.

---

[5] Bogert and May, THIS JOURNAL, 31,510 (1909).

the chlorine atom on position 2; that groups attached to carbon atom 4 are more labile than those on carbon atom 2 has been observed previously in the case of 4-methoxyquinazoline, which is easily hydrolyzed to 4-quinazolone, whereas 2-methoxyquinazoline required heating with concentrated hydrochloric acid in a sealed tube at 110–120° for one and one-half hours for a similar removal of the alkoxy group[6] and also in the greater ease with which the halogen is removed by hydrolysis from 4-chloroquinazoline as compared with the removal of halogen from 2-chloroquinazoline.[6]

In a similar manner it was found that it is possible to obtain the monochloromethoxyquinazoline. The monochloro-alkoxy derivatives are fairly soluble in petroleum ether; when the original reaction mixture in their preparation is recrystallized from this solvent, varying amounts of an insoluble by-product are obtained which consists almost entirely of the analogous monochlorophenoxy derivative and by varying the amount of phenol used in the reaction the yield of the chlorophenoxy derivative can be increased at the expense of the chloro-alkoxy derivative.

The reduction product of the chloromethoxy derivative was a light yellow oil with a pleasant odor, which did not crystallize on standing for a week in an ice box; whether it would have crystallized on longer standing is not known. However, the oil had characteristics which were the same as those given by Bogert and May[6] for 4-methoxyquinazoline prepared from 4-chloroquinazoline. When the chloromethoxy derivative is treated with sodium methylate in methyl alcohol it gives 2,4-dimethoxyquinazoline.[4]

These reactions for the replacement of but one of the two halogens by means of the presence of phenol appear to offer interesting possibilities in the case of quinazolines for the synthesis of mixed ethers and other similar compounds. Preliminary experiments have shown that this is possible and it is hoped to present these results in a later communication. The possibility of using phenol to repress the activity of the less reactive of two halogens in other types of compounds is also suggested.

Experimental Part

Preparation of 2,4-Dichloroquinazoline, $\overline{\mathrm{N{=}CClC_6H_4N{=}C}}\mathrm{Cl}$ (I).[6,7]—In an acetylating flask were placed 15 g. of benzoylene urea (2,4-diketotetrahydroquinazoline),[8] 40 g. of phosphorus pentachloride and 20 cc. of phosphorus oxychloride and the mixture was refluxed on an oil-bath at 125° for about four hours. The clear brown liquid which results was poured slowly with stirring into 600 cc. of finely crushed ice. The precipitated dichloroquinazoline was immediately filtered off on a Büchner funnel, holding the remaining ice back in the beaker with a stirring rod. The precipitate was thoroughly pressed on the funnel, the aqueous filtrate was discarded and the residue dissolved in

about 500 cc. of ether, using 50-cc. portions of ether at a time and filtering through the same funnel; a small amount of insoluble material remained and was discarded. The combined ether solutions were washed in a separatory funnel, first with dilute aqueous sodium carbonate and then with water. After drying the ether solution overnight with calcium chloride, the ether was removed by distillation from a water-bath, suction being applied at the end of the distillation to remove the last traces of ether. This product (12.4 g.) which remained in the distillation flask was slightly yellow but was found to be sufficiently pure for the syntheses described below. To obtain a very pure product it was dissolved in the minimum amount of boiling toluene, filtered hot, cooled, the crystals filtered with suction and washed with petroleum ether, in which it is insoluble; using the same quantities as above about 6 g. of recrystallized, colorless material was obtained; a further small amount was obtained by adding petroleum ether to the mother liquor; m. p. 120°. The compound must be used shortly after preparation as it gradually decomposes even when protected in a desiccator.

Preparation **of 2-Chloro-4-ethoxyquinazoline,** $\overline{\mathrm{N{=}COC_2H_5C_6H_4N{=}C}}\mathrm{Cl}$ (II).—To 50 cc. of absolute ethyl alcohol in a small flask was added 0.7 g. of sodium, keeping the solution cool; when all of the sodium had reacted, 1.4 g. of phenol was added and then 3 g. of dichloroquinazoline slowly with stirring. The mixture was heated just to boiling and allowed to stand at room temperature overnight; it was then poured into 500 cc. of cold water, where it coagulated in fifteen to twenty minutes; the precipitate was filtered with suction, pressed thoroughly on the filter and recrystallized from petroleum ether, yielding 2.3 g. of colorless crystals; m. p. 92° (corr.). It is readily soluble in benzene, ether, carbon tetrachloride or acetone, fairly soluble in petroleum ether or alcohol, crystallizing well from the latter, and insoluble in water. When subjected to steam distillation a part of the compound volatilized into the distillate; the balance because of hydrolysis to benzoylene urea remained as a non-volatile residue. To determine the best proportions of sodium and phenol, the preparation was carried out as above in 50 cc. of alcohol with 2.5-g. portions of dichloroquinazoline; 0.5 g. of sodium and 2 g. of phenol gave 1 g. of product; 0.5 g. of sodium and 1 g. of phenol gave 2.5 g. of product; 1 g. of sodium and 4 g. of phenol gave 0.8 g. of product and 2.4 g. of chlorophenoxyquinazoline, which is insoluble in petroleum ether and which is described below; 0.5 g. of sodium and 4 g. of phenol gave 0.4 g. of product and 2.1 g. of chlorophenoxyquinazoline. Molecular weight determinations by depression of the freezing point were made with naphthalene as the solvent; the values of 227 and 229 were obtained; the calculated value is 208.5.

Anal. Calcd. for $C_{10}H_9ON_2Cl$: C, 57.55; H, 4.35; N, 13.4; Cl, 17.0. Found: C, 58.01; H, 4.40; N, 13.5; Cl, 17.1.

Preparation **of 2-Chloro-4-methoxyquinazoline,** $\overline{\mathrm{N{=}COCH_3C_6H_4N{=}C}}\mathrm{Cl}$ (II).—This compound was prepared in a methyl alcohol solution in a manner similar to the preparation of the analogous chloro-ethoxy derivative as described above; 2.5 g. of product after recrystallization from petroleum ether was obtained from 0.7 g. of sodium, 50 cc. of methyl alcohol, 1.4 g. of phenol and 3 g. of dichloroquinazoline; it forms colorless crystals from petroleum ether or alcohol; m. p. 99–100° (corr.). It is readily soluble in benzene, ether, carbon tetrachloride or acetone, fairly soluble in petroleum ether, methyl alcohol or ethyl alcohol, and insoluble in water; it is volatile with steam but with partial decomposition into the non-volatile benzoylene urea. A molecular weight determination by the Rast method[9] using camphor for the solvent gave a value of 191; the calculated molecular weight is 194.5.

---

[9] Rast, *Ber.*, 55, 1051, 3727 (1922).

Anal. Calcd. for $C_9H_7ON_2Cl$: C, 55.52; H, 3.63; Cl, 18.2. Found: C, 56.28; H, 3.79; Cl, 18.4.

Preparation of **2-Chloro-4-phenoxyquinazoline,** $\overline{N=COC_6H_5C_6H_4N=C}Cl$ **(II).**—This compound was obtained by allowing 0.95 g. of sodium to react completely with an excess of molten phenol; then 8 g. of powdered dichloroquinazoline was mixed with the solid phenol–sodium phenate, which gradually liquefied during the mixing; after standing overnight the reaction mixture was poured into 700 cc. of cold water, when a viscous oil separated; this oil solidified and became granular after the aqueous solution was made slightly alkaline with sodium hydroxide; the solid residue was removed by filtration, washed with water and recrystallized from alcohol; 4.5 g. of colorless crystals was obtained; 2.1 g. of this compound was also obtained from the interaction of 0.5 g. of sodium, 4 g. of phenol and 2.5 g. of dichloroquinazoline in 50 cc. of ethyl alcohol, as described under the preparation of the chloro-ethoxy derivative. The compound is fairly soluble in ethyl alcohol, methyl alcohol, acetone, benzene or ethyl acetate, slightly soluble in ether or chloroform, insoluble in petroleum ether or water; m. p. 121° (corr.).

Anal. Calcd. for $C_{14}H_9ON_2Cl$: Cl, 13.8. Found: Cl, 13.9.

Preparation of **2-Chloro-4-resorcinoxyquinazoline,** $\overline{N=C(OC_6H_4OH)C_6H_4N=C}Cl$ **(II).**—Fifty cc. of absolute ethyl alcohol was treated with 2.5 g. of sodium; after all of the sodium had reacted, 16 g. of resorcinol was added and then 9 g. of dichloroquinazoline was added slowly in small portions during three hours; after standing overnight, the brown colored solution was poured into one liter of water, the mixture made neutral to litmus, the precipitate allowed to coagulate, filtered, washed with water and dried on a suction filter. The air-dried material (9.5 g.) was extracted with boiling petroleum ether, which removed 2.5 g. of chloro-ethoxyquinazoline; the residue of 7 g. was almost completely soluble in boiling alcohol, from which colorless crystals of 2-chloro-4-resorcinoxyquinazoline separated on cooling; m. p. 171–172° (corr.). The solubilities of this compound are like those of the corresponding chlorophenoxy derivative described above.

Anal. Calcd. for $C_{14}H_9O_2N_2Cl$: C, 61.65; H, 3.33. Found: C, 61.78; H, 3.46.

Preparation of **2,4-Diethoxyquinazoline (V).**—Thirty cc. of absolute ethyl alcohol was treated with 0.3 g. of sodium; after all of the sodium had reacted, 2 g. of chloroethoxyquinazoline was added; the solution was warmed gently for five to ten minutes and allowed to stand at room temperature overnight, when about 0.5 g. of sodium chloride separated and was removed by filtration. The filtrate was treated with water, which precipitated 1.8 g. of diethoxyquinazoline; after filtering and drying, it was recrystallized from alcohol, yielding colorless crystals; m. p. 55° (corr.). Although this melting point is 4° higher than that of the diethoxyquinazoline as reported by Bogert and May,[5] there is no doubt as to the identity of the two products, since a sample of the material obtained by their method of preparation also showed a melting point of 55° (corr.) and when the two preparations were mixed the melting point remained unchanged; examination of the two products under a polarizing microscope showed the same angle of extinction in each case.

Anal. Calcd. for $C_{12}H_{14}O_2N_2$: C, 66.02; H, 6.47. Found: C, 66.33; H, 6.62.

Preparation of **2,4-Dimethoxyquinazoline (V).**—This compound was prepared by the interaction of chloromethoxyquinazoline and sodium methylate in methyl alcohol in the same manner as the diethoxy derivative described above. Three grams of chloromethoxyquinazoline and 0.4 g. of sodium in 30 cc. of absolute methyl alcohol gave about 0.9 g. of sodium chloride and 2.7 g. of the dimethoxy derivative, which was recrystallized from alcohol; m. p. 75° (corr.); Bogert and Scatchard[7,8] reported a melting point of 74° for dimethoxyquinazoline but a sample prepared by their method when carefully purified was found to melt at 75°; an examination under a polarizing microscope and a mixed melting point determination of the two products proved their identity.

Anal. Calcd. for $C_{10}H_{10}O_2N_2$: C, 63.12; H, 5.30. Found: C, 63.25; H. 5.38.

Preparation of **4-Ethoxyquinazoline** (IV).—To 6 g. of chloro-ethoxyquinazoline (1 mol) dissolved in 50 cc. of absolute ether were added 0.67 g. of sodium (1 mol) in small pieces and then 0.93 g. methyl alcohol (1 mol); the sodium gradually reacted with the alcohol and after three days at room temperature the sodium chloride was removed by filtration, the ether removed from the filtrate by distillation from a water-bath, suction being applied at the end of the distillation; the light yellow oil which remained was poured on a watch glass and partly solidified on standing for a week in an ice box; the colorless crystals (1 g.) were filtered with suction, pressed between filter paper to remove adhering oil and were recrystallized with much difficulty from alcohol; m. p. 45–48". A better yield of the same product was obtained when 3.6 g. of chloro-ethoxyquinazoline was dissolved in 150 cc. of alcohol, 15 g. of zinc dust added and 25 cc. of glacial acetic acid added slowly with mechanical stirring; after standing at room temperature for twenty-four hours, the mixture was filtered to remove the excess of zinc and the filtrate poured into 500 cc. of cold water; the unreduced chloro-ethoxyquinazoline which precipitated was collected and recrystallized for recovery. The dilute alcoholic solution was made slightly basic by the addition of sufficient sodium hydroxide solution, which precipitated zinc hydroxide; the filtered solution (about 600 cc.) was then extracted with ether, the extract dried overnight with calcium chloride and the ether removed by distillation from a water-bath. The yellow oil which remained was distilled with steam the distillate extracted with ether, the ether solution dried with calcium chloride and the ether removed by distillation on a water-bath, removing the last traces of ether under a vacuum. As soon as the residual oil with a pleasant odor was poured on a watch glass it began to crystallize until the mass was almost completely solid; the material thus obtained was pressed between filter paper to remove traces of adhering oil and had a melting point of 46–48" (corr.); mixed with a known sample of 4-ethoxyquinazoline (m. p. 47–49°) prepared by the method of Bogert and May,[5] the mixture showed a melting point of 47–48°. Without further purification, this material obtained by the reduction with zinc and acetic acid was used for analysis.

Anal. Calcd. for $C_{10}H_{10}ON_2$: C, 68.93; H, 5.79. Found: C, 69.07; H, 5.81.

Reduction of 2-Chloro-4-methoxyquinazoline and **2-Chloro-4-phenoxyquinazoline.**—These reductions were made in alcohol with zinc and acetic acid as described above under the reduction of the analogous chloro-ethoxy derivative and in each case gave yellow-brown oils which did not crystallize on standing in a cold place; the product from the chloromethoxy derivative had a pleasant odor, whereas that from the chlorophenoxy derivative had a very disagreeable odor. Material of sufficient purity for analysis was not obtained.

Preparation of Benzoylene Urea (VI) by Hydrolysis **of Chloromethoxyquinazoline.**—Three grams of chloromethoxyquinazoline was suspended in 150 cc. of distilled water, warmed on the steam-bath for five hours, filtered, the insoluble portion washed with water, then with alcohol and dried; it was a white product which did not melt below 300°; it was submitted to analysis without further purification. The filtrate above gave a distinct test for chlorides and had a slight odor of methyl anthranilate.

Anal. Calcd. for $C_8H_6O_2N_2$: C, 59.22; H, 3.73. Found: C, 59.49; H, 3.87. Hydrolysis of chloro-ethoxyquinazoline similarly gave the same product.

Summary

A study has been made of the interaction of 2,4-dichloroquinazoline with sodium alcoholates in the presence of phenol and resorcinol and it was

found possible to replace but one of the two halogen atoms with an OR group (where R is either an alkyl or an aryl radical). The structure of the resulting compounds has been determined and shows that the halogen attached to the carbon atom at position 4 is more reactive than the halogen atom on carbon atom 2. Recrystallization of dichloroquinazoline from toluene or toluene plus petroleum ether yields a very pure product; these solvents are superior to benzene (which had been previously used in the preparation) because of the greater temperature coefficient of solubility. The following new compounds have been prepared: 2-chloro-4-methoxyquinazoline, **2-chloro-4-ethoxyquinazoline,** 2-chloro-4-phenoxyquinazoline and 2-chloro-4-resorcinoxyquinazoline.

THE PREPARATION OF CERTAIN GAMMA-LACTONES

BY WILLIAM L. NELSON AND LEONARD H. CRETCHER

RECEIVED JUNE 23, 1930 PUBLISHED SEPTEMBER 5, 1930

Gamma-butyrolactone was prepared by a method which involves (1) the condensation of the sodium salt of ethyl malonate with β-chloro-ethylvinyl ether to form ethyl vinyloxyethylmalonate,[1] (2) saponification of the ester, (3) liberation of the free acid with simultaneous hydrolysis and liberation of acetaldehyde to form β-hydroxyethylmalonic acid, (4) pyrogenic decomposition to the lactone of y-hydroxybutyric acid. The alpha-substituted ethyl and propyl butyrolactones were prepared in the same manner from the corresponding alkyl malonic esters.

Fittig and Chanlarow[2] prepared the a-ethyl derivative by hydrolysis of ethyl β-hydroxyethylacetoacetate. The unsubstituted lactone has been prepared by a variety of methods.[3]

It is interesting to note that in Pittig's description of a-ethyl butyrolactone he stated that a clear, approximately saturated water solution of the lactone on warming in the hand became clouded and remained so when placed in hot water until a temperature between 80–90° was reached, whereupon the second phase disappeared to reappear upon slight lowering of the temperature. When cooled more strongly, the solution again became clear. We have repeated Fittig's experiment with the same result. So far as the authors are aware, this is the first mention in the literature of a

system having both upper and lower consolute points. This fact **has** been overlooked by those who have investigated closed solubility curves.[4]

The present authors have found that the system α-propyl-γ-butyrolactone–water has no determinable lower consolute temperature because of the separation of water in the solid phase before the lower critical temperature is reached.

Experimental Part

Preparation of **γ-Butyrolactone.**—44.5 g. of ethyl vinyloxyethylmalonate was added to a solution of 43 g. of potassium hydroxide in 35 cc. of water. The mixture was slowly warmed, with continual agitation, in a water-bath. At about 30° the saponification took place, the temperature going spontaneously to the boiling point of alcohol. After the vigorous reaction was over, the solution was heated on a water-bath for thirty minutes. After cooling 140 cc. of 1:1 hydrochloric acid was added and the solution evaporated to dryness under reduced pressure. The solid mass was cooled and extracted several times with anhydrous ether. The ether was removed by distillation and the distilling flask placed in such a position that the side-tube was inclined slightly upward. A short air condenser was attached to the side-tube and the flask was provided with a thermometer immersed in the solution. Water was removed by cautious heating over a direct flame.

The temperature was raised to 180° to decompose the dibasic acid and the product was then distilled. The yield of lactone boiling at 201–205° was 72% of the theoretical.

Brucine Salt of **γ-Butyrolacetone.**—The brucine salt of the unsubstituted hydroxybutyric acid offered no difficulties in purification. The salts of the ethyl and propyl substituted acids were not obtained in pure condition and will not be described.

The brucine salt was prepared by heating a water solution of the lactone with an excess of the alkaloid. The excess brucine was extracted with chloroform, the solution filtered through "Nuchar" and evaporated to dryness under reduced pressure. The salt was twice dissolved in 95% alcohol, cooled and precipitated with ether. It was then dried to constant weight, *in vacuo*, over phosphorus pentoxide. The compound softened at 80° and melted at 147–148°. It is very hygroscopic.

Anal. Calcd. for $C_{27}H_{34}O_7N_2$: N, 5.62. Found: N, 588, 562.

Optical rotation. 0.2579 g. in 10.08 cc. of aqueous solution in a 1-dm. tube gave $\alpha = -0.69''$; $[\alpha]^{25}_{D}$ $-26.97°$.

Sodium **γ-Hydroxybutyrate.**—It was stated by Marvel and Birkhimer[3g] that on neutralization of the lactone of γ-hydroxybutyric acid with sodium hydroxide a 40% yield of the sodium salt was obtained. In order to determine, if possible, the cause of their low yield of salt, we neutralized the lactone, with results as follows: the calculated amount of *N* sodium hydroxide was added to a hot aqueous solution of 1.509 g. of the lactone. The ring was easily opened, as the pink color due to a drop of phenolphthalein disappeared after several minutes. The solution was evaporated under reduced pressure to dryness and the residue dissolved in hot alcohol. On cooling part of the salt crystallized. The precipitation was completed by addition of ether. The product, dried over phosphorus pentoxide, weighed 1.960 g., corresponding to a yield of 89% of the theoretical.

Anal. Subs., 0.1644: Na_2SO_4, 0.0930. Calcd. for $C_4H_7O_3Na$: Na, 18.27. Found: Na, 18.32.

---

[4] Cf. Cox, Nelson and Cretcher, THIS JOURNAL, 49,1080 (1927), for references to the literature of this subject.

When an excess of alkali was used for neutralization of the lactone a substance was formed which was not the sodium salt of the hydroxy acid. This substance was insoluble in alcohol or water.

α-Ethyl γ-Butyrolactone.—This compound was prepared from ethyl, ethylvinyloxyethyl malonate[6] in the same manner as y-butyrolactone except that the saponification was conducted in alcoholic solution. From 12 g. of the malonic ester 2.8 g. of product was obtained boiling at 214–218°. The yield was 59% of the theoretical.

α-Propyl-γ-butyrolactone was prepared as above from ethyl propylvinyloxyethyl malonate.[5] The product boiled at 230–235°; d_4^{25} 1.008. The yield was 63% of the theoretical.

Anal. Calcd. for $C_7H_{12}O_2$: C, 65.57; H, 9.45. Found: C, 65.23; H, 9.34.

Neutralization equivalent. Calcd.: 128.1. Found: 127.8.

Summary

A method is described for the preparation of y-butyrolactone and its a-alkyl derivatives.

SYNTHESES IN THE PHENANTHRENE SERIES.
I. ACETYLPHENANTHRENES[1]

BY ERICH MOSETTIG AND JACOB VAN DE KAMP

RECEIVED JUNE 23, 1930 PUBLISHED SEPTEMBER 5, 1930

The preparation of 9-acetylphenanthrene was described by Willgerodt and Albert[2] in 1911. These authors obtained the substance by the Friedel–Crafts reaction, and describe it as fluorescent leaflets of melting point 123°. Analysis and the formation of an oxime and a phenylhydrazone showed the compound to be a phenanthryl methyl ketone. Oxidation with chromic acid led exclusively to 9,10-phenanthrenequinone, showing that the acetyl group occupied the 9-position on the phenanthrene nucleus. The authors do not mention the yields obtained, but from their description it is to be gathered that the ketone is very difficult to obtain in a pure state because of accompanying oils and tarry material.

In attempting to prepare 9-acetylphenanthrene according to Willgerodt's directions, we have obtained results differing considerably from those mentioned above. Acetylation of phenanthrene with acetyl chloride and aluminum chloride in carbon disulfide solution, under Willgerodt's conditions, gave a small amount of crystalline material, together with resinous products and a considerable quantity of a thin oil. From the oil a small quantity of a ketone could be isolated as the semicarbazone; the oil dis-

[1] These researches have been supported by the Committee on Drug Addiction of the National Research Council.

[2] Willgerodt and Albert, *J. prakt. Chem.*, [2] 84,383 (1911).

tilled almost undecomposed in vacuum but boiled over such a wide range that further investigation has been delayed.

The crystalline portion, which was obtained in a yield averaging 5 to 10% (in one experiment which could not be duplicated, 50–60%), melted from 60 to 80° and contained some phenanthrene. Since this could not be removed by crystallization, the mixture was treated with semicarbazide. The semicarbazone proved, however, to be heterogeneous, and from it by laborious fractional crystallization two different semicarbazones could be obtained. When these were decomposed with hydrochloric or oxalic acid, two ketones of m. p. 72 and 143° were isolated. It therefore seemed desirable to improve the method of preparation of the ketones.

Lowering the temperature to 0 or to –15° gave no better results; substitution of aluminum bromide and acetyl bromide decreases the yield; stannic chloride as catalyst, or acetic anhydride in place of acetyl chloride, according to Adams,[3] were likewise without favorable result.

When, however, nitrobenzene was used as a solvent, the mixture of ketones was obtained in about 80% yield. The separation of these was accomplished through the difference in solubilities in methyl and ethyl alcohol. The sparingly soluble ketone (yield 15%) melts at 143°, the more soluble isomer (yield 63.5%) at 72°.

To determine the position occupied by the acetyl group, the isomers were oxidized with 2% sodium hypochlorite solution according to Graebe[4] ($RCOCH_3 + 3\ NaOCl \longrightarrow RCOONa + 2\ NaOH + CHCl_3$), to the corresponding carboxylic acids.

The 72° ketone gave an acid of m. p. 270°, whose methyl and ethyl esters melted at 94.5–95' and 56–57', respectively. The acid gives a very characteristic potassium salt.

The 143° ketone yielded an acid melting at 258.5 to 260°, whose methyl and ethyl esters melted at 96–96.5' and 73–73.5°, respectively. The sodium salt is very sparingly soluble in water, the potassium salt nearly insoluble.

The properties of the acids, their esters and salts pointed to their identity with the phenanthrene-2- and 3-carboxylic acids of Werner[5] and Fieser.[6]

Phenanthrene-9-carboxylic acid, prepared according to Pschorr,[7] was found by direct comparison of properties and mixed melting points to be different from the acids prepared from the two ketones. Therefore, in neither of these ketones does the acetyl group occupy the 9-position.

[4] Graebe, *Ber.*, **35**, 2753 (1902).

[5] Werner, *Ann.*, 321, 248 (1902), gives the m. p. 254" for phenanthrene-2-carboxylic acid, and emphasizes the slight solubility of the potassium salt. For the 3-carboxylic acid, the m. p. 269° is given.

[6] Fieser, THIS JOURNAL, **51**, 3101 (1929), gives the m. p of phenanthrene-7 carboxylic acid methyl ester as 974

[7] Pschorr, *Ber.*, 29, 497 (1896).

To prove that the acids derived from our two acetylphenanthrenes were actually the phenanthrene-2- and 3-carboxylic acids, these were synthesized by the method of Werner.[8]

Phenanthrene was sulfonated by Fieser's[9] modification of Werner's procedure. Under certain conditions, practically the only monosulfonic acids obtained are the 2- and 3-forms. The position of the sulfonyl groups in these acids, and consequently of the carboxyl groups in the carboxylic acids derived from them seems to be sufficiently proved by Werner's researches. That we were actually working with the pure sulfonic acids was proved by the preparation of the *p*-toluides (Fieser) and the methyl esters (Werner).

The phenanthrene-carboxylic acid prepared from the 2-sulfonic acid agreed in all characteristic properties and derivatives with that obtained by oxidation of the ketone melting at 143°; the carboxylic acid from the 3-sulfonic acid was similarly shown to be identical with the one obtained from our 72° ketone. On the basis of Werner's proof of the structure of these two sulfonic acids, therefore, we assign to the sparingly soluble ketone of melting point 143° the structure of 2-acetylphenanthrene; to the more soluble ketone of melting point 72°, the structure of 3-acetylphenanthrene.

Oxidation of the acetylphenanthrenes with chromic acid converts them smoothly into the 2-, and 3-acetylphenanthrene-9,10-quinones, respectively.

We have not yet been able to isolate any other acetylphenanthrene isomer from the reaction Very small amounts (0.1%) of a third substance, crystallizing in needles of melting point 279–280° were found, whose nature has not yet been determined.

Attempts to synthesize, from 9-substituted phenanthrene derivatives, the 9-acetylphenanthrene which was expected from Willgerodt's procedure have so far been fruitless. These experiments as well as those designed to introduce two acetyl groups and one or more benzoyl groups into the phenanthrene nucleus are being continued.

The marked favoring of the 2- and 3-positions observed in the above Friedel–Crafts acetylation over the 9-position, preference for which would be expected[10] from the presence of the 9,10-double bond, which recalls in many respects an olefinic double bond, is remarkable, and is not easy to bring into accord with the results of bromination,[11] nitration[12] and sulfonation.[13]

It is possible that an investigation of the oil which appears in such large quantities in the customary procedure in carbon disulfide solution will give further information. The extent to which the nitrobenzene used as solvent influences the reaction in a qualitative or quantitative way is difficult to estimate.

Experimental Part

The phenanthrene used in the experiments described below was a purified product of m. p. 98–99°; the nitrobenzene was dried over calcium chloride.

2- and 3-Acetylphenanthrenes, $C_{14}H_9COCH_3$.—One hundred and thirty-two grams of finely powdered aluminum chloride was added in small portions to 600 g. of nitrobenzene, and the resulting clear solution then mixed with a solution of 80 g. of phenanthrene in 240 g. of nitrobenzene. The solution was cooled in ice water and 48 g. of freshly-distilled acetyl chloride was added all at once. After half an hour's standing in ice water, the dark clear solution stood at room temperature (25°) for six to seven hours. It was poured into a large amount of ice and treated with 80 cc. of concentrated hydrochloric acid. In all, 400 g. of phenanthrene, in five lots, was so treated, and the united products distilled with steam to remove nitrobenzene as completely as possible. The distillation residue was a dark brown viscous mass which on digestion with ether largely went into solution. The ether-insoluble portion, a dark crystalline mass, was purified in two ways.

(1) It was spread on a clay plate to remove oils and then refluxed with animal charcoal in methyl alcohol. From the filtrate the 2-acetylphenanthrene separated in nearly pure, faintly colored, thick needles, of m. p. 138–142°. The methyl alcohol-insoluble carbonaceous mass weighed 5 g. After two recrystallizations from methyl or ethyl alcohol or benzene, the ketone was obtained pure white, m. p. 143° (corr.).

(2) To avoid the purification with methyl alcohol, in which the 2-acetylphenanthrene is very sparingly soluble (benzene cannot be used, because it dissolves the impurities as well), the ether residue above was twice distilled at a pressure of 2–3 mm. in a sabre flask. The colorless distillate crystallized immediately and was purified from benzene. The two methods gave about the same yields.

3-Acetylphenanthrene, $C_{14}H_9COCH_3$.—The ethereal solution from extraction of the steam distillation residue above was dried over sodium sulfate and the ether distilled off. The residue solidified soon to dumps of crystals. From methyl alcohol this separated only as an oil; it was therefore extracted in a Soxhlet apparatus with petroleum ether (b. p. 40–60°), leaving a very small portion undissolved. After removal of the petroleum ether, the product was distilled at 2–3 mm., giving an oil which soon crystallized. This could be recrystallized from methyl alcohol, in which it is very soluble, yielding 3-acetylphenanthrene as clumps of needles, m. p. 72°.

In this crystallization a small amount (0.5 g.) of a nearly insoluble substance was obtained as long thin white needles of m. p. 279–280° (uncorr.), which has not yet been identified. Traces of the 2-acetyl compound were also found at this point.

From 400 g. of phenanthrene, 315 g. of pure 3-acetylphenanthrene (63.5%), 75 g. of pure 2-acetylphenanthrene (15%), and 0.5 g. of the 280° product were obtained.

2-Acetylphenanthrene is soluble with difficulty in methyl or ethyl alcohol, petroleum ether or ligroin, more soluble in benzene or glacial acetic acid.

Anal. Subs., 0.0777: CO_2, 0.2471; H_2O, 0.0397. Calcd. for $C_{16}H_{12}O$: C, 87.23; H, 5.50. Found: C, 86.73; H, 5.72.

2-Acetylphenanthrene **Semicarbazone.**—One-half gram of the ketone was dissolved in hot alcohol and treated with 10% more than the calculated amount of semicarbazide hydrochloride and sodium acetate in concentrated aqueous solution. The mixture was warmed for ten minutes and after a short time the semicarbazone separated crystalline. It crystallizes from alcohol, in which it is only slightly soluble, in leaflets. After drying in vacuum at 100°, it melted at about 260" with gas evolution, then solidified and melted again at 297–299° (uncorr.) with decomposition. The same melting phenomenon was shown in a vacuum melting point tube.

Anal. Subs., 4.994 mg.: 0.678 cc. of N (27°, 747 mm.). Calcd. for $C_{17}H_{15}ON_3$: N, 15.16. Found: N, 15.18.

2-Acetylphenanthrene **Phenylhydrazone.**—A hot glacial acetic acid solution of 0.5 g. of ketone was treated with a hot solution of 0.27 g. (10% excess) of phenylhydrazine in glacial acetic acid. The phenylhydrazone separated after a short time in faintly yellow, shining leaflets, which were washed with a little acetic acid; m. p. in evacuated tube, 187–188" (corr.), turning brown.

Anal. Subs., 5.009 mg.: 0.406 cc. of N (27°, 750 mm.). Calcd. for $C_{22}H_{18}N_2$: N, 9.03. Found: N, 9.10.

Oxidation with Chromic Acid

2-Acetylphenanthrene-9,10-quinone, $C_{14}H_7O_2COCH_3$.—One gram of ketone was warmed to solution in 20 cc. of glacial acetic acid and treated with 1.0 g. of chromic anhydride in 2 cc. of water and 5 cc. of glacial acetic acid, not permitting the temperature to rise above 80°. After ten minutes at 70–80°, the solution was cooled and the quinone separated as a fine crystalline precipitate. Recrystallized from glacial acetic acid, it formed fine orange-yellow needles, melting in vacuum at 223–224° (corr.) (sintering at 218").

Anal. Subs., 0.1015: CO_2, 0.2862; H_2O, 0.0389. Calcd. for $C_{16}H_{10}O_3$: C, 76.78; H, 4.03. Found: C, 76.90; H, 4.29.

Oxidation with Sodium Hypochlorite

Phenanthrene-2-carboxylic Acid, $C_{14}H_9COOH$.—A suspension of 3.0 g. of ketone in somewhat more than the calculated amount of 2% aqueous sodium hypochlorite solution was boiled gently for three hours. After an hour, the sparingly soluble sodium salt of phenanthrene-2-carboxylic acid began to separate. The odor of chloroform was perceptible during the reaction. At the end of the oxidation sufficient water was added to dissolve the salt and the unchanged ketone shaken out into ether. The acid was precipitated from the aqueous solution by hydrochloric acid; the yield of the crude dry product was 70% of the theoretical. It was recrystallized from glacial acetic acid, m. p. 258.5–260° (uncorr.). It was analyzed in the form of its esters.

Phenanthrene-2-carboxylic Acid Ethyl Ester.—One gram of the acid in 20 cc. of absolute alcohol with 1.5 g. of concentrated sulfuric acid was refluxed for three hours. After removal of most of the alcohol in vacuum, the residue was poured into a large amount of water, whereupon the ester separated crystalline. It was extracted into ether and freed from unchanged acid by shaking with dilute sodium hydroxide. The residue from the ether was recrystallized from petroleum ether as white needles of m. p. 73–73.5°. The yield was nearly quantitative.

Anal. Subs., 0.1289: CO_2, 0.3844; H_2O, 0.0695. Calcd. for $C_{17}H_{14}O_2$: C, 81.56; H, 5.64. Found: C, 81.33; H, 6.03.

Phenanthrene-2-carboxylic Acid Methyl Ester.—This was prepared by esterification with methyl alcohol, in the manner described above. It was recrystallized from methyl alcohol, and consisted of white needles, m. p. 96–96.5° (corr.), yield quantitative.

Anal. Subs., 0.1130: CO_2, 0.3363; H_2O, 0.0533, Calcd, for $C_{16}H_{12}O_2$: C, 81.32; H, 5.12. Found: C, 81,17; H, 5.28,

Phenanthrene-2-carboxylic Acid Amide, $C_{14}H_9CONH_2$.—The amide was prepared from the acid chloride by the action of ammonia. Five grams of the acid was boiled for one and one-half hours with five times the calculated amount of thionyl chloride. By evaporation of the excess thionyl chloride in vacuum, a slightly colored crystalline acid chloride resulted directly, which was used without further purification. One gram of the crude acid chloride was added to a solution of 0.5 g. of sodium hydroxide in 12 cc. of 20% ammonia. This was warmed for three and one-half hours on the steam-bath with frequent shaking and addition of two 5-cc. portions of 20% ammonia. The precipitate of the amide was filtered out and washed with water. Only traces of the carboxylic acid could be detected with hydrochloric acid in the filtrate. The amide crystallizes from methyl alcohol or benzene, in which it is sparingly soluble, in silky white needles of m. p. 242–243° (corr.).

Anal. Subs., 4.512 mg.: 0.259 cc. of N (25°, 755 mm.). Calcd. for $C_{15}H_{11}ON$: N, 6.33. Found: N, 6.53.

For comparison with the product obtained from oxidation of the 2-ketone, phenanthrene-2-carboxylic acid was prepared from barium phenanthrene-2-sulfonate.[5,6] This yielded on dry distillation with potassium ferrocyanide the phenanthryl-2-cyanide, agreeing in melting point with Werner's[6] cyanide (104.5–105° corr.). The acid obtained by hydrolysis of the cyanide was identical with that from the 2-ketone, as shown by mixed melting point and mixed melting point of the methyl esters. The extreme insolubility of the potassium salt is noteworthy.

3-Acetylphenanthrene, $C_{14}H_9COCH_3$.—Isolation as described above; m. p. 72°; white needles, quite soluble in methyl or ethyl alcohol, glacial acetic acid or benzene; soluble with difficulty in petroleum ether.

Anal. Subs., 0.0972: CO_2, 0.3100; H_2O, 0.0482. Calcd. for $C_{16}H_{12}O$: C, 87.23; H, 5.50. Found: C, 86.98; H, 5.55.

3-Acetylphenanthrene **Semicarbazone.**—White needles of m. p. 228–230° (corr.), sparingly soluble in alcohol.

And. Subs., 5.045 mg.: 0.689 cc. of N (29°, 749 mm.). Calcd. for $C_{17}H_{15}ON_3$: N, 15.16. Found: N, 15.21.

3-Acetylphenanthrene **Phenylhydrazone.**—Faintly yellow needles of m. p. 192.5–194° (corr.) in vacuum.

Anal. Subs., 4.845 mg.: 0.389 cc. of N (26°, 753 mm.). Calcd. for $C_{22}H_{18}N_2$: N, 9.03. Found: N, 9.08.

3-Acetylphenanthrene-oxime.—A solution of 1.0 g. of 3-ketone in 15 cc. of alcohol was treated with an aqueous solution of 0.7 g. of hydroxylamine hydrochloride *(2* moles), neutralized with sodium carbonate and refluxed for one hour. After filtering from the sodium chloride, the reaction mixture deposited needles; recrystallized twice from methyl alcohol, these melted at 143.5–144° (corr.).

Anal. Subs., 4.588 mg.: 0.241 cc. of N (24°, 754 mm.). Calcd. for $C_{16}H_{13}ON$: N, 5.96. Found: N, 5.99.

From the mother liquors from the preparation of the oxime a more soluble substance of m. p. 181–182° (uncorr.) could be obtained in very small quantities. It is possible that this represents a stereoisomeric oxime; the small quantity available was not obtained pure enough for analysis.

3-Acetylphenanthrene Picrate.—The picrate was obtained by mixing hot alcoholic solutions of the calculated amounts of the components. It consisted of bright yellow needles of m. p. 125–125.5° (corr.).

Anal. Subs., 5.079 mg.: 0.411 cc. of N (24°, 755 mm.). Calcd. for $C_{22}H_{15}O_8N_3$: N, 9.36. Found: N, 9.24.

Oxidation with Chromic Acid

3-Acetylphenanthrene-9,10-quinone.—The oxidation was carried out like that of the 2-ketone; because of its greater solubility, the quinone must in this case be precipitated out with water. It crystallizes in brick-red needle rosets from glacial acetic acid, m. p. 217–218.5° (corr.) in vacuum (sintering at 214°).

Anal. Subs., 0.1307: CO_2, 0.3681; H_2O, 0.0500. Calcd. for $C_{16}H_{10}O_3$: C, 76.78; H, 4.03. Found: C, 76.81; H, 4.28.

Oxidation with Sodium Hypochlorite

Phenanthrene 3-Carboxylic Acid.—The oxidation, carried out as in the case of the 2-acetyl compound, gave a 75% yield of the 3-carboxylic acid as white needles, very sparingly soluble in glacial acetic acid, and melting at 270° (uncorr.).

Phenanthrene 3-Carboxylic Acid Ethyl Ester.—White needles from petroleum ether, of m. p. 56–57' (corr.).

Anal. Subs., 0.1278: CO_2, 0.3829; H_2O, 0.0671. Calcd. for $C_{17}H_{14}O_2$: C, 81.56; H, 5.64. Found: C, 81.71; H, 5.88.

Phenanthrene 3-Carboxylic Acid Methyl Ester.—White needles from methyl alcohol, m. p. 94.5–95° (corr.). (Recently prepared by Fieser[6] from the silver salt and methyl iodide.)

Phenanthrene-3-carboxylic acid amide (prepared from the crude acid chloride) melts at 233–234° (corr.); Werner gives the melting point as 228° (uncorr.).

For comparison, phenanthrene-3-carboxylic acid was prepared according to Werner, from potassium phenanthrene-3-sulfonate, and was found to agree in properties. Potassium phenanthrene-3-carboxylate crystallizes in unusual form, hair-like needles, bowed into semicircular form. No depression was observed in a mixed melting point of the free acids, esters or amides.

Phenanthrene-9-carboxylic Acid Methyl Ester.—White needles from methyl alcohol, m. p. 116" (corr.).

Anal. Subs., 0.1155: CO_2, 0.3443; H_2O, 0.0562. Calcd. for $C_{16}H_{12}O_2$: C. 81.32; H, 5.12. Found: C, 81.30; H, 5.44.

Phenanthrene-9-carboxylic Acid hide.— The amide was prepared from the crude acid chloride with ammonia. It crystallizes from benzene in silky needles of m. p. 232–233° (corr.).

Anal. Subs., 5.145 mg.: 0.289 cc. of N (24°, 755 mm.). Calcd. for $C_{15}H_{11}ON$: N, 6.33. Found: N, 6.41.

Summary

The preparation of 2-acetylphenanthrene and 3-acetylphenanthrene in satisfactory yields has been described.

Through the smooth oxidation of the acetyl derivatives to the carboxylic acids, a good preparative way to phenanthrene-2-carboxylic acid and phenanthrene-3-carboxylic acid is opened.

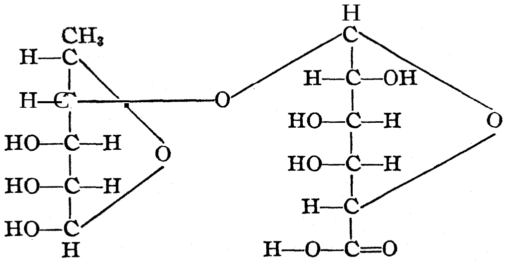
THE COMPOSITION OF AN ALDOBIONIC ACID FROM FLAXSEED MUCILAGE

BY ERNEST ANDERSON AND J. A. CROWDER

RECEIVED JUNE 30, 1930 PUBLISHED SEPTEMBER 5, 1930

In 1903 Hilger[1] hydrolyzed flaxseed mucilage and found in the hydrolytic products the sugars d-glucose, d-galactose, *l*-xylose and *l*-arabinose, together with an acid by-product. In 1913 Neville[2] verified the work of Hilger on this mucilage. Abderhalden[3] states that this mucilage yields in addition to sugars, an acid complex which contains pentoses and hexoses.

The investigation reported in this paper deals with the aldobionic acid formed during the partial hydrolysis of flaxseed mucilage. This acid is composed of one molecule of d-galacturonic acid joined through its aldehyde group to a molecule of l-rhamnose. While the position of the oxide ring in the galacturonic acid and of the glucosidic union on the *l*-rhamnose have not been established, the following structure is suggested.



Experimental Part

Preparation of the Calcium Salt of the Aldobionic Acid.—Flaxseed mucilage was prepared according to the directions of Neville.[2,4] One kilogram of the air-dry mucilage was dissolved in 6 liters of 4% sulfuric acid and heated in a boiling water-bath for twenty hours. The solution was cooled, neutralized by excess calcium carbonate, heated in a boiling water-bath to complete the neutralization and filtered from the insoluble material. The filtrate was concentrated in *vacuo* to a volume of 1.5 liters, decolorized by norit and the salts precipitated in a large dish by addition of 3 volumes of 95% ethanol. After standing overnight with fresh 95% ethanol the salts were triturated with a pestle until granular, filtered, washed with alcohol and ether and dried on a porous plate. The yield was 340 g.

Purification and Analysis of the Calcium Salts.—The crude calcium salts were purified by the method of Levene.[5] For this purpose 340 g. of salts was dissolved in

[5] Levene, J. *Biol.* Chem., 71,471 (1927); Goebel, *ibid.*, 72,813 (1927).

900 cc. of water, 1800 cc. of 95% ethanol added, the mixture heated in a boiling water-bath and then allowed to stand overnight. The clear supernatant liquid was decanted, concentrated in *vacuo* to a volume of 200 cc. and the salts precipitated by addition of 4 volumes of 95% ethanol. This was called salt "A." It weighed 24 g. Proceeding in the same general way, the solid residue was separated into fraction "B," weight 65 g., fraction "C," weight 60 g., and fraction "D," weight 75 g.

Samples of each of the above fractions were ground until they would pass an 80-mesh sieve and the analytical determinations described below then made.

Moisture.—Moisture was determined by drying 0.25-g. samples to constant weight in an Abderhalden vacuum drier using phosphorus pentoxide and a bath of boiling toluene.

Ash.—Calcium salts were burned at a low temperature and finally heated to constant weight over a blast lamp. Barium salts were burned at a low temperature but not heated over the blast. This gave barium carbonate. Barium was also determined as the sulfate in the regular way.

Uronic Acid.—The hexose uronic acid was determined by the method of Lefèvre.[6] This is an accurate determination. It is shown later that d-galacturonic acid is the uronic acid present. This can be determined approximately by oxidation to mucic acid by means of nitric acid but the method is not quantitative.[7]

Methyl Pentose.—It is shown later that *l*-rhamnose is present in the aldobionic acid; hence the percentage of this sugar is calculated from the pentosan determination. This determination was made according to the A. O. A. C.[8] Since the uronic acid yields furfural, the phloroglucide precipitate resulting from the decomposition of the uronic acid must be calculated, using the factor determined by Lefèvre.[9] When this calculated weight of phloroglucide is deducted from the total weight of phloroglucide, the remainder is the phloroglucide corresponding to the *l*-rhamnose present. From this weight the percentage of *l*-rhamnose hydrate is calculated using the table of Ellett.[10]

Since methyl furfural phloroglucide is soluble in alcohol, the percentage of *l*-rhamnose can also be determined by dissolving out the methyl furfural phloroglucide according to the method of Ellett and Tollens,[11] and Haywood.[12] It is well known that the methyl pentose determination is not accurate but merely an approximation.

The Aldehyde Group.—The percentage of aldehyde present, calculated as CHO, was determined by the method of Cajori.[13] This method was devised for the aldehyde group in mono and disaccharoses. Cajori states that the oxidation of glucose by iodine in sodium carbonate solution is complete in twenty-five minutes. Some sugars, however, require a longer time. The oxidation of the aldehyde group in the aldobionic acid under investigation required three hours for completion.

The purified calcium and barium salts of the aldobionic acid reduce Fehling's solution strongly. On the other hand, calcium and barium salts of the dibasic acid obtained by oxidation of the aldobionic acid with barium hypoiodite show no reduction of Fehling's solution.

TABLE I

THE ANALYSIS OF CALCIUM SALT OF THE ALDOBIONIC ACID

Ftaction	Ash (CaO), %	CO_2, %	Galacturonic *acid* as mucic *acid*, %	*Methyl* pentose, %	*Reducing* sugar *as* CHO, %	$[\alpha]^{20}_{D}$
A	13.23	11.01	41.4	..	5.7	+92.0
B	12.07	11.27	39.45	35.3	5.57	+95.5
C	10.61	11.05	42.6	41.3	4.83	+94.4
D	10.16	11.27	48.7	37.2	4.70	+92.8

An inspection of the above table indicates little difference in the composition of the various fractions. Deviations in the analyses of the various fractions, particularly in the ash, were probably due to the presence of calcium sulfate as an impurity. The data approximate the theoretical for the calcium salt of an aldobionic acid consisting of one hexose uronic acid molecule and one molecule of a methyl pentose, but the results are not conclusive.

Identification of **the** Constituents of the Aldobionic Acid.—The naphthoresorcinol test and the yield of carbon dioxide by the method of Lefèvre proved the presence of a hexose uronic acid. This was identified as *d*-galacturonic acid by the method of Heidelberger and Goebel.[14] Twenty grams of fraction D salts was dissolved in 200 cc. of 6% hydrobromic acid containing 10 cc. of bromine. This mixture was heated under a reflux condenser in a boiling water-bath. After four hours a white crystalline precipitate began to form. After heating for ten hours the precipitate was filtered off and found to weigh 6.4 g. It was purified by dissolving in the calculated amount of dilute sodium hydroxide and reprecipitating with acid, and identified as mucic acid, melting point 210'.

The sugar present in the aldobionic acid would be oxidized in the above process to a monobasic acid and remain in the filtrate from the mucic acid. This filtrate was freed of excess bromine and hydrobromic acid and concentrated to a volume of 15 cc. To this solution was added 1 g. of phenylhydrazine hydrochloride. After twelve hours a light brown crystalline needle-like solid separated out. After recrystallization from hot ethanol the product melted at 193° and was identical with *l*-rhamnonic hydrazide.

To further establish the presence of I-rhamnose in the aldobionic acid, 20 g. of calcium salts D was dissolved in six times its weight of 4% sulfuric acid and hydrolyzed in the autoclave at a gage pressure of one atmosphere for six hours. The acids were removed from this solution by neutralizing with calcium carbonate, filtering, concentrating and precipitating the salts with alcohol. The alcohol solution of the sugars was concentrated in *vacuo* to a sirup. **A** portion of this sirup in water solution was not fermented by yeast, though when glucose was added it readily fermented. This proves the absence of glucose, mannose and fructose. The remainder of the sirup was oxidized by bromine to the monobasic acid and this acid converted to the phenylhydrazide, which did not crystallize until seeded with pure rhamnonic hgdrazide. This on re-

---

[14] Heidelberger and Goebel, J. *Biol. Chem* , 74, 616 (1927).

crystallization from 95% ethanol gave crystalline needles melting at 193° and identical with *l*-rhamnonic phenylhydrazide.

Finally, crystalline *l*-rhamnose hydrate was isolated by hydrolysis of the acid, as follows. Fifty grams of mixed calcium and barium salts of the aldobionic acid was hydrolyzed in the autoclave and the sugar sirup isolated as already described. This sirup was decolorized by norit, all salts removed by solution in absolute alcohol and filtering, the solvent distilled off *in vacuo*, the gum dissolved in half its weight of water and an equal volume of glacial acetic acid added.[15] On seeding with *l*-rhamnose hydrate the mass became solid with crystals. The yield was 7 g. The melting point was 92–94° and the specific rotation was −7.8, constant after ten minutes.

Later experiments on the isolation of *l*-rhamnose hydrate from flaxseed mucilage indicate that the sirup must be fairly pure and contain small amounts of water. Salts and other impurities interfere with the crystallization.

Preparation and Analysis of the Barium Salt of the Aldobionic Acid.—Considerable difficulty was met in purifying the calcium salt of the aldobionic acid. Some calcium sulfate remained in all the fractions even after repeated precipitation of the salts. On the other hand, the barium salt in a fairly pure state can be more readily prepared. For this purpose 200 g. of the mucilage was mixed with six times its weight of 4% sulfuric acid and heated in a boiling water-bath for twenty hours. The acid was neutralized by the careful addition of barium hydroxide solution and an excess of barium carbonate. The barium sulfate was filtered off, the solution concentrated *in vacuo* and the barium salt isolated by precipitation with alcohol. The yield of salt was 40 g. This salt was purified by solution in water, a small amount of alcohol was added to precipitate a trace of gum and any suspended barium sulfate, the solution filtered and the pure barium salt precipitated by alcohol and analyzed.

Analysis of the Barium Salt of the Aldobionic Acid.—Barium determined as $BaCO_3$: found, 17.2%; calcd., 16.85%. Galacturonic acid from the CO_2 determination: found, 48.06%; calcd., 47.60%. Galacturonic acid from mucic acid determination: found, 41.92%; calcd., 47.60%. Aldehyde group: found, 7.09%; calcd., 7.11%. *l*-Rhamnose hydrate: found, 34.9%; calcd., 44.6%. Specific rotation, +79°.

The calculated percentages given above are for the barium salt of an aldobionic acid composed of one molecule of *d*-galacturonic acid and one molecule of *l*-rhamnose with the loss of one molecule of water. The experimental results check very closely with the theoretical values, except in the case of the mucic acid and methyl pentose determinations, both of which are known to be inaccurate methods.

Oxidation of the Aldobionic Acid to a Dibasic Acid.—Fifteen grams of the barium salt of the aldobionic acid was oxidized to the dibasic acid by means of barium hypoiodite.[5] The yield of the barium salt of the dibasic acid was 6.5 g. This salt did not reduce Fehling's solution but gave a positive naphthoresorcinol test and the following results on analysis: Ba as $BaSO_4$, found 24.8%; calcd., 26.00% galacturonic acid from CO_2 determination, found, 39.02; calcd., 39.46%—galacturonic acid from the mucic acid determination, found, 36.10%; calcd., 39.46%—specific rotation, +72°.

The Structure of the Aldobionic Acid.—The experimental work proves conclusively that the aldobionic acid consists of one molecule of *d*-galacturonic acid combined with one molecule of *l*-rhamnose. In this compound one aldehyde group is free and the other combined. If the aldehyde group of *l*-rhamnose is free and that of *d*-galacturonic acid is combined, then the dibasic acid formed by oxidation of the aldobionic acid with barium hypo-

---

[15] Sands and Klaas, THIS JOURNAL, 51, 3441 (1929).

iodite would consist of d-galacturonic acid combined with *l*-rhamnonic acid. Such a compound would give a high percentage of carbon dioxide when heated with 12% hydrochloric acid, a low percentage of furfural and a positive naphthoresorcinol test. These are the results obtained. On the other hand, if in the aldobionic acid the aldehyde group of the d-galacturonic acid is free while the aldehyde group of the *l*-rhamnose is combined, then the dibasic acid formed by oxidation would consist of mucic acid combined with *l*-rhamnose. Such a compound would give no carbon dioxide, a high percentage of furfural and a negative naphthoresorcinol test, These results were not obtained. These facts prove conclusively that in the aldobionic acid the linkage is from the aldehyde group of the *d*-galacturonic acid to one of the secondary alcohol group of the 2-rhamnose.

Summary

Flaxseed mucilage yields on hydrolysis an aldobionic acid consisting of one molecule of d-galacturonic acid and one molecule of 1-rhamnose. The molecule is joined together by a glucosidic linkage involving the aldehyde group of the d-galacturonic acid and an alcohol group of the *l*-rhamnose. This mucilage is similar in composition and structure to some of the plant gums.

Further work on the structure of the mucilage is in progress.

PARA-PHENYLPHENACYL BROMIDE, A REAGENT FOR IDENTIFYING ORGANIC ACIDS[1]

BY NATHAN L. DRAKE AND JACK BRONITSKY

RECEIVED JULY 3, 1930 PUBLISHED SEPTEMBER 5, 1930

Phenacyl bromide and the p-halogen substituted phenacyl bromides have been used with great success by Reid and his co-workers[2] for preparing esters which are excellently adapted for characterizing the organic acids therein combined. Such an ester may be prepared easily by the action of the bromide on the sodium salt of an acid in aqueous alcoholic solution; as a rule the ester crystallizes well and may be purified easily by a few crystallizations from aqueous alcohol. The reaction involved may be represented

$$p\text{-}XC_6H_4COCH_2Br + NaOCOR = p\text{-}XC_6H_4COCH_2OCOR + NaBr$$

---

[1] **From a thesis submitted to the Graduate School of the University of Maryland by Jack Bronitsky in partial fulfilment of the requirements for the degree of Master of Science.**

[2] **Reid and co-workers, THIS JOURNAL, 41, 75 (1919); 42, 1043 (1920); 52, 818 (1930).**

The melting points of the esters from a given acid increase as X varies from hydrogen to chlorine to bromine to iodine. The iodophenacyl ester has the highest melting point, but in certain cases the melting point of even this derivative is so low as to make purification by crystallization difficult, particularly when small quantities of material are involved. Furthermore, with several acids Reid was unable to obtain a satisfactory solid derivative with any of the above-mentioned reagents.

The authors appreciated the facility with which the phenacyl esters may be prepared, but they desired a reagent which would yield, with certain acids containing highly branched chains, esters of melting points sufficiently high that purification by crystallization would be easy. A few tenths of a gram of acid would then suffice for its identification.

p-Phenylphenacyl bromide was consequently prepared, in the hope that the phenylphenacyl esters which could be derived from it would satisfy these requirements. Inasmuch as diphenyl is today a readily obtainable substance[3] and all the reactions involved in the preparation of the bromide give good yields, phenylphenacyl bromide is inexpensive and easy to prepare. Furthermore, examination of the properties of the esters obtained from a number of representative organic acids listed in the table clearly shows that in every case they compare favorably in melting point with the corresponding *p*-halogenated phenacyl esters. Of the ten acids which admit of comparison, the melting points of the p-phenylphenacyl esters are higher than those of the *p*-iodophenacyl esters in five instances, and do not differ by more than three degrees in two others. With only three acids out of eighteen, *viz.*, succinic, citric and caproic, were esters obtained which melted lower than the corresponding *p*-bromophenacyl esters, and the maximum difference was 6.6°—the *p*-phenylphenacyl ester of caproic acid melted at 65°, and the *p*-bromophenacyl ester melted at 71.6°. In addition, the solubility behavior of the phenylphenacyl esters is such that purification by crystallization is easily accomplished.

A more significant advantage of the new reagent lies in the fact that no carboxylic acid which we have so far investigated has failed to give a solid derivative. Referring again to the table, it is seen that of the twenty-four acids selected from those with which Reid worked, but eighteen yielded crystalline derivatives. *p*-Phenylphenacyl bromide, however, yielded a solid derivative in every case. It was not found possible to prepare the *p*-phenylphenacyl ester of benzene sulfonic acid in the usual way.

The procedure adopted for the preparation of p-phenylphenacyl esters was as follows. A weighed amount of acid (0.005 mole) was added to 5 cc.

---

[3] Technical diphenyl is quoted in *Ind. Eng. Chem.*, for May, 1930, at 40 cents per lb. This substance is obtainable from the Federal Phosphorus Company of Birmingham, Alabama. The authors wish to express their thanks to this organization, which kindly supplied some of the diphenyl used in this research.

of water in a small Erlenmeyer flask, and then 0.0025 mole of sodium carbonate. The mixture was tested for acidity, and just enough more acid was added to make the solution acid to litmus; 10 cc. of alcohol was then put in, and if the salt of the acid was not thrown out of solution, 0.003 mole of the bromide was added and the mixture refluxed for an hour or more, depending on the acid involved.[4] If the acid salt was thrown out by the alcohol, a bit more water was added until the salt dissolved. The amounts of material recommended above yielded a quantity of ester which was sufficient, after purification, for elementary analyses. If only sufficient ester was desired for melting point comparisons, half of the amounts mentioned above yielded equally good results.

Some of the esters prepared were sparingly soluble in the reaction mixture and crystallized from the boiling solution. In the majority of cases, however, crystal formation did not take place until the reaction mixture was cooled, and in a few instances it was necessary to concentrate the solution to obtain a sufficiently large crop of crystals.

In most cases the ester formed rapidly, and many times a period of heating as short as twenty minutes was sufficient to bring about practically complete conversion of the acid salt into ester.

Certain dibasic acids whose sodium or potassium salts were sparingly soluble in aqueous alcohol of the requisite strength caused difficulty, and ester formation could not be brought about in the usual way. However, substitution of the methyl ammonium salts for the alkali salts made it possible to operate in such a fashion that at the outset all the reactants were in solution. When an ester was prepared in this way, it was found particularly important to have present a very slight excess of acid so that the reaction of the medium was not basic to litmus. If this precaution was not taken, colored by-products were formed which were very difficult to remove from the ester by subsequent recrystallizations. The ester prepared in the proper way was colorless.

In almost every case two recrystallizations of the crude ester proved ample to yield a substance whose melting point did not change on further crystallizations.

Experimental

Adam,[5] who first prepared phenylacetophenone, described his product as the 3-phenyl derivative. Vorlander,[6] however, showed that the compound which Adam prepared was probably 4-phenylacetophenone, and

---

[4] Reid recommends refluxing monobasic acids for one hour, dibasic acids for two hours and tribasic acids for three hours; in many cases it is certain that when using *p*-phenylphenacyl bromide refluxing for a shorter period would be equally satisfactory.

[5] Adam, *Ann. Chim.*, [6] **15**, 255 (1888).

[6] Vorlander, *Ber.*, **40**, 4535 (1907).

later work has confirmed Vorländer's contention. Dilthey,[7] by oxidation of the benzal derivative of Adam's phenylacetophenone, obtained a diphenyl carbonic acid whose melting point and properties proved it to be identical with an acid prepared by Schlenk,[8] whose carbonyl was in the 4-position.

p-Phenylphenacyl bromide is not mentioned in the literature, although the corresponding chloride was described by Collet,[9] who prepared it by the Friedel and Crafts synthesis

$$C_6H_5C_6H_5 + ClCH_2COCl \xrightarrow{AlCl_3} C_6H_5C_6H_4COCH_2Cl + HCl$$

He describes the substance as a crystalline yellowish powder, soluble in alcohol, and possessing a melting point of 122–123°. Collet proved the location of the substituting group by oxidizing the chloro ketone to the corresponding acid. Collet's chloride was undoubtedly impure and should have been colorless.

p-Phenylphenacyl bromide was prepared by a method illustrated by the reactions

$$C_6H_5C_6H_5 + (CH_3CO)_2O \xrightarrow{AlCl_3} C_6H_5C_6H_4COCH_3 + CH_3COOH$$

$$C_6H_5C_6H_4COCH_3 + Br_2 \xrightarrow{CH_3COOH} C_6H_5C_6H_4COCH_2Br + HBr$$

It crystallizes in long colorless needles and melts sharply at 125.5'.

Preparation of *p*-Phenylacetophenone.—The procedure used in preparing this substance was a modification of that for the synthesis of acetophenone;[10] 0.8 mole (120 g.) of diphenyl, 1.76 mole (236 g.) of anhydrous aluminum chloride and 700 cc. of anhydrous carbon disulfide were placed in a two-liter three-necked flask provided with a mechanical stirrer, a dropping funnel and a reflux condenser holding a tube to carry off the evolved hydrogen chloride. The mixture was heated on the steam-bath until gentle refluxing started, and then 0.8 mole (85 g.) of acetic anhydride (b. p. 136–137°) was added. The addition of the anhydride required about an hour and the reaction mixture was refluxed gently for one hour after all of the anhydride had been added. When about three-quarters of the anhydride had been added, the addition product began to separate from the solution in the form of a curdy mass. Decomposition of the addition product was effected in the usual way by pouring the reaction mixture over ice and hydrochloric acid. The precipitate of *p*-phenylacetophenone was filtered on a Büchner funnel, washed several times with water, dried and distilled *in vacuo*. The carbon disulfide contains considerable of the ketone which can be recovered by evaporating the solvent. With very little forerunnings, the product boiled from 195 to 210° at 18 mm. pressure. The yield of distillate was 131 g. with a melting point of 118". Crystallization from alcohol yielded a product melting at 120–121° in an amount corresponding to 80% of that theoretically possible.

Preparation of *p*-Phenylphenacyl Bromide.—The procedure used was a modification of that described by Reid[11] for the preparation of the halogenated phenacyl bromides;

---

0.183 mole (36 g.) of p-phenylacetophenone was suspended in 200 cc. of glacial acetic acid, warmed gently on the steam-bath until a clear solution resulted, and then cooled as far as possible without the formation of crystals. To this solution was added slowly 0.183 mole (29.4 g.) of bromine. During the addition of the bromine, the temperature was not allowed to rise above 45°. When about three-quarters of the bromine had been added, the brominated product separated from the solution. After two hours, the flask was cooled in an ice- and salt-bath, the product filtered and washed with a bit of cold glacial acetic acid and two 50-cc. portions of cold water. The yield of crude material was 42 g., its melting point 124.5–125.5°. Recrystallization from hot 95% alcohol, with the addition of some activated charcoal to remove color, yielded a product melting at 125.5°. Approximately 6.7 g. of *p*-phenylphenacyl bromide dissolved in 100 cc. of boiling alcohol, and about 1.3 g. in 100 cc. of cold (25°) alcohol.

In the table neg. means that the reaction did not occur, or yielded products of no significance. The leaders signify that data are not available. Compiled from data given by Reid, This Journal, **41,** 83 (1919); 42,1055 (1920); 52,818 (1930).

Summary

1. *p*-Phenylphenacyl bromide has been prepared.
2. This substance has shown itself to be well adapted for preparing

solid esters of organic acids. The properties of these esters render them useful in the identification of organic acids.

3. A number of representative esters have been prepared, and their melting points compared with those of the corresponding *p*-nitrobenzyl esters, phenacyl esters, and *p*-halogen phenacyl esters, where such comparison was possible.

COLLEGE PARK, MARYLAND

[A CONTRIBUTION FROM THE LABORATORIES OF THE UNIVERSITY OF MARYLAND AND THE U. S. INDUSTRIAL ALCOHOL COMPANY]

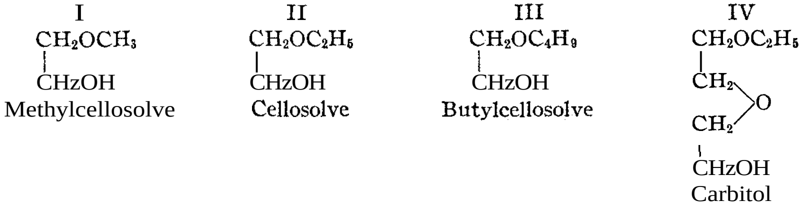
SOME REPRESENTATIVE CARBONATES AND CARBO-ETHOXY DERIVATIVES RELATED TO ETHYLENE GLYCOL[1]

BY NATHAN L. DRAKE AND RAY M. CARTER

RECEIVED JULY 8, 1930 PUBLISHED SEPTEMBER 5, 1930

Certain derivatives of ethylene glycol, in particular its ethers and esters, have become important in industry by reason of their solvent power for the cellulose esters. It seems strange, therefore, that there appears in the published literature no information regarding either the preparation or the properties of the carbonates and the carbo-ethoxy derivatives of the mono ethers of ethylene glycol. Allpress[2] describes some carbonates and carbo-ethoxy derivatives of ethylene glycol, but the corresponding mono ethers have apparently not been made.

It was decided, therefore, to study certain of these substances, in the hope that they might prove of value in the lacquer industry as plasticizers. The raw materials were



I $CH_2OCH_3-CH_2OH$ Methylcellosolve

II $CH_2OC_2H_5-CH_2OH$ Cellosolve

III $CH_2OC_4H_9-CH_2OH$ Butylcellosolve

IV $CH_2OC_2H_5-CH_2-O-CH_2-CH_2OH$ Carbitol

The carbonates were prepared by the reaction of phosgene and the glycol ether in a manner analogous to the preparation of alkyl carbonates. Phosgene was bubbled from a cylinder of the compressed gas into a weighed amount of the glycol ether in a tall narrow cylinder. The cylinder was immersed in a bucket of water in order that its temperature might be kept close to that of the laboratory, thus preventing the evolution of hydrogen chloride. At intervals the cylinder was removed and its increase in weight

---

[1] From a thesis submitted to the Graduate School of the University of Maryland by Ray M. Carter in partial fulfilment of the requirements for the degree of Master of Science.

[2] Allpress, *J. Chem. Soc.*, 125,2259 (1924)

determined. When this increase indicated that the correct amount of phosgene had been introduced, the solution was heated, gently at first, then with increasing heat until boiling ensued.[3]

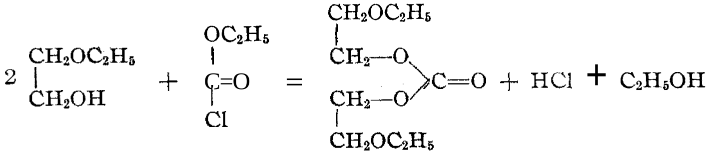
After the reaction was complete, the mixture was worked up in one of two ways: by washing with water, neutralizing with dilute sodium hydroxide, drying and fractionating, or by fractionating directly without preliminary neutralizing and drying.

In some cases this general method yielded unsatisfactory results. When methylcellosolve or carbitol were the starting materials, side reactions occurred between the hydrogen chloride and the ether, yielding halogen-containing products, among which was some alkyl chloride.

To obviate this difficulty, the glycol ether was first brought into reaction with metallic sodium and the resulting sodium glycolate treated with phosgene dissolved in benzene.

In preparing the carbo-ethoxy derivatives, ethyl chlorocarbonate was caused to react with the glycol ether. It was found early in the work, however, that a side reaction giving rise to considerable carbonate of the glycol ether occurred if the ether and chlorocarbonate were refluxed together.

Allpress[2] had noted earlier the formation of normal carbonate when ethylene glycol was heated with ethyl chlorocarbonate. In our case the reaction may be represented



$$2\begin{matrix}CH_2OC_2H_5\\ |\\ CH_2OH\end{matrix} + \begin{matrix}OC_2H_5\\ |\\ C{=}O\\ |\\ Cl\end{matrix} = \begin{matrix}CH_2OC_2H_5\\ |\\ CH_2{-}O\\ \\ CH_2{-}O\\ |\\ CH_2OC_2H_5\end{matrix}\!\!>C{=}O + HCl + C_2H_5OH$$

It was found, furthermore, that this side reaction could be minimized if the glycol ether was added dropwise to the ethyl chlorocarbonate boiling under reflux.

Here, also, certain of the glycol ethers yielded halogen-containing by-products, but in these cases the use of the sodium glycolate in benzene suspension obviated any difficulty.

All the compounds prepared had high boiling points, and preliminary experiments showed that it would be necessary to use a column that would maintain a high reflux ratio if good fractionation was to be accomplished. Two columns were used. One was 81 cm. from bottom outlet to side arm, the other 46 cm. Both were 2.5 cm. in internal diameter, the longer having a bottom outlet of 12 mm. internal diameter, and the shorter a bottom outlet of 19 mm. internal diameter. The longer of the two operated satisfactorily up to 225°, but above that point the lower outlet

---

[3] Except in the case of diethylene glycol ether, IV, where the boiling point was very high.

was too small for the amount of liquid refluxing, and the column flooded. The shorter column was therefore made, provided with a wider outlet. It operated satisfactorily up to 300° at a distillation rate of 120 drops per minute and an estimated reflux ratio of 20:1. Both columns were heavily lagged with asbestos, corks were covered with tin foil, and short pieces of glass tubing were used to pack the columns. It was found unnecessary to use water in the depblegmator; while distilling the lower-boiling liquids, air was blown through the dephlegmator, but for the higher-boiling substances the air current was not necessary

The solvent action of the different preparations on three different cellulose esters was examined. The cellulose esters used were *(1) 20–30* second *R. S.* nitrocotton, *(2) 15* sec. *A. S.* nitrocotton, *(3)* cellulose acetate, *0.4* poise viscosity. These tests showed that both the carbonates and carbo-ethoxy derivatives of cellosolve, methylcellosolve and carbitol had high solvent power for both the A. S. and R. S. nitrocotton. The corresponding derivatives of the butyl ether were not such good solvents, the carbo-ethoxy derivative being somewhat better than the carbonate.

The only compounds which would dissolve cellulose acetate were the carbonate and carbo-ethoxy derivative of methylcellosolve. The other preparations merely swelled the cellulose acetate.

The high boiling points of some of these materials, particularly the derivatives of diethylene glycol, make them of interest as possible lacquer plasticizers.

Table I summarizes some of the properties of the compounds prepared. The percentage of ester was determined by saponification in a pressure bottle with $N/2$ alcoholic sodium hydroxide. The only change in the standard procedure was the addition of *100* cc. of water and *50* cc. of 10% barium hydroxide to the contents of the bottle before back titration with $N/2$ acid. Specific gravity was determined by means of a pycnometer. The boiling point was obtained by applying the proper stem and calibration correction to the temperature read during the fractionation. Refractive index was determined using an Abbé refractometer calibrated against distilled water.

Experimental

Di(β-methoxyethyl) Carbonate.—Seventy-nine and five-tenths grams of clean sodium was added to a solution of 300 g. of the monomethyl ether of ethylene glycol in 300 g. of benzene and a water-bath was used to bring the reaction to completion. To this mixture was added a benzene solution of phosgene, while the whole was kept cool in ice water. Phosgene was added until a distinct odor of it remained after shaking the reaction flask. Approximately 180 g. of phosgene was required. The salt which separated was dissolved by adding water and, after separation of the aqueous layer, the remaining oil was washed twice with 100-cc. portions of water. The product was dried over calcium chloride and distilled.

Ethyl (β-Methoxyethyl) Carbonate.—Five hundred grams of the glycol ether was added dropwise to 827 g. of ethyl chlorocarbonate boiling under reflux. After all of the ether had been added, boiling was continued for an hour. The crude was fractionated without a water wash or any further treatment.

Di(β-ethoxyethyl) Carbonate.—Gaseous phosgene was bubbled into a water-cooled cylinder containing 679 g. of glycol mono-ethyl ether until the weight increase was 339 g. The resulting solution was refluxed for four and one-half hours, washed with water, dried over calcium chloride and fractionated.

Ethyl(β-Ethoxyethyl) Carbonate.—Five hundred grams of glycol monoethyl ether was added slowly to 604 g. of boiling ethyl chlorocarbonate. Refluxing was continued for three hours after the addition of ether was completed. The resulting crude was fractionated without washing or neutralizing.

Di(β-butoxyethyl) Carbonate.—Two hundred and seventy-four grams of phosgene was bubbled into 717 g. of cooled ethylene glycol monobutyl ether. The solution was then boiled gently under reflux for three hours. After a water wash, it was dried over calcium chloride and fractionated.

Ethyl (8–Butoxyethyl) Carbonate.—Five hundred grams of ethylene glycol monobutyl ether and 460 g. of ethyl chlorocarbonate were mixed and boiled under reflux for four hours. After washing and drying, the product was fractionated. A considerable amount of di(β-butoxy ethyl) carbonate was obtained, showing this method of preparation to be inferior to that in which the glycol ether is added to boiling chlorocarbonate.

Dicarbitol Carbonate.—Three hundred and fifty-four grams of phosgene was dissolved in 903 g of cooled carbitol (IV) and the mixture allowed to stand for eighteen hours before heating. The solution was then heated for four hours at a temperature of about 200°. After a water wash, the washings were extracted with benzene and added to the main bulk of the product, whereupon all was dried over calcium chloride and fractionated in *vacuo.*

Ethylcarbitol Carbonate.—Fifty-eight and 8 tenths grams of sodium was brought into reaction with 300 g. of carbitol in 300 g. of benzene. Heating on a water-bath was necessary to complete the reaction. To this mixture was added a solution of 278 g. of ethyl chlorocarbonate in 300 g. of benzene. The salt which separated was dissolved in water and the water-insoluble layer washed with more water. After drying the product was fractionated.

Summary

1. The carbonates and carbo-ethoxy derivatives of the methyl, ethyl and butyl ethers of ethylene glycol, and of the ethyl ether of diethylene glycol, have been prepared and their boiling points, specific gravities and refractive indices determined.

2. All of the substances except those derived from the butyl ether of ethylene glycol have good solvent power for nitrocotton.

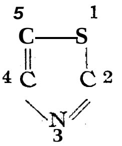
THE SYNTHESIS OF THIAZOLE AMINES POSSESSING PHARMACOLOGICAL INTEREST. IV

BY W. S. HINEGARDNER[1] AND TREAT B. JOHNSON

RECEIVED JULY 10, 1930 PUBLISHED SEPTEMBER 6, 1930

By bridging from carbon to carbon with a thiazole nucleus I in an aliphatic chain compound, it is theoretically possible to introduce structural features which make it practicable to study, from new points of view, the relationship between chemical constitution and physiological and pharmacological action. The thiazole nucleus I is chosen for such heterocyclic constructions because it contains both sulfur and nitrogen in cyclic linkage, and is a heterocycle which does not show high toxic effects when introduced into living organisms. Three distinct positions are available for carbon substitution in the ring (2,4,5), making it possible to obtain by synthesis interesting structural isomers for biological and clinical work. Furthermore, the thiazole cycle is a construction containing a stable molecular configuration with fined positions for the cyclic double bonds and with no possibility of structural alterations corresponding to lactam ⇄ lactim or keto ⇄ enol tautomeric changes. These same considerations apply also to heterocyclic combinations containing oxygen and selenium substituted in place of the thiazole sulfur, which will finally be included in our research program.



I

The organic constructions which are receiving our attention at present are the bridged thiazole derivatives of bases of the phenylethylamine type, II. It is a well-known fact that nucleus and side-chain substitutions in this base bring about pronounced physiological effects leading to products of therapeutic value. Our program calls for the study of compounds in which the aliphatic part is linked to the benzene nucleus by the thiazole ring, giving heterocyclic amines corresponding in structure to formulas III and IV. In this paper we shall report a practical procedure for preparing the new amine IV. In a later paper we shall describe a practical method for synthesizing the isomeric compound expressed by formula III.

[1] Metz Research Fellow in Organic Chemistry, 1928–1929.

All the amines of this type, so far studied biologically, have been shown to be substances of decided pharmacological interest.

The starting points for this research were the halogenated ketone, *sym.*-dichloro-acetone V and thiobenzamide[2] VI. So far as the authors are aware, this halogen compound has been used hitherto for thiazole syntheses only by Suter and Johnson.[3] By interaction with thioamides it makes possible the preparation of interesting chlorine compounds, VII, containing the halogen in an aliphatic side chain or reactive position and useful for fundamental syntheses involving the application of the principle of alkylation.

Our method of operating has been to apply a malonic ester synthesis with the thiazole halide VII, obtaining first the ester VIII. In this operation a small amount of the disubstitution product IX is always formed. These esters are then saponified to form the corresponding malonic acids X and XI, and finally converted to the respective acetates XII and XIV according to fundamental organic technique. The hydrazides XVI and XXI and corresponding azides XVXI and XXII are then prepared and the latter transformed into the two ureas represented by formulas XVIII and XXIII. In order to obtain the corresponding amines these ureas are then fused with phthalic anhydride according to the technique of Manske and Ing[4] forming the phthalimide derivatives XIX and XXIV and the latter then converted into the required amines by treatment with hydrazine. In this manner we have prepared successfully the 2-phenylthiazole-4-ethylamine IV (XX in Tables I and II) and the interesting derivative of isopropylamine, namely. di-(2-phenylthiazole-4)-1,3-isopropylamine represented by formula XXV. The various compounds prepared in the course of our work and the fundamental experimental data identifying and characterizing the respective thiazoles synthesized are recorded in the two tables, I and II, respectively. A preliminary pharmacological study of these two amines together with other representatives of this series has already been started.

[a] By using the sodium salt of diethylmalonate in 50% excess and by carrying on the synthesis at the temperature of boiling alcohol, the yield of the thiazole VIII was easily raised to 70% of the calcd. and with very little formation of the thiazole IX.

[b] Hydrochloride 91-92°.

[c] The monohydrochloride of this amine crystallizes as rhombic plates melting at 171–172° (calcd. Cl, 14.73. Found Cl, 14.77). The dihydrochloride crystallizes in needles and melts at 206–209°. (Calcd. Cl, 25.59. Found Cl, 25.41, 25.48.)

Experimental Part

2-Phenyl-4-chloromethyl Thiazole, VII.—This halide was prepared according to the method of Suter and Johnson.[3]

Diethyl-2-phenylthiazole-4-methyl Malonate, VIII.—For the preparation of this ester the usual technique applicable for a malonic ester synthesis was employed. By using 50% more than the calculated quantity of diethyl sodium malonate, the yield of monosubstituted ester VIII was raised to the maximum of 70%. The balance of the reaction product is the disubstituted ester IX, which is obtained in the form of a crystalline solid. This deposits from the crude ester reaction product on cooling at a low temperature. Both esters were carried through the same series of reactions and converted into the corresponding amines XX and XXV.

Saponification of these two esters with alcoholic potassium hydroxide led smoothly to the formation of the corresponding malonic acids. The latter on heating above their respective melting points are converted into the acetic acids XII and XV.

Preparation of the Hydrazides, XVI and XXI.—These are formed in excellent yields by digesting the esters XIII and XIV in alcohol with a slight excess of 40% hydrazine hydrate solution. The reaction requires for completion twenty to thirty hours of heating and the hydrazides are obtained in crystalline form without difficulty.

The hydrazides are converted into their corresponding azides by diazotization in glacial acetic acid solution. The latter were obtained in a crystalline condition and both compounds exploded with violence when heated above their respective melting points.

Summary

1. Using thiobenzamide and 2-phenylthiazole-4-chloromethyl thiazole as starting points in our synthetic research, twenty-four new thiazoles have been prepared.
2. The final products of the series of reactions recorded in this paper are the bridged thiazole amines—2-phenylthiazole-4-ethylamine and di-(2-phenylthiazole-4)-1,3-isopropylamine. Both of these bases are physiologically active substances.
3. Our work on thiazole amines is being continued.

THE ACTION OF BASES ON ALPHA,BETA-DIBROMO KETONES AND RELATED SUBSTANCES

BY E. P. KOHLER AND C. R. ADDINALL

RECEIVED JULY 16, 1930 PUBLISHED SEPTEMBER 5, 1930

The reaction between α,β-dibromo ketones and bases has often been used for the preparation of other substances but has seldom been studied with care. It has the interesting peculiarity of yielding products so diverse that some of them can be hydrolyzed to 6-diketones while others serve as the basis of a very general method for preparing the corresponding α-derivatives.

The process leading to β-diketones was discovered by Sorge[1] and studied by Wieland,[2] who showed that the action of methyl alcoholic potassium hydroxide on one of these dibromides occurs in a number of steps which ultimately end in an acetal of a β-diketone.

$$p\text{-}NO_2C_6H_4CHBrCHBrCOC_6H_5 \longrightarrow p\text{-}NO_2C_6H_4C(OCH_3)_2CH_2COC_6H_5$$

The method of converting these dibromides into a-diketones was discovered by Dufraisse and Moureu.[3] After careful study these authors decided that the action of the base—in this case piperidine—must be represented by the following scheme

$$RCHBrCHBrCOR \longrightarrow RCH{=}CBrCOR \longrightarrow RCH_2C(NC_5H_{10})BrCOR \longrightarrow RCH{=}C(NC_5H_{10})COR$$

This scheme assumes a mode of addition of piperidine which is different from that which has been observed in every case in which a base or any other hydrogen compound has been added to an α,β-unsaturated ketone or ester. Dufraisse and Moureu attribute this "inverse" addition to the influence of the bromine in the a-position—a conclusion that has important theoretical consequences and which should, if possible, be confirmed. An examination of this mechanism was the principal object of our investigation.

The mode of attack was based on observations that were made while preparing a series of 6-diketones by the method of Sorge. In the course of these preparations it became evident that in many cases the yields are far from ideal because products are formed which cannot be hydrolyzed to β-diketones. Moreover, the solutions that are left, after removing the β-diketone completely as copper derivative, have a yellow color that is strongly suggestive of that of solutions of a-diketones. Since the reaction with piperidine has already been carefully studied by Dufraisse and Moureu, we decided to work with sodium alcoholates, and a casual observa-

---

[1] Sorge, *Ber.*, 35, 1065 (1902).

[2] Wieland, *ibid.*, 37, 1148 (1904).

[3] Dufraisse and Mourcu, Bull. *soc. chim.*, [4] 41, 457 (1927).

tion led us to select the dibromide of benzal-*p*-bromo acetophenone for investigation.

When this dibromide was boiled with excess of methyl alcoholic sodium methylate, it formed a yellow solution from which after much manipulation we finally obtained two solids which separated from ether in large colorless crystals. These proved to be stereoisomeric acetals of a type very different from the one obtained by Wieland, namely,

$$C_6H_5CHOCH_3CHOHC(OCH_3)_2C_6H_4Br$$

These acetals constituted only about 40% of the products of the reaction, the remainder being composed of oils which on hydrolysis gave *p*-bromodibenzoylmethane. When sodium ethylate was substituted for the methylate all products were solid and it was possible to establish that the reaction leads almost exclusively to substances that are represented by the formulas

$$C_6H_5C(OC_2H_5){=}CHCOC_6H_4Br \text{ and } C_6H_5CHOC_2H_5CHOHC(OC_2H_5)_2C_6H_4Br$$

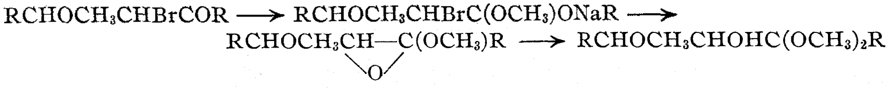
From these results it is clear that the reaction between α,β-dibromo ketones and alcoholates is not as simple as has been assumed. Following the course charted by Wieland, the dibromides first lose a molecule of hydrogen bromide to form an unsaturated a-bromo compound which in the alkaline solution combines with alcohol and forms a saturated bromo ether

$$RCHBrCHBrCOR \longrightarrow RCH{=}CBrCOR \longrightarrow RCHOCH_3CHBrCOR$$

Thus far all the dibromo ketones behave alike, and both the unsaturated and the saturated bromo compounds can be isolated when the solubility relations are favorable. Beyond this point the results depend upon the other groups present in the dibromides. In all the cases that we have examined some of the saturated bromo ether follows the course outlined by Wieland

$$RCHOCH_3CHBrCOR \longrightarrow RCOCH_3{=}CHCOR \longrightarrow RC(OCH_3)_2CH_2COR$$

Occasionally acetals of this type form the sole products of the reaction but this happens only when the dibromide has an unusually active hydrogen atom in the β-position as, for example, the *p*-nitro compound examined by Wieland and the ketonic esters studied by Rice.[4] In all other cases some of the saturated bromo ether reacts in a different manner



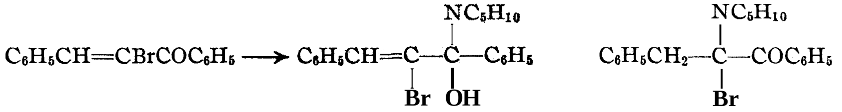
$$RCHOCH_3CHBrCOR \longrightarrow RCHOCH_3CHBrC(OCH_3)ONaR \longrightarrow RCHOCH_3\underbrace{CH{-}C}_{O}(OCH_3)R \longrightarrow RCHOCH_3CHOHC(OCH_3)_2R$$

The discovery that ethylene oxides may play a role in the reaction between bases and dibromo ketones supplies a basis for a new interpretation of the very interesting results of Dufraisse and Moureu. Our work on this phase of the problem has not been completed but in our opinion the course of the reaction between dibromo ketones and piperidine is quite different

---

[4] Rice, THIS JOURNAL, **50**, 1481 *(1928)*.

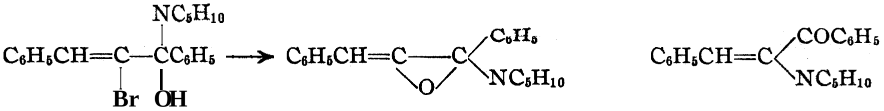
from that which was assumed by the French investigators. After the usual elimination of a molecule of hydrogen bromide the next step is 1,2-addition of piperidine to the carbonyl group. The result is the amine equivalent of a hemi-acetal; hence the great instability of the substance and the ease with which it loses hydrogen bromide—properties which appear to be quite inconsistent with the formula of Dufraisse and Moureu



$$C_6H_5CH{=}CBrCOC_6H_5 \longrightarrow C_6H_5CH{=}\underset{Br}{C}{-}\overset{NC_5H_{10}}{\underset{OH}{C}}{-}C_6H_5 \qquad C_6H_5CH_2{-}\overset{NC_5H_{10}}{\underset{Br}{C}}{-}COC_6H_5$$

D. and M.

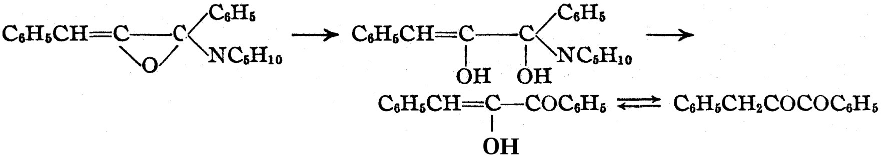
When this unsaturated bromohydrin is allowed to react with sodium methylate or a second molecule of piperidine, it undergoes the usual loss of hydrogen bromide and passes into an ethylene oxide



$$C_6H_5CH{=}\underset{Br}{C}{-}\overset{NC_5H_{10}}{\underset{OH}{C}}C_6H_5 \longrightarrow C_6H_5CH{=}C\underset{O}{\frown}C\begin{matrix}C_6H_5\\NC_5H_{10}\end{matrix} \qquad C_6H_5CH{=}C\begin{matrix}COC_6H_5\\NC_5H_{10}\end{matrix}$$

D. and M.

Like other ethylene oxides the product is capable of combining with bases, acetic acid and like substances. When it is hydrolyzed it inevitably passes into an a-diketone



$$C_6H_5CH{=}C\underset{O}{\frown}C\begin{matrix}C_6H_5\\NC_5H_{10}\end{matrix} \longrightarrow C_6H_5CH{=}\underset{OH}{C}{-}\underset{OH}{C}\begin{matrix}C_6H_5\\NC_5H_{10}\end{matrix} \longrightarrow$$
$$C_6H_5CH{=}\underset{OH}{C}{-}COC_6H_5 \rightleftharpoons C_6H_5CH_2COCOC_6H_5$$

In our opinion, then, Watson's brilliant red piperidine derivative is the first representative of an exceedingly interesting type of unsaturated ethylene oxide.[5] The twinning of the oxide ring with an ethylenic linkage results in a system that is almost as actively unsaturated as that of the ketenes. Like ketenes, therefore, it is highly colored, readily undergoes autoxidation and enters into a variety of reactions that involve the entire system.

Experimental Part

I. p-Bromo Series

Three substances were employed in the *p*-bromo series: the dibromide I, the α-bromo unsaturated ketone II, and the a-bromo-p-methoxy ketone III.

$$\underset{I}{C_6H_5CHBrCHBrCOC_6H_4Br} \quad \underset{II}{C_6H_5CH{=}CBrCOC_6H_4Br} \quad \underset{III}{C_6H_5CHOCH_3CHBrCOC_6H_4Br}$$

These substances were compared with respect to their behavior toward

---

[5] Watson, *J. Chem. Soc.*, 85, 1322 (1904).

methyl alcoholic sodium methylate at the ordinary temperature and also at the boiling point; with two moles of the methylate and with thrice this quantity. The distribution of the material between the two types of reaction differed but little if any, but at the higher temperature there was considerable cleavage of the products which lead to the β-diketone, and the difficulty of isolating solid substances was correspondingly increased.

When the reactions are carried out at the ordinary temperature the result is a pale yellow solution. In order to get any solid from this solution it is necessary to remove the methyl alcohol completely, without allowing the solution to come in contact with acid, secure a solution in equal parts of dry ether and petroleum ether, and allow this to evaporate slowly through a tube that protects it against the acid fumes of the laboratory. It then, in time, usually begins to deposit one or two substances in colorless crystals which gradually grow to unusual dimensions and which can be readily separated mechanically. The first crystals are extremely difficult to secure, but once these are available crystallization can be induced immediately by inoculation.

The structure of these colorless products was established in the following manner. The analyses showed that the composition of both substances is represented by the formula $C_{18}H_{21}O_4Br$, that each has three methoxyl groups and one active hydrogen atom, and that neither has any other group capable of reacting with methyl magnesium iodide. These quantitative results indicate acetals with hydroxyl and a third methoxyl group strung on the chain of benzal-*p*-bromo-acetophenone. Gentle hydrolysis confirmed this conclusion because each substance gave a product which had but one methoxyl group, and along with it an active hydrogen and a group, presumably carbonyl, capable of reacting with one equivalent of methyl magnesium iodide.

In order to get substances more suitable for degradation, each of these hydrolysis products was treated with phenyl magnesium bromide. The result was two new substances and when these were cautiously oxidized with chromic acid, each yielded methyl benzoate and *p*-bromo-benzophenone. These transformations bear but one interpretation

$$\underset{\text{IV}}{C_6H_5CHOCH_3CHOHC(OCH_3)_2C_6H_4Br} \longrightarrow \underset{\text{V}}{C_6H_5CHOCH_3CHOHCOC_6H_4Br} \longrightarrow$$

$$\underset{\text{VI}}{C_6H_5CHOCH_3CHOHC(OH)(C_6H_5)C_6H_4Br} \longrightarrow C_6H_5CO_2CH_3 + CO_2 + C_6H_5COC_6H_4Br$$

The separation of the stereoisomeric trimethoxy compounds (IV) from the ethereal solution was, naturally, incomplete but it was possible to get a fairly accurate estimate of the quantities formed by hydrolyzing the entire product. The resulting β-diketone could be removed completely as its copper derivative, leaving only the isomeric hydrolysis products V which are stable and crystallize much more readily than the corresponding acetals.

Preparation of Materials.—The dibromide I has been described by Weygand,[6] who found a melting point of 184". Our material was repeatedly recrystallized from chloroform and melted at 187°. The a-bromo compound II has also been prepared by Weygand, who distilled it in a high vacuum and noted a boiling point of 136–143°. We found that it distils without decomposition at 230° under 3 mm.

Anal. Calcd. for $C_{15}H_{10}OBr_2$: C, 49.2; H, 2.7. Found: C, 49.2; H, 3.0.

α-Bromo-β-methoxy-benzyl-*p*-bromo-acetophenone, 111.—The bromo methoxy compound was made by the procedure of Middleton? A suspension of equivalent quantities of benzal-*p*-bromo-acetophenone and mercuric acetate in dry methyl alcohol was warmed until the clear colorless solution gave no test for mercuric acetate with alkali. The solution was then evaporated to a small volume. It deposited a solid which after recrystallization from acetone melted at 140°.

Anal. Calcd. for $C_{18}H_{17}O_4BrHg$: Br, 13.8. Found: Br, 13.9.

The mercury compound was suspended in dry methyl alcohol, the suspension was cooled to 0° and treated with an equivalent quantity of bromine. The mixture was set aside until all the color had disappeared, then evaporated in a current of air. It left a colorless oil. This was dissolved in ether, the solution freed from mercury salts by shaking with saturated potassium bromide solution, dried and evaporated. The product was an oil which would not crystallize and could not be distilled. A sample which had been kept in a vacuum desiccator for several weeks was analyzed.

Anal. Calcd. for $C_{16}H_{14}O_2Br_2$: C, 48.3; H, 3.5; OCH_3, 8.0. Found: C, 48.5: H, 3.5; OCH_3, 8.2.

The Isomeric Methyl Acetals, **IV.**—These acetals were first obtained by treating 200 g. of the dibromide in the manner described earlier in this section. One of them crystallized from ether in very large colorless prisms which melt at 90°; the other, which is formed in much smaller quantities, separated from petroleum ether in tables melting at 77". These substances were subsequently obtained more easily and in relatively larger quantities from the α-bromo compound II. The procedure was as follows.

A suspension of 50 g. of the bromo compound in 50 g. of dry methyl alcohol and a solution of 4.5 g. of sodium in 80 cc. of the same alcohol were cooled to 0° and mixed. The mixture was left to itself for three hours during which the temperature was allowed to rise to that of the room. The orange-colored solution was then evaporated under diminished pressure and the residue poured into ether and ice water. The ethereal layer was thoroughly washed with ice water, which reduced the color to a very pale yellow, then dried with calcium chloride, concentrated, mixed with an equal volume of low-boiling petroleum ether and inoculated with both acetals. It deposited in the course of a week 15.5 g. of the higher and 2 2 g. of the lower-melting acetal. The bromomethoxy compound III on similar treatment gave almost exactly the same results: 14.9 g. of the higher-melting and 2.0 g. of the lower-melting acetal from 50 g. of the bromo ketone.

Anal. Calcd. for $C_{18}H_{21}O_4Br$: C, 56.7; H, 5.5; OCH_3, 24.4. Found: (90°) C, 56.8; H, 5.6; OCH_3, 24.5. Found: (77°) C, 56.6; H, 5.5; OCH_3, 25.0.

The acetals are moderately soluble in petroleum ether, readily soluble in ether and other common organic solvents. Neither is stable in the air; the crystals of the higher-melting form gradually become opaque as they become covered with a film of the hydrolysis product and the lower-melting modification soon liquefies and then, as hydrolysis becomes nearly complete, resolidifies.

Hydrolysis.—When the acetals are hydrolyzed with dilute acetic acid, each gives

---

[6] Weygand, *Ann.*, 459,118 (1927).

[7] Middleton, THIS JOURNAL, 45, 2763 (1923).

but one compound, while treatment with methyl alcoholic hydrochloric acid generally gives a mixture of both hydrolysis products. A solution of 5 g. of the higher-melting isomer in 25 g. of glacial acetic acid was diluted with an equal volume of water, and then digested on a steam-bath for thirty minutes. The clear colorless solution, on dilution, precipitated a colorless oil. This was collected in ether. The washed and dried ethereal solution on evaporation deposited a colorless solid which separated from ether–petroleum ether in stout needles or plates melting at 89°.

Anal. Calcd. for $C_{16}H_{15}O_3Br$: C, 57.3; H, 4.5; OCH_3, 9.2. Found: C, 57.2; H, 4.7; OCH_3, 9.4.

The lower-melting isomer, when treated in the same manner, gave a product which crystallized in tables or stout prisms and melted at 96°.

Anal. Calcd. for $C_{16}H_{15}O_3Br$: C, 57.3; H, 4.5; OCH_3, 9.2. Found: C, 57.1; H, 4.8; OCH_3, 8.7.

In the machine[8] these isomeric hydrolysis products behaved alike; each consumed two moles of reagent and liberated one mole of gas.

The Grignard Products, α-Phenyl-α-methoxy-β-hydroxy-γ-phenyl-γ-(4-bromophenyl)-γ-hydroxy-propane, VI.—An ethereal solution of 1.5 g. of the hydrolysis product (89°) was added to a solution of phenyl magnesium bromide prepared from 1 g. of magnesium. The mixture was boiled for fifteen minutes and then decomposed with iced acid. After the usual manipulations the operation yielded 1.5 g. of a solid product which crystallized from ether–petroleum ether in fine needles and melted at 119–120°.

Anal. Calcd. for $C_{22}H_{21}O_3Br$: C, 64.0; H, 5.1; OCH_3, 7.5. Found: C, 64.0; H, 5.3; OCH_3, 7.5.

The glycol is sparingly soluble in petroleum ether, readily soluble in ordinary ether and in methyl alcohol. It is very readily oxidized by chromic acid. A solution of 0.45 g. of the substance in 20 g. of glacial acetic acid was warmed to 70°. Into this solution was dropped an aqueous solution of chromic acid as long as the color disappeared immediately. The solution was then poured into cold water, which precipitated a crystalline solid. This was identified as pure p-bromobenzophenone by comparison with a sample on hand. The filtrate from the ketone was saturated with salt and extracted with ether. The ethereal solution, freed from acids by extraction with bicarbonate, was evaporated. It left an oil which was identified as methyl benzoate by the odor and by hydrolysis to benzoic acid.

The isomeric hydrolysis product (96°) was also treated with phenyl magnesium bromide but failed to give a crystalline product. The colorless oil that was left after evaporating the ethereal solution was therefore oxidized with chromic acid. Like its isomer it yielded p-bromobenzophenone, methyl benzoate and no other products. The hydrolysis products and the acetals from which they are formed must, therefore, be stereoisomers.

The Ethyl Acetal, $C_6H_5CHOC_2H_5CHOHC(OC_2H_5)_2C_6H_4Br$.—When the dibromide of benzal-p-bromo-acetophenone was shaken with excess of cold sodium ethylate it yielded, after the usual manipulation, a pale yellow solution that ultimately solidified almost completely. The solid was composed mainly of β-ethoxy-benzal-*p*-bromoacetophenone and an acetal. The unsaturated ethoxyl compound was readily isolated because it is far less soluble than the acetal but the isolation of pure acetal required patient fractional crystallization. It separates from petroleum ether in large colorless plates and melts at 99°.

Anal. Calcd.: C, 59.6; H, 6.4; OC_2H_5, 31.9. Found: C, 59.8; H, 6.6; OC_2H_5, 30.6.

---

[8] Kohler and Richtmyer, THIS JOURNAL, 52, 3736 (1930).

Hydrolysis, $C_6H_5CHOCH_2CH_5OHCOC_6H_4Br$.—The acetal, like the corresponding methoxyl compounds, is unstable in the air of the laboratory; it first liquefies, then resolidifies. The solid is the pure hydroxy ketone. This is easily obtained in quantity by hydrolyzing the acetal with dilute acetic acid in the usual manner. It is readily soluble in all organic solvents, crystallizes in needles and melts at 72°.

Anal. Calcd. for $C_{17}H_{17}O_3Br$: C, 58.4; H, 4.9; OC_2H_5, 12.9. Found: C, 58.4; H, 5.2; OC_2H_5, 14.2.

β-Ethoxy-benzal-*p*-bromo-acetophenone, $C_6H_5C(OC_2H_5){=}CHCOC_6H_4Br$.—The ethoxyl compound crystallizes well from all solvents, separating in plates from methyl alcohol and in very large tables from ether and from petroleum ether. It melts at 112° and on hydrolysis yields *p*-bromodibenzoylmethane.

Anal. Calcd. for $C_{17}H_{15}O_2Br$: C, 61.6; H, 4.5. Found: C, 61.7; H, 4.6.

II. Other Dibromides

A. p-Nitro Compounds

The behavior of a few other dibromides was examined for the purpose of ascertaining how the distribution of the material is affected by the presence of substituents in the phenyl groups. Wieland[2] treated the dibromide of *p*-nitro-benzalacetophenone (VII) with methyl alcoholic potassium hydroxide and obtained only the dimethyl acetal of *p*-nitrodibenzoylmethane. We employed sodium methylate and extended the experiments to include the two stereoisomeric unsaturated a-bromo compounds VIII, and the bromo methoxyl compound IX. All of these substances yielded at least 95% of the acetal obtained by Wieland.

$$NO_2C_6H_4CHBrCHBrCOC_6H_5$$

VII

$$NO_2C_6H_4CH{=}CBrCOC_6H_5$$

VIII

$$NO_2C_6H_4CHOCH_3CHBrCOC_6H_5$$

IX

a-Bromo-finitrobenzalacetophenone, VIII.—Weygand[9] boiled the dibromide VII with methyl alcoholic potassium acetate for eight hours and distilled the product in a high vacuum. He obtained an a-bromo compound that melted at 106°. This was evidently a mixture of the two stereoisomers. We suspended the dibromide in a mixture of equal volumes of acetone and methyl alcohol, added excess of potassium acetate and allowed the reaction to proceed in the cold. All the dibromide disappeared within an hour. The solution was evaporated in a current of air. It left an oil that soon solidified. By systematic fractional crystallization from acetone–methyl alcohol mixtures the solid was separated into pale yellow needles melting at 130° and darker yellow plates that melted at 62°.

Anal. Calcd. for $C_{15}H_{10}O_3NBr$: C, 54.2; H, 3.0. Found: (136°) C, 54.6; H, 3.1. (62°) C, 54.2; H, 3.1.

The Bromo Methoxy Compound IX.—The preparation of this substance is exceedingly difficult because the reaction between the unsaturated ketone and mercuric acetate is both slow and incomplete even in boiling methyl alcohol. The mercury compound was not purified but treated directly with bromine. The product crystallized from acetone and methyl alcohol in colorless plates melting at 131°.

Anal. Calcd. for $C_{16}H_{14}O_4NBr$: C, 52.7; H, 3.8. Found: C, 52.8; H, 4.0.

---

[9] Weygand, Ref. 6, p. 116.

All three of these compounds were treated with sodium methylate in the usual manner, but instead of attempting to isolate the acetals, the entire product was hydrolyzed with acetic acid. The residue left after removing the β-diketone as copper derivative in no case equaled 5% of the bromo compound that was used.

B. *m*-Nitro Compounds

In the m-nitro series we examined only the dibromide and the bromo methoxy compound. The former has been described by others; the latter was prepared as usual, by way of the mercury compound.

A suspension of 20 g. of the unsaturated ketone and an equivalent quantity of mercuric acetate in 500 cc. of dry methyl alcohol was boiled for twelve hours. The clear very pale yellow solution was concentrated step by step. It gradually deposited 20 g. of the mercury compound, which crystallized from acetone in hard nodules of colorless needles, sparingly soluble in ether and in methyl alcohol, readily soluble in acetone.

The mercury compound was suspended in methyl alcohol and treated with bromine. The reaction was very sluggish but the mercury compound gradually disappeared at the boiling point. The product, a colorless solid, was recrystallized from methyl alcohol.

Anal. Calcd. for $C_{16}H_{14}O_4NBr$: C, 52.7; H, 3.8. Found: C, 53.0; H, 4.0.

α-Bromo-β-methoxy-*n*-nitrobenzylacetophenone, $NO_2C_6H_4CHOCH_3CHBrCOC_6H_5$, is sparingly soluble in cold methyl alcohol, moderately soluble in hot methyl alcohol, readily soluble in acetone. It crystallizes from methyl alcohol in colorless needles melting at 132°. The yield was 80%.

α-Hydroxy-β-methoxy-*n*-benzylacetophenone, $NO_2C_6H_4CHOCH_3CHOHCOC_6H_5$.—The dibromide and the bromomethoxy compound were treated with sodium methylate in the usual manner, and in each case the mixture of products was immediately hydrolyzed with aqueous acetic acid. The ethereal solutions left after removing the *P*-diketone as copper derivative deposited the hydroxy ketone as a colorless solid. The substance was purified by recrystallization from ether–petroleum ether, from which it separated in colorless prisms melting at 110°. The yield from the dibromide was 30% and from the bromomethoxy compound 33%. As would be expected, the nitro group in the meta position has little influence.

Anal. Calcd. for $C_{16}H_{15}O_5N$: C, 63.8; H, 5.0. Found: C, 64.1; H, 5.2.

C. Anisyl Compounds

The behavior of the dibromide of benzalacetylanisole toward sodium methylate has been examined by Weygand[10] but we included it in our experiments because we expected it to be at least as favorable for the formation of the new type of acetal as the corresponding *p*-bromo compound. We have been unable to establish this because we did not succeed in getting either the acetal or its hydrolysis product in a crystalline form. In another respect, however, the behavior of the dibromide was gratifying; it provided the first case in which the dibromide could be transformed directly into the α-bromo-β-methoxy derivative.

α-Bromo-β-methoxy-benzylacetylanisole, $C_6H_5CHOCH_3CHBrCOC_6H_4OCH_3$.—A solution of 6 g. of sodium in 120 g. of anhydrous methyl alcohol was added to a suspension of 43.5 g. of the dibromide in 75 cc. of the same solvent. The mixture was shaken

---

[10] Weygand, Ref. 6, p. 107.

vigorously until solution was complete, then cooled first in ice water and finally in a freezing mixture. It deposited 30 g of a mixture of solids which was readily separated by recrystallization from methyl alcohol. The principal product was sparingly soluble in methyl alcohol but was readily recrystallized from a mixture of acetone and methyl alcohol from which it separated in colorless plates melting at 126°.

Anal. Calcd. for $C_{17}H_{17}O_3Br$: C, 58.5; H, 4.9. Found: C, 58.4; H, 5.0.

The bromomethoxy compound was obtained even more readily by shaking a suspension of α-bromo-benzalacetylanisole in anhydrous methyl alcohol containing a small quantity of sodium methylate. In the hope of getting a stereoisomeric bromomethoxy compound we also added mercuric acetate to benzalacetylanisole and brominated the product, but these operations gave the same bromo compound. This substance was, doubtless, also obtained by Weygand by boiling a suspension of the dibromide with methyl alcoholic potassium hydroxide. Weygand naturally assumed that the product would be an α-bromo-benzalacetylanisole and attributed his analytical results to the difficulties met with in the analysis of methoxyl compounds.

The remainder of the solid product was a mixture which was separated by recrystallization from ether and petroleum ether into the α-bromo and β-methoxy derivatives of benzalacetylanisole. These substances have been accurately described by Weygand.

A solution of the bromomethoxy compound in methyl alcohol was shaken with an excess of sodium methylate for thirty-six hours. The product was isolated in the usual manner but failed to give any solid compounds. It was therefore hydrolyzed with aqueous acetic acid. It yielded the diketone (about 70%) and an oil from which it has not as yet been possible to obtain any solid compounds.

Summary

1. α,β-Dibromo ketones may react with alcoholates in two different ways which ultimately lead to very different types of acetals

$$RC(OR)_2CH_2COR' \longleftarrow RCHBrCHBrCOR' \longrightarrow RCH(OR)CHOHC(OR)_2R'$$

2. Most dibromo ketones yield both acetals, but when the hydrogen in the β-position is unusually active, the acetal of a β-diketone may be the only product.

THE "MACHINE" FOR ANALYSIS WITH GRIGNARD REAGENTS

BY E. P. KOHLER AND N. K. RICHTMYER

RECEIVED AUGUST 12, 1930 PUBLISHED SEPTEMBER 5, 1930

Since the appearance of the original paper on an "apparatus for determining both the quantity of gas evolved and the amount of reagent consumed in reactions with methyl magnesium iodide,"[1] the apparatus has been redesigned and considerably improved. In view of a steadily increasing number of inquiries, dealing largely with the special stopcock, it seems desirable to publish the new design and to show how this beautiful but troublesome stopcock has been eliminated.

---

[1] Kohler, Stone and Fuson, THIS JOURNAL, 49, 3181 (1927).

By introducing the reagent into the top of the buret we have been able to use an ordinary two-way stopcock which comes in contact with the reagent at but one point, hence can often be used for a month or more without being regreased. In redesigning the apparatus we also eliminated the ground-glass joint at the top of the reservoir A and improved the shoulder, *i*, in order to secure a better control of the temperature of the gas inclosed in the shoulder.

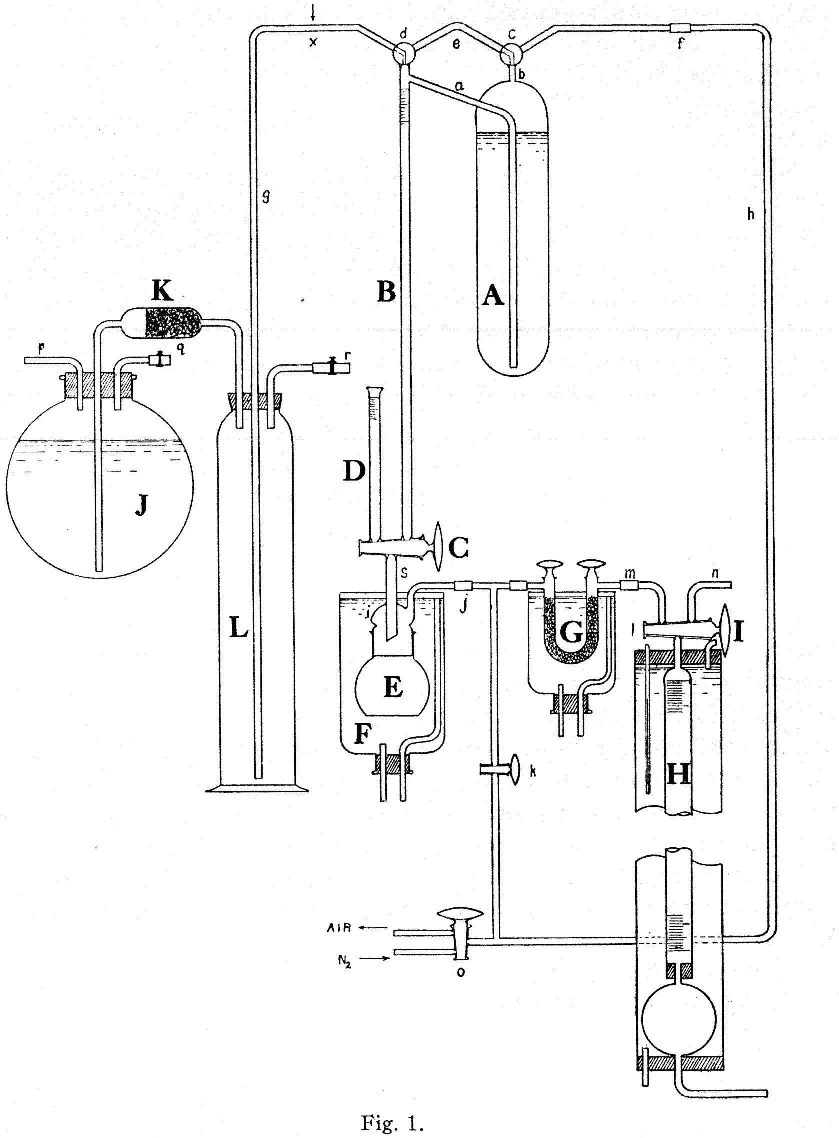

Fig. 1.

These alterations do not necessitate any serious changes in the operation of the machine. In order to clean the reservoir it is now necessary to dismount the entire machine but since a single charge serves for about a hundred analyses we do not regard this as a serious matter. After filling the reservoir we cut the tube g at x and clean the small section between x and d with a pipe cleaner. This leaves a light, compact apparatus which is relatively free from strain, and which we hold with a single clamp on the reservoir.

The reagent is now pressed from the reservoir to the reagent buret through a. After the desired amount has been introduced into the buret the stopcocks c and d are turned to open the reservoir to the air for an instant; this relieves the excess pressure in A. Then c and d are turned in such a manner that the nitrogen presses the reagent remaining in a, back into the reservoir, after which **A** is again momentarily opened to the air. All stopcocks can be removed, cleaned and regreased in a properly directed current of nitrogen without affecting the titer of the solution. It is well also to sweep the system o–k–j–i with nitrogen while spraying the shoulder i with alcohol and ether after an analysis has been completed.

For the preparation of the methyl magnesium iodide necessary to fill the 500-cc. reservoir we use the following procedure. In a one-liter three-necked, round-bottomed flask, equipped with motor stirrer, dropping funnel and condenser, are placed 12 g. of magnesium and 100 g. of isoamyl ether (distilled *in vacuo,* over sodium). In the course of one hour, with the temperature maintained below 20°, 60 g. of methyl iodide in 50 g. of isoamyl ether is added. Stirring is continued for two hours. The reagent is then diluted by the addition of 270 g. of isoamyl ether. The condenser is removed and the flask, immersed in an oil-bath, is heated at 120° for two hours; meanwhile a current of purified nitrogen is passed over the reaction mixture to carry away any readily volatile products. After being allowed to stand overnight, the reagent is transferred to the apparatus.

We have found it advantageous to substitute dehydrite for the phosphorus pentoxide in G, and to enlarge the overfiow bulb in the gas buret H to 50 cc.

NOTE

Mannitol from Haplophyton Cimicidum.—During the course of an investigation of the reported insecticidal properties of the plant *Haplophyton Cimicidum*, mannitol was isolated and identified. The crude crystalline material, separating from the concentrated alcoholic extract of this plant, from which pure mannitol was obtained, represented approximately 0.75% of the weight of the plant on a dry basis. The substance was identified by means of its tribenzacetol and hexacetyl derivatives.

COMMUNICATIONS TO THE EDITOR

AN X-RAY EXAMINATION OF THE HIGHER NORMAL PRIMARY ALCOHOLS

Sir:

X-ray examination of the higher normal primary alcohols reveals an interesting distinction between the odd and the even carbon chain series. As is usual with such long-chain compounds, the large crystal spacing increases linearly with increasing carbon content, and in the case of the higher alcohols, when crystallized from ethyl alcohol, the long crystal spacings for the odd alcohols lie on the upper Curve, I (Fig. 1), while those for the even alcohols (above C_{16}) lie on the lower Curve, II. The point of interest is, however, that below C_{16} the spacings of the even alcohols lie

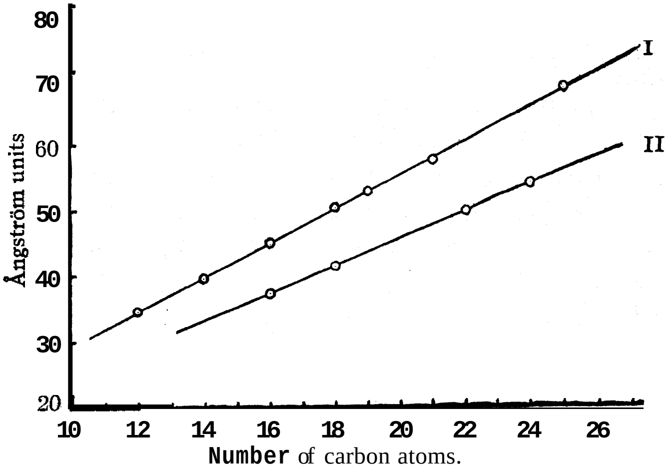

Fig. 1.

on the upper (odd) line, C_{16} alcohol itself gives two spacings, one on each line, while C_{18}, if fused, then gives a spacing on the upper line. The spacings of the odd alcohols, crystallized from solvents or fused, lie on the same upper line.

If the diameter of the carbon atom is taken as 1.54 Å., the spacings on Curve I correspond closely to a vertical chain of carbon atoms inclined tetrahedrally to each other, and those in Curve II to a similar chain tilted at an angle of 55° 40'. The vertical form is clearly a stable form for the odd alcohols and the tilted form for the even, but the latter change into the vertical form at some point below fusion. Apparently this change takes place considerably below the melting point since myristyl alcohol C_{14}, m. p. 38°, crystallized from alcohol, gives a spacing corresponding to the vertical form, and cetyl alcohol C_{16}, m. p. 49.0°, exhibits both spacings, thus indicating in the latter case that ordinary room temperature is near the transition point.

The following data were obtained using the Ka-rays of iron reflected from thin layers of the alcohols pressed or fused on a glass strip and mounted on a Müller spectrograph. The intensity distribution indicates that the alcohols crystallize in double molecules with the hydroxyl groups in juxtaposition.

X-RAY DATA FOR NORMAL PRIMARY ALCOHOLS

No. of carbon atoms	**12**	**14**	**16**	**18**	**19**	**21**	**22**	**24**	**25**
M. p., °C.........	**23.0**	**38.0**	**49.0**	**59.0**	**62.0**	**68.5**	**72.0**	76.5–77	**78.5**
Spacing, pressed layer, Å........	..	**39.7**	..	**41.35**	**52.75**	**57.4**	**49.95**	**54.0**	**68.5**
Spacing, melted, layer, Å........	**34.8**	..	**37.4** **44.9**	**50.2**	**52.8**	**56.9**	...	.....	..

It is hoped that these data will be of service to those working on the higher natural alcohols since x-ray analysis promises to afford a ready method of identification. In particular it should be useful in distinguishing between those higher alcohols of adjacent carbon content that are so difficult to identify by purely chemical means. In a subsequent paper it is hoped to give an account of the x-ray data for long-chain nitriles and iodides.

The writer wishes to express his thanks to Mr. S. H. Piper for his friendly interest in this work.

THE METALLIC PRECIPITATION OF ZIRCONIUM

Sir:

The preparation of zirconium of a high degree of purity is not easy. The element combines or alloys itself with the reducing agents employed to prepare it. Probably the best method now used was devised by A. E. van Arkel and H. de Boer, who have obtained the metal by passing the vapor of the tetraiodide over a heated tungsten filament. Many metals may be prepared by precipitation from solution by a more electropositive substance than themselves. H. N. Warren[1] appears to have been the only one to employ this method for the preparation of zirconium. He states that if a rod of magnesium be wrapped with a few coils of asbestos paper and immersed in a solution of a metallic salt, the metal is precipitated on the asbestos in crystalline form. "Even zirconium was gradually reduced." This statement is erroneous, for zirconium compounds hydrolyze in water with the formation of free acid which would react with the magnesium.

It was thought, however, that zirconium might be precipitated from a solution other than aqueous. It was found that zirconium sulfate was quite soluble in methyl alcohol, the salt dissolving with a hissing sound and crystallizing out on evaporation. The alcoholic solution of zirconium sulfate was treated with metallic zinc. Hydrogen was given off, and the surface of the zinc was covered with a dark deposit. The reactions were accounted for by the equations

$$Zn + H_2SO_4 \longrightarrow ZnSO_4 + H_2 \qquad (1)$$
$$2Zn + Zr(SO_4)_2 \longrightarrow 2ZnSO_4 + Zr \qquad (2)$$

Since all zirconium sulfate contains a small amount of free sulfuric acid, introduced by methods of manufacture and by hydrolysis, the presence of hydrogen may be accounted for by Equation 1. As the reaction continued, the amount of hydrogen evolved decreased until no more gas was given off. The acidity decreased proportionally until at this point it took as much as five minutes for blue litmus to turn red. When a part of the deposit was scraped off and treated with hydrochloric acid, the zinc removed along with the deposit dissolved, leaving undissolved zirconium on the bottom of the container.

When magnesium was substituted for zinc, a white precipitate of undetermined composition was formed and no zirconium was precipitated.

The inability to continue this study for some time has caused this preliminary report to be prepared

NEW BOOKS

The Condensed Chemical Dictionary. Compiled and edited by the Editorial Staff of the Chemical Engineering Catalog. FRANCIS M. TURNER, Editor. Second edition, completely revised and enlarged under supervision of THOMAS C. GREGORY, Editor, and ISABELLE M. WELCH, Assistant Editor. Book Department, The Chemical Catalog Co., Inc., 419 Fourth Avenue, at 29th Street, New York, U. S. A., 1930. 551 pp. 16 X 23.5 cm. Price, $10.00.

This book is essentially a list of useful chemical materials, the substances employed and produced in the chemical arts and industries, together with such information as formulas or compositions, colors, important properties, constants (d., b. p., m. p.), solubilities, derivations, grades, commercial containers, shipping regulations, fire hazards, etc. The cross indexing is unusually complete. The new edition contains some 12,000 titles as compared with about 7000 in the old. In spite of this very considerable increase in contents the volume is less bulky and more easily handled than the earlier one because of the use of thin paper and smaller type. The preferred usages of the American Chemical Society with regard to spellings and terminology are in general followed, although it is to be regretted that in this second edition as well as in the first, a few obsolescent forms such as sulfocyanide (for thiocyanate) are still used.

The book is especially valuable to the general chemist because of the inclusion of trade and proprietary names in great variety, in spite of the fact that a few common names (vitreosil, chromel, pyrex) for some reason do not appear in their respective alphabetical positions. The relationship of this volume to the bulky Chemical Engineering Catalog issued by the same publishers is close; and, although the general appeal of the Dictionary is to the industries, it furnishes much general information of interest to all chemists and not easily found elsewhere.

WILLIS A. BOUGHTON

L'Ancienne et la Nouvelle Théorie des Quanta. (The Old and New Quantum Theories.) By EUGÈNE BLOCH, Professor of Physics at the Sorbonne. Librairie Scientifique Hermann et Cie., 6, Rue de la Sorbonne, Paris, France, 1930. iii + 417 pp. Illustrated. 16.5 X 25 cm. Price, 90 fr.

This book, based on courses of lectures given by Professor Bloch at the Sorbonne in 1926–1927, 1927–1928 and 1928–1929, furnishes the most satisfactory introduction to the quantum theory that the reviewer has seen. It is elementary, in the very best sense of the word, in that it contains a clear, coherent and detailed discussion of the nature of the fundamental concepts of the old and new quantum theories, and presents simple and important examples of their application, without the burden of more complicated ones. It thus differs from those treatises which appear to contain a hodge-podge of everything the authors have ever heard about, unillumined by any clear understanding of the theoretical basis upon which they are presumably proceeding. It is written in a French which seems clear and beautiful even to one but meagerly acquainted with that language. Its translation into English to make it more widely available would seem eminently desirable.

After an introductory historical chapter which sketches the course of development both of the old and new theories, the first half of the book is devoted to the exposition of the old quantum theory, including a well-balanced correlation with experimental results. This part of the book also contains a useful chapter on fundamental results of analytical mechanics.

The second half of the book is devoted to the new quantum mechanics, and here the author's clear treatment of fundamental notions is in especially pleasing contrast to the work of minor scientists who hurry into print with the complicated applications of theories that they do not understand. The author first considers the waves of de Broglie and the actual experiments showing the wave character of the electron. This is followed by chapters on the wave mechanics of Schroedinger, and the matrix mechanics of Heisenberg, including a demonstration of their equivalence. Clear expression is given to modern ideas as to the principle of indeterminism, and the fundamental wave-particle duality in nature.

The transformation theory of Dirac and his treatment of the electromagnetic equations are not presented. The book concludes with a very good introduction to the new forms of statistical mechanics. It contains a fairly complete Table of Contents but no Index.

RICHARD C. TOLMAN

Chimica Farmaceutica e Tossicologica (Inorganica ed Organica). (Pharmaceutical and Toxicological Chemistry.) By BERNARDO ODDO, Professor at the University of Pavia. Casa Editrice, Dottor Francesco Villardi, Milan, Italy, 1930. Vol. I, vii + 486 pp. Vol. II, xii + 505 pp. Illustrated. 16.5 × 25 cm. Price, complete, lira 120.

This treatise is essentially a reproduction of the author's course of instruction in pharmaceutical and toxicological chemistry, including a brief exposition of the broader aspects of the subject. Departing entirely from the arbitrary custom of dividing the medico-pharmaceutical products into inorganic and organic groups, the author follows a pharmacological scheme of classification, treating the subject, in Vol. I, under the following heads: antiseptics, caustics, tonics and hematinics, purgatives, emetics, diuretics and uric acid solvents, vermifuges, vasodilators and -constrictors, while Vol. II is given over to antiseptics, anesthetics, sedatives, hypnotics, carbohydrates and artificial sweeteners, active principles of essential oils, alkaloids, glucosides, extractives, biological products, certain highly toxic principles and drug accessories. Throughout the entire work frequent reference is made to structural chemistry as related to pharmacological action for the proper evaluation of various synthetic drugs, in connection with the reasons for arriving at certain conclusions, and how it is possible to conceive and prepare new drugs to be tested pharmacologically. The treatise concludes with a chapter on toxicological analysis, in addition to a table of atomic weights, conversion tables and a comprehensive index.

W. O. EMERY

Die **Kolloide** in Biologie und **Medizin.** (Colloids in Biology and Medicine.) By Professor Dr. H. BECHHOLD, Director of the Institute for Colloid Research, Frankfort-on-Main. Fifth, revised edition. Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1929. xii + 586 pp. 87 figs. 16 X 23 cm. Price, unbound, RM. 32; bound, RM. 35.

In this fifth revised edition, Bechhold's well-known book has been brought up to date. The extent to which the author has mastered the increase in knowledge since the first edition appeared (1912) may be judged by the fact that the present edition, though greatly increased in scope, has almost been maintained in size within the limits of the first edition. This achievement may partly be ascribed to the nature of the recent developments in knowledge, many of which have replaced bulky empiricisms with concise theoretical formulations, partly to the splendidly critical sifting of material practised by the author. Any author who restricts his presentation to the most essential methods of a science which is in rapid development will inevitably stimulate discussion not only of the material included, but of that omitted.

The original subdivisions which proved so fruitful a means of presenting the vast material have remained unchanged. The first part of the book deals with the definitions and methods of colloid chemistry. Here considerable changes over the previous form have occurred and the author has brought the new material into the old plan without giving that feeling of lack of homogeneity which attaches to so many "revised" editions.

The second part is entitled "biocolloids." The main chapters are concerned with carbohydrates, lipoids, proteins, foodstuffs, enzymes and, as a new addition, immunity reactions. This chapter was written in collaboration with Dr. Laszlo Reiner. References to the current literature render these chapters extremely valuable, even though it be impossible to cover the immense field which might be comprised under the chapter heads.

Part three deals with the organism as a colloid system. In this part Bechhold has presented a great amount of histological, physiological and biological material from the point of view of the colloid chemist. To all those who are interested in medical science, this part, written with a profound knowledge of the problems involved, will be very stimulating. This is a clever selection of those fields in which the phenomena can at least be considered at this time.

Part four, finally, gives some of the applications of colloid chemistry to toxicology, pharmacology and microscopical technique. The very complete index, together with the references to the original literature, will be of great value to those who wish to follow the indicated problems.

For the sake of the reader with medical training, Bechhold has avoided, wherever it seemed possible, the use of mathematical formulas. It might be questioned if the medical reader ought not to be educated in the understanding of mathematical formulations through just such a book in which colloid chemistry is brought into contact with biology and medicine.

It may be concluded, I think, that the hope expressed by reviewer L. J. Henderson in these pages regarding the first edition, namely, "that this work will, through future editions, grow up with the subject" is in large part fulfilled by this new edition.

ALEXANDER VON MURALT

An Index to the Chemical Action of Microorganisms on *the* Non-Nitrogenous Organic Compounds. By ELLIS I. FULMER, Ph.D., Professor of Biophysical Chemistry, and C. H. WERKMAN, Ph.D., Associate Professor of Bacteriology, Iowa State College, assisted by Anella Wieben and Calvin R. Breden, Instructors in Chemistry, Iowa State College. Charles C. Thomas, Publisher, 220 East Monroe Street, Springfield, Illinois, 1930. xiii + 198 pp. 15.5 X 23 cm. Price, $4.50.

When we consider that there is probably no organic compound in nature that is not attacked by some microorganism, we must admire the courage of the authors in undertaking this index. They have delimited the field, however, by considering only "those instances in which a named organism acted on a named substance to produce a named compound." The material is arranged in three tables: Table I featuring the organisms, Table II the substrates and Table III the products. Each table includes the other two subjects and the references to the authorities cited—about 500 in number. The book contains much information in a compact and usable form. Every worker in the field of fermentation will want to have it on his desk for ready reference.

The chief criticism that must be made of the book is its incompleteness. While some subjects are treated rather fully, others are barely mentioned, or entirely neglected. No mention is made of the organisms which Conrad, Wehmer and Henneberg isolated from sauerkraut and to which they attribute the formation of this important food. In listing *Cl* acetobutylicum, the commercial butyl alcohol organism, the authors omit the paper on which the name is based. The fermentation of cellulose is dismissed with three references, while at least a half dozen important papers by Omelianski, Kellerman, et *al.*, Hutchinson and Clayton, Coolhaas, and Itano and Arkawa are omitted. The general occurrence of methane as a fermentation product in marshes, manure piles and the intestinal tract of animals would certainly entitle it to a place in the products table, but it is not listed, nor is Omelianski's organism, B. *methanigenes*, which produces it, given in the table of microörganisms. Two references are given to the formation of mannitol but the classic papers of Gayon and Dubourg, Van Steenberge and Miiller-Thurgau and Osterwalder are left unnoticed. The production of pyruvic acid and acetaldehyde by yeast is well indexed but some reference should also have been made to the equally important intermediate compounds, hexosephosphate and methyl glyoxal.

Some errors in the content of the tables have been noted. On page 73 it is said that propionic acid is formed by *Diplococcus pneumonia*. A careful reading of Brieger's original paper shows that not *Diplococcus pneumonia* but an unnamed short rod was the causal agent. The organism which is called B. *mobilis* on page 22 appears as B. *motilis* on page 84, and in the original paper by Orla-Jensen is given as B. *nobilis*. The reference, Mayer 1898, given in the tables does not appear among the references in the bibliography. Of forty references selected at random, sixteen contained more or less serious errors. The reviewer anticipates for the book a large demand which will call forth future editions and permit correction and expansion of its contents.

THE LINE SPECTRA OF IONS IN THE SOLID STATE IN THE VISIBLE AND ULTRAVIOLET REGIONS OF THE SPECTRUM. THE ABSORPTION SPECTRA OF $GdBr_3 \cdot 6H_2O$ AT ROOM TEMPERATURE AND AT THAT OF LIQUID AIR AND THEIR COMPARISON WITH THOSE OF $GdCl_3 \cdot 6H_2O$

BY SIMON FREED AND FRANK H. SPEDDING

RECEIVED MARCH 3, 1930 PUBLISHED OCTOBER 6, 1930

It is well known that the absorption spectra of the solutions of colored salts[1] consist of very broad bands and that the detail which the quantum theory requires to analyze them appears unattainable at present. The absorption spectra of crystals are less diffuse and they offer greater hope in this connection because the ions in a crystal lattice are subject to fields of greater regularity than exist in solution. It is a fact that the solutions of the rare earths possess relatively narrow bands and one would expect to find that their crystals would exhibit absorption spectra of exceptional sharpness.[2] In the next few paragraphs we shall attempt to show that the ions of the transition elements (the most common colored ions) should be regarded as polyatomic in the solid state and in solution, while those of the rare earths may be treated as atomic and hence as the simplest for spectroscopic study.

In his work on the spectra of complex atoms and ions in the gaseous state Hund[3] showed how to determine the character of the basic state of an atom (or atomic ion) from the number of the electrons in its various shells. He employed these basic states to calculate the magnetic moments of many ions but for lack of data upon paramagnetic monatomic gases he compared his results with the measured susceptibilities of ions in the solid state and in solution. The agreement was remarkably good in the case of the ions of the rare earths but there was no semblance of agreement with the ions of the iron group (the first long row of the periodic table). It seems then as if

[1] Jones and Strong, *Carnegie Inst. Wash. Pub.*, No. 110 (1909); No. 130 (1911); No. 160 (1916).

[2] Bunsen, Pogg. *Ann.*, 128, 100 (1866).

[3] Hund, *Z. Physik*, 33, 853 (1925).

Hund's assumptions do not apply here and it is not difficult to find the reason.[4]

Let us compare a particular example of an ion in the iron group with one in the rare earth group, chromic ion and gadolinium ion. The electronic configurations of these ions in the gaseous state are electronic shells

	1_1	2_1	2_2	3_1	3_2	3_3	4_1	4_2	4_3	4_4	5_1	5_2
Cr^{+++}	2	2	6	2	6	3						
Gd^{+++}	2	2	6	2	6	10	2	6	10	7	2	6

We observe that the ions in the iron group have their incomplete electronic shells in the outermost orbits where they can readily couple with electrons of other substances such as Cl^- or H_2O. It is well known since the work of Werner that Cr^{+++} in solution is really $Cr(H_2O)_6^{+++}$. On the other hand, the unbalanced electrons in the structure of the ions of the rare earths are within the kernel of the ion and are shielded from external coupling by the completely filled 5_1 and 5_2 shells. In fact, the rare earths do not form complex ions and it is well known that their colors are unaffected (or only to a slight degree) by changing the medium in which they are dissolved. The ions of the iron group are extremely sensitive to their medium. For example, the addition of ammonia or cyanide ion completely transforms the colors of chromic ion or cupric ion. We conclude that there is a radical difference between the electronic configurations of these ions in the gaseous state and their configurations in solution. That is, chemical bonds between the water molecules and the metallic ion have transformed the atomic ion into a polyatomic or molecular ion and hence Hund's theory[3] for atomic ions is not applicable. We must have recourse to theories concerning the stationary states of polyatomic molecules, such as have been devised to interpret band spectra. Among the ions of the rare earths, no chemical coupling has occurred, so that these ions are truly atomic in solution and in the crystal. Their magnetic properties establish definitely that they have the same electronic configurations here that they have in the gaseous state. The water molecules are attached to the positive ions by the forces of electrostatic polarization and not by chemical bonds (pairs of electrons whose magnetic moments have neutralized each other).

According to this reasoning, the absorption spectra of the rare earths resemble the line spectra of monatomic gases, whereas the absorption spec-

[4] A great deal has been written upon the paramagnetism of the ions of the iron group. Many of the ions in solution and in the solid state display a paramagnetism which can be expressed readily in terms of the Bohr unit of magnetic moment, $eh/\pi m$ where e/m is the ratio of the charge divided by the mass of an electron and h is Planck's constant. This unit is employed constantly in the spectroscopic study of gases. Sommerfeld, "Atombau," Vieweg and Sohn, Braunschweig, 4th ed., 1924; Stoner. "Magnetism and Atomic Structure," E. P. Dutton and Co., New York, 1926; Freed, THIS JOURNAL, 49, 2456 (1927).

tra of the ions in the iron group resemble the band spectra of polyatomic molecules. We actually found in our work on the rare earths, especially in the case of gadolinium, that the absorption spectra consisted of very sharp lines.[5]

It should be remembered that the positive ion in the crystal lattice is constantly in the electric fields of its neighbors. At higher temperatures when the oscillations are more violent the variation in the intensity of the fields will be greater and consequently there is a greater variation in the energy levels of the positive ion which are affected by these fields. That is, different ions will be exposed to fields of different intensities and directions and consequently the light associated with these energy levels will vary slightly in frequency so that the resultant line observed will be broader at higher temperatures. A reduction in temperature will permit a refinement in the absorption spectrum. This influence of temperature was studied by Becquerel.[6]

When the oscillations in the crystal lattice have been so reduced that their effect upon the characteristic absorption is slight, it becomes possible to measure the influence of the size, charge and other properties of the neighbors of the positive ion upon its energy levels. So direct a quantitative study of the influence of one ion (for example) upon another is clearly of great chemical importance. Already vast stores of data have been accumulated showing the influence of chemical combination upon the x-ray energy levels of ions. The unit of energy employed in these investigations is so huge that the influence of chemical combination appears as a slight difference in large magnitudes. X-ray measurements are concerned with the energy necessary to remove an electron from a shell which has its full complement of electrons far inside the kernel of the ion. In the investigation being reported the electrons that are most easily affected by the negative ion come into play, that is, those in the incomplete 4_4 electronic shell. In the x-ray region the smallest detectable energy difference is roughly a thousand times as large as can be detected in the visible region of the spectrum. The quantitative correlation of such magnitudes as heats of solution, etc., with the energy levels of the spectra we are working with is within the range of reasonable expectation.

Experimental Methods **and** Results.—We are now reporting upon the absorption spectra of $GdBr_3 \cdot 6H_2O$ taken at room temperature and at that of liquid air. We also wish to indicate differences between these spectra and those of $GdCl_3 \cdot 6H_2O$ reported elsewhere.[5] For details as regards some of our apparatus and the method of growing single crystals we must refer to the paper[5] previously mentioned.

The crystals grow in colorless flat rhombohedra. The light was passed

perpendicular to two parallel sides which did not require polishing. It has been known for a long time that the frequency of the light absorbed is the same along the different axes of a crystal. The intensities, however, may be different.[7]

The source of the continuous radiation in the ultraviolet was a hydrogen discharge tube with aluminum electrodes, as described by Bay and Steiner.[8] The spectrum was continuous and rather uniform in intensity down to 2000 Å.—the limit of our spectrograph.

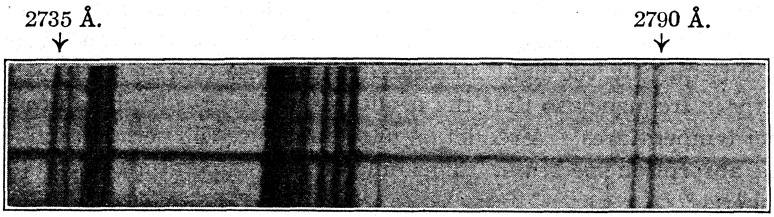

Fig. 1.—Absorption spectrum of $GdBr_3 \cdot 6H_2O$ at room temperature.

The absorption spectra of $GdBr_3 \cdot 6H_2O$ at room temperature were taken with a spectrograph having two quartz prisms with a dispersion of 3.5 Å. per mm. at 2350 Å. and 20 Å. per mm. at 4000 Å. This spectrograph was not available when the spectra at the temperature of liquid air were taken. The latter were photographed with a large Hilger spectrograph containing a single quartz prism. Its dispersion was 6 Å. per mm. at 2350 Å. and 34 Å. per mm. at 4000 Å.

The bromide is extremely hygroscopic and its handling was made easier by covering the crystal with a very thin layer of collodion, which was transparent in the spectral regions investigated.

It happened that the most satisfactory spectra of the bromide were obtained from a particular crystal about 0.8 mm. thick which originated from C. P. gadolinium oxalate procured from the Welsbach Company and twice reprecipitated and recrystallized. If any lines had appeared in the bromide which did not have their counterpart in the chloride, we should have been inclined to attribute them to slight impurities. (However, such was not the case.) Our chloride was made from a sulfate especially purified for us under the direction of Professor B. S. Hopkins of the University of Illinois, who was kind enough to give us also the following chemical history of the sulfate.

"Gadolinium material accumulated in this Laboratory (University of Illinois) from various rare earth sources was repeatedly precipitated as hydroxide by the addition of ammonia to a solution of the chlorides. The

mixture was then treated with hydrogen sulfide, filtered, and the rare earths in the filtrate were precipitated as oxalates with oxalic acid, ignited to the oxides, dissolved in hydrochloric acid, precipitated as hydroxides by ammonia, and finally converted to the nitrates by dissolving in nitric acid. Bismuth nitrate was added and the mixture was subjected to fractional crystallization of the simple nitrates in nitric acid solution. After prolonged fractionation, part of the material was precipitated as oxalate, ignited, and dissolved in nitric acid with the addition of sufficient magnesium oxide to form the double rare earth magnesium nitrate. This material was subjected to further fractional crystallization. All the gadolinium free from the other rare earths was then precipitated twice as oxalate to remove magnesium, then dissolved in hydrochloric acid and treated repeatedly with hydrogen sulfide to remove bismuth until no further precipitate of bismuth sulfide was obtained. The gadolinium was precipitated as oxalate, ignited, dissolved in nitric acid and fractionally crystallized five times as simple nitrate. The material was then precipitated as oxalate, ignited for twenty-four hours, and the oxide was suspended in a large volume of water to which sulfuric acid was added. The sulfate solution was evaporated slowly and the crystals were dried in an oven at 110°.

"The samarium present was estimated spectroscopically to be approximately 0.2%. No indication was observed of europium, while there was a possible trace of terbium, although no spectroscopic evidence of its presence was obtained. The sulfuric acid had the following limits of impurities (%)

[a] Looks like two lines. Very faint band. [b] Very faint band, looks like two lines. [c] Band unresolved due to smaller dispersion. [d] Barely resolved due to small dispersion. [e] Not completely resolved due to smaller dispersion. [f] Background so faint lines difficult to measure.

Discussion of Results.—The absorption spectra even at room temperature consisted of extremely sharp lines, as may be seen from the photograph and the precision with which the frequencies could be determined (see table). The spectra lay almost entirely in the ultraviolet region except for a few faint diffuse lines in the visible. These lines became markedly finer at the temperature of liquid air.

The magnetic measurements of Kammerlingh Onnes and his associates[9] show that the magnetic behavior of Gd^{+++} in the solid state conforms with that expected theoretically from a "perfect magnetic" gas throughout the entire temperature range, from room temperature to 1.3°K. This "gas" (Gd^{+++}) consists of a single species having ^8S for its basic electronic level.[10]

It follows that the other electronic levels are rather far removed in terms of energy from the ^8S, for, otherwise, the ions having the electronic configurations corresponding to these levels would have contributed to the measured susceptibility and produced deviations from the theoretical curve. The latter had assumed that only one species was present.

The Hund theory predicts that other electronic levels belonging to systems of lower multiplicity than ^8S originate from the seven 4_4 electrons of Gd^{+++}. They correspond to different relative orientations of the spin and orbital moments of the seven equivalent electrons. Goudsmit[11] has shown that the relativity doublet separation given by the formula of Sommerfeld employed in the x-ray region of the spectrum

$$\Delta\nu = \frac{R\left(\frac{2\pi e^2}{hc}\right)^2 (Z-\sigma)^4}{n^3 l(l+1)}$$

can often be applied in the optical region to such electronic configurations in order to obtain the separations between the multiplets. Av is the difference in frequency between the doublet levels, R is Rydberg's constant, e is the charge of the electron, h is Planck's constant, c is the velocity of light, Z is the atomic number of the atom, σ is the screening constant derived from x-ray measurements, n is the total quantum number of the electron and l is its orbital quantum number. The separations expected in the rare earths are of the order of magnitude found between the groups of the Gd^{+++} spectrum. It appears probable even at this early stage of study that each group of lines would be a single line (if the ion were gaseous) corresponding to a transition from the basic level to a multiplet level and that this single line has been decomposed into a group of lines by the electric fields within the crystal. However, some of the levels have not been

decomposed into their maximum number of components. We have already found from spectroscopic measurements in a magnetic field (Zeeman Effect on Solids) that further decomposition of some of the lines (or levels) can be effected.[12]

It is easy to tabulate many of the lines of the Gd^{+++} spectrum into multiplets having constant energy differences. Such a tabulation need not lead to unique energy levels even in the spectra of gases unless further information such as is furnished by the study of the Zeeman Effect, etc., is available. It is with the aim of getting unique energy relations that our work on the Zeeman Effect in crystals is being undertaken.

We have also made polarization spectra (which we shall publish later together with the work on the Zeeman Effect) which show that the lines are polarized in relatively different directions. Such a behavior cannot be attributed to any crystalline dissymmetry, for then all the lines would be polarized more or less uniformly.

It is characteristic of the Stark Effect, that is, the interaction of an electric field with radiant matter, that it produces lines which are polarized. The polarization of the spectral lines definitely expresses the electrical influence of the neighbors of the positive ion upon its spectrum. The identification of the polarization of the lines with that observed in the Stark Effect on gases is the same as the interpretation previously advanced[13] that the polarization discloses the regular orientation of the observing ions by the crystalline forces. In the Stark Effect the external field brings about an orientation or a quantization of the ion with respect to the direction of the field and then the transitions between the resultant states of the ion give rise to light which is polarized.

The astonishing sharpness of the lines in the spectrum of Gd^{+++} even at room temperature shows that the Gd^{+++} is not sensitive to the variation in the perturbing action of the external electric fields. One would expect 'that the thermal oscillation of the constituents in the crystal lattice would produce a great broadening, for example, such as is found in Sm^{+++}, Er^{+++}[14] at room temperature. The shielding of the 4_4 electrons by the complete shells of the 5_1 and 5_2 electrons is particularly effective in Gd^{+++}. As has been previously mentioned, the basic level of Gd^{+++} is an ^8S which implies that the orbital momenta of all seven electrons in the 44 shell have completely neutralized each other. Such a neutralization leads to a distribution of electron density having spherical symmetry, according to the quantum mechanics; that is, the electrons are probably grouped compactly inside the shielding 5_1 and 5_2 shells of electricity. In the language of

[12] Becquerel (Ref. 6) in studying the influence of a magnetic field upon the polarization of the light absorbed by his substances observed a splitting of some of the lines.

[13] Brunetti, *Physik. Z.*, 29, 571 (1928).

[14] Freed and Spedding, *Nature*, 123, 525 (1929).

orbits, we may say that the average time in which the 4_4 electrons are close to the perturbing agents is slight. In the less symmetrical electron distributions which exist among ions such as Eu^{+++} or Sm^{+++}, the eccentricity of their orbits implies that the electrons are very close to the sources of perturbation a considerable fraction of the time. Hence their energy levels are capable of great variation since they accompany the oscillations of the perturbing agents. Their spectral lines are more diffuse.

So symmetrical an arrangement of the seven electrons leads to a coupling of great stability. That is, the energy level corresponding to this coupling is considerably lower than any other (a sort of maximum stability). It is probable that the nearest energy level to which any rearrangement would correspond is so far above its basic level that ultraviolet light is necessary for any transition. (In other words, it would be surprising if any transitions could be brought about in absorption by means of infra-red radiation. If it occurs it would probably be faint and due to a transition from an activated level. We are inclined to believe that the faint diffuse lines in the visible are of a similar origin. Their very diffuseness suggests that the transition begins at an electronic state of less stability than the basic ^8S.)

At the low temperature, there is a general readjustment of the energy levels so that the lines shift slightly toward the longer wave length regions of the spectrum. This change (already discussed in our communication on $GdCl_3 \cdot 6H_2O$) may be attributed to the thermal contraction of the crystal. The constituents of the crystal are on an average nearer each other at the lower temperature and the closer approach of a bromide ion, for example, has probably shifted the outer energy level (corresponding to the activated state of Gd^{+++}) more than the inner. That is, the energy levels have approached each other (in terms of energy) and a transition between them corresponds to a smaller change in energy than at the higher temperature. The light is of longer wave length.

Comparison of Spectra of $GdBr_3 \cdot 6H_2O$ and $GdCl_3 \cdot 6H_2O$.—There appears to be a complete parallelism among the spectra of the bromide and the chloride, that is, a line for line correspondence in their spectra. It is fairly certain from analogies with salts of similar composition that the six molecules of water are grouped more or less symmetrically about the gadolinium ion. Hence any difference in the spectra of $GdCl_3 \cdot 6H_2O$ and $GdBr_3 \cdot 6H_2O$ can be ascribed to a first approximation to the difference in character between the bromide ion and the chloride ion. The results show that the corresponding lines in the two spectra are very nearly the same, a fact in keeping with the supposition that the molecules of water are between the negative ions and the gadolinium ion. The spectra indicate that the bromide ion induces a slight approach in the gross energy levels (that is, the hypothetically "unsplit" energy levels) of the gadolinium ion, as follows from the general displacement of the lines toward longer wave lengths as compared with the corresponding chloride lines. The bromide ion also brings about a slightly greater separation (on the average) between the lines comprising a group. We have attributed the existence of these groups to the electric fields surrounding the gadolinium ion (fields presumably arising principally from the polarized water molecules). Upon this basis, the displacement toward the red and the greater separation induced by the bromide ion can be related to the well-known deformability of the bromide ion, which would produce a greater negative charge upon the surface opposite the gadolinium ion than would the chloride ion.

Summary

We have discussed the possibility of applying the quantum theory of the line spectra of gases to ions in the solid state. We have concluded that the ions of the rare earths exhibit line spectra comparable with those of atomic ions in the gaseous state under the influence of external electric fields.

The absorption spectra of the crystal $GdBr_3\cdot 6H_2O$ were taken at room temperature and at that of liquid air. Its spectra even at room temperature consist of lines of extreme sharpness comparable with the lines of the iron arc which were used for comparison. The spectra lie almost entirely in the ultraviolet. There are a few faint diffuse lines in the visible.

At the temperature of liquid air there is a slight shift of the lines toward longer wave lengths and a greater separation between lines comprising each group. These displacements can be related to the thermal contraction of the crystal which brings the constituents of the crystal closer together. The fields due to the neighbors of the Gd^{+++} become then more intense than at the greater average distance at higher temperatures. The few diffuse lines in the visible become narrower and sharper at the temperature of liquid air. The spectra consist of groups of lines and these groups are separated by rather large intervals. We have regarded each group as corresponding to one line of the spectrum of Gd^{+++} ions in the gaseous state. This line has been decomposed into several lines by the electric fields arising from the neighbors of the Gd^{+++} ions in the crystal lattice.

Some of the potentialities of such investigations are sketched. The influence of bromide ion upon the positive ion is roughly compared with that of chloride ion (a preliminary communication on the spectra of $GdCl_3\cdot 6H_2O$ was published in Phys. *Rev.*, **34, 945 (1929))** and this difference is related to the greater deformability of the bromide ion.

We are continuing and extending the study of the spectra of the ions of the rare earths with the hope of obtaining unique energy levels.

THE ROLE OF THE LIQUID STATIONARY FILM IN BATCH ABSORPTIONS OF GASES. I. ABSORPTIONS INVOLVING NO IRREVERSIBLE CHEMICAL REACTIONS[1]

BY HAROLD S. DAVIS[2] AND GEORGE S. CRANDALL[3]

RECEIVED MARCH 26, 1930 PUBLISHED OCTOBER 6, 1930

In the studies on the rates of absorption of olefinic gases by sulfuric acid which were reported in a previous communication[4] it was noted that the specific absorption coefficient (cc. of gas absorbed per sec. per sq. cm. of surface) was not appreciably affected by agitation of the acid. However, in the absorption chamber used (a horizontal cylinder) stirring was obtained by rotation, which also changed the area of the liquid surface exposed. Accordingly a new apparatus (described below) has been devised in which gases can be absorbed at various pressures by liquids with a constant area of surface exposed, while a stirrer is operating at a controllable speed beneath the liquid surface.

The results with the new apparatus have confirmed and extended the generalizations made from the former measurements with the rotating absorber. Some of the facts are at first sight surprising, *e.* g., that ethylene was absorbed by concentrated sulfuric acid as rapidly when the acid was quiescent as when it was stirred (without breaking the surface or changing its area) at 400 r. p. m. The writers have found that the various phenomena encountered are best explained in terms of the so-called "two film theory" of gas absorption. For this purpose it has been necessary to study and extend further by experimental tests this important hypothesis.

"It is now becoming generally recognized that whenever a liquid and a gas come in contact there exists on the gas side of the interface a layer of gas in which motion by convection is slight compared to that in the main body of the gas and that similarly on the liquid side of the interface there is a surface layer of liquid which is practically free from mixing by convection. This phenomenon is frequently expressed by assuming the existence of stationary films of gas and liquid on the two sides of the interface."[5]

---

[1] This paper contains results obtained in an investigation on the "Relative Rates of Reaction of the Olefins," listed as Project No. 19 of American Petroleum Institute Research. Financial assistance in this work has been received from a research fund of the American Petroleum Institute donated by Mr. John D. Rockefeller. This fund is being administered by the Institute with the cooperation of the Central Petroleum Committee of the National Research Council.

[5] Lewis and Whitman, *Ind.* Eng. Chem.. 16, 1215 (1924).

There is good evidence that a similar liquid stationary film exists at a liquid–solid interface. Noyes and Whitney[6] showed that the rate of solution of a solid in water is proportional to the difference between the saturation concentration and its concentration in the water. They assumed that at the interface between the crystals and the liquid the solution is at each moment saturated. The velocity of solution according to this is conditioned only by the rate of diffusion through an unstirred layer close to the solid. Brunner[7] in a very important research extended this work and measured rates of solution per unit area of interface. Nernst[8] suggested that this hypothesis can be so generalized as to apply to all reactions in heterogeneous systems. The similarity of the phenomena caused by the liquid stationary films at various types of interfaces (liquid–gas, liquid–liquid and liquid–solid) should be emphasized.

This paper will be limited to consideration of the role of the liquid stationary film in determining the rates of gas absorption where no irreversible reactions are involved. When dealing with a pure gas of moderate solubility, the effect of the gas film is negligible.

Lewis and Whitman[5] state, "Resistance to diffusion due to the gas film is, of course, non-existent in the special case where an absolutely pure gas is being absorbed. This problem is very rarely encountered in practice, however, since the presence of very small amounts of inert gas which will concentrate at the liquid surface is sufficient to create an effective gas film." This statement might imply that the inert gas is adsorbed on the surface of the liquid and forms a gas film, even at equilibrium conditions, in which its concentration is greater than in the main body of the gas. To such a conception H S. Taylor[9] has objected that, "It is not in harmony with so much of the treatment found valid by Langmuir in the case of reactions at solid surfaces. On Langmuir's method of treatment there should be no gas film of the nature postulated by Whitman. A unimolecular layer of adsorbed molecules would represent the maximum film which could be formed."

However, it would appear that the fundamental assumption made by Whitman is that on either side of the liquid–gas interface there exists a film of relatively quiet fluid and the gas being absorbed must pass through these films by diffusion. From these postulates Hanks and McAdams[10] have shown that a gas film of the inert gas must exist at the interface when the solute gas is being absorbed from the main body of the gas into the liquid. For, since the solute gas passes inward through the stationary gas layer, by diffusion, it must form a gradient of decreasing concentration to the liquid surface, and since the total gas pressure of inert and solute gas remains constant, there must exist a similar gradient of the inert gas outward.

The stationary films are by no means monomolecular in thickness, nor must they be confused with adsorbed layers. They are much thicker. Thus for water stirred underneath at 1000 r. p. m. the effective thickness is about 0.0045 cm.,[5] which is over a hundred thousand times the diameter of the water molecule.

The reality of the liquid stationary film is confirmed by common-place observations. Thus, dust particles often remain motionless on the surface of water in a well-stirred thermostat. The phenomena stand out still more

plainly under the microscope in water containing fine particles, *e. g.*, freshly precipitated barium sulfate. The solid particles at the surface *and also* for *a short distance beneath it* appear to be in a separate medium of their own which slips along the water like a thin skin. A little deeper down, the particles are carried here and there by currents and move past the outlines of those at the surface like low-lying storm clouds against those high in the sky.

The writers determined the distance between the quiet particles on the surface and those moving freely beneath it, under a microscope at about 50 diameters magnification. The value obtained for quiescent water at room temperature, 0.04 cm., was checked with surprising closeness by different observers.

What causes the liquid "stationary" film? Some of the contributory factors can be pictured. Thus the upward motion of water in currents must cease before the surface is reached. Again, local currents across the surface are opposed by some force, perhaps that of surface tension. This is indicated by the tendency to preserve their relative spacing shown by particles lying on the surface. It is significant that the effective thickness of the liquid stationary film at the gas–liquid interface is of the same order as that of the liquid film at a liquid-solid interface (see Table I, Note b).

Whatever the causes of its existence, the liquid stationary film plays a major role in the absorption into or the evolution of gases from liquids. With moderate stirring, the main body of the liquid and the main body of the gas are each practically uniform in composition and the gas must pass from one phase to the other through the unstirred layers at the interface mainly by diffusion. In another communication it will be shown that where irreversible chemical reactions are involved, the whole reaction often takes place in the liquid stationary film and the gas never reaches the main body of the liquid at all.

When a pure gas, oxygen for example, is suddenly admitted at atmospheric pressure into contact with pure water from which all gases have been removed, the very surface layer, perhaps monomolecular in thickness, instantaneously becomes very nearly saturated with oxygen.[8] This must be true, because an oxygen pressure is at once exerted from the surface equal to the partial pressure against it, which is the condition necessary for a saturated solution.

The oxygen now begins to diffuse into the film at a tremendous rate, for although the solubility of oxygen in water is small, 0.0012 M, the gradient from the surface is very steep. We wish to stress this point because of its bearing on the rapid rates at which some olefinic gases are absorbed by sulfuric acid, although they are quite insoluble therein.

As diffusion proceeds the magnitude of this gradient quickly grows less and the absorption slows down, soon reaching a constant value *(initial absorption rate).* At this stage the gradient is uniform and the same quantity of oxygen is passed from the surface through each unit cross section of the film into the main body of the liquid which is still practically free from dissolved oxygen.

The Time Required to Build up an Oxygen Gradient through the Film of Water.—Table **I** shows that the time necessary to establish a uniform gradient through the stationary liquid film depends on the degree of agitation in the water. It can be practically established (98%) through the sides of bubbles in one-tenth of a second, whereas five seconds are required in the case of moderately stirred (60 r. p. m.) water and in the case of quiescent water a still longer period is needed since here an effective film thickness of several millimeters is sometimes encountered.

These conclusions are substantiated by the measurements of Monaweck and Baker[11] on the rates of absorption of pure ammonia gas by water. With stirring at 324 r. p. m., no high initial absorption was noted (readings being taken every ten seconds) and the rate remained constant for 110 sec. Evidently a uniform concentration gradient was very rapidly established through the **film.** Further, calculation shows that $k_L = 1.3 \times 10^{-6}$ for these experiments, which is in good agreement with a value 2.2×10^{-6} found by the writers from measurements of the absorption rate of carbon dioxide, a much less soluble gas, by water under similar conditions.

On the other hand they found that the absorption rate of pure ammonia by quiescent water fell off over a period of 100 seconds to less than one-sixth of its initial value.

TABLE I

SHOWING THE RISE OF THE CONCENTRATION WITH TIME IN THE CENTER OF THE LIQUID STATIONARY FILM DURING THE ABSORPTION OF OXYGEN BY WATER EXPRESSED AS PERCENTAGE OF THE VALUE AT UNIFORM ABSORPTION (= 0.5 SURFACE CONCENTRATION)[a]

Absorption conditions	*Thickness of film,[b] cm.*	Seconds					
		001	0.1	0.2	0.5	10	5
Water stirred at 60 r. p. m.	0 020	..	..	..	..	20%	88%
Water stirred at 1000 r. p. m.	0045	..	50%	80%	99%	..	..
Bubbles in water	0021	18%	98%	..	..	..	..

[a] In these calculations it has been assumed that the inner limit of the stationary film is sharply defined and that the concentration of dissolved oxygen at the interface, C_i, remains constant (saturation value), while that at the inner edge and in the main body of the solution can be regarded as zero.

It is further assumed that the course of the oxygen diffusion at all times satisfies the equation $\partial c/\partial t = \Delta(\partial^2 c/\partial x^2)$, (see, however, Lewis and Chang, ***Trans. Am. Inst. Chem. Eng., 21,*** 135 (1928)), where c is concn. of dissolved oxygen, moles per liter; t is time in seconds after oxygen comes into contact with the deoxygenated water; x is distance in cm. from the surface; A is diffusion coefficient for oxygen through water.

The writers are indebted to Professor F. C. Hitchcock for a solution of the &fferential equation for these conditions in terms of a Fourier series.

[b] These values are taken from the calculations of Lewis and Whitman except for

---

[11] Monaweck and Baker, ***Trans. Am. Inst. Chem. Eng., 22,*** 165 (1929).

that for bubbles in water, which was calculated by the writers from the data of Adeney and Becker discussed below.

It is interesting to compare these values for the thickness of the liquid stationary film at a gas–liquid (water) interface with those obtained by Brunner, Z. *physik. Chem.*, 47, 99 (1904), for the liquid stationary films at the surface of solids in well-stirred liquids—0.0030 cm. for pure water and 0.0028 to 0.005 cm. for various solutions.

Experimental

The absorption apparatus was designed to operate at atmospheric pressure or at any desired reduced pressure. Accordingly it was necessary that the seal around the stirrer should stand high vacua, so that an ordinary mercury ring seal could not be used.

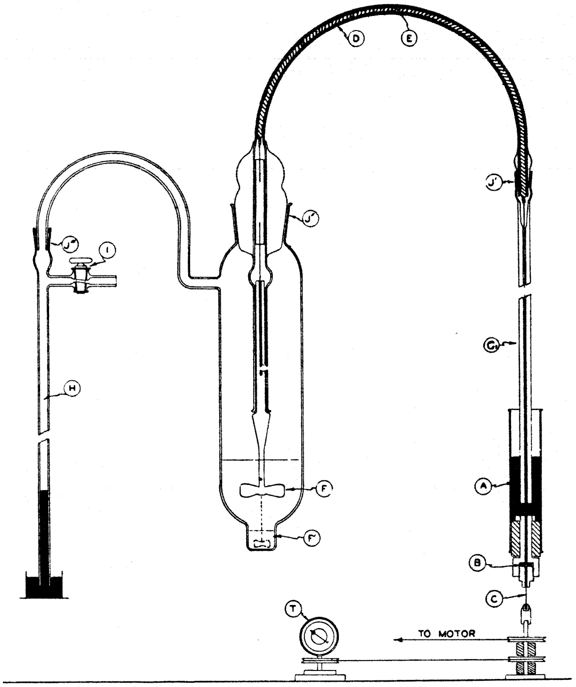

Fig. 1.—Diagram of apparatus for gas absorptions by liquids at atmospheric or at reduced pressures. **A,** mercury seal; B, packed joint through which drive shaft (C) passes upward through capillary tube (C_1); D, semicircular arc of glass tubing containing a flexible rope pattern watch chain; E, which transmits power to stirrer, F; $J^1J^2J^3$, ground-glass joints; H, manometer tube; T, tachometer calibrated to register r. p. m. of stirrer.

The main outline of the apparatus will be plain from the figure. Its unique feature is the manner in which the stirrer is operated. The mercury seal **(A)** is outside the apparatus at the bottom of the vertical capillary tube *(C)* which is longer than barometric height. The drive shaft (C) passes through a packed joint (B) in the bottom of the mercury cup, and extends to the top of the capillary tube. Thence the power is transmitted around the semicircular arc (D) by means of the flexible gold-filled, rope-pattern chain (E) to the stirrer proper (F) in the reaction chamber. The latter is suspended in a constant temperature bath.

Experiments at Constant Volume.—In the experiments a measured volume of the liquid was introduced into the bottom of the chamber by means of a long-stemmed funnel. The apparatus was then closed and evacuated through the side tube I. Next the gas was drawn in. The rate of absorption was followed by the change of pressure with time.

Suitable corrections were made for the changes in volume due to the rise of the mercury level in the drive tube and in the manometer tube.[12]

Experiments at Constant Pressures.—These were carried out with mercury-filled gas burets connected to the reaction chamber at I. In order to keep the gas pressure constant, the leveling bulb was slowly raised by means of a windlass and reducing gears whose speed could be suitably varied to correspond to the rate of absorption. Readings of the buret were taken with time. In the absorptions of olefins by sulfuric acid, in order to observe the rate when the quantity of olefin absorbed was 10% or more equivalent to the acid, two micro experiments were performed, using 1 cc. of acid. The regular stirrer was replaced by a smaller one which stirred the liquid in the small chamber without changing its surface.

The characteristics of the absorption chamber were as follows

Volume including connecting tubes[a] = 340.4 cc.

Area of liquid surface with 30-100 cc. of liquid[b] = 17 sq. cm.

Area of liquid surface in lower cup used for micro experiments (1 to 3 cc. of liquid)" = 1.41 sq. cm.

[a] Determined by change of pressure caused by addition of known volumes of air.

[b] Determined by adding known volumes of liquid and noting the rise in liquid level.

[c] Determined as in (b) except that the curvature of the meniscus had to be taken into account.

TABLE OF NOMENCLATURE

N = gram moles of gas
t = time in seconds
dN/Adt = rate of gas absorption per unit area of liquid surface—moles per sec. per sq. cm.

---

[12] $P = (I - R) - 8$, where $8 = (B - R)AR/V_0$
P = Pressure of gas at time t corrected to V_0
I = Initial manometer reading before introduction of gas
R = Manometer reading at time t
B = Barometric pressure (uncorrected)
A = Sum of the cross sectional areas of the mercury in the manometer and drive-shaft tubes
V_0 = Volume of gas space in apparatus at atmospheric pressure

$(dN)/(A\,dt)_{\text{Init.}}$ = initial rate of absorption after practically stationary concentration gradients have been established in the liquid film, moles per square centimeter per second

A = area of liquid–gas interface in sq. cm.

k_L = a constant which, according to the theory outlined above, is equal to the diffusion coefficient of the dissolved gas through the liquid stationary film, that is, the number of moles which would diffuse through 1 sq. cm. of cross section in one second if the difference in the concentrations of the dissolved gas at the interface and in the main body of the solution were molar

C_i = saturation concentration of the dissolved gas in moles per liter at its partial pressure during the absorption

C_L = molal concentration of dissolved gas in the main body of the liquid at time t

C_S = concentration, moles per liter, of the reacting solute in the main body of the solution. (See paper II in this series)

Cof. = cc. of gas absorbed per sec. per sq. cm. of surface, measured at its own partial pressure.

To avoid confusion the C used in a former communication to denote gas absorption rate is here replaced by *Cof.* The other symbols are similar to those of Lewis and Whitman except that gas quantities and concentrations are expressed in gram moles rather than in grams.

Table II gives collected data on the initial rates of solution of oxygen and a few other gases by liquids under different absorption conditions. Direct comparisons are possible because in each case the investigators have measured the area of the gas–liquid interface so that the absorption rate per unit area could be calculated. The absorption methods were as follows.

I. Liquids at Rest and Liquids Stirred without their Surfaces Being Broken.—The writers have measured the rates of solution of oxygen and of carbon dioxide by water and of oxygen by tetrachloroethane in the apparatus which is described above. Measurements were carried out both at constant volume and at constant pressure (area of gas–liquid interface 17 sq. cm.).

Becker measured the absorption rate of oxygen from air[13] at constant volume by water containing suspensions of ferrous hydroxide precipitated directly therein from ferrous sulfate and potassium hydroxide; volume of liquid, 100 cc.; Area of surface except at high stirring, 11 sq. cm.

II. Gas Bubbles in Liquids.—Adeney and Becker[14] measured the

[13] Becker, *Phil. Mag.*, 45, 681 (1923).

[14] Adeney and Becker, *ibid.*, 38, 317–337 (1919); 39, 385–404 (1920). The mathematical calculations of these investigators appear to contain certain errors which are confusing to the reader although they do not vitiate the important experimental data or the main conclusions. Thus they define "ω" as the "weight of gas per cc. in the upper layer" of liquid (cc. of gas instead of g. are given in their tables). However, they multiply its rate of change with time $d\omega/dt$ by V, the total volume of the liquid. in order to obtain the total rate of gas absorption. Evidently this latter relationship can only be true if ω represents the average concentration of the gas in the whole liquid. In Tables 1, 2, 3 and 4 of the first paper and Table 6 of the second, "w" and "a" should be "ωV" and "aV," respectively.

+ Calculated from the results obtained with air.

rates of absorption of oxygen and nitrogen at practically constant pressure from bubbles (vol., 15 cc.) moving upward through 94 cc. of water in a cylindrical tube 1 cm. in diameter; velocity of bubble upward, 10 cm. per sec.; velocity of water past cylindrical part of bubble through an annular space 0.05 cm. thick, 65 cm. per sec.

IIB.—Ledig and Weaver[15] measured the rate of carbon dioxide absorption at atmospheric pressure from bubbles, vol. 0.036 cc., suspended in downflowing water.

III. Liquids in a Shaken Absorption Chamber.—Conant and Scherp[16] have measured the rates of absorption of gases by 5–15 cc. of liquids when shaken in a 70-cc. flask 400 times a minute. Direct measurements showed the area of the liquid and wetted glass surfaces exposed during the shakings to be 50–75 sq. cm. A closer estimate was then made by determining the ratio of the over-all rate of ethylene absorption by concentrated sulfuric acid during shaking, to that at rest. This ratio was 5.6 and the area of the liquid surface at rest 11.5 sq. cm. On the assumption that the over-all rate of this particular absorption is proportional to the area of the acid surface and unaffected by the degree of its agitation,[4] the area during shaking was calculated to be 64 sq. cm.

Measurements carried out with the dissolved gases in the liquids at different degrees of saturation showed that the absorption rates satisfy fairly well the equation of Lewis and Whitman

$$\frac{dN}{A\,dt} = k_L(C_i - C_l)$$

Discussion

The Speed of Stirring and the Absorption Rate.—Becker measured the rates of oxygen absorption per unit area from air by suspensions of ferrous hydroxide stirred at various speeds (Expts. 6–12). He found the rate to be constant at any one speed, a result which has been confirmed by the writers, and he assumed it to be the same as the initial absorption rate by pure water (compare Expts. 3 and 8).

It will be seen that in Becker's experiments the absorption rate increased enormously with the stirring at first but tended to a maximum independent of further increases in the stirring speed. The value at 1000 r. p. m. was 5.2×10^{-9} mole per sq. cm. per sec., which is undoubtedly lower than the initial rate for pure water as pointed out below. (Unfortunately Becker did not record the quantities of ferrous sulfate and potassium hydroxide used.) Now Adeney and Becker (Expt. 16) found the value 11×10^{-9} mole per sq. cm. per sec. for the absorption rate of oxygen from the sides of bubbles. Considering the fact that in their experiments

---

[15] Ledig and Weaver, THIS JOURNAL, 46, 650 (1924).

[16] Conant and Scherp, unpublished data from the Converse Chemical Laboratory, Harvard University.

the water was streaming past the sides through an annular space **0.05** cm. thick at the rate of 65 cm. per sec. it appears that this value represents about the maximum oxygen absorption rate that could be obtained into pure water stirred without breaking or enlarging the surface.

If currents brought fresh liquid continually to the very surface, the absorption rate per unit area should increase almost proportionally with the degree of agitation nor would it tend to a maximum. Thoughtful consideration of these facts impresses one with the reality of the liquid stationary film.

The Effect of Renewing the Surface.—Adeney and Becker found oxygen to be absorbed at a faster rate (about 7.5 times) from the tip of bubbles than from the cylindrical portion and they offered the following explanation. "The rate at which the water streams past the head of the bubble is much less than that at which it passes down the cylindrical portion of it; hence the absorption due to the head of the bubble is much greater than might be expected from its area." But this would mean that agitation below the liquid surface decreases the rate of oxygen absorption whereas Becker has shown that exactly the reverse is true. The writers suggest that the greater absorbing power of thk head of a bubble is caused by a continual pulling out laterally of the surface in front, which brings fresh water into the stationary film. On the other hand, the surface slides down the cylindrical portion without changing in area. The fact that the average absorption rate per unit area was found to be the same from this portion in bubbles of different sizes proves that a uniform oxygen gradient was very rapidly established through the film, in agreement with the calculations in the last section.

Ledig and Weaver's value for the absorption rate of carbon dioxide by water represents the average for the whole surface of small bubbles and their value for $k_L \times 10^6 = 20$ (Expt. **19)** lies between those of Adeney and Becker for the head and for the sides of large bubbles.

The film coefficients calculated from Conant and Scherp's experiments (20-26) $k_L \times 10^6 = 20\text{–}36$ are almost half that for the head of bubbles in water. It appears that if the volume of the containing vessel is much greater than that of the liquid, then tossing it back and forth, continually spreads out new liquid surfaces on the walls and is an excellent way to secure high absorption rates. Under these conditions, diffusion no longer plays the dominating role in limiting the absorption. Currents in **the film** have become an important factor also.

A Comparison of the Rates of Solution of Gases by Water and by Organic Solvents.—In the experiments with stirred liquids the film diffusion coefficient k_L of tetrachloro-ethane was over twice that for water under the same conditions. On the other hand, in Conant and Scherp's experiments with shaken liquids, the coefficients were practically the same for absorption of oxygen and hydrogen into water, tetrachloroethane and bromobenzene. The magnitude of the absorption rate depended almost entirely on the solubility of the gas.

Hydrogen **and** Oxygen.—The film coefficients for hydrogen in Conant and Scherp's experiments are 1.3 to 1.4 times those for oxygen under the same conditions; but data in "International Critical Tables" show that hydrogen diffuses about 2.4 times faster than oxygen in liquids. Perhaps this bears out the assumption of Lewis and Whitman that the liquid film diffusion coefficients for all solutes are of about the same magnitude.

Absorption Rate and Reaction Rate.—When a gas, oxygen for example, is absorbed by a solution and reacts irreversibly with some substance dissolved therein, steady conditions are often reached where the rate of oxygen absorption is just equal to the rate at which it is consumed in the solution. What is the concentration of the dissolved oxygen? Evidently not the saturation value, for oxygen could not then be absorbed at all. If the absorption rate at the steady state is less than the initial physical absorption rate into the pure solvent, then an estimate of its fractional saturation in the solution will be obtained from the ratio of these rates. Hence the importance of determining the initial absorption rate.

Suspensions of ferrous hydroxide in dilute solutions can be used conveniently for finding the order of the value for the initial rate of oxygen absorption by water in an apparatus. However, experiments 3 and 4, Table II, show that the rate for a suspension in 1 N potassium sulfate is less than half that for pure water and the fact that the film diffusion coefficient is also lower shows that the effect is not entirely due to the lowering of the oxygen solubility by the potassium sulfate.

Miyamoto[17] has shown that when air is bubbled through suspensions of ferrous hydroxide in sodium hydroxide solution, the over-all absorption rate is independent of the quantity of the precipitate but is reduced by the addition of more alkali. It is to be regretted that absorption rates per unit area of surface cannot be calculated from the extensive data of this investigator.

If the oxygen absorption rate is greater than the initial rate it means that the main body of the solution contains little or no dissolved oxygen and that part or all of the reaction takes place in the liquid stationary film. This will be treated further in another communication.

Summary

1. The reality of the liquid stationary film, the thin unstirred layer, on the surface of liquids is emphasized. The important role of this film in gas absorptions, though known to engineers, has not perhaps been generally recognized. Its effective thickness depends on the absorption conditions.

---

[17] Miyamoto, Bull. *Chem. Soc., Japan,* *2,* *40* **(1927); 3, 137 (1928); 4,** *65* **(1929);** *Sci. Papers Inst Phys. Chem. Research* (Tokyo), *7, 35* **(1927); 9, 203 (1928).**

2. When a pure gas is suddenly brought into contact with a liquid, a gradient of dissolved gas, tending to uniformity, is rapidly built up through the film. The rates at which the gradients are established in oxygen absorption by water have been calculated for different effective thicknesses of the stationary film corresponding to various conditions of liquid agitation. In well-stirred water the gradient becomes practically uniform in a fraction of a second.

3. The absorption rate after stationary gradient conditions have been established in the film (initial absorption rate) is the maximum at which dissolved gas can reach the main body of the solution. At any time, for a moderately soluble gas, the rate is proportional to the fractional unsaturation of the liquid with dissolved gas.

4. The initial absorption rates per unit area of surface and the liquid film diffusion coefficients have been calculated from data on gas absorptions by water and a few organic liquids for (a) stirred liquids, (b) gas bubbles and (c) shaken liquids.

5. The absorption rate for liquids stirred without breaking the surface increases with the stirring but tends to a maximum. For oxygen absorption by water, this maximum appears to be about the same as the rate from the sides of cylindrical bubbles moving rapidly through deoxygenated water, 11×10^{-9} mole per sq. cm. per sec. at 25°.

6. Adeney and Becker showed that air is absorbed faster, per unit area of surface, from the head of a cylindrical bubble than from the sides. It is suggested that this phenomenon is caused by film renewal at the head where the surface is continually pulled out laterally. The absorption rate per unit area for shaken liquids can become greater than the maximum with stirring, due apparently to the continual spreading out of the surface layer.

7. With stirring, the liquid film diffusion coefficients of water were less than, but of the same order as, those of organic liquids under the same conditions. With shaking the coefficients were practically identical for all the liquids. The absorption rates were then simply proportional to the solubilities of the gases.

8. It is suggested that the ratio of absorption rate of a pure moderately soluble gas by a liquid under any one set of conditions, to the initial absorption rate under the same conditions, affords a measure of the fractional unsaturation of the liquid with gas. If the gas reacts with the solvent itself, an inert gas of similar solubility could be used.

9. Where the effects of foreign substances on rates of reaction in solution are being measured by the rates of absorption or evolution of gases, the importance of also checking up their effects on the initial absorption rate of the gas is suggested.

THE ROLE OF THE LIQUID STATIONARY FILM IN BATCH ABSORPTIONS OF GASES. II. ABSORPTIONS INVOLVING IRREVERSIBLE CHEMICAL REACTIONS[1]

BY HAROLD S. DAVIS[2] AND GEORGE S. CRANDALL[3]

RECEIVED MARCH 26, 1930 PUBLISHED OCTOBER 6, 1930

In the preceeding communication[4] it was pointed out that under fixed absorption conditions (agitation, temperature, gas pressure, etc.), the *initial* absorption rate is the highest at which a gas can pass by physical dissolution into the main body of a liquid.

The present paper deals with the relationships between the absorption rate and other factors when the gas reacts irreversibly in the solution. With rapid reactions the rate of absorption can be much greater than the initial speed of pure physical solution.

Let us consider the absorption of a pure gas through an unbroken surface into a well-stirred liquid, when any irreversible chemical reactions taking place are instantaneous compared to the rate of absorption. The following postulates will be made for these conditions.

1. The effect of the gas film is negligible and the surface of the liquid is kept saturated with gas.
2. The main body of the liquid is homogeneous right up to a sharply defined surface that marks the inner limit of the stationary liquid film.
3. The specific diffusivity of each solute through the liquid stationary film is the same.[5]

---

[1] This paper contains results obtained in an investigation on the "Relative Rates of Reaction of the Olefins," listed as Project No. 19 of American Petroleum Institute Research. Financial assistance in this work has been received from a research fund of the American Petroleum Institute donated by Mr. John D. Rockefeller. This fund is being administered by the Institute with the coöperation of the Central Petroleum Committee of the National Research Council.

[4] Davis and Crandall, THIS JOURNAL, 52, 3757 (1930).

[5] This is the assumption originally made by Lewis and Whitman, *Ind. Eng. Chem.*, 16, 1215 (1924), and there is indeed a surprising similarity in the values which have been found for the coefficients of diffusion of solutes in aqueous solution under similar conditions (see "International Critical Tables," Vol. V, pp. 63–72). On the other hand, Schwab and Beringer, *Z. physik. Chem.*, 138A, 55–74 (1928), concluded that the liquid film diffusion coefficients for five permanent gases in water were practically the same at 20° but changed relatively to each other as the temperature was raised. The results of these investigations are somewhat puzzling. Although they claim an accuracy of 10% for their experiments (bubble method of Adeney and Becker, *Phil. Mag.*, 39, 385 (1920)), yet values for the solubilities of the gases calculated from their data show large deviations from those obtained by other investigators, as the table shows.

The concentration gradients which will now be examined are those existing in the film after a uniform absorption (initial absorption rate) has been reached but while the concentration of the reaction products in the main body of the liquid is still negligible.

Case **A.** The Absorption of a Pure Gas by a Liquid **with** which it Does not React Irreversibly.—This case has been considered in our previous communication; however, for the purpose of comparison, the conditions in the film are shown diagrammatically in Fig. 1, Case A. The sloping line denotes the gradient of decreasing concentration of the dissolved gas inward from the surface. It is uniform because the same quantity of solute passes per second through each unit cross section of the film made parallel to the surface.

$(\mathrm{d}N)/(A\,\mathrm{d}t)$Init. $= k_\mathrm{L}C_\mathrm{i}$ or in general as the gas builds up in the main body of the solution $\mathrm{d}N/A\mathrm{d}t = k_\mathrm{L}(C_\mathrm{i} - C_\mathrm{L})$. The same nomenclature is used as in the preceding article.

Case B. The Absorption of a Pure Gas by a Solution of a Substance with **which** it Reacts Irreversibly in One Stage and Mole **for Mole.**—The position of the Zone **A,** Fig. 1, Case B, at which the reaction takes place will depend on the relative magnitudes of C_i and C_S, the concentrations of the gas at the interface and of the solute in the main body of the solution, respectively.[6]

COMPARISON OF DATA ON SOLUBILITIES OF GASES IN WATER

a = cc. gas (at 760 mm. and 0°) dissolved by 1 cc. liquid when partial pressure of gas is 760 mm.

	O_2				H_2	
	20°	30°	60°	80°	20°	30°
Schwab and Beringer	0.020	0.021	0.016	0.016	0.018	0.016
Landolt–Bornstein–Roth "Tabellen"	0.031	0.026	0.019	0.017	0.018	0.017
Adeney and Becker	0.029	0.025	...	...	...	...

	CO_2			C_2H_4		C_2H_2	
	20°	30°	60°	20°	30°	20°	30°
Schwab and Beringer	0.68	0.50	0.34	0.10	0.08	0.67	0.63
Landolt–Bornstein–Roth "Tabellen"	0.88	0.67	0.36	0.12	0.10	1.0	0.84
Adeney and Becker	..	..	..	..	..	..	..

Further, it would appear from their data that the initial absorption rate of oxygen by water at 30° is almost twice that at 20°, whereas Adeney and Becker found it less. Until these discrepancies have been explained, some hesitation must be felt in accepting the conclusions of Schwab and Beringer that the differences in the diffusivities, calculated from their data, indicate the degrees of hydration of the dissolved gases.

[6] Similar diagrams of the concentration gradients of the reactants and of the reaction zone for the dissolution of a solid in a solution of a substance with which it reacts have been given by Brunner [Z. *physik. Chem.*, *47*, **67**, *et seq.* (1904)]. The similarity of the liquid stationary film at the two types of interfaces should be emphasized. Weber and Nillson, *Ind. Eng. Chem.*, 18, **1070 (1926).** and Hatta, *Tech. Reports Tohôku Imp. Univ.*, 8, 1 (1928), have also given diagrams of concentration gradients in films.

The quantities of dissolved gas and solute diffusing to the reaction zone in unit time and of the reaction product diffusing away are equal and it is evident that

$$\frac{(\mathrm{d}N)}{(A\,\mathrm{d}t)\mathrm{Init.}} = k_L(C_i + C_S)$$

The molar concentration of the reaction product between the surface and the reaction zone is uniform and equivalent to that of the solute in the main body of the solution. If the solubility of the reaction product is low and its metastable limits are exceeded, it may precipitate as a solid or liquid (the case of a gas is not considered here) which tends to fall into the main body of the liquid or rise to the surface. In any case the presence of the precipitated reaction product will cut down the absorption and may almost stop it.

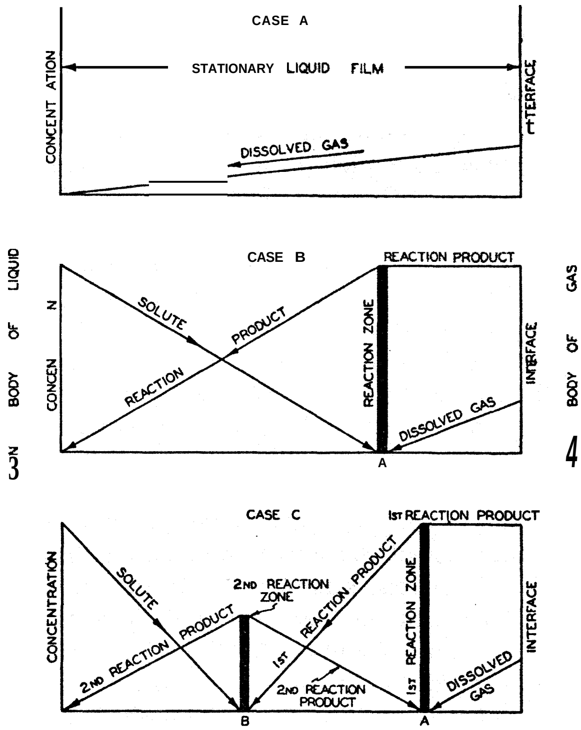

Fig. 1

Case C. The Absorption of a Pure Gas by a Solution of a Substance with which it Reacts in Two Stages in Instantaneous Irreversible Reactions (Fig. 1, Case C).—As in Case B the primary reaction product exists in uniform concentration between the first reaction zone and the surface. The secondary reaction product diffuses in both directions from the second zone but never reaches the surface.

$$\frac{(\mathrm{d}N)}{(A\mathrm{d}t)\text{Init.}} = k_L(C_i + C_S)$$

The following factors have not been considered in these pictures: (1) the time required for the completion of the reactions (they are assumed to be instantaneous with respect to the diffusion rates); (2) the effects of the reaction products on the solubility of the gas; (3) the effects of the reaction products on the effective thickness of the stationary film and on the diffusivities of the solutes; (4) the heat produced in the film by the reactions. (It must also flow away by diffusion since it is assumed convection plays a minor part in the film.)

Keeping in mind these limitations, which will be considered later, the main conclusions from these pictures will now be tested by experimental data of the authors and other investigators.

Experimental Part.—The apparatus used was that described in the preceding paper in which gas absorptions can be carried out at constant volume or at constant pressures into a known area of liquid surface while the liquid is being stirred beneath the surface.

General Relationship.—According to these postulates the rate of absorption of a pure moderately soluble gas by a concentrated solution should be largely independent of the gas pressures (since C_i is negligible compared to C_S) and the experiments at constant volume showed this to be indeed the case. Even in the absorption of sulfur dioxide by 1.8 M potassium hydroxide, Expt. 13, Table I, the pressures decreased almost uniformly with time, about four-fifths as much gas being absorbed per second at one-fifth as at one atmosphere. It may be seen from Table I that under similar conditions there is a qualitative agreement between the ratios of the rates of absorption determined experimentally (Col. 9) and the ratios calculated on the simple assumption that the rate is proportional to $(C + C_S)$ (Col. 10). The relationship appears to be valid in the absorption of carbon dioxide by water and by very dilute alkaline solutions (Expts. 2, 4, 5) but falls down as the concentration of the solute is increased (Expts. 6, 7, 8 and Table II). Even when the gaseous solubilities are quite different, the relationship still holds, *e. g.*, Expts. 12, 13, and a remarkable agreement is found in the absorption of ethylene by bromine water (Expt. 11), even though the reaction is quite different. Detailed treatment of the absorption of ammonia by water and by hydrochloric acid is given later. Nevertheless, the relationship is only qualitative and a more exact one must include the four neglected factors noted above. For this purpose the following studies of the absorption of carbon dioxide by water and by alkaline solutions are presented.

[a] Mr. H. W. Scherp, working at the Harvard Chemical Laboratory, obtained the value Cof. = 1.8×10^{-4}, using the very same acid and ethylene that was used in our experiments. He used an apparatus with a sensitive manometer filled with tetrachloro-ethane (sp. gr. 1.6) and a compensator to avoid the necessity of correcting for changes in barometric pressure. [b] Revolutions per minute of rotating absorption chamber. [c] The surface of the liquid was drawn down in the center and thrown up on the sides by the rapid stirring so that its area was greatly increased. [d] These experiments were performed in the small chamber with 1 cc. of acid, [e] Quantity of isobutene absorbed. 100% = 1 mole isobutene per 1 mole sulfuric acid.

Hatta[7] has investigated the rates of absorption of carbon dioxide by stirred solutions of potassium hydroxide. He concluded that the reaction to bicarbonate is slow, being negligible in the film, while the reaction to normal carbonate is instantaneous at a zone inside the film. Accordingly the concentration gradients at the stationary state should be of the type shown in Case B of Fig. 1 (except that two moles of hydroxide unites with one of the dissolved gas).

However the writers submit for consideration the following evidence that the reaction to bicarbonate is rapid, taking place principally in the film, and that the concentration gradients are of the type shown in Case C of Fig. 1.

1. The initial rate of absorption of carbon dioxide by 0.1 M sodium carbonate is considerably higher than the initial rate of physical dissolution into pure water (Expts. 2 and 5, Table I). Indeed it is practically the same as that of 0.1 M sodium hydroxide. This was proved not only by experiments with prepared solutions of the two but also by following the absorption rate at constant pressure into 0.1 M sodium hydroxide until no more gas was absorbed. The rate at the stage represented by complete transformation to normal carbonate was almost exactly half the initial rate, and the total quantity absorbed corresponded to that necessary to form bicarbonate and physically to saturate the solution.

2. There is strong evidence that sodium bicarbonate precipitates in the stationary film when carbon dioxide is absorbed by solutions of sodium hydroxide or sodium carbonate stronger than approximately 1.5 *M*. When carbon dioxide is brought into contact with quiescent 2.5 *M* sodium

[7] Hatta, *Tech. Reports Tohôku Imp. Univ.*, 8, 1 (1928).

hydroxide, the whole surface is soon covered with a mat of crystals. These cannot be the normal carbonate because sodium hydroxide of this concentration will readily dissolve an equal molecular quantity of sodium carbonate and it is difficult to conceive how in a closed space the concentration of carbonate in the surface layer could ever exceed by very much, that of the hydroxide in the main body of the solution. Hence the crystals must be sodium bicarbonate. This conclusion is confirmed by the observation that crystals can be seen to form on the quiescent surface of sodium carbonate about three-quarters saturated, when allowed to stand in contact with carbon dioxide.

The phenomena stood out still more clearly under the microscope at about fifty diameters magnification. The solution to be examined was placed in a small cell 12 mm. wide and 2 mm. deep made by cementing a glass ring upon a slide. The cell and the objective of the microscope were surrounded by a glass cylinder 22 mm. wide and 25 mm. deep pressed tightly against the slide. The carbon dioxide was introduced through a side tube in the cylinder so that the whole solution was covered with the gas at substantially atmospheric pressure. To facilitate observations some particles from a lead pencil were rubbed into the solution. As soon as the gas entered, the particles below the surface of the solution became agitated by thermal currents while those at the surface remained practically stationary. Precipitation in the film showed as a cloud which sometimes gradually and sometimes quickly (after a lapse of a few minutes) obscured the field of vision. The results were as follows

Solution	Observations
0.5 M NaOH	No cloud
1.3 M NaOH	Gradual dimming of field
2.6 M NaOH	Distinct cloud suddenly appearing after one to three minutes
2 6 M KOH	Field actually brightened, no cloud. Thermal currents rapid until alkali was neutralized by carbon dioxide
9 M KOH	Thick cloud in a little over one minute

These results should be studied in relation to Tables I and II and leave no doubt but that actual precipitation of either primary or secondary reaction product occurs in the liquid stationary film at approximately the concentration of alkali at which it would be predicted from our postulates. Visual observations, especially with the aid of a microscope, can be of great service in studies of these reactions which take place in the film.

The Effects of the Reaction Products on the Liquid Film Diffusion Coefficient.—Experiments 2 and **3,** Table I, show that the absorption rate of carbon dioxide by 0.1 M sodium bicarbonate was 36% less than by pure water, although the solubility was only decreased 8%. This indicates that the liquid film diffusion coefficient of the 0.1 *M* salt solution is only 0.7 times that for pure water. Figure 2 shows the general relationship (determined by separate experiments similar to 2 and 3) between the values for k_L, relative to that for pure water, and the concentration of bicarbonate. It is important, however, to note that this is not simply a salt effect because k_L for 1 *M* potassium chloride was found to be practically identical with that for pure water.

Using the corrected value for the film coefficient, the ratio of the absorption rates of either 0.1 M sodium hydroxide or 0.1 M sodium carbonate to that of pure water should be $0.7\ (0.1 + 0.030)/(0.033) = 2.8$, whereas the values actually found were 2.5 and 2.3. In a similar way the values in Col. 11, Table I, and in Col. 5, Table II, have been calculated.

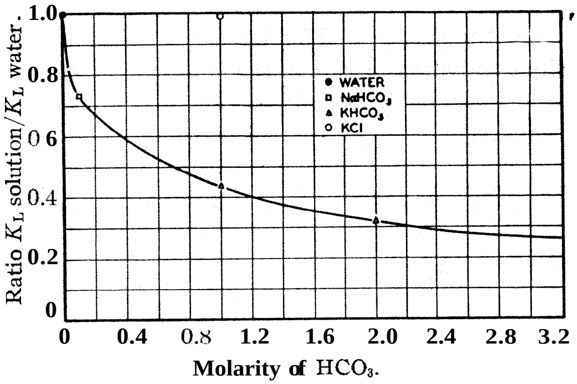

Fig. 2.

The legitimate objection will be raised that these modified values of k_L determined for bicarbonate solutions have been applied to the calculations in the absorption of carbon dioxide by solutions of caustic alkalies whereas bicarbonate exists only in the outer portion of the film. The writers can only suggest that the secondary product (normal carbonate) which exists in the inner portion may have a similar effect. At any rate, the agreements between the calculated and the experimental ratios is rather striking up to the point where the reaction product begins to precipitate. The effects of reaction products and of other substances on the liquid film diffusion coefficient offer a field worthy of further study.

Ledig and Weaver[8] measured the rates of absorption, per unit area, of carbon dioxide from bubbles into water, and into solutions of sodium and potassium hydroxides. By an ingenious device the bubble (vol. 0.036 cc.) was held stationary in the solution in a closed system by running the liquid downward at a rate sufficient to compensate for the tendency of the bubble to rise. The changes in volume were followed by the movement of the surface of the liquid in a capillary tube open to the atmosphere.

---

[8] *Ledig and* Weaver, THIS JOURNAL, 46, 650 (1924); *Ledig, Ind. Eng. Chem.*, 16, 1251 (1924).

They state that "the rate is not constant during the whole period of absorption from a bubble (at constant pressure) but follows a three-stage cycle. This can best be seen in the absorption curves for very dilute solutions (see Fig. 3 reproduced from their article) and the higher concentrations undoubtedly follow the same course though this is not entirely evident if a curve is studied by itself. The cycle is begun by a very high absorption rate at the newly formed liquid–gas interface but as absorption goes on it falls again very quickly to a rate where an equilibrium condition exists, the rate being controlled by the diffusion of the reagent to the surface and of the reaction product away from the surface. The third stage in the cycle begins when the diluting gas starts to retard diffusion of gas to the surface. This latter state is undoubtedly affected by the diminished buoyancy or rate of rising as the bubble becomes smaller and there is a decrease in the stirring action which renews the absorbing liquid at the surface."

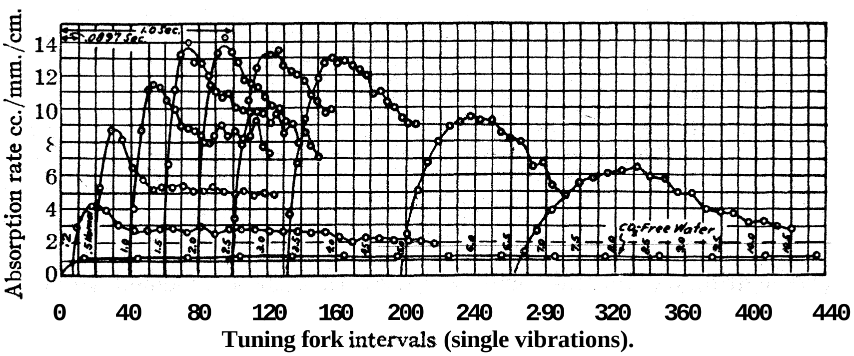

Fig. %.—Effect of concentration upon rate of absorption in NaOH solutions. (After Ledig and Weaver.)

Examination of the curves shows that no initial high absorption rate was detected in the case of absorption into pure water. This suggests that the high initial values clearly shown for absorption into sodium hydroxide solutions are caused by the hydroxide already in the freshly formed film. This diffuses outward to meet the carbon dioxide diffusing inward and the extension of the gradient of the latter into the film will increase, that is, the rate of gas absorption will decrease until the sodium hydroxide is diffusing uniformly from the main body of the solution into the film. The greater the initial concentration of the hydroxide in the film, the longer the time required to reach the conditions for constant absorption which might finally not appear at all. And this is exactly what the absorption curves show.

The initial absorption rate, by pure water, of carbon dioxide from the bubbles of Ledig and Weaver was $dn/(Adt)_{\text{Init.}} = 680 \times 10^{-9}$. This is over seventy times the value found by the writers (Table I) for water stirred underneath at 400 r. p. m. Nevertheless, the ratios of the rates into caustic solutions to that into pure water are very much the same in both cases. See, for example, 2.3 potassium hydroxide 19.1, Table I, and 3.0 potassium hydroxide 18, Table II. Apparently our generalizations hold for widely different absorption conditions.

Columns 3 and 4, Table II, give the ratios of the absorption rates at the stationary state found by Ledig and Weaver. Column 5 gives the ratios calculated on the assumption that they are proportional to $k_L (C_i + C_S)$. The results are striking. The calculated ratios for sodium hydroxide agree fairly well with the experimental up to the concentration where bicarbonate would be expected to precipitate, the experimental rates then remain constant up to a concentration somewhat beyond that of saturated sodium carbonate and finally steadily decrease. For potassium hydroxide the experimental and calculated ratios agree even better up to a point where potassium bicarbonate should precipitate, after which the former remain fairly constant for the range given in the table.

Ledig and Weaver found, however, no decrease in the rate for potassium hydroxide beyond a concentration corresponding to saturation of normal carbonate but on the contrary a rapid rise for concentrations somewhere above 9 *M*. They state "an attempt has been made to link this rapid rise of rate with the known properties of the solutions—solubility of the carbonates, viscosity of the solution and ionization of the hydroxide and carbonate solutions—but no quantitative relation has yet been found." The writers suggest that this phenomenon is caused by the large quantity of hydroxide brought into the film in the case of concentrated potash, by its renewal at the head[9] of the bubble. It has been pointed out that the period of persistence of the high preliminary rate increased with the concentration of the hydroxide. The quantity initially in the film for 0.1 M hydroxide was calculated to be about 1×10^{-7} mole. This is negligible compared to the amount of gas in the bubble, 1.3×10^{-5} mole, but the quantity for 6 M hydroxide, 0.6×10^{-5} mole, must play an important part in the absorption when the film is being renewed at the head. The conclusion is confirmed by the fact that in our experiments where the liquid was stirred without renewing the film, 12 M potassium hydroxide actually absorbed at a slower rate than 2.3 M solution.

Temperature Changes in the Film.—Adeney and Becker[10] found that the rate of oxygen absorption by water decreased slightly over the range 2.5 to 35.1°. The film coefficient increased almost 100% but was compensated for by a corresponding decrease in gaseous solubility.

---

[9] For a discussion of the renewal at the head see Davis and Crandall, Ref. 4.

[10] Adeney and Becker, Phil. *Mag.*, 39, 391–402 (1920).

Nevertheless, these same investigators[11] have shown that oxygen is absorbed by water considerably faster from dry air than from air saturated with water vapor and have attributed this in part to local cooling of the surface layer by evaporation into the dry air. This indicates that considerable local temperature changes in the film may take place even for simple physical absorption of gases.

All the heat produced in the film by chemical reactions must flow away by diffusion to the surface or to the inner boundary, if convection plays only a minor part, so that the temperatures in the film will always be higher than in the main body of the solution. The writers found the rate of carbon dioxide absorption by unstirred 12 M potassium hydroxide to be three times that into the solution stirred at 400 r. p. m. Evidently a great rise in temperature takes place in the film of the liquid at rest and the absorption rate is high because of the increased solubilities of the reaction products and the increased film diffusion coefficient. Stirring helps to dissipate the heat into the main body of the liquid.

The Relative Rates of Carbon Dioxide Absorption by Solutions of Sodium Hydroxide and of Potassium Hydroxide.—The assumption of equal diffusivities for all solutes in the film appears to be only an approximation. Ledig and Weaver state that "potassium hydroxide solutions absorb carbon dioxide more than twice as fast as sodium hydroxide solutions at the lower concentrations." However, they compared the averages of the rates over the whole period of the absorption, including the high initial speeds. The ratio of the rates at the steady state (when uniform concentration gradients had been established) was about 1.5. This accords with the fact that the specific diffusivity of potassium hydroxide in dilute solutions is about 1.5 times that of sodium hydroxide. It seems clear that the differences in the absorption rates of carbon dioxide by the two is related to diffusivities and not to actual differences in the reaction rates as assumed by Hatta.[12]

The Experiments of Whitman and D. S. Davis.[13]—These investigators determined the rates of absorption where a gas was passed over 4 liters of liquid with 405 sq. cm. of surface exposed. Both gas and liquid were stirred by separate blades at 60 r. p. m. The following table has been prepared from their data.

Oxygen was absorbed so slowly that the over-all liquid film diffusion coefficient for this case was assumed to be identical with the true liquid film diffusion coefficient. However, in the fast ammonia absorption the surface could not become saturated because of the resistance of the gas film through which a considerable gradient had to be established in order:

TABLE IV

DATA OF WHITMAN AND DAVIS

Solute	Average partial pressure of solute in air mixture, mm.	Liquid	$\left(\frac{dn}{Adt}\right)_{\text{Init.}}$	K_L (Over-all)
Oxygen	746	Water	$0\ 87 \times 10^{-9}$	0.92×10^{-6}
Ammonia	2.3	Water	580×10^{-9}	0.29×10^{-6}
Ammonia	19.09	2.3 *N* HCl	1100×10^{-9}	....

to convey the ammonia to the liquid surface at such a rapid rate. It will be assumed here that the fractional saturation of the surface layer is shown by the ratio of the over-all coefficient to the true coefficient $0.29/0.92 = 0.31$ (which is true if the gas follows Henry's law). Water at 30° saturated with ammonia at 21.3 mm. is about 2 *M*,[14] so that the surface concentration for the absorptions into water was 0.62 *M*.[15] Whitman and Davis assumed that during the absorption into 2.3 N hydrochloric acid the concentration of the ammonia in the surface layer was negligible. These values were used in calculating the ratios given in Table III (1 to 2.0 experimental and 1 to 3.7 calculated, the divergence may be due to changes in k_L).

Absorptions of Gaseous Olefins by Sulfuric Acid.—In a former communication[16] it was pointed out that the values of the absorption coefficient in a rotating chamber were characteristic for the separate olefins. It will be noted that values obtained in the new apparatus agree very well with the former ones (see Cols. 6 and 7, Table III). The absorption rates are expressed both as *Cof.* and as dN/AdT to facilitate comparisons of the latter values with the former. This agreement holds even where the ratio of liquid surface to liquid volume is changed over a large range (from 12.2 rotating and 2.45 sq. cm./cc. at rest in the former to 0.57 sq. cm./cc. in the new apparatus). As has been shown in that communication, the absorption coefficient *Cof.* calculated from the constant volume experiments should equal the rate at which the olefin would be absorbed at constant pressure, the gas being measured at that pressure. It will be noted that the initial rates of absorption at constant pressure agree well with the values of *Cof.* calculated from the constant volume experiments.

In the experiments with ethylene and propene using concentrated sulfuric acid, the absorption rate per unit area was not affected by stirring.[17]

---

[14] Haslam, Hershey and Keen, Ind. *Eng. Chem.*, **16**, 1224 (1924).

[15] Whether or not the gas film is controlling in the absorption of a very soluble gas such as ammonia in water can be conveniently tested by measurements of the absorption under similar conditions by a solution (*e. g.*, hydrochloric acid), with which the dissolved gas reacts instantaneously.[13]

[16] Davis and Schuler, THIS JOURNAL, 52, 721 (1930). *Cof.* instead of *C* is used in the present paper for The Coefficient, because here *C* denotes concentration.

[17] The statement of Damiens, *Compt. rend.*, 175, 585 (1922), that stirring at 200

However, in the absorption of isobutene into 70% acid the rate of absorption **was** greater into the stirred acid than into acid at rest but within the range investigated was independent of the rate of stirring. Further, the rate at rest was irregular, falling off quite rapidly toward the end. In this experiment a layer of polymer insoluble in the acid was found on top of the acid at the end. For isobutene and 60% acid the absorption rate was less when the acid was stirred but independent of the rate of stirring (within the range investigated). The absorption curves for this experiment (Fig. 4, Nos. **E5A** and E5B) merit careful study. That of 5A (r. p. m. = 0) starts at a faster rate than that of 5B (r. p. m. = 240). When the stirring conditions were reversed the two curves cross. Finally, at the end for the same stirring conditions (r. p. m. = 0) the curves are parallel. All the reaction products in this case were soluble

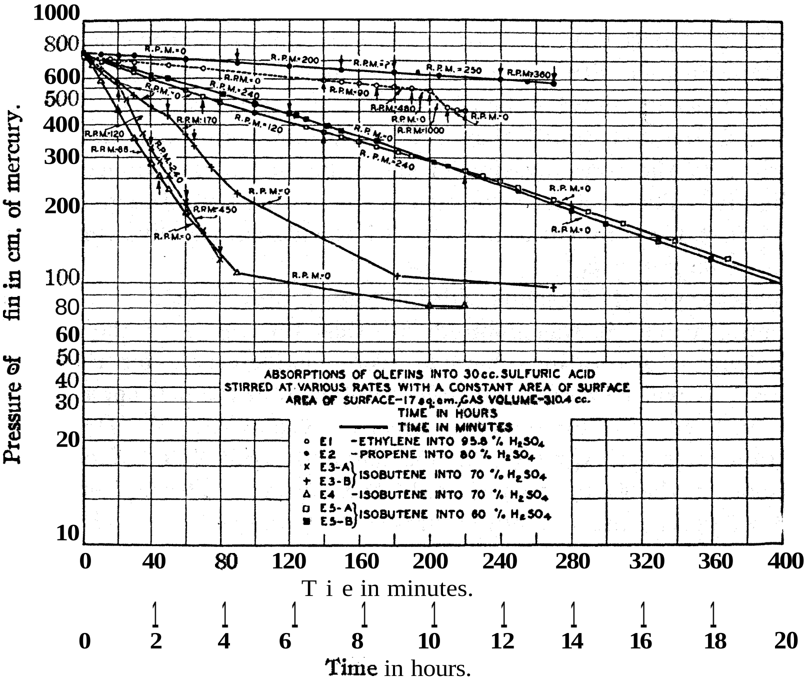

Fig. 4.

r. p. m. increases the absorption rate of ethylene by concentrated sulfuric acid **20–27** times has been frequently misinterpreted. Unfortunately the full experimental details are not given. He found the absorption rate to be proportional to the partial pressure of the gas and to the surface of contact.

The writers suggest that a method for determining the effective area of a liquid when stirred or shaken can be based on these facts. The over-all absorption rate of ethylene by concd. sulfuric acid under the same conditions of agitation should be divided by its absorption rate per unit area into the acid at rest.

in the acid. Further, *tert.*-butyl alcohol was salted out when the acid was neutralized in the cold with sodium hydroxide. The rate of absorption of isobutene at constant pressure by 60% acid increased as more olefin was absorbed up to 0.4 mole of isobutene per mole of acid and then fell off. However, in the absorption of propene by 87% acid the rate steadily decreased from the first.

It has been shown[16] that the physical solubilities of the olefinic gases in sulfuric acid are very low, and yet enormous rates of absorption are observed in some cases. It is inconceivable that under these conditions the dissolved olefin could penetrate to and react in the main body of the liquid. The entire reaction must take place either at the surface or in the stationary film. In the latter case it can only penetrate a short distance because the concentration gradients from the surface must be very steep. For instance, 500×10^{-4} cc. of propene was absorbed per sec. per sq. cm. by 97% sulfuric acid and a uniform gradient carrying oxygen under atmospheric pressure into water at that rate could only extend in from the surface about 0.00001 cm.

The conclusion that the olefin never reached the main body of the liquid in our experiments is confirmed by the facts that the absorption rates were in the majority of cases unaffected by stirring underneath the surface or by changing the acid volume.[18]

The conclusion that the reaction does take place inside the film rather than at the interface is confirmed by the experiments with isobutene. As pointed out above, the absorption rate of isobutene into an excess of 60% sulfuric acid at rest rises slightly as the absorption proceeds. The rate is brought back to normal if the solution is stirred. At constant pressure, with stirring, the rate per unit area increases slowly to a total absorption of 0.4 mole per mole of sulfuric acid and then slowly decreases. When isobutene is absorbed by acid of this concentration, *tert.*-butyl alcohol is formed directly[19] and is only slowly polymerized at 25°. The sulfuric acid functions as a catalyst for the union of water with the olefin. The intermediate sulfate has never been isolated. It seems reasonable to attribute the "abnormal" effects just cited to the *tert.*-butyl alcohol. This accumulates in the film of the unstirred liquid until its rate of diffusion into the main body of the acid equals the rate of formation. Its presence increases the solubility of the isobutene and hence the absorption rate is higher. This illustrates again how much the presence of reaction products may affect an absorption rate. It has actually given rise to a maximum in the rate of absorption in this case.

---

[18] Plant and Sidgwick, *J. Soc. Chem. Ind.*, 40, 14–18T (1921), absorbed ethylene into concentrated sulfuric acid by bubbling the gas through the liquid. Their assumption that "the liquid phase must be regarded as saturated with ethylene" appears to be unjustified.

[19] Michael, *Am. Chem. J.*, 38, 267–279 (1912).

On the other hand, the absorption of propene at constant pressure into stirred 87% acid decreases continuously with the quantity taken In. Here isopropyl sulfate is formed, which decreases the concentration of the acid. The separate olefins are absorbed at widely different rates by the same concentration of acid. It is concluded that the reaction rates of the dissolved olefins are different. However, the absorption rates cannot be directly proportional to the reaction rates. For, consider the case of two olefins of equal solubility but with reaction rates in the ratio 1:2; evidently, at any time, there is more of the slower reacting one in the solution, so that the quantity which reacts in unit time, and therefore its absorption rate, is more than half that of the other. The slower reacting one has an unfair advantage.

Summary

1. The two-film theory of gas absorption proposed by Lewis and Whitman has been extended to cases where rapid chemical reactions take place in the solution.

2. The reactions between the dissolved gas and a solute, for the cases studied, appear to occur inside the liquid. If the reaction rates are very fast compared to the rates of diffusion through the liquid film, then the reactions take place at zones in this film parallel to the liquid surface.

3. Diagrams are given of the concentration gradients in the film at the initial state of uniform gas absorption for instantaneous reactions taking place in one stage and in two. The primary reaction product exists between the surface and the first reaction zone, in concentration equal to that of the solute in the main body of the solution. If the metastable limit of its solubility is exceeded, it will precipitate.

4. A general equation is proposed for calculating the rate of absorption of a pure gas by a liquid (physical solution, or when reacting instantaneously with a solute) from its solubility, the concentration of the solute and the liquid film diffusion coefficient. The validity of this relationship is supported by calculations from gas absorption rate data of the authors and of other investigators for gases of widely different solubilities and for reactions of very different types.

5. A study is given of the rates of absorption of carbon dioxide by water and by solutions of sodium and potassium hydroxides. Conditions are described under which the precipitation in the film of a reaction product, sodium bicarbonate, can be seen during the absorption. Explanations are offered for the various phenomena observed by Ledig and Weaver regarding the absorption of carbon dioxide from minute bubbles by alkalies.

6. A study has been made of the effects of the reaction products on the magnitude of the liquid film diffusion coefficient. Some observations are given on the effects of the heat produced by reactions in the film.

7. The absorption rates of several olefin gases by sulfuric acid both at rest and stirred beneath its surface have been measured. The values for the absorption coefficients agree well with those obtained in a previous investigation using a rotating absorbing chamber.

8. The reactions between the olefins and sulfuric acid take place mainly in the liquid stationary film itself. This is indicated (a) by the enormous rates of absorption obtained in some cases, although the physical solubilities of the gases in the acid appear to be very low and (b) by the fact that stirring the acid underneath the surface or changing its volume, in most cases, did not change the absorption rate. The reaction rates of the dissolved olefins are quite fast and are not proportional to the absorption rates as is often assumed.

9. The fact that isobutene is absorbed by 60% sulfuric acid faster when the acid is at rest than when it is stirred is attributed to a greater accumulation of the reaction product, *tert.*-butyl alcohol, in the liquid stationary film of the quiescent acid.

10. It is suggested that the over-all rate of absorption of ethylene by concentrated sulfuric acid (the rate per unit area being independent of the agitation) may be used to determine the area of the surface of a liquid when stirred or shaken in an apparatus.

[COMMUNICATION NO. 29 FROM THE EXPERIMENTAL STATION, E. I. DU PONT DE NEMOURS AND COMPANY, WILMINGTON, DELAWARE]

STUDIES IN GASEOUS OXIDATIONS. I. THE HOMOGENEOUS UNCATALYZED REACTION BETWEEN OXYGEN AND ACETYLENE

BY GEORGE B. KISTIAKOWSKY AND SAM LENHER

RECEIVED MARCH 27, 1930 PUBLISHED OCTOBER 6, 1930

The problem of the oxidation of hydrocarbons has been of great scientific and technical interest for many years. The present work was undertaken to study in detail the features of a simple hydrocarbon oxidation in the hope that it would contribute to the general knowledge of the mechanism of gaseous oxidations. Acetylene was chosen because it reacts with oxygen at lower temperatures than other hydrocarbons; this made it possible to isolate intermediate reaction products.

A systematic study of the slow reaction of simple hydrocarbons was initiated by Bone[1] about thirty years ago. More recently Pease[2] and also

[1] Bone and Townend, "Flame and Combustion in Gases," Longmans, Green and Co., London, 1927.

[2] Pease and Chesbro, *Proc. Nat. Acad. Sci.*, 14, 472 (1928).

Pope, Dykstra and Edgar[3] and Thompson and Hinshelwood[4] have described experiments dealing with the slow thermal oxidations of the hydrocarbons by oxygen. Pease in particular has demonstrated that these reactions can occur in the gas phase exclusively and are inhibited by glass surface—a characteristic of chain reactions.

Bone and Andrew[6] studied the combustion of acetylene in sealed bulbs between 200 and 350°. They concluded that an excess of oxygen over and above an equimolecular proportion always retards the oxidation, and postulated the presence of an unstable product $C_2H_2O_2$(HOC≡COH), which decomposed directly to carbon monoxide and formaldehyde. Recently Briner and Wunenburger,[7] in studying the reaction between acetylene and ozone at low temperatures, found the liquid products of reaction to be mainly glyoxal, CHO—CHO.

Experimental Results

The oxidation of acetylene was studied by the flow method at atmospheric pressure. Acetylene and oxygen at a regulated rate of flow passed through separate purifying trains and were mixed at the entering point of the reaction vessel. Both gases were taken from commercial cylinders. Oxygen was freed from water vapor by passing it through two wash-bottles filled with concentrated sulfuric acid. Acetylene (Prest-O-Lite) was passed through two spiral wash-bottles containing water to remove acetone vapor and was dried over calcium chloride. The pyrex cylindrical reaction vessel, 22 mm. in diameter, was heated in a large electric tube-furnace. Temperatures were read by means of a chromel–alumel thermocouple enclosed in a thin-walled glass tube placed in the center of the reaction vessel.

The gases, after passing through a trap cooled in solid carbon dioxide, were led through a spiral wash-bottle containing a standardized barium hydroxide solution to absorb carbon dioxide quantitatively, and were collected in a water gasometer. The gas was transferred to a 500-cc. Hempel pipet containing alkaline pyrogallol solution and shaken until all oxygen was consumed; it was then transferred to a bromine water pipet, and acetylene was removed by shaking; bromine vapor was removed from the residual gas by shaking with potassium iodide solution in a small Hempel pipet. The gas was then analyzed for carbon monoxide and hydrogen in a Burrel gas analysis apparatus[8] after checking for absence of oxygen and acetylene. Gases originally containing less than 1% of carbon monoxide could be analyzed satisfactorily. Carbon dioxide was determined by titrating the barium hydroxide solution with hydrochloric acid. The condensable reaction products were determined by oxidation with standardized potassium dichromate solution in concentrated sulfuric acid and iodimetric titration of the excess potassium dichromate. The potassium dichromate solution was added from a buret to the trap while still cold so that even volatile products (formaldehyde) were included in the analysis. The condensable products were mainly formic acid and

formaldehyde. Checks with standardized formic acid solution showed that two equivalents of iodine are consumed in the oxidation of formic acid by potassium dichromate, the reaction being

$$HCOOH + {}^1/_2O_2 = CO_2 + H_2O$$

Oxidation of formaldehyde requires very nearly four (3.6) equivalents of iodine, the principal reaction being

$$CH_2O + O_2 = CO_2 + H_2O$$

although the other reaction

$$CH_2O + {}^1/_2O_2 = CO + H_2O$$

takes place to some extent.

A standard gas mixture containing equal volumes of acetylene and oxygen was used. The rate of flow of each gas was 0.1 cc./second, corresponding to an average contact time of 200 seconds for a 78-cc. vessel at an average temperature of 290°. Three hundred and sixty cubic centimeters of acetylene–oxygen mixture was used. Table I presents the results of these experiments. The amounts of formic acid and formaldehyde given in the last column have been calculated on the assumption that no other condensable products were present, and that these two substances were present in the ratio 6:1. Justification for this assumption will be given below in the discussion of the condensable products. From Table I it will be seen that the main products of acetylene oxidation are carbon monoxide and the "condensable matter." Carbon dioxide is also formed in considerable quantities whereas hydrogen, although present, plays a much less important role.

The composition of the condensable products, which in the above experiments were measured only by the amount of potassium dichromate consumed, was determined with a sample obtained by carrying out the reaction for twelve hours at 310–315°. One and six-tenths grams of condensed products was collected in the cooled trap and diluted with two cc. of water.

The resulting solution was opaque, and a small quantity of a resinous substance collected at the surface on standing. Small samples were withdrawn from the solution and analyzed. The condensate gave a positive test for formic acid, using the mercuric oxide test.[9] Titration of two samples with barium hydroxide indicated 56.1 and 53.3% of formic acid. Oxalic acid was not present, for no precipitate of barium oxalate was formed. Formaldehyde was determined by two methods: the potassium cyanide reaction,[10] which yielded in three determinations 4.7, 4.7 (small samples) and 5.4% (large sample) by weight, and the iodimetric method,[10] which yielded in three determinations 9.2, 8.3 and 8.9% by weight. These determinations accounted for about 65% by weight of the condensate. The chemical nature of the remainder was established by titrating another sample with standard potassium dichromate solution. If it is assumed that formic acid and formaldehyde were present in the ratio 55:9, the oxidation analysis gave their total amount as 71.7% of the condensate. The remaining 28.3% was non-oxidizable and was undoubtedly water.

The discrepancy between 64% obtained by acid and aldehyde determinations and 72% calculated from oxidation analyses we suspected was fictitious, and was due to the assumption that formaldehyde was the only aldehyde present. Condensate was collected for thirty hours to obtain material to test this point. This was added to a solution of 5 g. of p-nitrophenylhydrazine in 50% acetic acid solution and allowed to stand for thirty-six hours. The brick red precipitate was filtered off, neutralized with warm 10% sodium carbonate solution, washed with hot distilled water and dried. The precipitate was extracted with hot benzene to dissolve the nitrophenylhydrazone of formaldehyde.[11] The residue was recrystallized from hot pyridine, yielding brick red needles melting over the range 250–270°. As the di-*p*-nitrophenylhydrazone of glyoxal is the only probable *p*-nitro or di-p-nitrophenylhydrazone having a higher melting point than that of the formaldehyde compound (185°), it seemed clear that we were dealing with the glyoxal derivative. The di-p-nitrophenylhydrazone of glyoxal was prepared from glyoxal sodium bisulfite compound and on recrystallization gave a melting point of 305°. When the pure di-p-nitrophenylhydrazone of glyoxal was mixed with the derivative from the condensate (m. p. 250–270°), the mixture did not melt at 278°, but decomposition took place. The di-*p*-nitrophenylhydrazone of glyoxal derived from the condensate gave the characteristic Bamberger test[12] of a deep blue color with alcoholic potassium hydroxide. The characteristic color of the derivative from the condensate, the high melting point as well as the mixed melting point, and finally the color test shows that glyoxal was present in appreciable quantities in the condensate.

To complete the analysis of the condensable products, the water-insoluble resinous substance (3.78 mg.) was subjected to microcombustion after it had been dried for twenty-four hours by exposure to the atmosphere. This yielded 52.71% carbon, 8.65% hydrogen and 1.77% ash, the rest being undoubtedly oxygen. Such a compo-

sition does not correspond to any single substance probable under the circumstances and it must be assumed that a mixture was present. If one attributes all of the oxygen to water present in the analyzed sample (41.5% by weight), the composition is 1.0 carbon : 0.92 hydrogen, approximating the composition of acetylene. The behavior of the sample is further support for this assumption of water in the resinous matter, for it appeared to dry or harden on standing.

The effect of the time of contact on the speed of reaction and its course was studied by increasing the rate of flow. Results of these measurements made at two temperatures are presented in Tables II and III. In the experiments given in Table III, the condensate was weighed and the acid content determined by titration with barium hydroxide. The results of this determination are given in the last column together with the percentage weight of formic acid in the condensate. The experiments summarized in Table II show that the yields of all products decrease with the time of contact. This phenomenon finds an adequate explanation only in the assumption that the reaction exhibits an induction period. A more detailed consideration of Table II shows that the yields of various reaction products are not affected in the same way. The amount of carbon dioxide decreases most rapidly, then the carbon monoxide, while hydrogen and particularly the condensable substances diminish only very slightly in quantity. There appear to be two explanations of this specific influence of

the time of contact: either the induction period is different for different products, or the analyzed reaction products are not all due to the primary reaction. If this latter assumption is accepted, one can deduce further that the condensable substances, and possibly hydrogen, are the first products of the oxidation (or decomposition) of acetylene, while carbon monoxide and dioxide result from secondary decompositions or oxidation of these products. Although on first glance the results at 310°, Table II, seem to differ greatly from those at 278°, in reality they agree quite well. At 310°, 30% of the acetylene reacts during the longest contact time, and since the reaction velocity depends strongly on the acetylene concentration (see below), the velocity must decrease during the reaction period owing to consumption of acetylene in the reaction. On further decrease of contact time to fifty seconds the influence of the induction period overweighs that of the consumption of acetylene, and a general decrease in the reaction velocity is observed. The data in Table II show that the yields of carbon monoxide and dioxide decrease more rapidly with the contact time than do the other reaction products; in fact, the yield of condensable substances even increases slightly.

A decrease in the contact time has little effect on the absolute amount and the weight concentration of formic acid. The increase in the total amount of oxidizable matter in the condensate shows that with decreasing contact time the amount of water present must decrease, whereas the aldehyde fraction must increase. Indeed, the iodine determination of aldehydes carried out on a sample obtained with fifty seconds' contact time yielded 30% of aldehydes in the condensate as compared with 9% obtained with 200 seconds' contact time.

The influence of gas composition on the reaction velocity was established by runs made with gases composed of 75% acetylene, 25% oxygen and 25% acetylene, 75% oxygen. These runs, which are presented in Table III, show that the reaction velocity falls off very rapidly with decreasing acetylene–oxygen ratio. The variation in reproducibility of the experiments makes uncertain any conclusions as to whether all reaction products decrease in this same ratio or not. The average decrease of two main products, carbon monoxide and the condensable matter, is about ten-fold for a change of composition from 75 acetylene–25 oxygen to 25 acetylene–75 oxygen, or a three-fold change of each of the reactants. This makes it probable either that the reaction velocity is proportional to the square of acetylene concentration, or that it is proportional to its first power and is retarded by oxygen. Runs were made with a gas mixture containing 25% acetylene and 75% oxygen in one case and 75% of air in the other case to decide between these two possibilities. These runs are presented in Table III, Series B, which shows that notwithstanding a five-fold change in oxygen concentration, the reaction velocity is not greatly changed. As a slight increase in the reaction velocity in the mixture containing air can be observed, it appears probable that oxygen has only a slight retarding influence. Accordingly, to account for the results given in Table III, one must assume that the reaction velocity is proportional to the square of the acetylene concentration and is very slightly retarded by oxygen.

To study the influence of the walls of the reaction vessel on the reaction velocity, a pyrex tube was filled with broken pyrex glass of a size between 6- and 14-mesh. The surface in this vessel was increased many-fold and the average diameter of the free spaces was reduced from 20 mm. in the open vessel to 1 mm. or less. Considerable difficulty was experienced at the beginning of these experiments from an inconstancy of the reaction velocity. Table IV presents two consecutive series of experiments and shows that a prolonged exposure of the vessel to the acetylene–oxygen mixture results in a decreasing reaction rate. An attempt to produce more constant conditions was made by treating the packed vessel with a normal solution of sodium chloride, washing once with distilled water, and drying. Pease[2] has observed in oxidation of other hydrocarbons using potassium chloride on glass that the salt treatment of the glass surface brought about a marked decrease in reaction velocity. Our treatment with sodium chloride did not have such an effect. The reaction velocity was speeded up slightly and was more reproducible. The absence of a lasting effect of sodium chloride is not astonishing because the glass surface in both the treated and untreated vessels became coated with a thin deposit of carbon, which was in contact with the acetylene-oxygen mixture. Table V presents the data obtained with the coated vessel and an equimolal mixture of acetylene and oxygen. The remarkable feature of the experiments is that they indicate a reaction velocity in the packed vessel many-fold slower than in the empty one. Thus at 315° some 30% of acetylene reacted in the empty vessel, whereas in the packed tube the reaction amounted to only 3 to 4%. At the same time the course of reaction is profoundly changed; the main products are now carbon dioxide and water. Increase in the amount of water in the reaction products was established by weighing the cooled trap before and after several runs. The change in the course of the reaction is manifest also from experiments on the influence of the time of contact and of the composition of the gas mixture on the reaction velocity. These data are presented in Table VI, Series A and B.

It is apparent from these experiments that the induction period characterizing the reaction in the unpacked vessel has disappeared. The velocity of reaction is now approximately independent of the time of contact and no distinct difference can be observed in the behavior of the various products of reaction. Accordingly there are no grounds to assume now that carbon monoxide and carbon dioxide are products of secondary reactions, as there were in the case of the unpacked vessel where the primary reaction led to the formation of "condensable substances." Series B, Table VI, shows the influence of the composition of the gas mixture on the reaction velocity. Variations in the compositions of the gas mixture leave the reaction velocity almost unchanged. Mixtures rich in acetylene show a somewhat higher

rate, but the increase is much less than the ten-fold change observed in the unpacked vessel. This means that the reaction velocity is no longer proportional to the square of the acetylene concentration. The experiment of Series C, Table VI, in which a part of the oxygen was replaced by nitrogen, shows further that the rate, instead of being weakly inhibited by oxygen, now is more or less proportional to the oxygen concentration.

Discussion of Experimental Results

A comparison of the reaction rates in packed and unpacked vessels shows that the oxidation of acetylene under the conditions employed here is a homogeneous gas reaction. An increase in the glass surface does not increase the rate; instead, such an increase of the surface decreases the reaction rate many-fold. It has been shown by Pease,[2] Hinshelwood and Thompson,[13] and Semenoff[5] that this behavior characterizes chain reactions. The abnormal dependence on the concentration of the reactants is further evidence favoring the chain character of the reaction. Oxygen, which must enter the reaction mechanism, not only does not favor the reaction but even slightly inhibits it. Such behavior is incomprehensible from the point of view of classical chemical kinetics.

The analysis of the oxidation products shows glyoxal, formaldehyde and formic acid, aside from gaseous products. It is obvious that the formation of glyoxal must precede the formation of formaldehyde and formic acid in a stepwise oxidation. The change in the amounts of glyoxal, formaldehyde and formic acid with contact time demonstrates clearly the stepwise character of the oxidation which has already been suggested by Bone.[6] However, we do not consider his scheme correct in detail. Instead of a primary product containing two hydroxyl groups, a substance of the same total composition, $C_2H_2O_2$, but consisting of two aldehyde groups, namely glyoxal, is obtained.

---

[13] Hinshelwood and Thompson, *Proc. Roy. Soc. (London)*, 118A, 170 (1928).

There is a variety of possible reactions which glyoxal may undergo under our experimental conditions. Since reactions involving more than two molecules simultaneously are kinetically less probable than bimolecular and unimolecular processes, we can limit our discussion to the latter.

$$\begin{array}{lll}
\mathrm{CHO{-}CHO} & \longrightarrow \mathrm{CO} + \mathrm{HCHO} & (1)\\
\mathrm{CHO{-}CHO} & \longrightarrow 2\mathrm{CO} + \mathrm{H_2} & (2)\\
\mathrm{CHO{-}CHO} + \mathrm{O_2} & \longrightarrow \mathrm{CO_2} + \mathrm{HCOOH} & (3)\\
\mathrm{CHO{-}CHO} + \mathrm{O_2} & \longrightarrow \mathrm{CO} + \mathrm{O} + \mathrm{HCOOH} & (4)\\
\mathrm{CHO{-}CHO} + \mathrm{O_2} & \longrightarrow \mathrm{CO} + \mathrm{CO_2} + \mathrm{Hz0} & (5)
\end{array}$$

Our experiments enable us to distinguish between the relative importance of these reactions. Reaction 3 certainly does not take place to any considerable extent, for otherwise a much larger relative yield of carbon dioxide would be obtained than was actually observed. Reaction 2 cannot be predominant because only small quantities of hydrogen were obtained throughout. On the other hand, the fact that the hydrogen yield decreased only slowly on decrease of the contact time makes it probable that it is this reaction and not a decomposition of formaldehyde or formic acid that produces hydrogen. Bone maintains that hydrogen in the reaction products is due to a reaction of the type, $\mathrm{HCOOH} \longrightarrow \mathrm{H_2} + \mathrm{CO_2}$, but our experiments point strongly against this inasmuch as they show that, on variation of the contact time, the yields of carbon dioxide and of hydrogen are quite different. Accordingly Reaction 2 may be considered as playing a secondary role in the reaction sequence. Bone attributes the formation of formic acid to a secondary oxidation of formaldehyde only. Our experiments are not conclusive enough to decide whether Reaction 4 or the process $\mathrm{HCHO} + \mathrm{O_2} \longrightarrow \mathrm{HCOOH} + \mathrm{O}$ produces formic acid. In both cases one would expect decreasing yields of acid when the time of contact is decreased, but Reaction 4 would lead to a slower decrease than its formation in the oxidation of formaldehyde. A slight decrease in the amount of formic acid was actually observed; this might be construed as showing the occurrence of Reaction 4. A final decision will be possible only after a more detailed study of the yields of formic acid and formaldehyde.

The occurrence of Reaction 5 is also uncertain at present. The fact that the yields of carbon dioxide and water both decrease rapidly on shortening the contact time speaks in favor of our theory of the formation of these stable reaction products in some later stages of the reaction sequence, perhaps in the decomposition or oxidation of formic acid. The origin of carbon monoxide in the reaction is probably due to several processes. Its main source, especially at the lower temperatures, is Reaction 1. At higher temperatures additional sources of carbon monoxide may be the reactions

$$\begin{array}{l}
\mathrm{HCHO} \longrightarrow \mathrm{H_2} + \mathrm{CO}\\
\mathrm{HCOOH} \longrightarrow \mathrm{CO} + \mathrm{H_2O}
\end{array}$$

The experiments in the packed vessel show that an increase in the glass surface changes the kinetics and the entire course of the reaction. It appears that a heterogeneous oxidation of acetylene directly to carbon dioxide and water, which was quite subordinate in the unpacked vessel, has been sufficiently accelerated to overshadow the homogeneous reaction. The fact that the glass surface has a profound influence on the yield of carbon dioxide is in favor of this explanation.

A problem which remains to be discussed is the coördination of the chemical side of the processes involved in the oxidation of acetylene with the chain character of the reaction and with the kinetic relations observed. Since none of the reactions are reversible under the experimental conditions and glyoxal appears in only small quantities, it must be the primary process of oxidation of acetylene that is the rate-determining process, namely, $C_2H_2 + O_2 = C_2H_2O_2$.

Accordingly one would expect the reaction rate to be proportional to the product of the concentration of acetylene and oxygen, but this is not the case. The reaction rate is proportional to the square of the acetylene concentration and is practically independent of oxygen. Furthermore, the reaction exhibits an induction period. Similar characteristics have been observed by Thompson and Hinshelwood[4] in the oxidation of ethylene. These authors' explanation of the reaction order is essentially this: a molecule resulting from addition of oxygen to ethylene will collide with a molecule of either ethylene or oxygen; the collision with ethylene is favorable to the propagation of a reaction chain while the collision with oxygen puts an end to further chemical processes. This scheme expressed kinetically yields the experimental order. Our results with acetylene can be interpreted in the same manner. The formation of glyoxal, being an addition reaction, must take place through a three-body collision.[14] A formal agreement with experiment is obtained if it is assumed that only with acetylene as the third body is glyoxal formed, while the action of oxygen is different. It is astonishing that glyoxal is formed at all as a primary product because the direct formation of carbon monoxide and formaldehyde, $C_2H_2O_2 = CO + HCHO$, being also highly exothermic, does not need a three-body collision and therefore should occur much more readily.

The presence of reaction chains has been shown, but their mechanism remains at present uncertain. The deduction can only be made from the existence of the induction period that the presence and further oxidation of intermediary products speed up the primary oxidation of acetylene. It is quite possible that free oxygen atoms resulting in some of the single reaction steps discussed above play an important role in the reaction.

Summary

Experiments are described that show that the thermal oxidation of acetylene by oxygen can be conveniently studied in pyrex vessels between

250 and 315°. A comparison of the reaction rates in packed and unpacked vessels shows not only that the reaction is homogeneous but that it is of the chain type.

The change in composition of the condensable reaction products with time of contact shows that the oxidation proceeds through the stages glyoxal–formaldehyde–formic acid. The gaseous products consist mainly of carbon monoxide, together with carbon dioxide and hydrogen. A study of the change in gas composition with contact time indicates that carbon monoxide originates mainly from the direct decomposition of glyoxal, and that carbon dioxide is due to oxidation or decomposition of formic acid, whereas the origin of the traces of hydrogen is at present uncertain.

The velocity of reaction is proportional to the square of the acetylene concentration and is independent of the oxygen concentration.

In packed vessels the homogeneous oxidation is almost entirely suppressed, and a heterogeneous oxidation of acetylene on the glass surface directly to carbon dioxide and water takes place. The rate is roughly proportional to the first power of the acetylene and oxygen concentrations. The mechanism of the reaction has been discussed.

A MAGNETO-OPTIC METHOD OF CHEMICAL ANALYSIS

BY FRED ALLISON AND EDGAR J. MURPHY

RECEIVED MAY 13, 1930 PUBLISHED OCTOBER 6, 1930

This paper reports some results of a method which promises to be of value as a new means of chemical analysis. It also suggests a new angle of approach to certain aspects of the problem of ionization in liquids. The method is a refinement of one previously described by Allison[1] in the investigations of the time lag differences of the Faraday effect behind the magnetic field in certain liquids as a function of the wave length of the light used.

In a study of solutions it was subsequently found that each chemical compound, regardless of the presence of other substances, produces its characteristic minimum (or minima) of light intensity, which persists until the concentration is reduced to about 1 part in 10^{11}.[2] This fact suggested that the method might have application in some cases of chemical analysis.

The authors[3] have extended these findings of Allison to include a rather comprehensive series of solutions of chlorides, nitrates, sulfates and hydroxides.

The experimental arrangement is diagrammatically shown in Fig. 1. The apparatus together with its manipulation has already been described.[1,2,3] A kenetron tube K replaces the Wehnelt interrupter of the original set-up, the condenser C being charged from the high voltage side of the transformer M. Sliding rheostats R_1 and R_2 are in series with the primaries of the main transformer and the filament transformer, respectively. B_1 and B_2 represent the cylindrical cells which are placed co-axially within the helices of wire, N_1 and N_2 the polarizing and analyzing Nicol prisms, L a converging lens, F Wratten filters and T_1T_1 and T_2T_2 the sliding trolleys. A steady source of light in connection with a monochromator has at times been used instead of the spark A, the latter being screened.

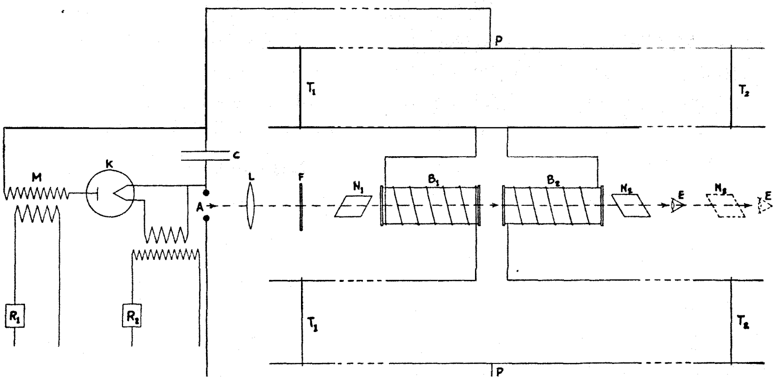

Fig. 1.—Diagram of apparatus and connections.

For some time we have often found convenient a combination of the air or light path and the wire path in measuring these time effects. The sliding trolley, although itself equipped with a vernier, becomes the coarser scale, while the finer settings are made by displacing the cell B_2 by means of a rack and pinion motion. The trolley is first set at a point within a few centimeters of the position at which a minimum is observed and the minimum is then finally located with surprising precision on the rack and pinion scale. The wire and light paths are then simply combined.

Representative results are given in Table I. The compounds of each series are arranged in columns in the order of the increasing chemical equivalents of their metallic elements. In the first column under each compound are recorded the positions of the characteristic minima of the compound as read on the wire path scale. In the second columns are tabulated the differential time lags, all of which are with reference to carbon bisulfide. The zero of the wire path scale is at 15.00. The differential lags are therefore found by subtracting the scale readings of the minima from this zero point, since the scale is laid off in units of 30 cm. The lags are thus

computed on the assumption that the electric surges in the wires travel with the speed of light, because in practice it is more convenient with a given set-up to adhere strictly to the readings on the wire path scale and because we no longer find it worth while to check the readings on the light path scale. There has not been opportunity, for lack of both time and material, to locate the minima corresponding to those compounds for which no values appear in the table. Some salts, such as cuprous nitrate and stannous nitrate, were obtained by the addition of the corresponding acid to dilute solutions of the chlorides. We are publishing data for only such hydroxides as we have been able to procure, though we do find in general the hydroxides present when the salts of the metals are in solution.

Since the position of each minimum corresponding to a compound is tabulated in terms of a scale whose units are marked off in lengths of 30 cm., which in time units have the value of 10^{-9} sec., the second decimal refers to a length of 3 mm. or a time of 10^{-11} sec. The various regions of the scale occupied by the nitrates, hydroxides, sulfates and chlorides will be noted from the data of the table. The chlorides have the advantage of what may be termed greater resolving power in the location of minima. In seeking to determine the presence of a metal, a very valuable check is afforded by observing the minima corresponding to each of the four compounds. There are overlapping regions, as will be seen from a study of the table, but when one gains familiarity with the order in which the minima occur, there is little ground for confusion. It should be kept in mind that these time intervals recorded are differential, the time lag for each compound being with reference to carbon bisulfide. (Other liquids than carbon bisulfide have been used in cell B_1. When this is done the characteristic minima due to compounds in B_2 fall at different parts of the scale in consistent agreement with the differential time lag between the new liquid in B_1 and carbon bisulfide.)

After reading the minima of a number of compounds, it appeared upon a study of the results that the positions of the minima were functions of the atomic weights of the metallic elements of the compounds or, more precisely, of the atomic weights divided by the valence, that is, the chemical equivalents. In other words, the differential time lag in general decreases with increasing chemical equivalent. In each of the four series of compounds of Table I the longest differential lag is thus produced by the compounds of hydrogen, the shortest by those of thallium. Furthermore, elements which have two different valences exhibit as a rule two minima, or two series of minima, in different regions of the scale corresponding to the chemical equivalents in the two cases, the number of minima being the same for each valence. Cases of more than two valences have not been studied. There are several slight exceptions to the law of decrease of differential lags with chemical equivalence. Among these will be noted the minima of the compounds of nickel and cobalt and those of some of the heavy metals which have a number of isotopes, the minima of the latter compounds overlapping in certain regions of the scale. In reading across the table, it will be seen that for any metallic element there also exists this relationship between differential time lag and chemical equivalent in the case of the chlorides, sulfates and nitrates, the hydroxides falling somewhat out of line in this respect.

It will be further noted from the tabulated results that each compound produces either a single minimum or two or more close minima. The number of these minima, with few exceptions, is the same as the number of the known isotopes of the metallic elements of the compounds, whether the elements be in the chloride, nitrate, sulfate or hydroxide form. This is in keeping with the relationship discussed in the preceding paragraph, namely, the variation of the differential lag with atomic mass. The isotopes of the metallic element, in each series of compounds, alone seem to be operative in producing minima. Hydrochloric, nitric and sulfuric acids each produce two minima, for which we are unable to account. It will now be seen that the cobalt minimum takes its place regularly with respect to the minimum of the heavier isotope of nickel but not with respect to that of the lighter.

Several compounds at great dilution behave as if the magnetic rotation exerted by them is of negative sign. For example, repeated observations failed to reveal minima characteristic of ferric sulfate. Upon reversing the field in B_2, however, the two minima appeared in the appropriate region of the scale, as shown in the table. These results are suggestive of those reported by Roberts[4] and others concerning the magnetic rotary dispersion of certain paramagnetic solutions. It is planned to make further study of this behavior of solutions.

Since water in all the reported results was the solvent of the compounds, considerable time has been devoted to searching for minima when the purest water which we have available fills the cell B_2, namely, that distilled in quartz. There are some four or five minima distributed over the scale which we have been unable to remove by redistillations. One of these, because of its distinctness, we have attributed to water. The others we have been unable to identify. Some are doubtless due to compounds dissolved from the glass cell even during the short time the water is in contact with the glass before an observation can be made. These unknown minima, being always at fixed points of the scale, are not a source of confusion but they are actually an advantage in supplying fiducial points along the scale. It is planned to investigate further the causes of these minima.

We have thus far had the opportunity to make a study of practically no inorganic compounds except those listed in the table. A great deal of laborious observation is required to locate the characteristic minima with precision for a large series of compounds. Once the table is determined, however, it affords a rather rapid means of analysis for any compounds of the series. It is planned to construct in the near future tables for carbonates, phosphates, etc., as well as for certain organic compounds. There is reason to believe that this method is applicable to most, if not all. compounds.

The method appears to be a reliable one, as attested by a large number of successful tests and chemical analyses. Several advantages inherent in it may be suggested. One is the speed with which the presence of a compound may be detected. Another is due to the fact that the sample is not destroyed by the analysis, since it is merely subjected to the passage of a beam of light through it. Inasmuch as very small quantities are easily detectable, substances which are very slightly soluble, whether transparent or opaque, readily lend themselves to this sort of analysis. It may be further remarked that the apparatus necessary is comparatively inexpensive. Its operation, however, requires the attainment of a considerable amount of experience and technique on the part of the observer. It is not to be expected, in the present stage of development, that the method will yield dependable results in the hands of the average observer. Improvements are still being made, however, and it is hoped that ultimately it will be adapted to more general usage.

[4] R. W. Roberts, *Phil. Mag.*, 9,361 (1930).

An analogy with spectrum analysis may be of interest. Instead of spectrum lines characteristic of the chemical elements, we have disposed along a scale (some 25 feet long) the minima characteristic not of the elements alone but of the chemical compounds. For example, the various compounds of sodium, $NaCl$, $NaNO_3$, Na_2SO_4, $NaOH$, show minima in different regions of the scale, by means of which each compound when in solution may be recognized. The metallic element in the compound seems to be chiefly effective in producing minima. At any rate, we have found no minima which we could ascribe to the negative part of the molecule. Such minima, of course, may occur in the extended regions of the scale which have not been carefully explored.

Since we find it far more convenient to use the wire path method (or a combination of the wire and light paths), observations have been carried out on the three different set-ups, all built of somewhat different dimensions and in two different rooms, to determine how the positions of the minima correspond on different scales as read on the wire path scale. It is found that, when the set-ups are constructed symmetrically, there is very close agreement in the differences between corresponding minima on the three. Each new set-up, however, should have its wire path calibrated by finding the exact positions of the characteristic minima corresponding to the compounds for which analyses are subsequently to be made. The positions of the minima are not changed, within the errors of observations, by wide variations in the resistance, capacitance or inductance of the circuit, though the distinctness of the minima is affected by such changes. Optimum conditions for sharp minima may be found by experiment through the adjustments of the constants of the circuits. The beginner is likely to meet with considerable difficulty here, since he will probably fail to note the minima at all until this optimum condition is approximated. No fixed rules can be laid down for this adjustment, owing to the variations in the constants of different circuits. It is especially important that the capacity of the condenser be adjustable to the proper magnitude.

Settings on a minimum may be repeated by the same observer, or by different observers, within a deviation of a very few millimeters. Rather close minima may therefore be distinguished with considerable ease. The minima are surprisingly sharp, some more so than others. The hydroxides produce minima which are least sharp and most difficult to locate with precision,

The sensitiveness of the method has proved to be surprisingly great. Tests have been carried out on a representative number of solutions of compounds of graded concentrations. The results show that about 1 part in 10^{11} of the solvent can be detected. This is true for both organic and inorganic compounds. The minima show no appreciable change in distinctness at various stages of concentration until the dilution at which they vanish is approached, when they gradually fade out, usually between 1 part in 10^{11} and 1 part in 10^{12}. The sensitivity is not appreciably affected by the presence of other compounds in the solution, but it depends somewhat upon the observer, the chemical compound and the adjustment of the apparatus. The sensitiveness of this magneto-optic method in comparison with other methods is indicated in the following table (the data are quoted from Aston).[5]

	Mass in am. at which the method breaks down
Ordinary chemical balance	8.5×10^{-5}
Quartz micro-balance	2.58×10^{-9}
Spectrum analysis (Na lines)	3.23×10^{-10}
Ordinary microscope	6.25×10^{-13}
Ultramicroscope	2.38×10^{-18}
	5.15×10^{-22}
Magneto-optic method about	1×10^{-11}

It is recognized, of course, that the results reported in this paper cannot be accounted for on the classical theory of magneto-optics nor are they in accord with experiments on the variation of the magnetic rotation with concentration. Furthermore, our findings are difficult perhaps to reconcile with the modern theory concerning ionization in very dilute solutions. While we are as yet unable to offer a satisfactory interpretation of our results, there are several points that should be mentioned. The effect is certainly a time effect, because the characteristic minima are produced by changes in the light path alone, as well as by changes in the wire path. This is further borne out by the fact that when the two cells are exchanged, the positions of the minima are shifted to points of the scale in keeping with this interpretation. Furthermore, when a tube of water is introduced between B_1 and B_2, the position of a given minimum is displaced forward on the light path scale in proportion to the lengthening of the optical path by the water. (This is of additional interest in suggesting a new method for the direct measurement of the speed of light in transparent liquids.) In searching for oscillations several methods were employed. A test coil attached to a vacuum thermocouple was placed alternately in the helix of B_1 and B_2 and the trolleys moved along the scale. The deflecting instrument showed no indication of maxima or minima. A neon tube also failed to give such indications when moved along the scale between the trolley wires. A thermo-galvanometer connected in series with one branch of the circuit showed no maximum and minimum readings corresponding to different points of the scale as the trolley was displaced. An effort was also made to detect oscillations by resonance in a vacuum tube circuit set up for the purpose, but no oscillations capable of affecting our results could be found.

---

[5] Aston, *J. Franklin Inst.*, 193, 583 (1922).

In the present light of our investigations we believe that the phenomena are most probably to be interpreted as due to differential time lags in the Faraday effect. Such an abnormal magnetic rotation in these very weak solutions may possibly be accounted for because of several factors, namely, the high frequency of the magnetic field, the enormous instantaneous amperage and the steepness of the wave front of the transient surges of current. That the form of wave front may be effective is suggested from our experience last summer, with the coming of the first rains. As our research room, situated in the basement, became more and more humid, the minima entirely disappeared, though no changes in our apparatus had been made. Corona losses were obviously rather large. We tried the expedient of bringing in several heaters, when, within a few hours, the minima were visible again. We found it necessary to control the humidity in this way throughout the summer. During nine months of the year no such control is necessary. While as pointed out above a differential Faraday time lag still seems the most plausible interpretation, the experimental results herein reported would not be undermined should this interpretation subsequently be found untenable, since these results are based upon actual measures of some time effect.

Investigations are now in progress to ascertain to what extent the method is applicable for the quantitative estimation of compounds present in extremely small amounts. The preliminary results are very encouraging. With a series of increasing and known concentrations of a given compound in water (serving as standards), observations are carried out to find at what concentration the characteristic minima of the compound first appear. Most compounds for which quantitative tests have been made reveal their presence when the concentration is near 1 part in 10^{11}. By making observations on a corresponding series of increasing concentrations of the unknown solution in water, one notes as before the concentration of the unknown solution in which the minima characteristic of the particular compound are first observed. By a simple computation the quantity of the compound in the unknown solution may then be determined. As the gradations in the increasing concentrations of the solution may be made as small as one desires, it is believed that the method has possibilities of an accuracy in quantitative analysis that will render it valuable for some purposes. In a later paper it is planned to give a more definite report on the quantitative aspects of the method.

Our recently reported evidence[6] of the presence of element 87 in certain samples of pollucite and lepidolite ores is based upon the location of minima characteristic of an element of the atomic weight and valence ascribed to eka-cesium. An additional report of this investigation is contemplated in the near future.

[6] Allison and Murphy, *Phys. Rev.*, 35, 285 (1930).

It is a pleasure to acknowledge the helpful cooperation of a number of chemists. We mention in particular our indebtedness to Dr. J. L. McGhee, of Emory University, who has contributed greatly by his collaboration in the work of chemical analysis and otherwise; to Professor H. D. Jones, formerly our colleague and at the present time an industrial chemist, who has checked some of our observations and has made analyses by the method; to our colleague, Professor H. M. Martin, whose advice in problems of inorganic chemistry has been frequently sought; in fact, to the entire faculty of chemistry in this Institution for their cordial attitude of cooperation. We wish also to express our thanks to Mr. J. H. Christensen, student assistant in physics, for taking many observations, particularly with the hydroxides, and for making a number of checks on our work.

Summary

1. Each compound studied produces its own characteristic minimum, or minima, of light, regardless of the presence of other compounds.
2. The characteristic minima of those compounds for which quantitative tests have been made do not disappear until the concentration is reduced to about one part of the compound in 10^{11} parts of water.
3. These minima appear at points along the scale in the order of the chemical equivalents of the metallic elements of the compounds, or the differential time lag is some inverse function of the chemical equivalent.
4. The number of characteristic minima, with few exceptions, is equal to the number of known isotopes of the metallic element of the compound.
5. The method promises to be of value in quantitative as well as in qualitative analysis in work dealing with very small quantities of materials.

HEATS OF NEUTRALIZATION BY THE CONTINUOUS FLOW CALORIMETER

BY LOUIS J. GILLESPIE, RAYMOND H. LAMBERT AND JOHN A. GIBSON, JR.

RECEIVED MAY 17, 1930 PUBLISHED OCTOBER 6, 1930

The continuous flow calorimeter[1] served to locate a serious error in an accepted value[2] for the heat of neutralization of sodium hydroxide with hydrochloric acid, in agreement with the findings of Richards and Rowe,[3] which were published at the same time. Richards and his collaborators at Harvard have given a large body of data which seem to be of high precision, and repetition or extension of their measurements appears pointless

unless the chemicals used, especially the alkalies, are pure to within about 0.1 Now the continuous flow calorimeter demands large supplies of carefully controlled solutions. Furthermore, it furnishes merely temperature changes and cannot be used alone, therefore, to extend the data of Richards and his collaborators into temperature regions where no specific heat data exist. We have been forced to limit our efforts to verification of some of the results of Richards and his collaborators at the temperature of their experiments, and to test the applicability of the Kirchhoff equation[4] by a few direct measurements at other temperatures.

We supposed at first that we should be able to check the work of the Harvard investigators only with respect to the temperature changes due to the reactions, but found that enough experimental work was available by other workers to furnish independent specific heats, and therefore afford heats of reaction completely independent of the Harvard work.

The apparatus and method used were essentially the same as that of Keyes, Gillespie and Mitsukuri, with minor improvements of the method of controlling the speed of flow and with one change of technique which enabled the rise of temperature to be obtained at unusually slow rates of flow.

When the rate of flow is too small, the mixing at the double concentric nozzles is imperfect when the average effluent is neutral, but may be good enough when the average effluent is either acid or alkaline. It was found possible at such a rate of flow to determine the rise of temperature for a neutral effluent by plotting the change of temperature against excess of acid or of alkali as indicated by neutralizing 100 cc of effluent. Excess of alkali was plotted as negative excess acid, and two intersecting straight lines were used to smooth the observations and to find the maximum rise of temperature.

Platinum thermometry was used as before. The two thermometers were tested from time to time for the fundamental interval and the delta value. It was necessary to have a new calorimeter constructed, and the inside of the Dewar space was silvered. The silvering reduced the heat loss considerably. The small difference in indication of the two thermometers was rendered of no influence by determining the difference of readings when pure water was run through both sides of the apparatus; it was found possible to set the temperature of the preliminary thermostat at such a value that the difference of readings was practically independent of the rate of flow within the necessary range, and this adjustment was made and the difference determined for each experiment. This difference was then applied as a correction to one thermometer, thus basing all temperatures on the indications of a single thermometer.

Chemicals Used. Ordinary distilled water of good quality was used. A good grade of hydrochloric acid was made up to constant boiling composition and distilled into three fractions. The middle third was further divided into three portions by distillation and the middle third kept. It was standardized gravimetrically by the silver chloride method. A precision within 0.1% was apparently obtained. The results were satisfactorily checked by reference to recrystallized acid potassium phthalate. Fresh solutions were used, though the carboy in which they were kept had been used for years to hold hydrochloric acid and tests of the acid by acidimetric titration and by the silver chloride method showed no change of the acid on standing even for several weeks.

---

[4] When approximately integrated

The alkalies were standardized acidimetrically by reference to the acid, using weight burets.

The carbonate content was determined by first passing acid into base in the presence of carbon dioxide-free air. Secondly, base was added to a new portion of the acid in a stream of carbon dioxide-free air.

A good grade of potassium hydroxide from alcohol was dissolved in water and freed from carbonate in the apparatus of Knobel,[5] who very kindly lent us his apparatus. In this apparatus potassium amalgam is formed by electrolysis in one of two flasks which communicate at the bottom under mercury, and decomposed by distilled water in the other. The resulting solution contained only 0.05 mole of potassium carbonate per hundred moles of total alkali.

For sodium hydroxide the apparatus was not suitable. An initial phase of sodium amalgam reacted very slowly and appeared unstable. After some time a new phase seemed to appear that would hardly react with water, so that sufficient hydroxide could not be obtained for an experiment even after a week of electrolysis. Hence, from sodium hydroxide partially freed from carbonate by sedimentation from a concentrated solution, a viscous amalgam was formed by electrolysis. This was washed many times with cold conductivity water and placed in a large bottle, the amalgam filling about one-fourth the volume of the bottle. Steam was then passed through the amalgam. The hot water reacted rapidly with it. By the time the bottle was filled with condensed liquid, sufficient alkali had been formed to make a strong solution. After the washing with conductivity water the operations were carried out in the absence of carbon dioxide. The solution contained less than 0.2 mole of sodium carbonate per hundred moles of total alkali.

Unfortunately such alkali was not available for all of the experiments and in such a case sodium hydroxide freed from carbonate by sedimentation was used. Owing in part to the large volumes taken. this method was not uniformly successful and the solutions used for the experiments contained sometimes more carbonate than is desirable in a precision experiment.

The Specific Heats of Aqueous Solutions of Sodium Chloride and of Pofassium Chloride.—The continuous flow calorimeter gives temperature elevations to a high degree of precision and in order to calculate heats one should know the heat capacities of the products (or of the factors) of the reaction to an equal precision. In the present case the heat capacities of solutions of sodium and of potassium chloride were needed at several temperatures, and it proved necessary to construct original specific heat tables, smoothed for both temperature and concentration. Fortunately the work of Bousfield and Bousfield[6] proved to be very consistent with that of Richards and Rowe[7] at 20°, and with that of Randall and Bisson[8] at 25°, so that reliable results could be obtained without any attempt to utilize scattered data, or data without the appearance of special precision, of other investigators.

Bousfield and Bousfield[6b] determined over a series of concentrations the

total heat in joules required to raise the temperature in steps of 13° from 0.5 to 39.5'. They had previously[ea] done the same for water. They recognized in their second paper that their values for water might be in error, and in fact they are, according to recent values of the Bureau of Standards? but they believed their results for solutions to be comparable with those for water, and this belief is borne out by the present calculations.

To deduce specific heats from their data, the total heat in joules was differentiated graphically with respect to temperature (at each concentration), and the tangent was divided by the instantaneous value of the specific heat of pure water given by their earlier experiments and expressed in their equation for J_θ (Reference 5, page 236). This gave the true specific heat referred to water at the same temperature. From the Bureau of Standards data[g] conversion factors were found by interpolation to convert specific heats in calories at t° to 20'-calories. The so-converted values were smoothed at the desired temperatures with respect to concentration, plotting the deviation from linearity of $1 - C_p$ with concentration expressed in moles of substance per mole of water, and were finally interpolated by means of the deviation plots for evenly spaced values of the concentration as well as for the particular concentrations needed for the calculation of heats.

As a check on the results at 20°, the specific heats given by Richards and Rowe[7] for both salts at 18° in 18'-calories were used to find values at 20° in 20'-calories, using smoothed temperature coefficients from the data of Bousfield and Bousfield and the conversion factors from the Bureau of Standards data. Examination of Table I, in which these Richards and Rowe values (R-R) are given together with the values from Bousfield and Bousfield (B-B), show the excellent agreement. At the concentrations at which values were needed for calculations of heats, the agreement is perfect. At 25° the deviation curve through the Bousfield data for sodium chloride passed beautifully through the two points of Randall and Bisson. Because little use was made of the excellent work of the Bousfields in the compilation of the "International Critical Tables," specific heats from their data alone are given in Table I, rather than values, possibly better, derivable from more than one source. The specific heats of sodium chloride solutions have been given by Lipsett, Johnson and Maass[10] for both 20 and 25°. Since these were determined indirectly and are not altogether independent of the values of Richards and Rowe, they were not utilized for the present comparisons.

The values at 50° were determined entirely by extrapolation without the aid of check determinations, and cannot be regarded as accurate. They are given mainly as an aid to the correction of our calculations of heats,

[a] Severely extrapolated.

The specific heats actually used for heat calculations were interpolated with the aid of the same deviation plots used in constructing the tables, and were found for the final concentration of the solutions and for a temperature equal to the initial temperature plus one-half the temperature rise due to the reaction. Only at 50° did it make a difference of more than one calorie in the heat whether the specific heat was calculated for this mean, or for the initial temperature. The concentration at which the specific heat was calculated was not quite the concentration of moles of NaCl (from NaOH) per mole of water, but the total moles NaCl from NaOH, NaCl from Na_2CO_3, and $NaHCO_3$ from Na_2CO_3. Here the loss of heat capacity due to the presence of $NaHCO_3$ was assumed to be the same as for NaCl, which was safe, as the total error made, if the NaCl and $NaHCO_3$ from the small concentration of Na_2CO_3 had both been neglected in the calculation of the heat capacity, would have been only 2.7 calories in the worst case. The water formed during the reaction was naturally taken into account in calculating the concentration.

The calculation of the results was in general the same as before,[1] except for some small added corrections. The effect of carbonate in the alkali was allowed for in the same way. The necessary corrections were applied to give − AH, the heat evolved at constant pressure, for the reaction

$$NaOH \cdot 0.5(h-1)H_2O + HCl \cdot 0.5(h-1)H_2O = NaCl \cdot hH_2O - AH, \text{ at } t° \qquad (1)$$

where h is the number of moles of water associated with 1 mole of salt in the product of the neutralization. Atomic weights were used as in the Harvard calculations, namely, "International Critical Tables" values with the exception that 1.008 was used for hydrogen. Consistently with their recent work, the heats are given in 20'-calories.

Since the concentrations of the acid and alkali were not identical, the results were corrected to the form of Equation 1 by the use of heats of dilution, obtained directly from the Harvard work[7,11,12] or indirectly with the aid of their recent heats of dilution and Kirchhoff's law. These corrections never exceeded **3** calories.

The treatment of the potassium chloride data was the same as for sodium chloride, and the corrections smaller.

TABLE II

RESULTS OF THE CONTINUOUS-FLOW CALORIMETRY

No. 6 is the recomputed value from the previous work[1]

No.	Salt	t	h	x	t'	$1/h'$	C_p	- AN	$-\Delta H$(R)

4	NaCl	32 27	568.8	.38	32 917	.001771	.9922	13211	...
5	NaCl	32 27	566 0	.20	33 953	.001774	,9922	13274	...
6	NaCl	32.3	520.5	.42	33.008	.001921	.9916	13284	...
7	NaCl	50 04	52.87	.10	57.04	.01895	.9359	13237	...
8	NaCl	50.04	99 91	.13	53.58	.01003	.9642	12676	...
9	KC1	20	547.8	.05	20.705	.001827	.9896	13864	13861

The results of the calorimetry are given in Table II. t, h and — AH refer to Equation 1; x is the number of moles of sodium carbonate or potassium carbonate per 100 moles of base in the alkaline solution used for the experiment. t' and $1/h'$ are the temperature and the moles of salt per mole of water for which the specific heat, C_p, was interpolated from the deviation plots representing the Bousfield data. In the last column, $-\Delta H$(R) gives the interpolated values for the same concentration and temperature (20°) furnished by the data of Richards and collaborators, as noted. For this interpolation the deviations from linearity of the heat versus $1/h$ were calculated and plotted against the square root of $1/h$; taking the square root removed an excessive bend in the plots. The values of the heat for infinite dilution used were the extrapolated values found in the summary of Richards and Rowe[3] for the formation of potassium chloride, and of Richards and Hall[13] for the formation of sodium chloride. At the time our experiments were concluded the 1929 articles from the Harvard laboratory had not been published and our results for sodium chloride differed from the interpolated values from the older work of Richards and Rowe by about 25 calories, but it will be seen from Table II that our results are in good agreement with the recent values.

In order now to compare our six results at temperatures other than 20°, it is necessary to have temperature coefficients of the heat of neutralization.

---

[11] Richards and Gucker, THIS JOURNAL, 51, 712 (1929).

[12] Richards, Mair and Hall, *ibid.*, 51, 727 (1929)

[13] Richards and Hall, *ibid.*, 51, 731 (1929).

The values of Richards and Rowe need corrections, according to the 1929 articles. Using the latest data for sodium hydroxide and hydrochloric acid, and the (R-R) specific heats for sodium chloride given in Table I, new values of the temperature coefficient were calculated from Kirchhoff's law. They lie near a gently sloping line, when plotted against the concentration $(1/h)$, and intercept the axis of zero concentration very close to the value of Noyes, Kato and Sosman.[14] Since, however, ideas have necessarily been used in the interpolation of some of the specific heat data on which the values of the temperature coefficient in the dilute region are based, we see no guarantee that this temperature coefficient curve is substantially correct at low concentrations, and it is not here reproduced. We have used it, however, in an effort to compare our results at various temperatures with the interpolated Harvard values at 20°. From this curve, interpolated values of the temperature coefficient were read off for the necessary concentrations, and our results were corrected to 20° by means of them, assuming, of course, that the coefficient is constant over the whole temperature interval, which cannot be the case from 20 to 50°. The comparison is given in Table III.

TABLE III

ATTEMPTED COMPARISON OF DATA BY THE USE OF TEMPERATURE COEFFICIENTS

Temperature	24.99	32.27	32.27	32.3	50.04	50.04
Dilution (h)	1101	569	566	521	52.9	99.9
Percentage deviation	0.45	0.24	0.71	0.70	0	–1.22

The percentage deviation is the heat of reaction (evolution) calculated from our results minus the corresponding results of Richards and Hall,[13] in percentage of the latter results. Bearing in mind the close agreement shown at 20° in Table II, which was only reached after their recent revision, we do not believe that the disagreement shown in Table III (unless, it may well be, at 50°, in view of the unsatisfactory specific heats at that temperature) is mainly due to experimental error in our heats. Neither does it seem to be principally due to a variation of the temperature coefficient with temperature. The suggestion is strong that the temperature coefficients, extrapolated into the dilute region, cannot be trusted.

Summary

From the measurements of Bousfield and Bousfield, specific heat tables, apparently quite accurate, were deduced for sodium chloride solutions at 20, 25 and 32°, and for potassium chloride solutions at 20 and 25°.

Some data were obtained for the formation by neutralization of sodium and potassium chlorides. The results were computed in the form

$$NaOH\cdot 0.5(h-1)H_2O + HCl\cdot 0.5(h-1)H_2O = NaCl\cdot hH_2O - \Delta H, \text{ at } t^\circ$$

---

[14] Noyes, Kato and Sosman, THIS JOURNAL, 32, 159 (1910).

Our experiments at 20° agree very closely for both chlorides with the exact results of Richards and his collaborators for 20°, but when our experiments at other temperatures are compared with them with the aid of temperature coefficients, the agreement is poor. The concentrations at which the discrepancies are significant are rather low, and it appears that the temperature coefficients are not known at sufficiently low concentrations to establish the extrapolated value at zero concentration.

DOUBLE SALT FORMATION AMONG THE CARBONATES AND BICARBONATES OF SODIUM AND POTASSIUM

BY ARTHUR E. HILL

RECEIVED JUNE 2, 1930 PUBLISHED OCTOBER 6, 1930

When aqueous solutions of the carbonates and bicarbonates of sodium and potassium are brought to crystallization, five solid phases of the general nature of double salts have been found and identified with certainty. The best known of these is Trona, $Na_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$, which has been known for a long period of time and which has been studied from its lower temperature of formation, 21.26°, up to 50° by Hill and Bacon,[1] and more recently up to 89° by Wegscheider and Mehl;[2] at this temperature the latter investigators also believe that two new double salts are formed, for which the evidence is, however, less conclusive than for toe five here under discussion. Known also for a long time, but incorrectly classed as a definite compound in the earlier literature, is the hydrated solid solution $(K_2, Na_2)CO_3 \cdot 6H_2O$, which was shown by Hill and Miller[3] to exist in contact with alkali carbonate solutions over a rather wide range of concentrations, from 34° downward. The anhydrous double carbonate $KNaCO_3$ has been shown[3] to be stable in contact with solution from 25.12' upward to at least 50°, and probably much higher. Recently, in a study of the reciprocal salt pair $K_2CO_3 + 2NaHCO_3 \rightleftarrows Na_2CO_3 + 2KHCO_3$, Hill and S. B. Smith[4] found a new double salt of the formula $K_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$, belonging to the class of double salts without common ion which Meyerhoffer[6] has called tetragene salts. This salt was found only in four-component solutions, and its occurrence and the limits of its field were determined, it was thought, with surety. At the same time that this paper was published, there appeared the valuable and comprehensive work of Teeple upon the

---

[1] Hill and Bacon, THIS JOURNAL, 49,2487 (1927).

[2] Wegscheider and Mehl, *Monatsh.*, 49,283 (1928).

[3] Hill and Miller, THIS JOURNAL, 49, 669 (1927).

Searles Lake deposits; in this there is given[6] a 35° isotherm by de Ropp for the same system, in which our tetragene salt does not appear, but its place is given over to a potassium salt, $K_2CO_3 \cdot 2KHCO_3 \cdot 3H_2O$, which we had not found in our work. and which is the fifth of the double salts which have been claimed for the system. As it was considered necessary to clear up this contradiction, the four-component work has been repeated at the two temperatures in question, 25 and 35°, with the resulting conclusion that both earlier publications contained an error of omission; as will be shown below, both the tetragene salt and the potassium sesquicarbonate (though with a different degree of hydration, as will be shown in the paper following this) occur at both temperatures, with a division of the disputed field between them.

Experimental Methods.—The experiments at the two temperatures have been carried out as in the previous work of Hill and Smith.[4] Pure specimens of the carbonates and bicarbonates of sodium and potassium, in suitable weighed amounts, have been treated with weighed amounts of water and tumbled in a thermostat usually for two days before pipetted samples of the saturated solutions were withdrawn and analyzed. Attainment of saturation with respect to two salts on the lines of isothermally univariant equilibrium, and with respect to three salts at the isothermally invariant points, was proved in every case by the method of adding the components necessary to give the composition of the saturating salts, tumbling the mixture for another day, and again analyzing the solution; where it remained unaltered within the errors of the analysis, equilibrium was assured. For the analysis, one sample of solution was titrated for total alkali with standard hydrochloric acid, using methyl orange as indicator; a second sample was evaporated to constant weight to give total potassium and sodium as carbonate; a third sample was analyzed for total carbon dioxide by adding sulfuric acid and absorbing the evolved gas in soda lime in a Flemming bottle. From these data the composition of the solution was calculated. The samples were weighed from volumetric pipets, from which data densities can be calculated, but not with a high degree of accuracy.

The 25° Isotherm.—The data at 25° are given in Table I and reproduced graphically in Fig. 1. In the table, the abbreviation T. S. is used for the tetragene salt $K_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$, and D.S. for the double salt $K_2CO_3 \cdot 2KHCO_3 \cdot 3/2H_2O$.

It will be seen from Fig. 1, which reproduces on a large scale a part of the four-component diagram previously given[4] in full, that the double salt $K_2CO_3 \cdot 2KHCO_3 \cdot 3/2H_2O$ found by Teeple at 35° has an existence in this system, but is stable only over a small range of concentrations.

the double salt and the tetragene salt; this was confirmed by preparing the single salts, each within the concentration range indicated, and subjecting each to an analysis which confirmed its composition beyond doubt. The other points in the diagram were found to be in qualitative agreement with de Ropp's findings, but varying from his by several per cent. in composition. As compared with the 25° isotherm, the figure shows that a rise of temperature increases the range of concentrations within which the double salt can form and decreases the range for the tetragene salt.

Summary

Partial isotherms at 25° and at 35° for the four component system $K_2CO_3 + 2NaHCO_3 \rightleftarrows Na_2CO_3 + 2KHCO_3$ in water have shown that at both temperatures there exist as solid phases the double salt $K_2CO_3 \cdot 2KHCO_3 \cdot 3/2H_2O$ and the tetragene salt $K_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$.

HYDRATED POTASSIUM SESQUICARBONATE, $K_2CO_3 \cdot 2KHCO_3 \cdot 3/2H_2O$

BY ARTHUR E. HILL

RECEIVED JUNE 2, 1930 PUBLISHED OCTOBER 6, 1930

The existence of a sesquicarbonate of potassium, intermediate in composition between the normal carbonate and the bicarbonate, has been claimed frequently over a long period of time, and at least as frequently disputed. It appears to have been mentioned first by Berthollet,[1] who obtained it by boiling and cooling a solution of the bicarbonate, and also by cooling a solution of equimolecular proportions of the carbonate and bicarbonate; it is obvious that these operations gave partial decomposition of the bicarbonate into carbonate and that therefore the composition of the solutions was unknown. The only known analyses of the salt were performed by Flückiger,[2] who used an incrustation found upon an earthenware jar containing crude potash, and by Bauer[3] and by Rammelsberg,[4] who prepared their specimen by evaporation and crystallization of a bicarbonate solution; Flückiger assigned to the salt the formula $K_2CO_3 \cdot 2KHCO_3 \cdot 5H_2O$ and Bauer and Rammelsberg gave it the formula $K_2CO_3 \cdot 2KHCO_3 \cdot 3H_2O$; these formulas will be discussed later in this paper. The salt has also been reported more recently by Appleby and Lane,[5] incidental

to a study of a four-component system, and by de Ropp;[6] in these two publications no analytical data are given, and the formula of Bauer and Rammelsberg is used. A large number of investigators have failed to find this salt upon studying carbonate–bicarbonate solutions, justifying the comment of Mellor,[7] "there is room for doubting the existence of these salts as chemical individuals until the systems have been explored by the aid of the phase rule." Having been among those who failed to find the compound at one time[8] and found it at another,[9] I have thought it well to make a systematic study, to determine the temperature range and concentration range within which the compound has stable existence, and to determine as correctly as possible its true composition.

Experimental Methods.—Solubility measurements have been made for the three-component system K_2CO_3–$KHCO_3$–H_2O at four temperatures. The potassium carbonate, a Kahlbaum preparation which showed as high purity as the sodium carbonate used as the ultimate standard, was first heated over a burner for several hours and then stored in an electric oven at 110°; attempts to dehydrate the sesquihydrate $K_2CO_3 \cdot 3/2H_2O$ at this temperature are likely to be futile, unless very long periods of time are used. The pure bicarbonate was stored over sulfuric acid in an atmosphere of carbon dioxide Weighed amounts of these salts, with weighed amounts of water, were put into 40-cc. glass-stoppered pyrex tubes and revolved in a water thermostat; although twenty-four hours were allowed for the attainment of equilibrium in nearly all cases, it is certain that equilibrium with the liquid is attained in a much shorter time, even when the double salt has to crystallize out as solid phase; an important point, however, is the necessity for adding the carbonate first and insuring that it is well broken up and brought to complete solution before the bicarbonate is added, to prevent the formation of hard lumps of the hydrated carbonate which may remain incompletely changed for long periods. The high heat of hydration of the anhydrous salt makes it easy to bring it completely into solution. After attainment of equilibrium, two 5-cc. samples were withdrawn from each tube; one was titrated for total alkali by hydrochloric acid solution, using methyl orange as indicator, and the second was treated with sulfuric acid in a suitable train and the carbon dioxide absorbed by soda lime in a Flemming bottle. Tests showed that these two determinations were accurate to within 0.1%; the calculation of the carbonate–bicarbonate ratio from them includes a multiplication which would make errors in the total composition of the order of 0.5%, but the smoothness of the curves obtained

abbreviation D. S. is used for the double salt as solid phase, $K_2CO_3 \cdot 2KHCO_3 \cdot 3/2H_2O$.

At each of these four temperatures, there is clear proof of the existence of three solubility curves, one each for $K_2CO_3 \cdot 3/2H_2O$, for $KHCO_3$, and for the double salt; the isothermal invariance of the points marked B and C was established by analyses of two or three solutions in each case, made up from varying ratios of the three components. The solubility curve for the compound is very short, covering only a concentration range of 1 to 2%, as shown by the curve BC in Fig 1, the isotherm for 25°; the narrow limits of this concentration give the explanation as to why the salt has been overlooked on so many occasions. Figure 2 has been drawn so as to show these solubility curves on a much larger scale, from which it appears that the range of stable existence for the double salt, always narrow, becomes more and more restricted as the temperature falls; a rough graphic extrapolation of the curves drawn through the B and C values indicates that the

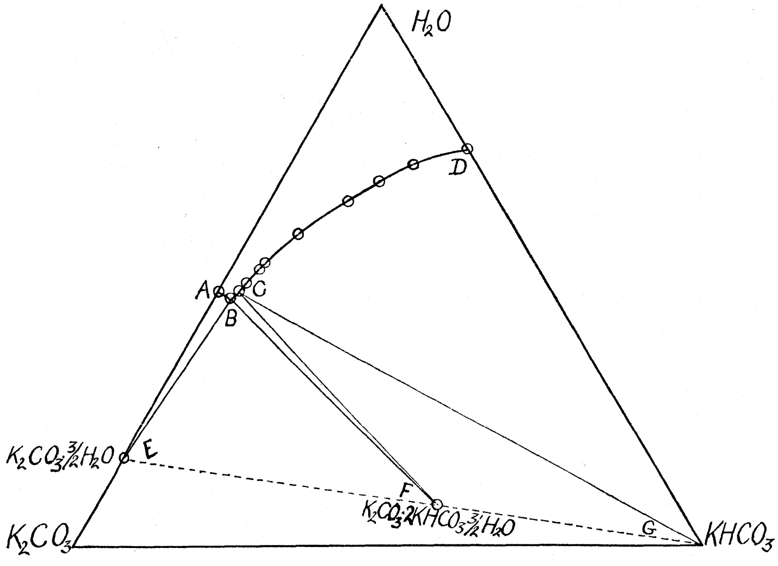

Fig. 1.—25° Isotherm for system K_2CO_3–$KHCO_3$–H_2O.

salt must cease to have stable existence at some temperature not greatly below 5°. It was possible, however, to draw some *a priori* conclusions as to this lower ternary transition temperature of the salt, by means of thermochemical considerations. Since the salt exists only above this temperature, it follows by application of the van't Hoff law of mobile equilibrium that the phase reaction by which it is formed from solution and the solid salts adjacent to it in the diagram must be an endothermal reaction. If it were formed from the bicarbonate and the sesquihydrate $K_2CO_3{\cdot}3/2H_2O$, its formation would in all probability be exothermal, since the reaction would be a simple additive reaction of the two salts. In order to have the reaction endothermal, the compound would have to be formed from compounds of a higher degree of hydration; of such compounds, only one is known, the hexahydrate $K_2CO_3{\cdot}6H_2O$, which Hill and Miller[10] have shown to exist only below −6.2°; it may be concluded, therefore, that the ternary transition temperature of the compound is below −6.2°, and that the phase reaction is

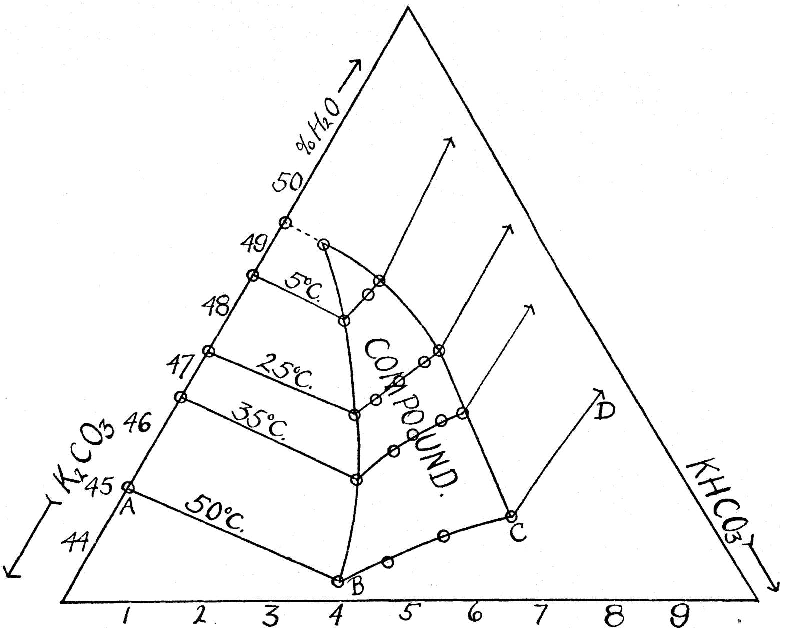

Fig. 2.—System K_2CO_3–$KHCO_3$–H_2O; partial isotherms.

$$K_2CO_3{\cdot}6H_2O + 2KHCO_3 \rightleftharpoons K_2CO_3{\cdot}2KHCO_3{\cdot}3/2H_2O + \text{Solution} - x\ \text{cal.}$$

Experimental confirmation of this reasoning was had by means of cooling curves of complexes made up to fall within the proper range at low temperatures; they were first cooled to about −8° and seeded with the compound

---

[10] Hill and Miller, This Journal, 49, 669 (1927).

$K_2CO_3 \cdot 6H_2O$ which can be secured only by undercooling potassium carbonate solution to below $-20°$.[10] The temperature then rose nearly to $-6.2°$, indicating that the transition temperature of hydrated potassium carbonate is but slightly affected by the small amount of bicarbonate in the solution. On being subjected to the temperature of an ice–salt bath, the solution could be undercooled a few tenths of a degree but showed a long continued halt at $-9.2°$, this being taken as the decomposition temperature of the compound. Efforts to secure a halt in the warming curve were all fruitless, indicating that the formation of the compound is not a rapid reaction. Inasmuch as the ternary transition temperature could not be confirmed on rise of temperature the best approximation is the temperature $-9.2°$, which is the highest temperature obtained on the cooling curve.

Composition of the Compound.—Early in the work it became apparent that the compound could not possibly have the composition assigned to it by Fluckiger or by Bauer and Rammelsberg; the tie lines in the area for the compound showed at each temperature a much steeper inclination toward the base line of Fig. 1 than could be made to pass through the alleged composition of the salt. This indicated that the compound must contain either more potassium carbonate than assigned to it previously or less water; a decision could not be arrived at through this means alone, for the extrapolation of lines so nearly parallel as are the tie lines in this narrow area would require an accuracy of analysis which is not attainable. Inspection of the original analytical data of the three authors mentioned showed that their agreement with the proposed formulas was really a fictitious one; arranged by them in terms of percentage of K_2O and CO_2 found, the agreement with the formulas did not look bad, but when recalculated to the ratio of K_2CO_3 to $KHCO_3$ the disagreement is startling. The results of the calculation are given in Table II, together with the critical analysis discussed later in this paper.

TABLE II

COMPOSITION OF DOUBLE SALT

		Ratio $\frac{\text{Moles } K_2CO_3}{\text{Moles } KHCO_3}$	Proposed formula
Rammelsberg	1883	1.00:2.57	$K_2CO_3 \cdot 2KHCO_3 \cdot 3H_2O$
Bauer	1883	1.00:2.27	$K_2CO_3 \cdot 2KHCO_3 \cdot 3H_2O$
Flückiger	1883	1.00:2.08	$K_2CO_3 \cdot 2KHCO_3 \cdot 5H_2O$
Hill	1930	1.00:1.94	$K_2CO_3 \cdot 2KHCO_3 \cdot 3/2H_2O$

Examination of these figures makes it problematical why Rammelsberg should assign the formula for a 1:2 ratio when the ratio found is less than 2:5. The results of Bauer and Fluckiger, while nearer to the 1:2 ratio, are still distinctly high, and the water content given is very much higher in all three cases than I have found it to be. The explanation is not hard to give for all three cases; the solids used for analysis in every instance must have contained as impurity solid $KHCO_3$ and solution, the latter tending to give a high value for water and (by its high K_2CO_3 content) tending also to give a high figure for K_2CO_3 and thus to counteract the effect of the first impurity. Since the ratios are nevertheless high in $KHCO_3$ content, the samples must have contained very large amounts of solid $KHCO_3$.

Although the necessary conditions for obtaining a pure specimen of a salt showing incongruent solubility follow quite directly from phase-rule considerations, these conditions do not appear to have been stated often and have been observed still less often. A brief discussion of them is not out of place. The first necessary condition is that the compound be isolated after a complete phase-rule study at the temperature decided upon, to insure that it has been precipitated as the one solid phase in equilibrium with its saturated solution and not as one of the two phases precipitated from isothermally invariant mixtures, such as those covering the large areas BEF and GCF of Fig. 1. Second, comes the trying question of the mother liquor, which in all cases of incongruent solubility is different in composition from the salt and in this case is very widely different. Recrystallization from water is, of course, out of the question, since water brings about the decomposition of an incongruently soluble salt. Removal of as much mother liquor as possible, by mechanical means such as centrifuging, is highly desirable; but the essential point is that, inasmuch as mother liquor is necessarily present, its amount shall be definitely known, so that a correction of the final analysis may be made. The practice of allowing the moist crystals to undergo air-drying before analysis is entirely useless, except in so far as it reduces the water content to a closer approximation to the truth; the salt is then contaminated by the residuum from the evaporated mother liquor, the amount of that contamination being entirely unknown and not capable of being allowed for in the calculation. To determine the amount of such mother liquor, the well-separated crystals may be placed in a desiccator over the next lower hydrate and brought to constant weight; the loss of water corresponds to a definite precipitation of salts, known in amount and character from the analysis of the solution, which quantities may then be introduced into the subsequent analysis as a perfectly definite and reliable correction. Such a procedure will give material which may be analyzed with confidence as to its composition in respect to salts and also as to water of crystallization.

Preliminary examination by this method showed that the double salt of this discussion contained K_2CO_3 and $KHCO_3$ in ratio close to 1.00 to 2.00, and that the water content is between 7 and 8%. The water of crystallization, as reported by Rammelsberg, Bauer and Flückiger, is of the order of 15 to 20%, showing the presence of a very large amount of mother liquor in the moist crystals; such large amounts are inevitable if simple filtration is used with so highly concentrated a solution as exists in this case. The clear deduction as to these three analyses is that those investigators analyzed very wet samples, and therefore found the apparent water of hydration much too high. This large amount of mother liquor would give the crystals a large excess of K_2CO_3 over the true ratio; to account for the fact that the analyses show, on the contrary, too much $KHCO_3$, we must believe that the systems, at the time the samples were taken, were represented by complexes within the isothermally invariant triangle FCG and that the solid was, therefore, a mixture of the double salt with excess $KHCO_3$. This accords wholly with Rammelsberg's and Bauer's method of preparation by partial decomposition of a solution saturated with $KHCO_3$.

For a final analysis, a large sample of double salt was prepared from a solution analyzing as containing 49.96% K_2CO_3, 1.93% $KHCO_3$ and 48.11% H_2O, falling on the solubility curve for the double salt at 5°. The sample was centrifuged for two minutes at 4000 r. p. m., and brought to constant weight over double salt partially dehydrated by sulfuric acid. The water lost as water of solution for two samples was, respectively, 2.7 and 5.65% of the wet solid. Table III gives the results for the two samples.

Sample 1						
K_2CO_3	40.45	38.60	1.00	38.47	1.00	37.82
$KHCO_3$	51.21	53.41	1.91	54.13	1.94	54.78
H_2O	8.34	7.99	1.59	7.40	1.48	7.40
Sample 2						
K_2CO_3	42.21	38.99	1.00	38.60	1.00	37.82
$KHCO_3$	46.78	52.28	1.85	54.00	1.93	54.78
H_2O	11.01	8.73	1.71	7.40	1.47	7.40

In Col. 2 are given the results of the analyses of the samples as brought to constant weight. Column 3 gives the results corrected for the loss of 2.7 and 5.65% of water of solution from the wet samples. These corrected results show, by the molar ratio of Col. 4, that the two salts approximate a 1:2 ratio, and that the water of hydration is distinctly less than two moles. From this it may be assumed that the water of hydration is probably 1.5 moles, corresponding to that of the sesqui-hydrated potassium carbonate. On that basis a further correction may be made, namely, that the slight excess of water found (0.59 and 1.33%) represents mother liquor enclosed by the process of drying, and not given up during the drying periods, which were ten and thirty days, respectively. We can then determine algebraically the excess solution still present and correct for its presence, as in the former case. Correcting so as to bring the water content down to the assumed value of 7.40%, we have the figures of Col. 5 and the molar ratio of Col. 6, which agree with the calculated values as closely as may be expected. The formula of the salt is thereby established as $K_2CO_3 \cdot 2KHCO_3 \cdot 3/2H_2O$, an addition compound of $K_2CO_3 \cdot 3/2H_2O$ and $KHCO_3$ without change in hydration.

Summary

1. Isotherms have been constructed for the ternary system K_2CO_3–$KHCO_3$–H_2O at 5, 25, 35 and 50°.

2. The double salt first observed by Berthollet has been found to have a stable existence in contact with solution from $-9.2°$, its lower transition temperature, to something above 50°, but always within a very narrow range of concentrations.

3. A critique is offered of the methods for preparing incongruently soluble double salts for analysis.

4. The formula of the double salt is found to be $K_2CO_3 \cdot 2KHCO_3 \cdot 3/2H_2O$.

THE QUENCHING OF MERCURY RESONANCE RADIATION. I. THE SATURATED HYDROCARBONS

BY JOHN R. BATES

RECEIVED JUNE 6, 1930 PUBLISHED OCTOBER 6, 1930

The reactions of the saturated hydrocarbons under the influence of excited mercury atoms have been studied by Taylor and Hill,[1] who found that, with the exception of methane, they are all decomposed to give hydrogen, methane and high-boiling mixtures such as are obtained in the thermal "cracking" of hydrocarbons. This behavior, which is analogous to that observed in the presence of hydrogen atoms,[2] seemed worthy of further study to determine whether the inactivity of methane arose from its inability to receive the energy of the mercury atom or whether it was similar to the case of hydrogen and excited cadmium atoms,[3] where the energy is transferred, but no reaction results.

Measurements have therefore been made of the quenching of mercury resonance radiation by the four hydrocarbons—methane, ethane, propane and butane—which make quite clear the reasons for the results obtained by Taylor and Hill and also furnish values for the collision radii for collisions of the second kind between excited mercury atoms and the hydro-

carbons, which are becoming of interest in the light of recent theoretical considerations of such collisions.

Experimental

The method used is that due to Zemansky.[4] A source of mercury resonance light (L in Fig. 1) is focused on one quartz window of a resonance lamp T, which consists of a tube containing mercury vapor at a definite pressure. The resonance light excited is then taken out of the quartz window perpendicular to the first and collimated by a lens. This parallel light is passed through a cell (B) of 8 mm. thickness and 40 mm. diameter, immediately behind which is an iris diaphragm. Behind this is a quartz platinum hydrogen filled photo-electric cell which can be moved so that it is either in contact with the diaphragm (position R) or at a distance of 15 cm. The photo-electric current is measured by a Compton quadrant electrometer.

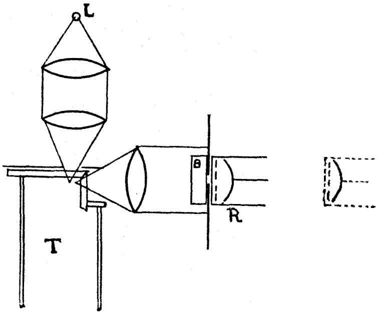

Fig. 1.

In measuring the quenching a reading is taken with B containing mercury vapor at 20°, and the photo-electric cell at R. The cell is then moved back to a position which records only the parallel light passing through the diaphragm. The difference between these two readings $I_{\mathrm{R}} - \mathrm{I}$, is the resonance light emitted by B. With the photo-cell at R, readings are then taken at various pressures of the foreign gas whose quenching is to be determined. The percentage of resonance light emitted, J, is then calculated from the equation

$$J = \frac{(I_{\mathrm{R_p}} - I_{\infty_\mathrm{v}})}{(I_{\mathrm{R_v}} - I_{\infty_\mathrm{v}})} \times 100$$

As a source of light a mercury arc rich in resonance light, which has already been described,[5] was used.

In order to have a standard by means of which fluctuations of the intensity of resonance light emitted by the resonance lamp could be corrected for, the cell B was made movable and could be replaced by a fused quartz window covered with a film of gelatin. Immediately before and after each reading of the resonance light a reading of the light transmitted by this "standard" was made.

To have as monochromatic resonance light as possible the precautions described by Kunze[6] were taken in constructing the resonance lamp.

Preparation of the Gases.—The hydrocarbons were obtained from cylinders containing these gases, whose source was natural gas. It was thought these would be considerably freer from hydrogen than any laboratory source. Since hydrogen is known to quench mercury resonance radiation at pressures of the order of 0.01 mm., it was important to insure its absence.

Methane, propane and butane were taken from the tank, dried over phosphorus pentoxide, frozen out and redistilled twice *in vacuo*, the middle fraction being taken both times.

Ethane, which contained 10–15% ethylene as it came from the tank, was twice bubbled through saturated bromine water and carried a distance of approximately

three meters saturated with bromine vapor, then through sodium hydroxide solution, soda lime and phosphorus pentoxide. Higher-boiling substances such as bromine and bromides were removed by a solid carbon dioxide–ether mixture. It was then subjected to the distillations as in the other cases.

The intensity of the light falling upon the cell from the resonance lamp is very small and quite insufficient to bring about enough decomposition of the hydrocarbons into hydrogen to affect the values observed. Furthermore, this was experimentally shown by the following method. The gas was admitted in successive small quantities, a reading being taken after each addition. This process takes about six hours, allowing sufficient time to reestablish the equilibrium vapor pressure of mercury. disturbed by the flow of gas into the cell. The gas was then pumped out in successive quantities, readings were again taken and found to agree within the experimental error with those observed previously.

Experimental Results

The quenching curves for the hydrocarbons are given in Figs. 2 and 3. They are represented by plotting J, the percentage of resonance light emitted, against the pressure of the various gases.

In determining the efficiencies of collisions between excited mercury atoms and foreign gas molecules, it has been the custom to take the value of the pressure where J equaled 50% and, assuming this to be the pressure at which the mercury atom has an equal chance of emitting or losing its energy on collision, calculate the number of fruitful collisions.[7] However, Zemansky[8] has derived a more exact relationship where τk = f (J,p,α,d); τ being the mean life of an excited mercury atom in the 2^3P_1 state (10–7 sec.), k the number of second kind collisions per atom per second, p the vapor pressure of mercury in the cell, a the absorption coefficient of mercury under the conditions employed, and d the thickness of the cell. From τk the value σ_E, or collision distance between excited mercury atoms and foreign gases, can be obtained from the gas kinetic equation

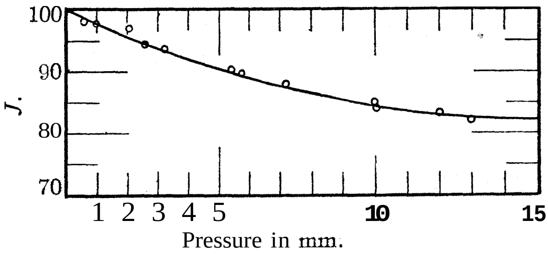

Fig. 2.—Methane.

$$K = 2\sigma_E^2 \times 9.81 \times 10^{18}\frac{p}{T}\sqrt{2\pi kT\left(\frac{1}{M}+\frac{1}{m}\right)} \tag{1}$$

Substituting for T = 293.0°, and multiplying through by τ

$$\sigma_E^2 = \frac{\left(\frac{\tau K}{p}\right)}{3355\sqrt{\frac{1}{M}+\frac{1}{m}}} \tag{2}$$

---

[7] Stuart, *Z. Physik*, **32, 262** (1925).

[8] Zemansky, Phys. Rev., 31, **812** (1928).

Since the relationship between τk and J involves a laborious calculation involving the absorption coefficient of mercury, which could not be accurately determined by the system as set up, a curve representing this dependence was obtained from a curve of τk against p obtained through the kindness of Dr. Zemansky, who measured propane taken from the same sample as that used in the present measurements. From this and the propane curve in Fig. 3, the curve in Fig. 4 was obtained. Then from a knowledge of J:p and τk:J (Figs. 3 and 4) the final results in Fig. 5, which give the number of collisions of the second kind per excited mercury atom at any given foreign gas pressure, were obtained. The relationships for the various hydrocarbons are remarkably linear with respect to pressure, which is as expected. The slope of these curves gives $\tau K/p$ which, when placed in the numerator of Equation 2, gives values for σ_E.

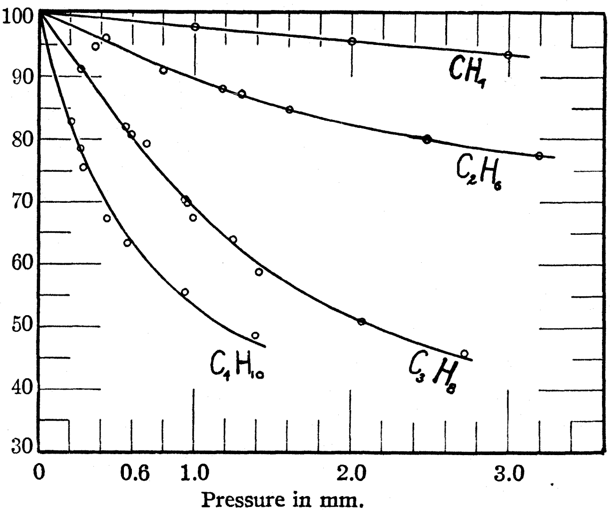

Fig. 3.

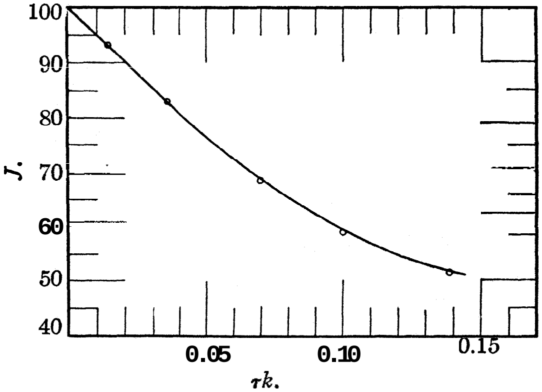

Fig. 4.

In Table I are shown the values of $\tau k/p$, and σ_E^2 thus obtained, together with σ_N^2 from kinetic theory. The values are accurate to within 5% and within themselves agree probably to a much better value.

[a] Herzfeld, "Handbuch der Physik," Vol. 22, p. 409.

[b] Taken from Zemansky for comparison.

From the $\tau k/p$ values it can be seen immediately that the relative probability of a transfer of the energy of the mercury atom does decrease as we go from butane down to methane, reaching a very small value for the latter. However, this does not indicate that methane should he entirely unaffected, especially at high pressure, if the energy is given over at all. There is always the possibility that the mercury atom only gives up the 0.2 volt which separates the 2^3P_1 state from the metastable 2^3P_0 level, which process is known to occur in many cases, e. g., helium, carbon monoxide, nitrogen, water, etc. In this case the energy transferred, being too small to bring about any chemical reaction, would be accommodated in the translational and vibrational degrees of freedom of the methane molecule, and at low pressures the metastable mercury atom, having a long life, would diffuse to the walls and give up the remaining energy. At higher pressures, where the metastable atoms make a large number of collisions in diffusing to the walls, there is a probability that in some collision there will be sufficient kinetic energy available to bring the mer-

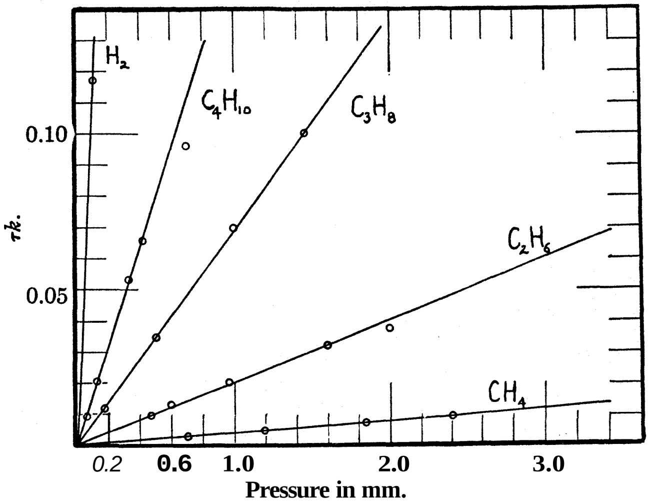

Fig. 5.

cury atom back to the 2^3P_1 level, where it may either radiate or be quenched once more.[9] The effect of this would obviously be to lower the apparent quenching at high pressures,

In order to see whether this occurred, the measurements on methane were extended to pressures of 200 mm. The results are plotted in Curve I of Fig. 6. The value of J at first decreases and then increases to impossibly high values, due to decreased absorption of mercury vapor in the presence of methane at higher pressures. The latter was determined by measurement and shown in Fig. 7, expressed as percentage transmission with transmission in *vacuo* 100%.[10] It will be seen that this change

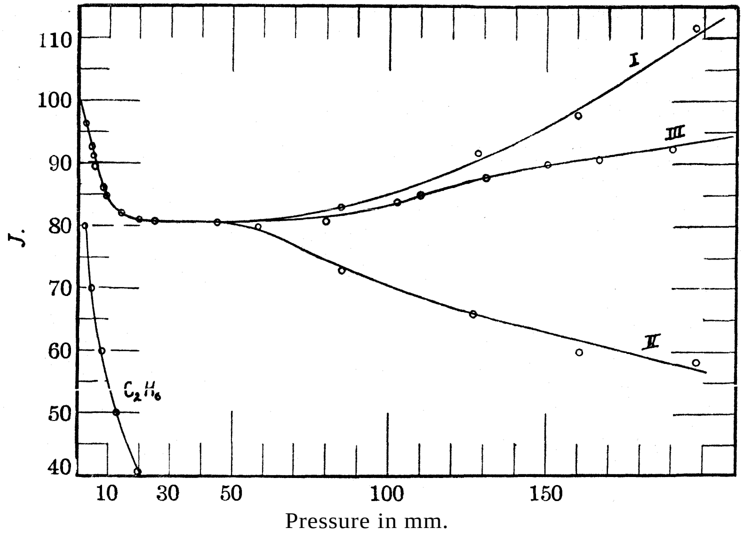

Fig. 6.

in absorption will not affect the results in Fig. 2, since at the pressures there considered, there is no measurable difference from vacuum conditions. However, at high pressures the equation $J = (I_{R_p} - I_{\infty v})/(I_{R_v} - I_{\infty v})$ must now have $I_{\infty p}$, instead of $I_{\infty v}$ in the numerator. This correction, applied to Curve I in Fig. 6, gives Curve II. An additional correction to this, due to the fact that, with lower absorption, there is naturally proportionately lower emission of resonance light, gives as the final result III for the corrected quenching curve of methane at high pressures, obtained by multiplying the values of II by the corresponding values

---

[9] See Foote, Phys. *Rev.*, 30,288 (1927), and many other papers.

[10] The shape of the curve is very readily understood when it is realized that the line emitted even by a resonance lamp is somewhat broader than the Doppler breadth of mercury absorption in *vacuo*. Hence when the absorption line is at first broadened absorption increases, until the breadths coincide, after which there is a decrease. See Zemansky, Orthmann, and others for a quantitative treatment of this effect.

of transmission as obtained from Fig. 7. While this is perhaps not exact, due to the necessary assumptions, it is a very close approximation, and is what would be expected for a gas which quenched by lowering the mercury atoms to the metastable level. These atoms are able to diffuse to the walls and give up their energy to a pressure of about 10 mm., where an appreciable number begin to be returned to the 2^3P_1 level. This is also an indication that the methane used was surprisingly free from hydrogen, since metastable mercury atoms are efficiently quenched by this gas.[11] The values for ethane are shown up to 20 mm. (the curve continued for somewhat higher pressures) to show that there is no break similar to that in methane. This does not necessarily mean that ethane does not bring some atoms to the metastable level, but, that if it does bring any considerable number, the transfer between these atoms and the ethane molecule is extremely efficient. Water, for instance, is known to bring about both types of transfer.[12]

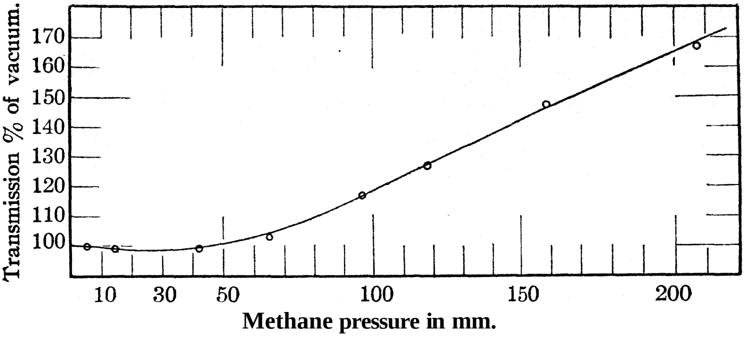

Fig. 7.

Discussion of Results

The fact that methane quenches mercury resonance radiation in the same manner as the more inert type of gas molecules is quite in agreement with the other properties of the methane molecule.[13]

It is interesting to compare the pressure at which the methane quenching curve undergoes a break (about 10 mm.) with the value of the minimum in Zemansky's[8] determination of β, the exponential in the expression for the lifetime of an excited mercury atom in the presence of nitrogen, which is at 8 mm. These should roughly correspond, since the minimum in the β-curve is also due to the presence of a large number of metastable atoms, which are prevented from diffusing to the walls.

A calculation of the number of collisions made by a mercury atom in

diffusing a distance of 1.5 mm. (the average distance traveled in a layer 3 mm. thick, where, in the side of the cell nearest the source of light, about 50% of the excited atoms are formed) using the Einstein displacement equation

$$AX^2 = 2Dt$$

where t is the time in seconds and D the diffusion coefficient, obtained from the value for that of mercury into nitrogen (the values of diffusion coefficients into methane and nitrogen are, as a rule, very close in value) in the "International Critical Tables," and the value of K, the number of collisions per second per atom, gives a value of 7×10^4. The number of collisions made in which one has sufficient energy available to raise a metastable atom to the 2^3P_1 state is about 2.5×10^3, making every atom, in diffusing this distance, suffer about 28 collisions in which it might be raised to the higher level.

These results explain very satisfactorily why methane does not react as do the other hydrocarbons, since it cannot obtain sufficient energy from the excited mercury atoms,

The mechanism of the reactions of the higher hydrocarbons is in all probability quite complicated. In all cases, as soon as some hydrogen is formed, the reactions go in two ways—by the direct action of the excited mercury atoms on the hydrocarbons, and also by the reaction of hydrogen atoms produced by collisions with hydrogen molecules. From the ratios of the $\tau\bar{K}/p$ values in Table I we can see that with ethane there is an equal probability of hydrogen atom or hydrocarbon decomposition, when hydrogen is present to the extent of 2%, with propane at 6%, and butane at 15%. Thus, in those reactions of Taylor and Hill where hydrogen predominated, the majority of the action came through the agency of hydrogen atoms.

Thanks are due Dr. M. Zemansky for much helpful advice and discussion during the course of this work.

Summary

The quenching of mercury resonance radiation by the gases methane, ethane, propane and butane has been measured, and values for the effective collision cross section have been calculated. Methane has been shown to quench to the metastable level. The results are in agreement with the mercury photosensitized decompositions of these hydrocarbons.

AN X-RAY STUDY OF THE CONSTITUTION OF SOME COPPER–NICKEL–ALUMINUM–MANGANESE ALLOYS[1]

BY LYMAN J. WOOD

RECEIVED JUNE 9, 1930 PUBLISHED OCTOBER 6, 1930

Previous work[1a] has shown that certain copper–nickel–aluminum–manganese alloys composed of 1% Mn, 2–6% Al and having a nickel–copper ratio of 1.5–2.5 possess some very valuable properties. Some of these alloys will effectively resist corrosion by strong nitric acid for long periods of time, have tensile strengths of from 60,000 to 100,000 pounds per square inch and can be machined very easily. The manganese appears to have a very important influence on the tensile strength, the alloys containing 1% of manganese having approximately double the tensile strength of those without it.

A comparison has also been made between the properties of these alloys when chill-cast, sand-cast and annealed and the equilibrium diagram studied by means of cooling curves, photomicrographs and density changes.[2] It has been shown that these alloys are for the most part composed of one kind of solid solution but a second constituent was indicated which could not be positively identified by means of photomicrographs. In view of this fact an x-ray study has been made of the part of the system copper–nickel–aluminum–manganese having the composition indicated above.

Methods and Apparatus.—The apparatus was constructed according to suggestions of Wyckoff[3] and Bain.[4] The sample was reduced to a 200-mesh powder and rotated at the center of an arc of approximately 10 cm. radius inside of which the x-ray film was placed. The film holder was arranged so that the first few lines of the pattern were obtained on each side of the zero. The film holder was standardized by using sodium chloride as a standard, the salt being mixed with the sample in order to avoid errors due to differences in densities. The tube, which had a molybdenum target, was operated continuously at 35 kv. and 10 ma. and the x-rays were filtered through zirconia. The rays used were the MoKα doublet.

Table I shows data for check runs for salt and for one of the alloys where L stands for the film distances in millimeters from the zero beam to the

The data given in Table II show that the sample was located at the center of a perfect arc within the limit of measurement, which from Table I appears to be somewhat less than 0.1 mm. along the film which corresponds to an arc of about 1'30" or about ±0.005 Å. in terms of interplanar distances.

Results.—The alloys examined had the composition indicated in Table VI and were all annealed as previously described. Table III shows the data obtained in the case of one of the alloys. The observed data are compared with values calculated for a face-centered cube and are seen to check within the limit of error in measurement. The sum of the squares of the *hkl* indices of the planes which give lines in the case of a face-centered cube (pure metal) are 3, 4, 8, 11, 12, 16, 19, 20, 24, etc. The number and arrangement of the lines obtained for this alloy are in perfect agreement with the assumption of a face-centered cube.

Table IV shows the results of some intensity measurements made by means of a differential photo-electric photometer built according to a description by Richtmyer. (The author's sincere thanks are hereby expressed to Dr. F. E. Poindexter of the Physics Department of St. Louis

University for the use of this apparatus.) A comparison of observed values with values calculated on the assumption of a face-centered cube shows very close agreement.

Table V shows the experimental data obtained for the alloys examined when a stands for the unit cube edge and A stands for the average atomic weight. The calculated values of a were obtained by means of the third equation given in the heading of the table. The values of A used in these calculations were obtained by means of the last equation given in the same heading, which assumes a substitutional solid solution. The values of a observed from the different planes vary among themselves slightly, which is not surprising in view of the fact that we are dealing with a solid solution and hence the distribution of a given kind of atom in the various sets of parallel planes may vary. Also, the calculated values for a are in some cases appreciably larger than the observed values, a possible explanation for which will be offered below.

The observed values of a obtained from the 111 planes are considered most reliable, for in these cases the values of L were obtained by measuring the film distance between corresponding lines on the two sides of the zero beam and dividing the distance by two. The values of L for the other sets of planes were obtained by measuring from the 111 lines and adding to the

L value for the 111 planes. The absolute error in measuring the values for L for the 111 planes is thus seen to be one-half that for the other planes.

The observed values for *a* obtained from the 111 planes are shown in Table VI. The values for *a* are compared with the nickel–copper ratio for a constant aluminum content. The cube edge generally increases with rising aluminum content and falls with rising nickel–copper ratio, which in each case is what would be expected if the alloys are solid solution of one kind. In two or three cases the observed values almost reach the calculated values while the others are lower. These facts can be explained if it

is assumed that in the case of most of the alloys not all of the aluminum is held in what has been called the a-solid solution. On a few films a few "Extra Lines," *i.* e., lines not belonging to the a-solid solution pattern, were found. The locations of these lines are given in Table VII.

[a] All of these are taken as some form of cubic lattice.

Equilibrium Diagram.—Both the photomicrographs and x-ray patterns show conclusively that these alloys are in the main a-solid solution. According to Austin and Murphy,[6] alloys of copper and nickel with up to about 10% of aluminum should form the a-solid solution at temperatures just below the solidus. With alloys higher in aluminum these authors indicated the formation of a eutectic constituted of α- and 0-solid solutions, the β-solid solution resulting from a solution of NiAl and Cu_3Al in each other. Evidence presented by Guillet[7] and the present author indicates that aluminum is less soluble in copper and nickel at lower temperatures, especially when the percentage of copper is lowered. Jette, Phragmen and Westgren[S] did not find evidence for Cu_3Al in copper–aluminum alloys. These authors found aluminum dissolving in copper up to 8% and also evidence for a γ'-phase, the cube edge of which varied from 8.704 to 8.652 Å. for alloys with 16–25% aluminum.

Discussion.—The results shown in Table V seem to indicate that in the case of most of the alloys not all of the aluminum was held in the solid solution. The physical properties of these alloys, photomicrographs and

the "Extra Lines" listed in Table VII indicate a second phase of some sort. It might be expected that this second phase would be a solid solution the composition of which is not known at the present time. The "Extra Lines" occur on the films at about the correct positions for a solid solution having a cube edge of 8.674 Å. (see Table VII), which is intermediate between the high and low values given by Westgren for the γ'-phase in copper–aluminum alloys. It might not be unreasonable to expect a similar γ'-phase in nickel-copper–aluminum alloys, since nickel and copper are known to form a continuous series of solid solutions. However, the "Extra Lines" could be almost equally well explained as being derived from solid solutions having, respectively, cube edges of 4.54, 6.42 or 7.51 Å. Which of these, if any, is correct will have to be determined by further work.

Some preliminary results indicate that the cube edges for the unannealed alloys are larger than the values given in Table V for the annealed alloys, indicating more'aluminum held in the a-solid solution in the sand-cast (unannealed) condition than in the annealed condition. This is in agreement with the results obtained from the photomicrographs but is in apparent disagreement with the x-ray evidence for alloy number 127 in which case "Extra Lines" (evidence for a second phase) were found for the unannealed alloy but none for the annealed.

The x-ray study of this alloy system is being continued in order to define more clearly, if possible, the nature and constitution of the second phase, evidence for which has been given. It is also proposed to study some chill-cast alloys of these same compositions, in order to determine whether or not more aluminum is held in solid solution when the alloy is cooled rapidly.

The present study has not thrown any new light on the important influence of the 1% of manganese on the physical properties of these alloys.

Summary

An x-ray study has been made of the constitution of some copper–nickel–aluminum–manganese alloys. Previous work has already indicated that these alloys are in the main a-solid solutions. The present x-ray examination confirms this former finding. Some evidence for a second constituent is presented but complete identification has not yet been made.

THE VAPOR PRESSURE AND CRITICAL TEMPERATURE OF FLUORINE

BY G. H. CADY AND J. H. HILDEBRAND

RECEIVED JUNE 10, 1930 PUBLISHED OCTOBER 6, 1930

The vapor pressure of liquid fluorine has heretofore been known at only one point, the boiling point being given by Moissan and Dewar as approximately −187°.[1] It seemed worth while, therefore, to utilize the equipment and experience available in this Laboratory to determine the vapor pressure of this element over a range of temperatures.

Experimental

Fluorine was generated by the electrolysis of fused potassium bifluoride in an apparatus of the type designed by Argo, Mathers, Humiston and Anderson[2] as modified by Simons.[3] The generator now in use has been further modified by increasing its capacity to 2.4 liters and by casting the vessel with a disk attached to the top rim of the cylinder sufficiently wide to cover the electrical heating coils and their insulating packing The outer edge of the disk was further provided with a vertical rim. It had been found in working with the older form of generator that the electrolyte gradually crept over the rim of the containing vessel and worked down to the heating circuit. The present arrangement successfully prevents this difficulty.

Fluorine from the generator was passed through the copper trap, A (see Fig. 1), which was kept at a temperature of about 86°K. by a bath of liquid air rich in oxygen. This vessel served to remove impurities less volatile than fluorine, which probably were hydrogen fluoride, evolved from the molten bifluoride, fluorides of carbon, from the graphite anode, oxygen and oxygen fluoride[4] produced from traces of water in the electrolyte. Since neither O_2 nor OF_2 could be completely condensed in A, both having appreciable vapor pressures at 86°K., preliminary electrolysis of the molten salt was carried on for several hours, thereby decomposing the dissolved water. Fluorine, which was generated at a rate of about five grams per hour, was passed through the apparatus for thirty minutes, in order to sweep out the enclosed air. At the end of this time, the glass tube at D was sealed shut and gas was condensed in the cylindrical copper bulb, B, which was constantly maintained at the boiling temperature of the liquefied gas. After the desired quantity of liquid had been collected the tube at E was sealed shut. Pieces

of small German silver tubing were inserted in the line immediately above B to diminish the heat leak to the liquid fluorine.

C is a glass equalizing mercury manometer of about 1.5 cm. diameter attached to the copper tubing by a copper to glass seal. Since fluorine reacts with mercury. forming a thin skin of mercury fluoride which adheres to the walls of the tube, it was not possible to observe both mercury levels accurately when balancing the air pressure upon the right-hand column against the fluorine pressure on the left. The vapor pressure was, therefore, taken as equal to the air pressure required to bring the mercury surface, in contact with the air, to the position of balance at the start of the experiment. The error in pressure readings, caused by the consumption of mercury during a run, was found to be not more than a millimeter of mercury. Temperatures were read with a copper–constantan thermocouple made from wire kindly furnished us by Professor W. F. Gianque. Since samples of wire from the same spools had been carefully calibrated,[5] we were able to use a thermocouple correct to within 0.05°K. The junction of the thermocouple was soldered to the outside of the bulb, B, at a point near the surface of the fluorine inside.

A Leeds and Northrup type *K* potentiometer was used to measure the e. m f. of the thermocouple. Results were reproducible to about one millionth of a volt, which corresponds on the temperature scale to abuut 0.05".

The bulb, B, was immersed in a liquid-air bath. Various temperatures could be obtained either by changing the composition of the liquid or by lowering the pressure of the gas phase. Constant temperatures could be maintained for sufficient time for the attainment of vapor pressure equilibrium.

When glass bulbs were used for A and B, no two samples of fluorine gave the same vapor pressure curve and their boiling points all increased when part of the liquid was allowed to boil away. Boiling points ranged from 83 to 86°K., and one sample would change as much as from 84 to 85.5°K. while boiling away. All attempts at fractionation failed to give pure products. In spite of these results we had reason to believe that the boiling point of fluorine was near to 84.9°K., because the bath about the condensing gas had to be kept within 0.2° of 84.8°K. while the atmospheric pressure was 76 cm.

When the metal apparatus was used, the first sample of fluorine condensed behaved very satisfactorily. It represented the product of four hours of electrolysis with a current of eighteen amperes and probably amounted to about 18 cc. of liquid. No appreciable change in boiling point could be observed when part of it boiled away. Fully half of the specimen must have been set free during such tests, so we were working with either a constant boiling mixture or pure fluorine. The former state of affairs is very improbable, because the water in the electrolyte had been decomposed by preliminary electrolysis. Not more than traces of oxygen and OF_2 could have been in the fluorine, and our constant boiling point indicates that even these were absent.

Vapor Pressure of Fluorine.—The results are given in Table I. The first column gives the observed temperature in degrees absolute; the second, the observed pressure in centimeters; the third, the pressure calculated by substituting the observed temperatures in the equation given below.

The data are represented by the empirical equation

$$\log_{10}P = 7.3317 - \frac{406.8}{T} - 0.007785T$$

where P is in cm. of mercury and T in degrees Kelvin. No observed point

80.96	48.03	47.48			

departs from this equation by more than 0.1°. The data are plotted in Fig. 2, and the line represents the equation.

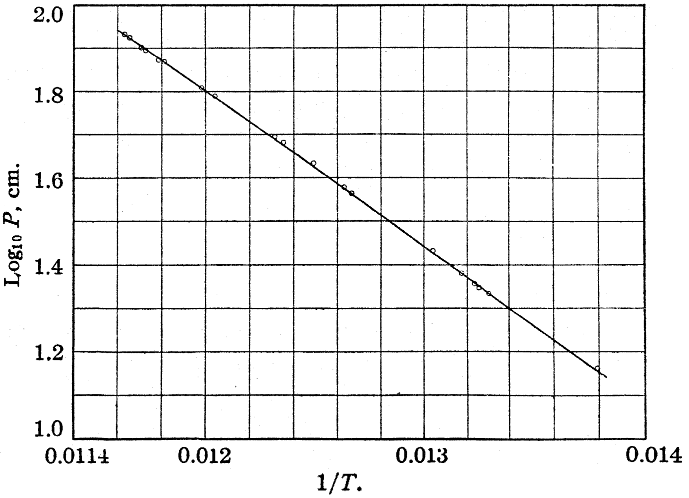

Fig. 2.—Vapor pressure of fluorine.

The boiling point of fluorine is calculated from this equation to be 84.93°K. Taking into account not only the experimental error in our vapor pressure measurements but also the chance that our temperature scale might have been wrong by a few hundredths of a degree, this value is probably correct within 0.1°.

Moissan and Dewar[1] obtained the boiling point by condensing the gas in a glass bulb cooled with liquid oxygen under reduced pressure. They found the minimum reduction of pressure which allowed condensation of fluorine to be 32.5 cm. of mercury and concluded that fluorine boils at −187°C. or 86.1°K. Unfortunately they do not state the atmospheric pressure at the time of this observation, but if we assume that it was 76.0 cm. and employ recent data for the vapor pressure of oxygen,[6] the calculated boiling point is 85.10°K., a figure which is in rather good agreement with our value.

The Critical Temperature of Fluorine.—We have made a few measurements of the critical temperature in a capillary glass tube. Since our previous experience with glass was not very satisfactory, we made no extended efforts to obtain reproducible results. One tube gave 143.3°K., and another, treated more carefully, gave 144.1°K. An approximate value of the critical temperature, is therefore, 144°K.

The critical pressure can be estimated with considerable confidence, since a plot of log P against $1/T$ for related gases shows the critical pressure lying above the vapor pressure line by only about 2 atmospheres.? Using our vapor pressure measurements in this way we get $P_c = 55$ atmospheres

The heat of vaporization of fluorine at the boiling point may be determined, from the slope of the vapor pressure curve given above, to be 1600 cal. per mole. Giauque and Wiebe[S] have found that by substituting the value of P as calculated from Berthelot's equation of state in the equation of Clapeyron, a closer approximation to the calorimetric heat of vaporization of hydrogen chloride is obtained than one gets from the slope of the vapor pressure curve. From our value for the critical temperature and from the density of liquid fluorine as given by Moissan and Dewar[1] we have made a similar calculation. The results at the boiling point are A H = 1540 cal. and A S = 18.1.

Summary

1. Measurements of the vapor pressure of fluorine have been made between 15 and 86 cm. which are closely given by the equation

$$\log_{10}P(\text{cm.}) = 7.3317 - \frac{406.8}{T} - 0.007785T$$

2. The boiling point is calculated to be 84.93°K.

FREEZING POINTS OF THE SYSTEM WATER–HYDROGEN FLUORIDE

BY G. H. CADY AND J. H. HILDEBRAND

RECEIVED JUNE 10, 1930 PUBLISHED OCTOBER 6, 1930

The highly polar nature of both water and hydrogen fluoride suggested that an especial interest would attach to a determination of the solid compounds they might form with each other. We wished particularly to learn whether any of these might be regarded as resulting from the partial substitution of water in the polymer $(HF)_6$, which Simons and Hildebrand[1] assumed to explain the vapor densities of hydrogen fluoride over a considerable range of pressure and temperature. In spite of the excellent agreement of the assumption with the data, it is quite possible that the association actually involves more numerous molecular species, one of which might be $(HF)_4$, which has been proposed by Berliner and Hann.[2] They point out that the hydrofluorides of amines have the general formula $B \cdot 4HF$ in which B stands for the molecular formula of the base. Other compounds such as $KF \cdot 3HF$ and $MgF_2 \cdot 2NaF$ may be regarded as derivatives of the hypothetical acid H_4F_4. If water behaves in a manner similar to the amines, one compound formed should be $H_2O \cdot 4HF$.

Although no complete study of the system $HF–H_2O$ has previously been made, the freezing points of hydrogen fluoride,[3] of the compound $H_2O \cdot HF$,[4] and of dilute hydrofluoric acid solutions in concentrations ranging up to 4.140 molal[5] have been known for several years. Mr. L. Clark, working in this Laboratory during 1938, made a partial investigation of the system. but his work was considered of too preliminary a nature to warrant publication

Experimental Part

The apparatus used is illustrated in Fig. 1. The equilibrium mixture was contained in a gold cup of about 175-cc. capacity. This was surrounded by a taller copper cup

which fitted closely into a small Dewar cylinder, thereby partially protecting the glass against attack by hydrofluoric acid vapor. To afford still further thermal insulation, the small Dewar was placed within a one-gallon vacuum jar. Both vessels had covers of light wood provided with suitable holes for the introduction of the gold-plated stirrer, the platinum pipet for removing samples for analysis, and the thermocouple, which was encased in a platinum tube. The pipet had a capacity of about 10 cc. and was equipped at the bottom with a filter of platinum gauze and spongy platinum.

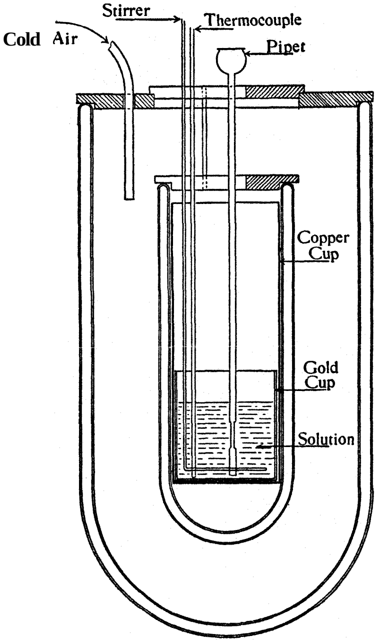

Fig 1.—Apparatus for determining freezing points of aqueous hydrogen fluoride solutions.

For solutions of smaller concentration than 0.51 mole fraction of HF, Baker and Adamson's C. P hydrofluoric acid was used. To obtain more concentrated acid, it was necessary to decompose KHF_2 by heating."

The following simple procedure was found to give reproducible freezing points over most of the range. To about 100 cc. of solution in the gold cup, enough liquid air was added to partially freeze the solution. After stirring continually for about fifteen minutes to allow the attainment of equilibrium between solid and solution, the temperature was read, and immediately afterward a sample of the liquid phase was removed in the pipet. This sample, usually from 1 to 5 cc., was dissolved in water contained in a paraffin bottle and its weight determined by difference. A titration of the acid in this dilute solution with sodium hydroxide then gave the composition of liquid in equilibrium with the frozen solid at the observed temperature. Following the suggestion of Haga and Osaka,[6] phenolphthalein was used as the indicator.

For mole fractions of hydrofluoric acid between 0.68 and 0.89. the above treatment did not give very reproducible results. The crystals of solid seemed to be so small that they clogged the filter in the pipet and prevented the removal of large enough samples of solution. It was, therefore, found necessary to determine warming curves and to take the final sudden change in slope as the freezing point. An analysis of the completely liquid solution then became an easy matter.

Table I gives the experimental points, and they are plotted in Fig. 2.

.675	204.9	$H_2O{\cdot}HF$	.982	187.6	HF
.685	197.9	$H_2O{\cdot}HF$ and $H_2O{\cdot}2HF$	1.000	190.1[3]	HF

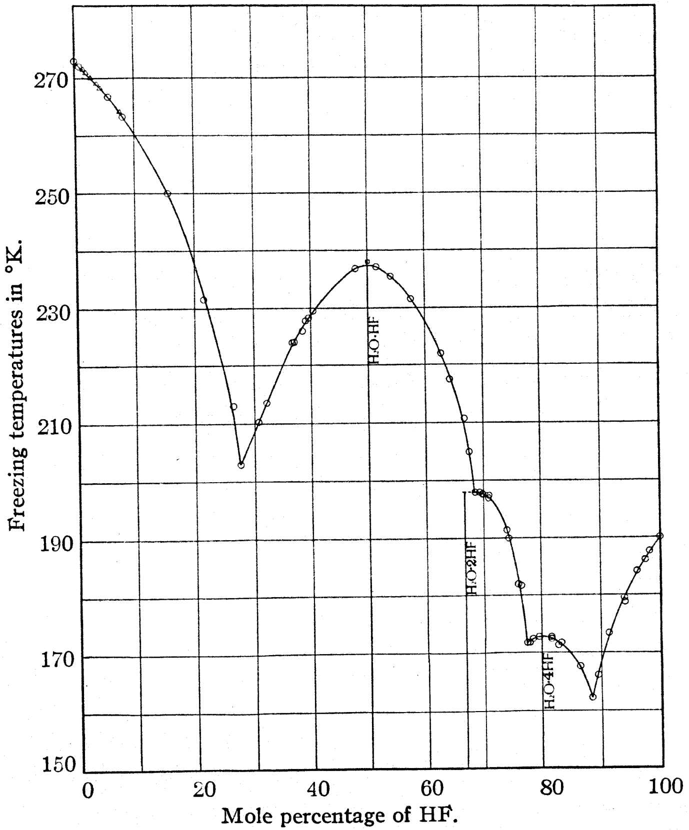

Fig. 2.—Freezing points of aqueous solutions of hydrogen fluoride. Circles refer to this research, the square to Metzner[4] and the triangles to Anthony and Huddleston.[5]

Three distinct addition compounds are indicated by the curve: $H_2O·HF$, $H_2O·2HF$ and $H_2O·4HF$. The second does not quite melt congruently, but the shape of the curve hardly leaves any doubt that it has the composition given. The first of these has been prepared by Metzner[4] by freezing it from hydrofluoric acid solutions. He reports its melting point to be −35°, which is not far from our value, −35.4".

Before anything very definite can be said concerning the configuration of these compounds, it will be desirable to have data bearing upon their crystal structures. We will merely call attention to the fact that the observations of Berliner and Hann[2] are extended by the discovery of the compound $H_2O·4HF$ and that the existence of two compounds with an excess of HF, while there are none with an excess of H_2O, harmonizes with the view that HF tends to assume a more complex polymerization than water.

Summary

The freezing point-composition diagram for the system water–hydrogen fluoride has been studied over the entire range. In addition to the solid compound $H_2O·HF$, previously known, we have discovered the compounds $H_2O·2HF$ and $H_2O·4HF$.

BERKELEY, CALIFORNIA

[COMMUNICATION NO. 430 FROM THE KODAK RESEARCH LABORATORIES]

MEASUREMENTS OF THE FLUORESCENCE OF CELLULOSE ACETATE, CELLULOSE NITRATE AND GELATIN IN ULTRAVIOLET LIGHT

BY JAMES G. MCNALLY AND WALDEMAR VANSELOW

RECEIVED JUNE 11, 1930 PUBLISHED OCTOBER 6, 1930

The fluorescence of cellulose in ultraviolet light was first noted by Hartley[1] in 1893 but no further attention seems to have been given the subject until Judd-Lewis began a series of experiments in 1918. In his first communication, Judd-Lewis[2] described the appearance of various cellulosic derivatives when held where the photographic plate is normally placed in a quartz spectrograph. Cellulose acetate, viscose, filter paper and "normal" paper showed strong fluorescence in the ultraviolet region while nitrocellulose and paper treated with ethyl malonate showed very little fluorescence.

A method of photographing the fluorescent spectrum was devised by this author[3] in which a camera was mounted in the back of the spectrograph arm and the spectrum photographed by reflected light, a procedure necessi-

---

tated by the opacity of the materials under investigation. The densities of the spectral lines obtained on the plate were compared with the corresponding lines of an arbitrarily chosen standard paper, the specifications for which are not given. It is not possible, therefore, for other workers to compare their results with those of Judd-Lewis, but a qualitative idea of some of his results may be gained. Various types of filter paper were found to give divergent results and no relation was observed to exist between the fluorescent power and any other property of the paper. It was certain, however, that moisture content had little to do with the phenomenon. The fluorescence of hydrocellulose increased markedly as the period of time the pulp was left in the beater increased, the most rapid rate of change taking place in the interval between two and three hours' beating. This might be taken to mean that ultraviolet fluorescence increases as the molecular degradation of cellulose proceeds, which cannot be true without limits because the ultraviolet fluorescence of glucose is less intense than that of cellulose.

In the last papers by Judd-Lewis[4] a description was given of the fluorescent spectrum of a large number of cellulose products examined in a tungsten arc lamp. It was shown that fluorescence was excited by all the wave lengths present below $\lambda 330$ mμ. The physical condition of the specimen seemed to play no part in determining the fluorescent spectrum, as a comparison of data obtained with the same cellulose acetate in the form of a powder, a paper and a transparent film showed little if any difference. The fluorescence did appear to be sensitive to slight chemical changes, as cellulose, hydrocellulose and oxycellulose could be easily distinguished by this means.

Pringsheim and Gerngross[5] have reported that the fluorescence in ultraviolet light of a number of organic polymers—lichenin, cellulose, glycogen, inulin, acetate, gelatin, etc.—increased as the colloidal material was disgregated. The observations were made visually and it was suggested that this property of organic colloidal materials in general might be used to characterize their state of aggregation.

Data of a conflicting nature were obtained by the present authors while attempting to use this property of cellulose acetate to indicate something about the micellar structure of the material. Visual evidence was obtained that the physical structure of the substance was related to its fluorescent power and that marked changes in colloidal properties might be accompanied by no variation in fluorescent properties. The quantitative experiments described in this paper were carried out to determine what relation, if any, existed between the physical and colloidal structure and fluorescent properties of cellulose acetate and cellulose nitrate and gelatin.

The Fluorescence of Cellulose Acetate and Cellulose Nitrate Films

Method of Measurement.—When the image of a mercury arc spectrum is focused on a film of cellulose acetate, the lines of the spectrum are visible in a dark room down to **A241** mμ. The region from **A241** mμ to *365* mμ is so far below the limit of visual perception that no question exists but that the visible light is fluorescent light excited by the ultraviolet. The fluorescent radiation is gray-blue in color and the color is independent of the frequency of the exciting radiation. The fluorescence is not polarized and is passed with high intensity by the K2 Wratten filter but is almost completely absorbed by the **K3** filter, which fact places the wave length of the light emitted as between **A485** mμ and *505* mp, the limits for 60% transmission for the **K2** and **the K3** filters, respectively.

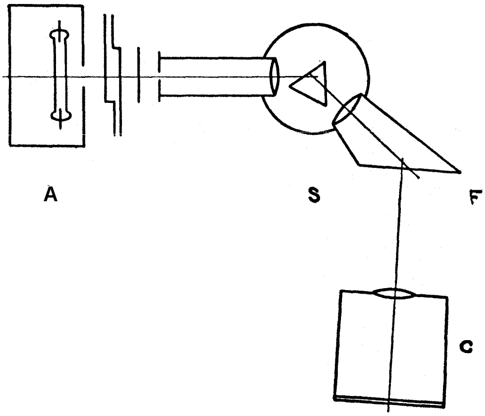

Fig. 1.—Apparatus for measuring fluorescence in films.

The apparatus used to record the fluorescent light emitted by the cellulose acetate films is indicated by the diagram in Fig. 1.

Light from the Cooper-Kewitt quartz mercury arc **A** was resolved by the Gaertner quartz spectrograph S and images of the slit formed on the film under investigation at F. The fluorescent image was photographed by the camera C. The lamp was operated at 155 volts. Using an f 4.5 lens in the camera and Eastman Speedway plates, a suitable time of exposure was found to be forty minutes. The plates were all developed in metol-hydroquinone process developer to a gamma of one.

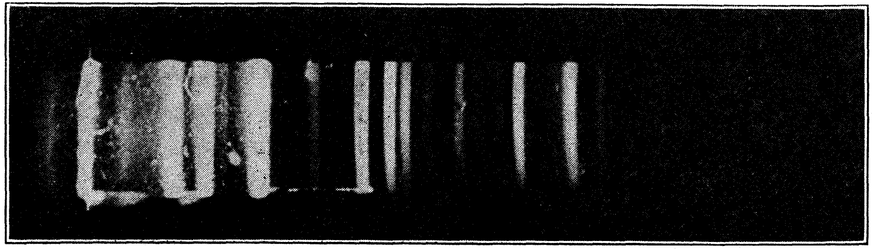

Fig. 2.—Fluorescence of cellulose acetate in the mercury arc spectrum.

Figure 2 is a photograph of the fluorescent light excited by ultraviolet radiations falling on a film of cellulose acetate. To compare the fluorescence of different samples, the densities of the lines in this plate were measured by a micro-densitometer and compared with the densities of the lines obtained by making a direct photograph of the ultraviolet spectrum by placing the photographic plate at F, the time of exposure being one-tenth of a second. The ratio density of fluorescent line to density of spectral line was plotted against the wave length of the exciting radiation. This ratio approaches proportionality to intensity of fluorescent light/intensity of incident light so long as the exposures are low, but as either or both exposures increase, it becomes more nearly proportional to $(P_1 \log I_1)/(P_2 \log I_2)$ where P_1 and P_2 are the Schwarzschild coefficients for the respective wave lengths of fluorescent and incident light. This ratio will be noted hereafter as R.

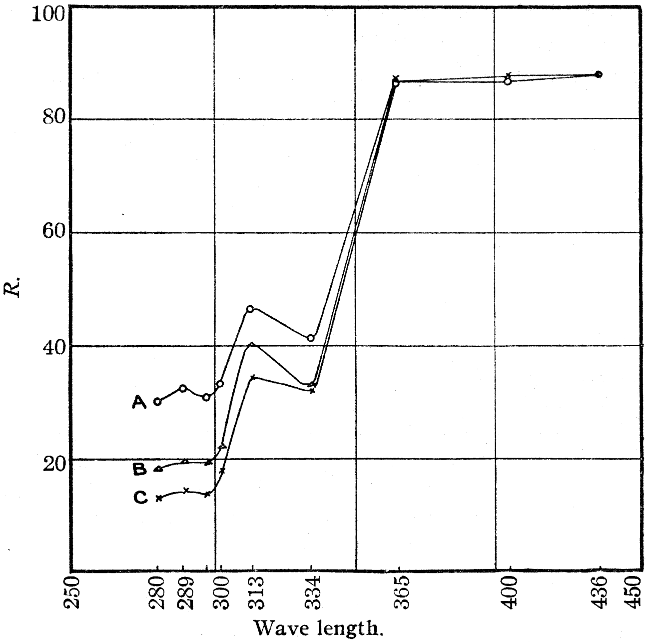

Fig. 3.—Fluorescence of cellulose nitrate films: A, not stretched; B and C, stretched.

Relation between Structure and Fluorescence in Cellulose Nitrate Films.—The curves shown in Fig. 3 were constructed in the manner indicated above and show the fluorescence of three sheets of cellulose nitrate film prepared from the same solution of the original cellulose nitrate. It is evident from the figure that in the region of λ280 to 334 mμ there exists a marked difference in the fluorescent powers of the films forming the order A, B, C, in their ability to fluoresce in this spectral region. The film that showed the fluorescence described by Curve A was formed by evaporating the cellulose nitrate dope to dryness on a glass plate. The other two films were removed from the plate on which the dope was coated while they still contained about 15% of solvent and were further cured while held under tension from two ends, the film represented by Curve C being under higher tension than the film B. It has been shown by one of the present authors and S. E. Sheppard[K] that the tensions on a colloidal film during drying alter the micellar orientation of the film to such an extent that films may be prepared showing the typical optical properties of different crystallographic systems. The film **A** behaves optically as a section of a uniaxial crystal cut perpendicular to the optical axis while the films B and C behave as biaxial films, C being more highly anisotropic than B. It has been shown that the micellar orientation of the film[6] determines its optical properties and it must now be concluded that the ultraviolet fluorescence of the film is also related to its micellar structure.

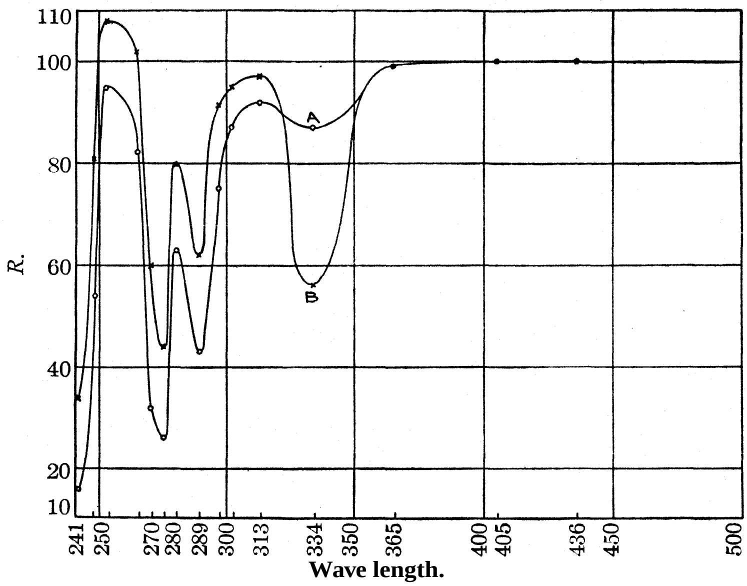

Fig. 4.—Fluorescence of cellulose tri- and diacetate films: A, cellulose triacetate; B, cellulose diacetate.

Fluorescence in Cellulose Acetate Films.—Before proceeding with an examination of the fluorescence of a large number of cellulose acetate films, it was first ascertained that variations in the thickness of the film within wider limits than encountered with our specimens produced very little change in the photograph of the fluorescent light. **A** comparison of the fluorescence of two films of the same material, one **0.16** mm. thick and the

---

[6] J. *G.* McNally and S. E. Sheppard, J. *Phys. Chem.*, 34, 165 (1930).

other 0.08 mm. thick, showed a difference in the R ratio of less than 3% at any value for λ.

The fluorescence excited on cellulose triacetate and diacetate films show points of similarity and of difference. In Fig. 4 the curve A represents the fluorescence of a chloroform-soluble triacetate while B was obtained from an acetone-soluble diacetate, both films being optically uniaxial. The two curves have the same general shape but the fluorescence of the diacetate falls below that of the triacetate at λ334 mμ. The curves in Fig. 5 show that this change in fluorescence is a progressive one as a triacetate is hydrolyzed to a diacetate. The data plotted in this figure were taken from samples obtained during an acid hydrolysis of a first stage dope, the samples A, B and C having acetyl values of 40, 37 and 35% and acetone viscosities of 50, 75 and 200 seconds, respectively. By milder treatment in acetylation and second stage hydrolysis, cellulose acetates may be prepared with the same acetyl values as any of the above samples but having higher acetone viscosities. The film D was made from an acetate prepared under such conditions; its acetyl value was 41% and acetone viscosity 600 seconds. When the fluorescence curve for this film is compared with the others in Fig. 5, it is seen more closely to resemble the acetate with the nearest acetyl content rather than the one most closely like it in viscosity, indicating that the chemical constitution, that is, the percentage acetyl-

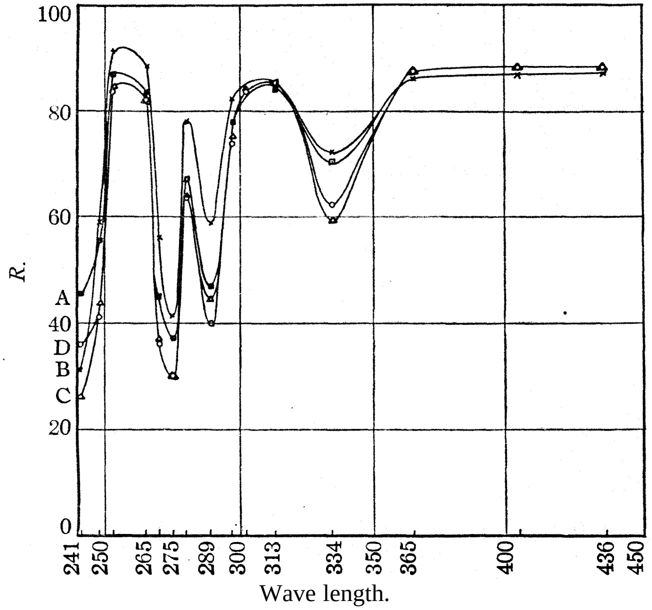

Fig. 5.—Fluorescence of cellulose acetate films of different acetyl content.

ation, is a more important factor in determining the fluorescence of the material in ultraviolet light than any loosening of secondary valency forces caused by the second stage hydrolysis, or eventual depolymerization.

Divergent results were obtained when the fluorescences of stretched and unstretched films were compared in the case of two different acetates. In Fig. 6 the data show that the stretched film B fluoresces more strongly than the unstretched film A and the difference is particularly marked in the region of λ334 mμ. The data from the second acetate plotted in Fig. 7 indicate that in this case the unstretched film A is more strongly fluorescent than the stretched film B and here the difference is most pronounced from λ265 mμ to 300 mμ. The two acetates were typically the same, having similar viscosities and both approximating the acetyl content required for a diacetate. We know of no difference in the properties of the two materials that would account for this difference in their fluorescent power.

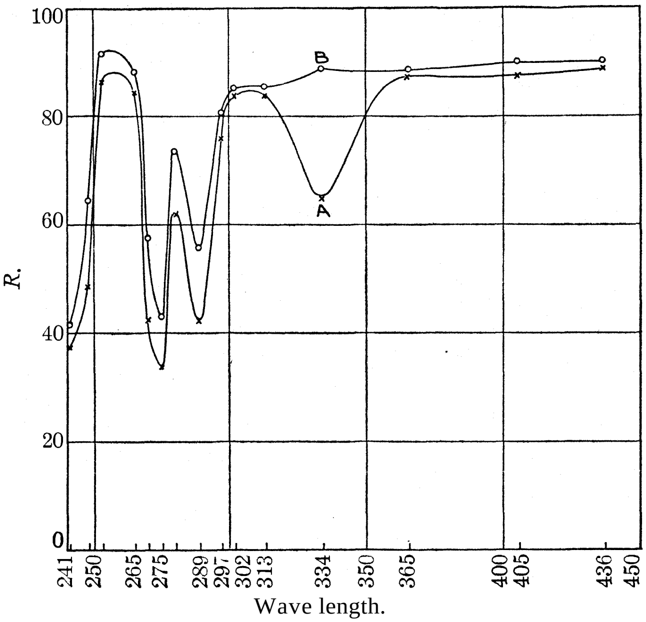

Fig. 6.—Fluorescence of cellulose acetate films: **A,** not stretched; B, stretched.

Fluorescence in Solutions of Cellulose Acetate.—In a well darkened room, solutions of cellulose acetate can be seen to fluoresce when irradiated by ultraviolet light. The fluorescence can be observed to increase in intensity as the concentration of cellulose acetate in the solution increases; but even in the case of a 15% solution, we were unable to photograph the spectrum of the fluorescent light by means of a Gaertner quartz spectrograph after four hours' exposure. We have, therefore, excited fluorescence in the solutions by monochromatic radiation and measured the fluorescent light given off. Figure 8 is a diagram of the apparatus used for this purpose. Light from the quartz mercury arc lamp **A** passed through the quartz windowed water cell W, and 18A Wratten filter, F, and illuminated the slit S_1 of a Bausch and Lomb quartz monochromator, the optical parts of which are indicated by the lenses L_1, L_2 and the prism P. The solution being investigated was placed in an 11-mm. quartz absorption cell C which was enclosed in a light-proof box B. The shutter E opened adjacent to the monochromator slit S_2. The Wratten filter K2 and the photographic plate

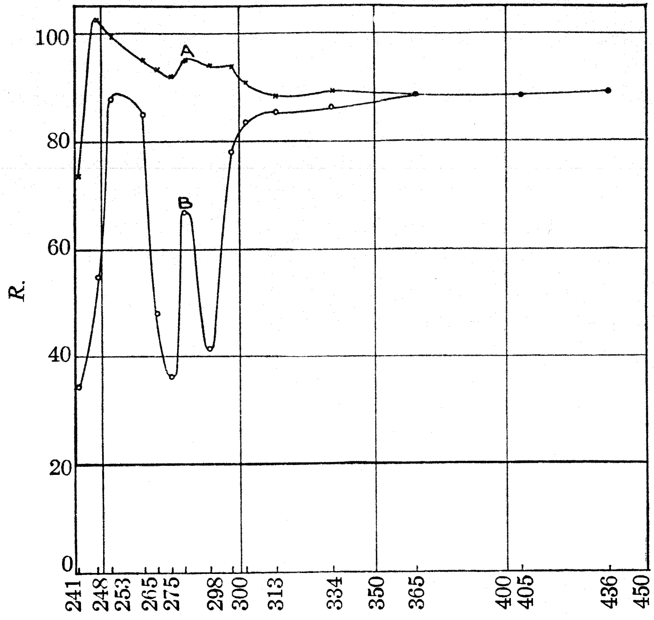

Fig. 7.—Fluorescence of cellulose acetate films: A, not stretched; B, stretched.

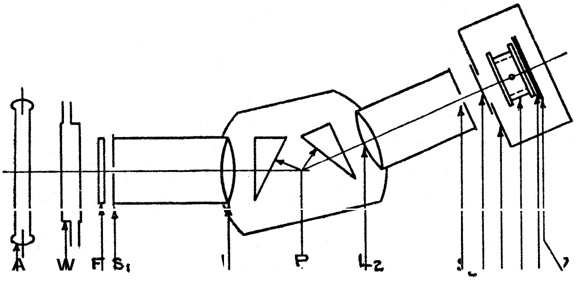

Fig. 8.—Apparatus for measuring fluorescence in solutions.

D were placed in contact with the side of the cell away from the slit. The K2 filter was found to absorb the ultraviolet light completely and transmit the fluorescent light in the case of the solutions used as well as the solid film.[7] Satisfactory plates were obtained with a 15% gelatin solution after a forty-five minutes' exposure, the plates being developed as before to a gamma of one. The densities of the plates were measured by means of the densitometer described by Capstaff[8] and the fluorescent power of the solutions compared on this basis.

The fluorescence of 15% acetone solutions of four cellulose acetates differing in their properties by very wide limits was determined by the method outlined above and the data obtained assembled in Table I. The figures in the first line refer to ball drop viscosity tests. The next line gives the percentage of acetyl group combined, and the final one, the density of the photograph of the fluorescent light after forty-five-minutes' exposure.

TABLE I

THE FLUORESCENCE OF CELLULOSE ACETATE SOLUTIONS

Sample no.	**A**	**B**	**C**	**D**
Viscosity	500	20	20	8
Acetyl, %	40	40	37.8	37.5
Density	0.36	0.40	0.42	0.42

Prom a consideration of the above data it appears that there is no relation between the state of aggregation of the micelles in a cellulose acetate solution and their fluorescence in ultraviolet light of wave length 365 mμ.

The Fluorescence of Gelatin Solutions.—The circumstance that films made from partially broken down gelatin are so brittle that they cannot be handled conveniently makes it a matter of great difficulty to investigate the relation between fluorescence and state of polymerization in gelatin film. We have, however, made such a study of gelatin sols using the same procedure that was outlined for use with the cellulose acetate sols.

A 10% solution of de-ashed gelatin was made up having a PH of 5.2. The flask containing this solution was fitted with a reflux condenser and the solution boiled for twenty-four hours. Samples were taken from time to time and measurements made of the viscosity and fluorescence of the solution. Table II is a summary of these results, the density being, as before, the photographic density caused by the fluorescent light on forty-five-minutes' exposure. The viscosity measurements were made by Dr. Robert Houck and are reported in centipoise units at 40°.

---

[7] Aesculin and a number of glass filters were substituted for the K2 but while they had the proper adsorption limits, they fluoresced to a considerable extent in ultraviolet light and were unsuitable for the purpose at hand. No satisfactory substitute was found for the K2 filter.

[8] J. G. Capstaff, *Trans. Soc. Mot. Pict. Eng.*, **11**, 607 (1927).

TABLE II

THE FLUORESCENCE OF HYDROLYZED GELATIN

Hours boiled....	0	0.33	0.55	1.33	2.25	5.00	24.00
Viscosity......	17.8	14.5	11.5	7.6	5.1	2.4	1.55
Density........	0.88	0.72	0.72	0 70	0.60	0.58	0.74

Sheppard and Houck[9] have concluded that diminution of the viscosity of gelatin sols by heating at elevated temperatures is to be accounted for by hydrolytic decomposition of the gelatin. The part of the hydrolysis reaction that causes the reduction of the viscosity, probably by the breakdown of large colloidal molecules, was complete in our experiment in the first five hours of heating and during this period the fluorescence of the sol in ultraviolet light showed a progressive decrease. In the interval between five and twenty-four hours, the solution became amber colored and the fluorescence makes a marked regain toward its initial value. No sensible change in viscosity took place during this time so it seems evident that the increased fluorescence must be associated with changes other than those of micellar nature that might be expected to alter the flow characteristics of the sol.

Discussion of Results

The results of this investigation are not in accord with the conclusions of previous experimenters that the fluorescence of cellulose derivatives is independent of the physical form of the material and related only to changes in chemical composition, and that the fluorescence of gelatin in ultraviolet light becomes more intense as the material is subjected to progressive disgregation. Enough data have been presented in the present paper to prove that: (a) the fluorescence excited by ultraviolet light in cellulose acetate and nitrate films depends on the micellar structure of the film; (b) when the micellar structure is similar, acetates resemble each other in fluorescence when they are alike in chemical composition rather than in colloidal properties; (c) the fluorescence of cellulose acetate sols is independent of the colloidal properties of the sol; (d) the fluorescence of gelatin sols decreases during the part of the hydrolysis causing a change in micellar magnitude and increases later because of some secondary change.

It seems likely that the amount of strain in a cellulose acetate or nitrate film affects the fluorescence of the film and that the effect is different for cellulose ester films made from different materials. The "temporary dichromatism" observed by Kundt[10] and quantitatively investigated by Pulfrich[11] in the case of stretched rubber affords an interesting suggestion as to the cause of the observed change in fluorescence in stretched cellulosic

films. If the absorption coefficients for different wave lengths in the ultraviolet shift independently of each other as a cellulose acetate or nitrate film is stretched, as they do in the visible region in the case of rubber, the amount of fluorescent light emitted by these wave lengths would vary as the energy absorbed varied. It is planned to investigate this matter further.

The evidence seems conclusive that as far as the λ365 mμ is concerned, the fluorescence of gelatin in ultraviolet light decreases as the aggregates responsible for the high viscosity of the sol are broken up. The subsequent increase in fluorescence is connected with some other change in the solution. The darkened color of the solution suggests that humin formation accompanied by partial oxidation and carbonization had taken place. Brooks[12] has remarked that the formation of fluorescent material is almost universally observed when organic material is partially carbonized by heat, which indicates an explanation for our observed rise in the fluorescent power of the solution.

Summary

The intensity of fluorescence of cellulose nitrate and acetate films in ultraviolet light depends on the wave length of the exciting radiation, and the chemical composition and the micellar structure of the film. The intensity of fluorescence of acetone solutions of cellulose acetate in light of wave length 365 mμ is independent of the colloidal properties of the solution. A decrease in the viscosity of gelatin solutions caused by hydrolytic disgregation of micellar structures is accompanied by a decrease in the intensity of fluorescence in light of wave length 365 mp. Subsequent chemical changes cause an increase in the fluorescence.

AMMONATES OF COPPER SELENATE[1]

BY LOREN C. HURD AND VICTOR LENHER

RECEIVED JUNE 23, 1930 PUBLISHED OCTOBER 6, 1930

Certain of the metallic salts which form complex addition products with ammonia have been subjected to numerous investigations on the part of several workers of the past. Outstanding is the work of Alfred Werner and his students on the preparation and study of the members of the cobalt and platinum systems. In contrast to the cobalt ammines, which are for the most part relatively stable, there exists another class of compounds, the ammonates, which are relatively unstable and which may be represented by the general formula $MA \cdot xNH_3$. As a part of the study of selenium and its compounds carried out at this Laboratory, it was thought that an investigation of the compounds formed by the action of ammonia on the metallic selenates and selenites might yield results of interest. The present report deals with the compounds formed by the addition of ammonia to copper selenate.

Dennis and Koller[2] prepared three ammonates of copper selenate, two of which were products resulting from the partial decomposition of their primary salt, $CuSeO_4 \cdot 4NH_3 \cdot H_2O$. The method utilized by these workers was to pass ammonia gas into a solution of copper selenate to which had been added an excess of ammonium hydroxide. After the ammonia had been passed into the solution for about two hours, clusters of dark blue crystals separated. The product was washed twice with ammonia solution and dried over lime for two hours. Analysis of the material yielded results in accord with the formula ascribed to the tetrammonate monohydrate. Finely ground crystals of the salt were dried in the air for two hours. Ammonia was lost and the resulting pale blue compound was found to be $CuSeO_4 \cdot 3NH_3 \cdot H_2O$. Crystals of the tetrammonate monohydrate were desiccated over lime at a pressure of 25 mm. of mercury for one week. Analysis of the resulting compound showed that one molecule of water had been lost with the formation of the tetrammonate, $CuSeO_4 \cdot 4NH_3$. Willy Lange[3] has recently reported the formation of an ammonate of copper selenate corresponding to the formula $CuSeO_4 \cdot 4NH_3 \cdot 2H_2O$. The method of preparation was not stated. The product was described as a very solu-

ble, sky-blue crystalline material. The author states that the compound lost water to give the tetrammonate—a blue-violet product. The tetrammonate upon heating decomposed without melting to give the green diammonate. Identification of the tetrammonate is based on one copper determination. No analysis is reported for the diammonate.

Materials

Selenic acid was prepared from purified selenium dioxide by direct chlorination of a 10% solution of selenious acid, according to the method of Metzner.[4] The resulting selenic and hydrochloric acid mixture was neutralized with basic copper carbonate, the solution filtered, and the bulk of the copper selenate isolated from the copper chloride by means of precipitation with ethyl alcohol according to the method of Lenher and Kao.[5] Following four or five precipitations of the selenate by means of alcohol the material was twice recrystallized from water. Chlorides were shown to be absent by testing a 1% nitric acid solution of one gram of the copper selenate with a few cc. of saturated silver selenate solution. Failure of a turbidity or opalescence to appear was taken as evidence of the absence of appreciable amounts of chloride.[6]

The ammonia used throughout this work was obtained for the most part from the National Ammonia Company. The commercial material was transferred into a small iron tank containing sodium. Gas used for the preparation of the ammonates described was obtained by distillation from the dry liquid.

Analytical Methods

Selenium.---Selenium was determined according to the method of Lenher and Kao[7] as described by Hoffman and Lenher?

Copper.—Copper selenate when ignited in a porcelain crucible over a Bunsen burner leaves a residue of copper oxide. The selenium is volatilized as the dioxide. In the case of the ammonates of copper selenate the direct immediate ignition must be avoided because of the reducing action of the ammonia on the copper residue at high temperatures. Consequently it is necessary first to drive off most of the ammonia at a low heat, and then to follow the preliminary heating by a gentle ignition. The temperature of the crucible is then raised to the full heat of the burner. If the preliminary heating is not sufficiently slow, the results obtained will be erratic and the crucible will become stained with a rose-colored deposit produced by the action of metallic copper or cuprous oxide on the glaze of the crucible.

[5] Lenher and Kao, THIS JOURNAL, 47,1521 (1925).

[6] Chung Hsi Kao, B.S. thesis, University of Wisconsin. 1924. Dr. Kao states that the sensitivity of this test is limited only by the solubility of silver chloride in water.

[7] Lenher and Kao, THIS JOURNAL. 47, 769 (1925).

[8] Hoffman and Lenher, *ibid.*, 51,3178 (1929).

That the method of ignition is satisfactory for the determination of copper oxide in compounds of the type to be described was demonstrated by numerous analyses, the following two of which may be considered representative.

Compound	CuO, Calcd., %	CuO found %	Detns.	Max. dev.,
$CuSeO_4 \cdot 5H_2O$	26.79	26.73	3	0 14
$CuSeO_4 \cdot 3NH_3 \cdot H_2O$	28.85	28.92	3	0.07

In cases where because of small amounts of sample or difficulty in weighing, it was desirable to estimate the copper content of the filtrate from the selenium determination, the determination was made according to the sulfocyanate method of Rivot[9] as modified by Treadwell.[10]

Ammonia.—Ammonia was determined by distillation of the gas from an alkaline solution which had been freed from copper. In the course of an investigation of the copper sulfate complexes, Horn and Taylor[11] experienced considerable difficulty in the direct distillation of ammonia from alkaline solutions of the ammonates. These workers found that when sodium hydroxide is added to a solution containing appreciable amounts of copper sulfate, the ammonia is expelled with difficulty and prolonged boiling is necessary to drive over the last traces of ammonia. In all cases they found that it was necessary to distil until the residue in the Kjeldahl flask had evaporated almost to dryness in order to arrive at quantitative results.

it was found that copper selenate behaves in a like manner. Because of this difficulty it was considered necessary to remove the copper from the solution before distillation. This was accomplished by warming the sulfuric acid solution of the ammonate with a piece of metallic aluminum. The copper was quantitatively deposited along with a portion of the selenium. Evaluation of the amount of ammonia remaining in the solution was then made by distillation into an excess of acid of known strength and back-titration with sodium hydroxide.

Water.—Horn and Taylor[11] collected the water evolved from the combustion of the ammonates of copper sulfate by absorption in a U-tube containing solid potassium hydroxide. The evolved ammonia passed through the alkali tube and was absorbed in sulfuric acid. An attempt was made to apply this method of determining water and ammonia to the ammonates of copper selenate. It was found that when the temperature was raised to a point required for the complete decomposition of the ammonate, a partial combustion of the ammonia took place. As a result the water results were high and the ammonia low. The explanation for this behavior probably lies in the fact that ammonates of copper selenate de-

---

[9] Rivot, *Compt. rend.*, 38,808 (18.54).

[10] Treadwell and Hall, "Analytical Chemistry," Vol II, 1924, 5th ed., p. 186.

[11] Horn and Taylor, *Am. Chem. J.*, 32,253 (1904).

compose principally into copper oxide, selenium dioxide, ammonia and oxygen at 190°. Inasmuch as it is necessary to heat the compounds to at least 180° in order to drive off the last two molecules of ammonia, it is probable that the oxidation takes place when the selenate group decomposes to yield the selenite. Heating in a current of oxygen-free dry nitrogen likewise yielded high water results and low ammonia results.

The method adopted for the determination of water in the ammonates was that of complete combustion in a tube containing copper oxide and metallic copper. Selenium was retained in the boat by covering the sample with a layer of sodium chromate of known water content. The percentage of ammonia having been determined in a separate sample, the water existing as such in the compound was calculated.

Hydrated Ammonates of Copper Selenate

Copper Selenate Tetrammonate Monohydrate.—The method of Dennis and Koller[2] was followed in the preparation of this salt: 100 g. of copper selenate pentahydrate was dissolved in 125 cc. of concentrated ammonia solution and ammonia gas passed into the dark blue solution for two hours. The crystals were filtered on a sintered glass plate, washed with a cold concentrated ammonia solution and desiccated over soda lime for three days. Analysis of the material was in accord with the formula assigned by the above workers.

Anal. Calcd. for $CuSeO_4{\cdot}4NH_3{\cdot}H_2O$: CuO, 27.16; Se, 27.04; NH_3, 23.22; H_2O, 6.15. Found: CuO, 27.04 (av. 3 detns.); Se, 26.91 (av. 4 detns.); NH_3, 22.94 (av. 4 detns.); H_2O, 6.31 (av. 3 detns.).

Ammonia results were usually found to be slightly lower than the calculated values. This was probably brought about as a result of loss of ammonia during the drying process. The color is close to that of Mulliken's standard BV—Shade 2.[12]

Attempts were made to prepare the compound by adding alcohol to ammoniacal solutions of copper selenate. The blue precipitate produced was found to be a basic salt the composition and color of which varied with the preparation. The precipitate corresponded most nearly with the tetrammonate monohydrate when small amounts of alcohol were used in strongly ammoniacal solutions of the selenate.

Copper Selenate Triammonate Monohydrate.—Copper selenate tetrammonate monohydrate when treated with a current of dry air loses one molecule of ammonia to form the triammonate monohydrate. Samples of the tetrammonate were treated in the manner described by Dennis and Koller.[2] Analysis of the product yielded results in harmony with the findings of these workers.

Anal. Calcd. for $CuSeO_4{\cdot}3NH_3{\cdot}H_2O$: CuO, 28.85; Se, 28.72; NH_3, 18.52; H_2O, 6.98. Found: CuO, 28.91; Se, 28.78; NH_3, 18.51; H_2O, 6.90 (all av. of 3 detns.).

The color of this salt is almost identical with that of standard B—Tint I.[12]

The monohydrate of copper selenate under ordinary conditions is the most stable ammonate of the series. The composition of the salt is not altered by prolonged exposure to the air and desiccation over phosphorus pentoxide for several weeks fails to remove the molecule of water. When heated to a temperature of 110° under a pressure of 2 mm. of mercury, water and ammonia are lost. Samples treated in this manner

---

[12] Mulliken, "Identification of Pure Organic Compounds," John Wiley and Sons, Inc., New York, 1904, Color Charts, Vol. I.

were found to come to constant weight after a loss of approximately 14%. The calculated loss in weight for the conversion of the triammonate monohydrate to the dihydrate is 12.72%. Analysis of the residue showed that in all cases the amount of ammonia in the material was lower than the calculated amount for the diammonate, the average ammonia content of three typical preparations being 13.65% against a calculated value of 14.14%. Copper and selenium results were correspondingly high.

Copper Selenate **Tetrammonate Dihydrate.**—Willy Lange[3] has reported the isolation of an ammonate of the composition $CuSeO_4 \cdot 4NH_3 \cdot 2H_2O$. The only analysis reported upon the compound is one water determination which is about 1% lower than the calculated value. The compound is described as a very easily soluble, sky-blue crystalline substance which by the loss of water yields the blue-violet anhydrous tetrammonate.

Various methods were used in an effort to isolate this compound. Ammonia gas when passed into either dilute or concentrated solutions of copper selenate always yielded the monohydrate. It had been previously noticed that by cooling the reaction tube during the precipitation of the tetrammonate monohydrate, an increased yield of the product was obtained. It was thought that the greatly lessened solubility might indicate that the dihydrate was the stable phase at temperatures in the neighborhood of 0° and that during subsequent operations decomposition took place with the formation of the monohydrate. Accordingly an effort was made to isolate and dry the product at a temperature but slightly above 0°. Precipitation of the salt was brought about by passing ammonia gas into a solution of copper selenate contained in a pyrex test-tube. The tube was immersed in an ice–salt mixture at a temperature of about −2° at the time of precipitation. It is interesting to note that the deposition of the ammonate from solution is nearly complete at this temperature, the supernatant liquid having but a faint blue color after crystallization. The precipitate was quickly transferred to a sintered glass filter provided with a jacket through which cold brine was circulated. The blue material was washed several times with a solution prepared by saturating water with ammonia gas at 0°, transferred to a soda lime desiccator and placed in the lower compartment of an electric refrigerator. At no time did the temperature of the product greatly exceed 4°.

Analysis of several products so prepared did not yield results in agreement with the calculated values for the dihydrate. In order to safeguard against possible loss of appreciable amounts of ammonia or water during the weighing process, large samples were taken from previously weighed glass stoppered bottles, quickly transferred to dilute acid solutions and diluted to known volumes. Analysis of aliquot portions enabled us to determine the percentages of the various constituents in the original sample. Water thus determined by difference was usually high by one or two per cent. In no case did the complete analysis agree with the calculated values for the dihydrate.

Because of our inability to isolate the dihydrate with the aid of ordinary precautions, it was thought advisable to investigate the warming curve of the compound formed by the action of ammonia gas on a solution of copper selenate at 0°. Accordingly a large quantity of the ammonate was precipitated at −1° and isolated in the usual manner. When the deposition of the product was complete the supernatant liquid was removed and the ammonia inlet tube replaced by a thermometer. The ammonia gas was swept from the tube by means of a blast of air and the sample quickly mixed with about one-third its volume of cold copper selenate tetrammonate monohydrate of established purity. The reaction tube, which throughout this manipulation was cooled in brine, was wrapped in several thicknesses of cold cloth and allowed to warm slowly. Examination of one of the characteristic curves obtained in this manner (Fig. 1) shows the absence of the break which usually accompanies a change of the solid phase. Temperature readings were taken every thirty seconds and the total time of the experiments was about forty-five minutes. It is to be concluded as a result of the physical and chemical investigation either that the compound described by Lange does not exist or that it is not formed under the conditions described in the above experiments. The product obtained by Lange was in all probability the tetrammonate monohydrate which contained water mechanically retained in the crystals. It has been noted that the monohydrate is dried with difficulty.

Anhydrous Ammonates of Copper Selenate

Copper Selenate **Pentammonate.**—Copper selenate pentahydrate when exposed to ammonia gas behaves in much the same manner as the corresponding hydrate of copper sulfate.[13] Copper selenate pentahydrate when exposed to a stream of ammonia gas very quickly evolves heat, turns dark blue and assumes a pasty consistency. The tetrammonate monohydrate behaves in a similar manner. Prolonged exposure of either of the two salts to anhydrous ammonia under a pressure of 10 cm. of mercury and at a temperature of 0° results in a quantitative absorption of ammonia to produce the pentammonate of copper selenate, a dark blue product which upon warming evolves ammonia and which very quickly decomposes in moist air. The pentammonate may be prepared most conveniently by the action of liquid ammonia on copper selenate tetrammonate. The monohydrate is first treated with a slow stream of anhydrous ammonia gas at slightly elevated temperatures in order to remove the water. The resulting product is transferred to a pyrex test-tube and immersed in a Dewar flask containing liquid ammonia. Liquid ammonia is then condensed in the reaction chamber. The low temperature and the pressure are sufficient completely to transform the tetrammonate to the pentammonate. Samples of the product after removal of the excess liquid ammonia were sealed in small tubes, weighed and broken under dilute hydrochloric acid. Analysis for various constituents was then made on the filtrate in the usual manner.

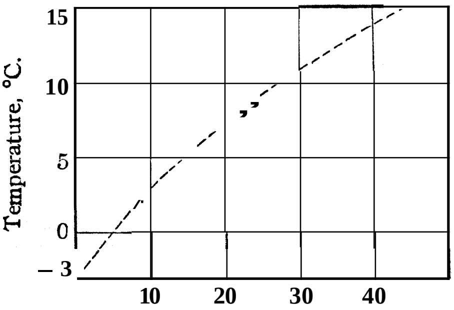

Fig. 1.

Anal. Calcd. for $CuSeO_4 \cdot 5NH_3$: CuO, 27.22; Se, 27.13; NH_3, 29.25. Found: CuO, 27.01; Se, 27.05; NH_3, 29.12 (all av. of 4 detns.).

The transition point for the system copper selenate pentammonate–copper selenate tetrammonate was determined dilatometrically to be at 19 ± 0.3°. The color of the pentammonate is between that of the standards B and BV of the normal tones.[12]

Kao[6] found from a study of the copper selenate–water system evidence which led him to suspect strongly the existence of a heptahydrate of copper selenate at low temperatures. Attempts to isolate the heptammonate of copper selenate have failed. Chemical analysis of the product formed by the action of liquid ammonia on copper selenate, copper selenate pentammonate and copper selenate tetrammonate yielded results which were not concordant with different preparations and which did not correspond to those calculated for any one simple compound. Inasmuch as Ephraim[14] has shown that in some cases of this type a continuous series of solid solutions exists between different ammonates and ammonia, it is doubtful if analytical results would have great

---

[13] Horn, *Am. Chem. J.*, 39, 195 (1908).

[14] Ephraim, *Ber.*, 52, 940 (1919).

significance anyhow. Investigation of the warming curve of the copper selenate–ammonia system between the temperature of boiling liquid ammonia and 15" yielded no irregularity which might be attributed to compound decomposition. It is to be concluded that if the pentammonate of copper selenate does exist it is not stable at atmospheric pressure above the boiling point of liquid ammonia.

Copper Selenate Tetrammonate.—This compound has been previously reported by Dennis and Koller[2] and more recently by Willy Lange.[3] The former investigators obtained the product as a result of the decomposition of copper selenate tetrammonate monohydrate at room temperature under a pressure of 27 mm. of mercury and in the presence of freshly ignited quicklime. Lange gives none of the details of preparation but states that the compound is formed as a result of the decomposition of the tetrammonate dihydrate with the production of the anhydrous product.

The directions of Dennis and Koller were followed in the preparation of this compound. After seven days in a desiccator containing lime and at a pressure of about 17 mm. of mercury it was found that the tetrammonate monohydrate had lost water and that there was formed the anhydrous tetrammonate. Analysis of representative samples yielded results substantially in agreement with those calculated from the assigned formula.

Anal. Calcd. for $CuSeO_4 \cdot 4NH_3$: CuO, 28.94; Se, 28.84; NH_3, 24.76. Found: CuO, 28.41; Se, 28.81; NH_3, 24.94 (av. of 4 detns.).

The tetrammonate is stable above 100" provided the sample is maintained in an atmosphere of ammonia gas. Because preparations made according to the method of Dennis and Koller usually appeared to have undergone a secondary decomposition with the production of a small amount of the triammonate monohydrate and basic salts, the following method of preparation was devised to yield a product free from the triammonate monohydrate.

Copper selenate pentahydrate of established purity was dissolved in water and 50 cc. of the saturated solution transferred to a large pyrex test-tube fitted with a delivery and outlet tubes. Ammonia gas was passed into the hot solution and after most of the water had been removed the tube was transferred to an oil thermostat regulated to about 120°. Passage of the ammonia was continued through the blue mass until the last traces of water had been removed. The preparation was removed, crushed and again treated with ammonia gas at 120°. Analysis of several products prepared in this manner yielded results in strict agreement with the calculated values. In two typical preparations the ammonia content was found to be 24 70 and 24.76% against the calculated value of 24.76%. The color of the tetrammonate is between that of standards VB and BV of the normal tones.[12]

Copper Selenate Diammonate.—Horn and Taylor[11] prepared a series of apple-green decomposition products of copper sulfate tetrammonate and concluded that the products were basic salts and not definite chemical individuals. Lange[3] has reported that if heated the tetrammonate of copper selenate will pass directly without melting to the diammonate.

It was found that if the anhydrous tetrammonate of copper selenate was heated with access to air there were formed various decomposition products, the ammonia content of which was usually lower than that calculated from the diammonate and which varied depending upon the length and rapidity of heating as well as with the maximum temperature. Samples of the tetrammonate placed in an oven regulated at 80° lost approximately 12.5% in weight. Although this loss corresponds rather closely to the calculated loss in the conversion of tetrammonate to the diammonate, the analytical results were not in close agreement for the calculated values for the diammonate. If. however, the sample is maintained in an atmosphere of ammonia gas at atmospheric pressure, the loss in weight will not be appreciable until the temperature of 178" is reached. At this point ±2° the compound breaks down to form the diammonate. Analyses of the products obtained by heating copper selenate tetrammonate to a temperature of 185° in an atmosphere of ammonia gas at atmospheric pressure are in close agreement with the calculated values.

Anal. Calcd. for $CuSeO_4 \cdot 2NH_3$: CuO, 33.04; Se, 32.88; NH_3, 14.14. Found: CuO, 33.03; Se, 32.56; NH_3, 14.14 (all av. of 3 detns.).

The diammonate is a light blue powder. It corresponds somewhat to the BG normal tone of Mulliken's standards[12] and is insoluble in water but soluble in dilute mineral acids and ammonia solution. The compound is stable if preserved in a closed container. Below 178° the material absorbs ammonia to form either the tetrammonate or the pentammonate depending upon the temperature and pressure. Heated above 192' the diammonate is decomposed with the production of ammonia and a black residue which consists of a mixture of copper oxide and copper selenide. Selenium dioxide has been noticed in the cooler parts of the reaction tube when the temperature exceeds 200".

Summary

1. Copper selenate pentammonate and copper selenate diammonate have been prepared and identified.
2. A new and satisfactory method for the preparation of copper selenate tetrammonate has been described.
3. No evidence was found for the existence of the tetrammonate dihydrate of copper selenate reported by Lange.
4. Copper selenate tetrammonate monohydrate, copper selenate tetraammonate and copper selenate triammonate monohydrate have been prepared according to the methods of Dennis and Koller. Analysis of the products indicates composition in accord with ascribed formulas.

MOLECULAR RAY EXPERIMENTS. THE CHEMICAL ACTIVITY OF MOLECULAR AND ATOMIC OXYGEN[1] .

BY WORTH H. RODEBUSH AND W. A. NICHOLS, JR.

RECEIVED JUNE 23, 1930 PUBLISHED OCTOBER 6, 1930

The initial purpose of this investigation was to find some chemical reaction by which the image of a beam of oxygen molecules could be formed on a target for a Stern–Gerlach experiment. The first attempts in this direction in this Laboratory were made at the time that the magnetic moment of atomic hydrogen was measured. It became evident[1c,d] at that

---

time that there were certain interesting chemical problems in connection with the reactions of molecular rays and that, furthermore, molecular rays constitute an especially powerful method of studying heterogeneous reactions because it is possible with an inhomogeneous magnetic field to determine not only the molecular species that is reacting but the actual state of excitation as expressed by the spectroscopic term. For instance, the only absolute test for atomic hydrogen is the Stern–Gerlach experiment. The main purpose of this paper has been the investigation of the chemical activity of the various molecular species that can be produced in oxygen.

Molecular Oxygen.—Molecular oxygen reacts readily with the polished surfaces of certain metals, *e.* g., copper, at slightly elevated temperatures and the film of oxide formed is readily visible One interesting question which arises at once is: will the reaction take place between a beam of cold molecules and a hot surface or between a beam of hot molecules and a cold surface? In this connection it should be noted that the average temperature of a molecule beam is higher than the temperature of the gas in front of the source slit. The average kinetic energy normal to the surface of the molecules striking a surface is kT. If we interpose a slit system we select only the faster molecules, so that the average kinetic energy in the direction of the beam is now $2kT$. This process of selection lowers the effective pressure of the beam enormously, so that it is difficult to obtain beams with effective pressures greater than 10^{-6} mm. This pressure is often considerably less than the pressure obtainable with the best pumping conditions in the apparatus beyond the slit system and constitutes a serious limitation to the chemical activity.

The reactivities of cold surfaces of metallic silver, copper and sodium, phosphorus, indigo and a number of lower oxides, including those of lead and molybdenum, were tried without any observed result. In a number of trials the oxygen molecules were heated to temperatures of several hundred degrees centigrade. No reaction was observed in any case. It was thought that the oxide film might be difficult to observe and a copper target which had been exposed to a beam of oxygen molecules was exposed to mercury vapor. If a similar experiment is made with electrons, the spot which has been bombarded does not amalgamate[2] but complete amalgamation was always obtained with targets bombarded by oxygen molecules. It seems probable that the temperature of the surface itself must be raised in order to bring about a reaction with oxygen molecules. The part played by water in oxidation must not be overlooked. In the high vacuum the surfaces must be very dry and it is well known that in the case of sodium, for example, the presence of moisture catalyzes the oxidation of the surfaces. It could be predicted in advance that no reaction would be obtained between a beam of oxygen molecules and a hot copper

---

[2] Carr, *Phys. Rev.*, 33, 1068 (1929).

or silver surface because the dissociation pressure of the oxide is greater than the partial pressure of oxygen in the beam.

Atomic Oxygen.—Langmuir's[3] method of thermal dissociation was tried. An iridium filament was used at first. Iridium has a high melting point and its oxide is reported to dissociate at high temperatures, so that furnaces wound with iridium wire can be operated in contact with the atmosphere. At low pressures of oxygen, however, the glass walls near the filament were soon coated with a black deposit of what was presumably iridium oxide so that the use of iridium was abandoned in favor of platinum. With a platinum filament heated near its melting point in an oxygen pressure of a few tenths of a millimeter marked oxidizing action was obtained on a large number of substances which were introduced into the chamber within a few centimeters of the filament. It was not possible to say whether the active species was atoms or activated molecules, and it was not possible to obtain any activation in a beam formed with the hot filament directly in front of the source slit. The lack of activity in the beam is probably accounted for by the very small concentration of active species existing in the neighborhood of the filament.

In all further experiments upon atomic oxygen the electrodeless discharge was used. This arrangement eliminates the disturbing action of the electrodes and the frequent replacement of electrodes necessary with a gas such as oxygen. Details of such an apparatus have been described by Kurt and Phipps.[1g]

The reaction of oxygen in the electrodeless discharge at a partial pressure of 0.1 mm. is strongly oxidizing upon any substance placed in the discharge tube. Lead oxide is oxidized to the dioxide, the blue reduced oxide of molybdenum is converted to the yellow trioxide and numerous other substances were tested in a similar way. No exceptions were found to this generalization and the reaction was extremely rapid.

Reducing Action of Atomic Oxygen.—The only reaction hitherto recorded for molecular beams from the oxygen discharge is the conversion of lead oxide to the dioxide, which was used by Kurt and Phipps. They showed by the magnetic moment that this reaction was due to the atom.

It is well known in chemistry that molecular oxygen is evolved by hydrogen peroxide in the presence of many metallic oxides and the reaction is usually described as reduction. A satisfactory mechanism is provided if it is assumed that the hydrogen peroxide liberates atomic oxygen. This suggested to the authors that a similar reducing action might be anticipated with atomic oxygen. Silver oxide was tried first and afterward a number of other metallic oxides, including the trioxides of tungsten and molybdenum. A surface coated with the oxide was exposed to the beam from the electrodeless discharge in oxygen for some hours. The beam was formed by two

---

[3] Langmuir, THIS JOURNAL, 37, 417 (1915).

slits 0.1 mm. in width by 1.4 mm. length placed six cm. apart. No reaction was obtained with any oxide except molybdenum trioxide. In the case of molybdenum trioxide a slate-blue image was produced on the target which appeared like the image produced by atomic hydrogen. The slate blue color is generally accepted as characteristic of one of the lower oxides of molybdenum, probably Mo_3O_8. The image could be obtained with atomic hydrogen in about fifteen minutes. With atomic oxygen a somewhat longer time was required but the image always appeared in less than an hour.

Pure oxygen was prepared from various sources and passed over heated copper oxide to remove traces of hydrogen. The oxygen was always passed through a liquid-air trap. In every case the reaction was obtained, so that it was shown conclusively that the reaction was produced by pure oxygen containing only the traces of water vapor that might be given off by the walls of the discharge bulb. As the discharge bulb was often operated continuously for hours and in some cases a second liquid-air trap was connected directly to the discharge bulb, the amount of moisture in the oxygen must have been very small indeed in some runs, but the reaction was not noticeably affected. Copeland[4] has reported that an appreciable amount of water vapor must be present in order to obtain a good line spectrum with the electrodeless discharge in oxygen. We are not able to confirm this. The discharge was not quite so steady when the second liquid-air trap was connected directly to the bulb but in all cases the line spectrum of oxygen was obtained and the reaction with the trioxide. It is our opinion that water vapor is not necessary to bring about the dissociation of oxygen, but that its presence is necessary to prevent the recombination of the atoms on the walls of the tube is shown conclusively by the work of Rodebush and Troxel on the heat of dissociation.[5]

The molybdenum trioxide was "smoked" on the target in a finely divided condition by burning a molybdenum wire under it. It was not possible to produce enough of the "reduced" oxide to make any sort of a chemical analysis but when beams of atomic oxygen and atomic hydrogen were alternately impinged on the target no change in the appearance of the blue image was observed. It was not possible to produce the blue coloration with atomic oxygen unless the target was separated from the discharge tube by two slits. When a single pinhole slit was used, no action was obtained on the target.

In order to identify the active species the oxygen beam was passed through an inhomogeneous magnetic field using the arrangement described by Kurt and Phipps. The central undeviated line was obtained but the fainter side lines characteristic of atomic oxygen were not obtained although the run was continued for more than twenty-four hours.

---

[4] Private communication to the authors.

[5] To be published shortly.

The reaction which takes place between a beam of atomic oxygen and molybdenum trioxide is believed to be

$$3MoO_3 + O = Mo_3O_8 + O_2$$

It has not been proved of course that the reaction is the same for atomic oxygen as for atomic hydrogen. It seems very doubtful, however, if a higher oxide of molybdenum than MoO_3 would have an appearance identical with the partially reduced oxide and none is known to exist. This conclusion is strengthened by the fact that the blue oxide is quickly changed to the yellow trioxide on direct contact with the discharge in oxygen, which has been shown to have a strongly oxidizing action on most substances.

The Stern-Gerlach experiment shows that the reducing action cannot be due to *hydrogen,* traces of which might be produced from the water evolved from the glass surfaces. Since the side lines characteristic of the oxygen atom were not obtained, it does not prove conclusively that atomic oxygen is the reducing agent. The central undeviated line might be due to the OH molecule or to an activated oxygen molecule in the $^1\Sigma$ state for example. Since the hydroxyl molecule must be present in vanishingly small amounts and it is difficult to formulate a reaction for either hydroxyl or the oxygen molecule, there seems to be no reason to doubt that the reaction is due to the oxygen atoms.

There remains to be considered the question of why the side lines were not obtained in the Stern-Gerlach experiment. These side lines are characteristic of the $^3P_1$ and $^3P_2$ states of the oxygen atom. It might be assumed that only the $^3P_0$ state reacts with the molybdenum trioxide but this would appear a fanciful hypothesis. The more reasonable explanation is to be found in the fact that the reduction can only be brought about when the active species is passed through a double slit system. Evidently the reducing action can only take place in the presence of a very low pressure of molecular oxygen. The partial pressure in the deflected beam of the atoms in the $^3P_1$ and $^3P_2$ states is very small indeed and we may suspect that there is a critical value for the ratio of the partial pressure of atoms to the partial pressure of molecules below which the reduction does not take place.

Summary

An exhaustive search failed to discover any surface with which a beam of oxygen molecules will react to give a visible image.

A beam of oxygen atoms appears to give the same reaction with molybdenum trioxide as a beam of atomic hydrogen. This reaction is believed to be represented by the equation

$$3MoO_3 + O = Mo_3O_8 + O_2$$

THE VAPOR PRESSURE OF ANTIMONY TRIOXIDE[1]

BY W. B. HINCKE[2]

RECEIVED JUNE 26, 1930 PUBLISHED OCTOBER 6, 1930

During the past few years the Pacific Experiment Station of the U. S. Bureau of Mines has received many inquiries regarding the vapor pressure of antimony trioxide. The applicability of such information to the study and improvement of technical methods involved in lead softening, as well as the possible value of such data to the manufacturer of pigments and rubber fillers, has been the incentive in making the following measurements. This work also has an essential place in a general program of investigation being carried on by the Pacific Experiment Station of the Bureau, dealing with the determination of the thermodynamic properties of metallurgically important materials, such as oxides and sulfides.

Preliminary Measurements and Selection of Methods.—Solid antimony trioxide exists in two crystalline forms, cubic and' orthorhombic, and has a transition temperature at 570 ± 10° as determined by Roberts and Fenwick.[3] The cubic form is stable below the transition temperature, and the orthorhombic modification is stable from the transition temperature to the melting point, which has been given by Quercigh[4] as 656°. Preliminary experiments showed that vapor pressures ranging from a fraction of a millimeter to a total of several centimeters prevail in the temperature range 500–800°.

Two serious difficulties beset any attempt to measure vapor pressures of antimony trioxide. At very low total pressures, thermal dissociation of the oxide becomes apparent, and in fact it proved impossible to resublime even under moderate vacua without always producing small amounts of antimony metal. At higher temperatures, and especially in the case of the molten oxide, the material is an active slagging as well as oxidizing agent, preventing the extensive use of both vitreous and metallic containers.

After some testing of a variety of materials, silica glass was found usable below about 800°, when the time of contact of liquid oxide and glass was not too great, although it was slowly and continuously slagged.

From these preliminary experiments it was apparent that the inert gas saturation method would be suitable for the determination of the vapor

pressures of the solid oxide, but that ordinary methods such as the "boiling point" method would be unsuitable for the liquid, both because of the order of magnitude of pressure involved, and because long contact and agitation were to be avoided to prevent excessive slagging. By the use of a special form of tensimeter the difficulties attendant upon measurements of the liquid oxide were overcome in sufficient degree to furnish adequate, if not completely satisfactory, vapor pressures. Experiments upon the solid oxide, by the inert gas method, and upon the liquid by the new method, will be described separately, and in order.

Part I. Sublimation Pressures of Solid Antimony Trioxide

Preparation of Materials.—Samples of cubic and orthorhombic crystals were prepared by repeated sublimation and condensation in vacuum, and finally in nitrogen, at a temperature at which only the desired crystalline form was stable. Since antimony trioxide readily absorbs oxygen at elevated temperatures, to give more stable higher oxides (tetroxide), great care was taken to prevent the presence of elemental oxygen both during preparation and measurement.

Method.—The inert gas saturation method used for the solid forms of oxide was practically identical with that used by Eastman and Duschak[5] and need not be again described. One essential modification which was made, however, consisted in the fitting of the apparatus with a condenser tube of very light mass (about 1 mm. bore) which could be weighed on the button balance. Experiments of long duration were unsatisfactory because of the slight corrosive action of antimony trioxide vapor on the weighing tube even at a few millimeters' partial pressure. It was better, therefore, to use a sensitive button balance to determine a few milligrams of condensed oxide rather than to attempt to secure equal accuracy from greater amounts of condensed oxide produced over longer sublimation periods.

The lower limit of pressures measurable by the saturation method was determined by the precision with which minute quantities of sublimate deposited in the gas outlet tube could be weighed. All other factors, such as the completeness of saturation and the accuracy of measurement of the volume of nitrogen and the temperature of the furnace, were so controlled as to produce negligible errors in comparison with the unavoidable variations of weights. By the use of the button balance the limit of the vapor pressure measurements was extended to a low range; in fact, weighings were made of samples of condensate as small as 0.00016 g., corresponding at 460° to a partial pressure of 0.0169 mm. of antimony trioxide vapor in the saturator.

At temperatures above 600° the corrosive action of the antimony trioxide vapor began to glaze the inside surface of the quartz saturation chamber as well as to attack the quartz outlet tube with considerable effect on the accuracy of weighing the deposited sample. This glazing action, although not completely disastrous to the method up to 640°, may account for the slight irregularity of the values in this range (see Fig. 2).

---

[5] Eastman and Duschak, U. S. Bureau of Mines Technical Paper 225.

Results of Inert Gas Method.—In Table I are shown the results obtained by measurements on cubic crystals of antimony trioxide, and Table II shows similar figures for the orthorhombic form. In the calculation of vapor pressures, the mole of trioxide in the gas phase was taken as Sb_4O_6, in accordance with the results of V. Meyer and H. Mensching[6] and of Biltz.[7] The pressures are reduced to millimeters of mercury at 0°.

The determined values in Tables I and II are shown as individual points in the chart of Fig. 2, where the logarithm of pressure is plotted against the reciprocal temperature in the conventional way.

Part II. Vapor Pressures of Liquid Sb_2O_3

Method.—The tensimeter method used for liquid oxide is best described by reference to the diagram of Fig. 1. A U-manometer of silica glass, M, has parallel legs five or six inches long, axially separated some four inches. Each leg is provided with a silica glass hook, H, one of which engages the fixed support R, the other being connected

---

[6] V. Meyer and H. Mensching, Ber., 12, 1282 (1879).

[7] H. Biltz, *Z. physik. Chem.*, 19, 385 (1896).

through the quartz glass fiber *G* with the arm of a good analytical balance, B. The whole manometer is thus freely suspended in the uniform temperature zone of an electric furnace, F. The leg at the fixed support has the side arm S, containing the oxide to be measured. The manometric fluid B is metallic bismuth. Both legs of the manometer are highly evacuated at the beginning of an experiment, and sealed, the temperature of the whole being below that at which vapor pressure is detectable. When the whole manometer is now slowly heated, the displacement of the bismuth column due to vaporization of oxide is determinable from the weight necessary to restore the zero position of the balance.

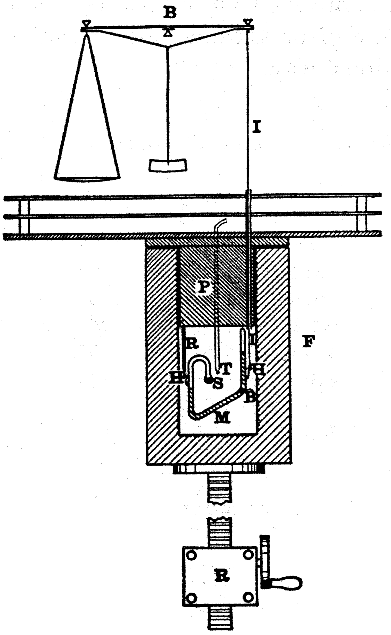

Fig. 1.

The manometer swings freely between the supports and finds its equilibrium position. It is obvious that the center of gravity must be so adjusted that the two legs of the manometer remain stable in the vertical plane, but the center of gravity must not be too far below the axis of support if good sensitivity is to be obtained.

The balance B is well shielded from the heat of the furnace, the quartz fiber connection being made through a small-bore silica glass tube inserted in the insulating material and plug P. The top of the furnace and the balance are rigidly mounted by suitable supports. The furnace itself is cylindrical in shape with inside dimensions 5 × 14 inches. It is mounted on a geared rack and may be raised about the manometer and fitted snugly about the top plug P.

It is apparent that this tensimeter must be calibrated before use. The balance weighings give in effect only the displacement of the center of gravity of the instrument as produced by the shift of the manometer liquid. The calibration is accomplished by determining the change in apparent weight produced by known heights of mercury in the cold manometer.

The manometer tubes were selected for uniform bore, and so formed that the two arms were parallel and straight over the height of column to be used. For the purpose of calibration the ends were left unsealed and were about half filled with clean mercury. A small Bunsen valve was fitted on the high side of the manometer in order that the mercury might be held at various levels during the calibration. The furnace F was lowered and the manometer with the mercury was suspended so that the high side hung from the quartz fiber. The supports were so adjusted that the center of gravity was well up near the line between the two supports, but low enough so that the manometer was always stable in the vertical plane, when the difference in columns was a maximum. When the manometer is held in the zero position, as indicated by the pointer of the balance, only vertical forces are transmitted by the fiber suspension.

For the actual calibration a cathetometer was used to make readings of the heights of the various displacements of the mercury column corresponding to the weights balancing the downward force on the quartz fiber. Figure 3 shows a graph of such weighings in grams and corresponding heights in centimeters of mercury, and constitutes a calibration for one of the manometers used. If the manometer were perfectly constructed and the suspension were frictionless and unaltered during the calibration, the points would fall on a straight line. Each manometer had its own characteristic curve, but the slope of the line depends only upon the bore of the tube and the distance between the two supports. The nearly precisely constant ratio between increases in weight and increases in pressure over the whole range of the manometer is shown in Fig. 3, by the close approximation to a straight line. The chart shows that an increase in 1 g. weight of the downward force on the quartz fiber support corresponds to an increase of 0.5823 mm. of mercury pressure in the manometer. Since silica glass has little thermal expansion, the calibration of the apparatus remains practically unaltered over wide temperature ranges. Moreover, it is obvious that for any other manometer fluid of different density ranging over the same heights of column for which the calibration

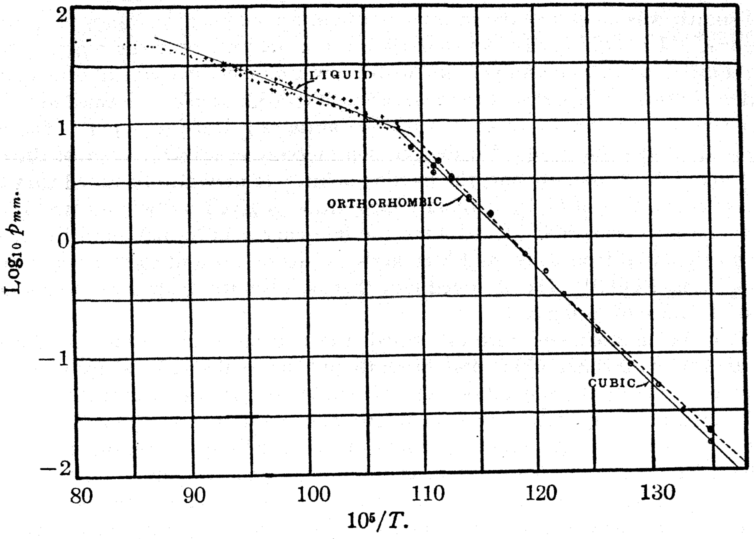

Fig. 2.

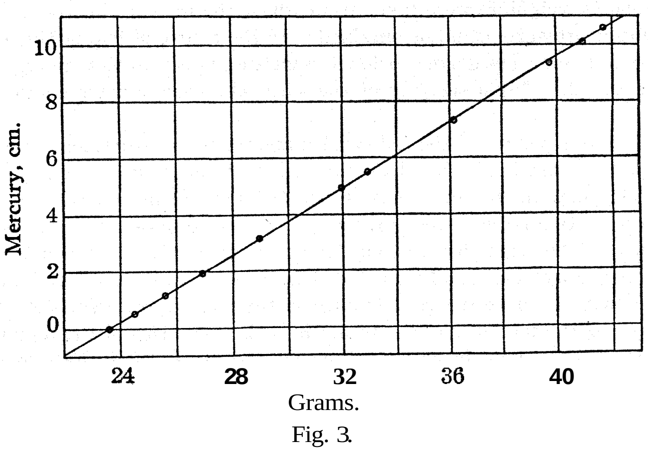

Fig. 3.

was made, the increment of weight above that corresponding to zero pressure will always be proportional to the pressure (measured in mm. of mercury) as determined from the calibration chart with mercury, provided that the bore of the manometer is true to within the accuracy of weighing. This avoidance of density corrections for the manometer fluid at high temperatures is one of the chief advantages of the tensimeter.

Bismuth was chosen as the manometric fluid for making the vapor pressure determinations. It is liquid and has a negligible vapor pressure over the range of temperatures required, and has no stable oxide with a lower dissociation pressure than antimony trioxide. If this latter were not the case bismuth trioxide would be formed in the sample side of the manometer by reaction with the antimony trioxide vapor. The work of Simon and Thaler[8] has shown the dissociation pressure of $(Sb_2O_3)_2$ to be of the order of magnitude of 10^{-8} mm. at 656°, the melting point. It may also be noted that the free energy of formation of Sb_2O_3 at room temperature as given by Schuhmann[9] is -148.6 Cal., which is considerably greater than the free energy of formation of Bi_2O_3, -119.2 Cal., as calculated from Ditte and Metzner's[10] value of ΔH and the known entropies of Bi,[11] O_2[12] and Bi_2O_3.[11] The observed fact that no bismuth oxide was formed confirms the initial choice of bismuth.

After the manometers were calibrated, the two open ends were sealed onto two silica glass tubes through which pure bismuth and the solid sample of antimony trioxide were introduced into the apparatus. It was found to be very important that both sample and bismuth be completely outgassed before sealing the manometer and again pulling off the evacuating tubes. This was practically accomplished by heating the bismuth to a red heat for a considerable time while maintaining a good vacuum on both sides of the manometer. Finally the sample of antimony trioxide was fused in the small bulb S and the manometer sealed off and disconnected from the evacuating apparatus.

The outgassed and sealed tensimeter was now ready to suspend in the furnace. The furnace was brought up to temperature beforehand so that the danger of the bismuth freezing and breaking the manometer was avoided. At the outset the temperature was such that a weighing corresponding to a negligible pressure of $(Sb_2O_3)_2$ could be determined. The temperature of the furnace was then gradually increased and at regular intervals weighings were taken from which the increase in weight and the corresponding vapor pressures could be obtained. In the course of two or three hours a temperature range from a few degrees below the melting point up to temperatures of about 800° was covered. Rapid slagging of the silica glass manometer commenced at this point.

To check the results of the balanced manometer, measurements were also made with a stationary tensimeter in which the height of the manometer columns was read directly. This manometer was similar to the balanced form, but was fixed in a special furnace made of two large electric muffle heaters placed about 2.5 cm. apart in a well-insulated box. The silica glass manometer was in the middle uniform temperature region between the two plates. Bismuth was again used as manometer liquid. Narrow slits covered with clear mica were left open in the two opposite ends of the furnace in order to observe the meniscus of the bismuth in the two arms of the manometer. The lighting of the inside of the furnace was through the slot in the furnace opposite to that through which the cathetometer was sighted. The side of the manometer containing the sample of antimony trioxide was evacuated and sealed. The arm into which the

liquid bismuth was displaced was kept connected to an evacuating system during the measurements. The pressures were determined by reading the height of the bismuth column directly with a cathetometer.

In using the stationary tensimeter, corrections for the density of the liquid bismuth at various temperatures are necessary. The data for this were taken from the work of Yoscharu and Maleyama.[13]

Results of Measurements on Liquid Oxide

The method of the balanced manometer furnishes a large number of experimental observations at temperatures differing by small intervals, and it would seem unnecessary to present data for all individual points. Figure 2 shows the individual points obtained. The results of the balanced nanometer method are shown as dots and the direct readings as crosses.

The determinations by the balanced manometer method were made on a single sample of oxide with the manometer for which the calibration curve is shown in Fig. 3. Two complete series of determinations were made over the temperature range from 600 to 800°. In a third final series the temperatures were carried to the slagging point of the sample, evidenced by a noticeable vapor-pressure lowering. This occurred at about 800°, as is clearly shown by the falling off of the plotted values at the high temperature end of the liquid-phase curve of Fig. 2. The last series was stopped at 975°, and at this temperature the contamination of the sample with slagged silica was such that there was no further vapor-pressure increase with temperature rise. There exists a range of about 150° over which the vapor pressures of the liquid phase were satisfactorily measurable. Because of the extremely corrosive nature of liquid antimony trioxide and its power to react with materials suitable for apparatus construction, it is doubtful whether the range could be lengthened.

The results obtained with the stationary manometer, shown as crosses in Fig. 2, are in fair agreement with those obtained by the balanced manometer method. Two series of determinations on a single sample were made over a temperature range from 650 to 800°. The first series was made on slowly ascending and the second on a descending temperature–pressure scale. At the completion of the measurements the sample of antimony trioxide solidified crystalline, but analysis showed a molal content of 10% of silica. This large content of silica in the sample may have been partly due to a thin shell of quartz glazed with antimony trioxide which scaled off the inside of the manometer on removing the mass of solidified sample.

Derived Vapor Pressure Data.—Assuming that the data obtained may be expressed by a straight line upon a log p–$1/T$ chart, analytic expressions may be obtained for the various forms of oxide. The vapor pressure of

---

[13] Yoscharu and Maleyama, *Sci. Refits. Tôhoku, Imp. Univ. 1st series,* *18,* 19–46 (1929).

cubic antimony trioxide as shown in the corresponding curve of Fig. **2** is

$$\log_{10} p_{\text{mm.}} = 12.195 - \frac{10{,}357}{T}$$

that for orthorhombic,

$$\log_{10} p_{\text{mm.}} = 11.318 - \frac{9625}{T}$$

and for the liquid

$$\log_{10} p_{\text{mm.}} = 5.137 - \frac{3900}{T}$$

where log p is the common logarithm of vapor pressure expressed in millimeters and T is the absolute temperature.

The molal (Sb_4O_6) heats of vaporization at the temperatures of the experiment, calculated from the slopes of the lines of Fig. 2 are as follows: for the cubic modification, AH = +47,320 cal.; for the orthorhombic, $\Delta H = +44{,}080$ cal.; and for the liquid antimony trioxide, $\Delta H = +17{,}830$

cal. From these data the molal heat of transition of cubic into orthorhombic oxide is $\Delta H_{830} = +3240$ cal., and the molal heats of fusion are 26,250 cal. for the orthorhombic and 29,490 cal. for the cubic. For convenience of reference, vapor pressures as read from the chart of Fig. 2 are shown tabularly in Table III, which shows the vapor and sublimation pressures of the stable modification at 25'-temperature intervals over the determined range.

Summary

1. The vapor pressures of cubic and orthorhombic solid antimony trioxide have been measured between the temperatures 470 and 650° by the gas saturation method.
2. The vapor pressure of liquid antimony trioxide has been determined over the temperature range from 656 to 800°, using a new type of static balanced tensimeter. These values were checked by direct tensimeter measurement.
3. Heats of vaporization and transformation have been calculated from the vapor pressure data.

THE IONIZATION CONSTANT OF WATER AT 25° FROM THE ELECTROMOTIVE FORCE OF CELLS WITHOUT LIQUID JUNCTION

BY ELLIOTT J. ROBERTS

RECEIVED JUNE 27, 1930 PUBLISHED OCTOBER 6, 1930

In view of the fact that all previous determinations of the ionization constant of water by the electromotive force method have involved cells containing liquid junctions, it appeared to be worth while to make a determination involving no liquid junctions. This has been accomplished by a new method, the basis of which consists of the measurement of two electrodes of the second kind, directly against each other in a common solution containing ions requisite to the reversibility of both electrodes.

In the present case, the two electrodes of the second kind were Pt,H_2,H_2O,OH^- and $Ag,AgCl,Cl^-$, and the solution in which they were measured was a mixture of sodium hydroxide and sodium chloride. Thus the complete cell was

$$Pt,H_2,NaOH\ (m_1) + NaCl\ (m_2),AgCl,Ag$$

The electromotive force of this cell at 25° may be represented by the equation

$$E = E^\circ_a - E^\circ_b - 0.05915 \log m_{Cl^-}/m_{OH^-} - 0.05915 \log \frac{\gamma_{Cl^-}\alpha_{H_2O}}{\gamma_{OH^-}} \qquad (1)$$

where E_a° is the normal potential of the electrode Pt,H_2,H_2O,OH^- and E_b° is the normal potential of the electrode $Ag,AgCl,Cl^-$. If, now, we define a quantity E' by the equation $E' = E + 0.05915 \log m_{Cl}/m_{OH^-}$, Equation 1 becomes

$$E' = E_a^\circ - E_b^\circ - 0.05915 \log \frac{\gamma_{Cl^-}\alpha_{H_2O}}{\gamma_{OH^-}} \tag{2}$$

and at zero concentration of ions

$$E' = E_a^\circ - E_b^\circ \tag{2*}$$

Furthermore, the extrapolation of the E' values to m = 0 should be linear with the ionic strength in dilute solutions, since the last term in Equation 2 contains a ratio of two activity coefficients. Thus, a series of determinations leading to E' at zero concentration will enable a calculation of E_a° if E_b° is known; but[1]

$$E_a^\circ = -0.05915 \log K_w \tag{3}$$

where K_w is the ionization constant of water in terms of activities. E_b° may be obtained from measurements of cells of the type $Pt,H_2,HCl,AgCl,Ag$ by means of an extrapolation involving the use of the theoretical equation of Hückel.[2] Although measurements of the hydrochloric acid cells have been made at 25° by several investigators,[3] further measurements were deemed advisable to insure a uniformity of technique and to avoid possibility of error due to differences in electrodes. Accordingly, measurements on hydrochloric acid cells as well as sodium hydroxide–chloride cells have been made in the present investigation. These measurements furnish data for calculating E' at zero concentration and E_b°, from which E_a° and K_w follow by Equations 2* and **3.**

Similar measurements with hydrogen and silver chloride electrodes on mixtures of sodium chloride with a weak acid and its sodium salt in equimolal proportions should lead to the ionization constant of that weak acid, provided that the constant has a value lying between 10^{-5} and 10^{-9}; or, if suitable corrections are made for ionization or hydrolysis, the range may be extended to 10^{-4} and 10^{-10}. The principal limitation to the use of this type of cell is that no change of phase shall occur at either of the electrodes due to reaction with the foreign ion.

Experimental Procedure

A Leeds and Northrup Type K potentiometer was used and the working standard cell was repeatedly checked against two cells recently standardized by the Bureau of

Standards. The two pyrex electrode vessels used were of the U-type, and were adapted to a vacuum technique by having an outlet tube at the base of the silver chloride electrode limb and an inlet tube about one-third of the way up on the hydrogen electrode limb. A three-way cock attached to the inlet tube allowed this to be used for the introduction of both hydrogen and solution. Auxiliary outlets through the rubber stoppers carrying the electrodes assisted in washing and removing gas bubbles. The electrode vessels were permanently mounted in an air thermostat maintained at 25±0.02°, with the inlet and outlet tubes projecting, respectively, through the side and base of the thermostat. Hydrogen prepared by the electrolysis of a 15% solution of sodium hydroxide was passed through pure water at 25° before reaching the electrode vessels. Platinum strips, 0.5 by 2.5 cm. coated with platinum black for two to ten minutes at 150 milliamperes, served as hydrogen electrodes. After each determination they were heated to a white heat before re-use. The silver chloride electrodes were of the Noyes and Ellis type and were used for a number of measurements before being replaced. Recrystallized sodium chloride was added in the required amount to an 0.2 *M* solution of carbonate-free sodium hydroxide, prepared as described by Cornog,[4] and the resultant solution was analyzed for hydroxide and chloride ions. This solution was diluted with carbon dioxide-free distilled water as required. A carefully standardized 0.2 M solution of hydrochloric acid was prepared from distilled acid. The solutions used in the hydrochloric acid measurements were prepared by dilution, both the stock solution and the distilled water being weighed to one part in five thousand. All solutions were freed from dissolved oxygen by boiling in *vacuo* before being drawn into the electrode vessels. correction being made for the water lost. One liter of solution was used for each washing and filling of a cell. The capacity of each cell was 100 cc. The process of washing occupied about thirty minutes, which allowed considerable time for soaking out the silver chloride electrodes. Constant potential was reached one to two hours after starting the hydrogen. Three factors contributed to the elimination of error due to adsorption or reaction of the solutions with glass: namely, the use of pyrex vessels, the rapid attainment of equilibrium, and the approach of the determinations from both more concentrated and more dilute solutions. Removal of dissolved oxygen was shown by Güntelberg[5] to be necessary in the case of hydrochloric acid. In confirmation, results 0.3-0.4 mv. higher were obtained when 0.01 M solutions were introduced into the cells without boiling.

Experimental Results

Table I presents the results of measurements on sodium hydroxide–chloride cells in which the ratio of m_{Cl^-} to m_{OH^-} was within 1% of unity. Column 1 gives the total molality, $m_1 + m_2$; Col. 2, the observed e. m. f. corrected to 1 atm. partial pressure of hydrogen and to unity ratio of m_{Cl^-} to m_{OH^-}, the latter correction amounting to −0.29, −0.10 and −0.08 mv. in the three stock solutions made up.

Table II presents the results of measurements on hydrochloric acid cells. Column 1 gives the concentration of hydrochloric acid in moles per kilo of water in *vacuo,* Col. 2, the observed e. m. f. corrected to 1 atm. partial pressure of hydrogen, and Col. 3, the deviation of the individual E_b° values, as calculated by Equations 5 and 8, from the average of these values (−0.22239).

Calculation of Results

The extrapolation of the E' values of Table I to $m = 0$ gives 1.05080 volts. Values of E°_b were calculated by means of the equation

$$-E^\circ_b = E_{\text{obs.}} + 0.1183 \log m + 0.1183 \log \gamma_\pm \qquad (5)$$

The values of $\log \gamma_\pm$ were calculated by means of Hückel's equation, using three different combinations of constants, as follows

$$\text{(a)} \quad \log \gamma_\pm = -\frac{0.5000\sqrt{c}}{1 + 1.4\sqrt{c}} + 0.136\,c - \log(1 + 0.036\,m) \qquad (6)$$

which is the formula used by Güntelberg[5] for his results at 20°

$$\text{(b)} \quad \log \gamma_\pm = -\frac{0.5049\sqrt{c}}{1 + 1.329\sqrt{c}} + 0.1426\,c - \text{bg}\,(1 + 0.036\,\text{m}) \qquad (7)$$

which is the formula used by Scatchard[6] for results at 25°

$$\text{(c)} \quad \log \gamma_\pm = -\frac{0.5044\sqrt{c}}{1 + 1.45\sqrt{c}} + 0.1338\,c - \log(1 + 0.036\,m) - N \qquad (8)$$

where N is the second term of formula No. 107 of Gronwall, La Mer and

---

[6] Scatchard, THIS JOURNAL, 47, 2098 (1925).

Sandved,[7] and has a maximum value of 0.09 mv. The two constants 1.45 and 0.1338 were determined by trial, with the aid of Scatchard's[8] results above 0.1 M. The values of c were calculated by means of the equation

$$c_{25^\circ} = M - M\,(0.0029 + 0.0184\,M + 0.0001\,M^2) \qquad (9)$$

which was derived from data in the "International Critical Tables."

The average values for E_b° as calculated by means of the three equations are -0.22247, -0.22235 and -0.22239 volt, respectively, with mean deviations from the average of 0.08, 0.09 and 0.08 millivolt, respectively. The average of the three values, -0.22240 volt, may therefore be used for E_b° (E° of the silver chloride electrodes used). By Equation 2*

$$\mathrm{Pt,H_2,H_2O,OH^-};\ E^\circ = 0.82840 \text{ volt } \pm 0.10 \text{ mv.}$$

Therefore, by Equation 3

$$K_w = (0.988 \pm 0.004) \times 10^{-14}$$

Summary

The ionization constant of water has been determined at 25° from the electromotive force of cells without liquid junction and found to be equal to $(0.988 \pm 0.004) \times 10^{-14}$.

A new method has been outlined for the determination of the ionization constants of weak electrolytes from the electromotive force of cells without liquid junction.

THE AMMONATES OF COPPER SELENITE[1]

BY LOREN C. HURD, GEORGE I. KEMMERER AND V. W. MELOCHE

RECEIVED JUNE 30, 1930 PUBLISHED OCTOBER 6, 1930

As a part of the study of selenium and its compounds being made at this Laboratory, it was thought that an investigation of the compounds formed by the action of ammonia on the metallic selenates and selenites might yield results of interest. The present report deals with the compounds formed by the action of ammonia on copper selenite.

During the course of an investigation of a number of ammonates of metallic salts, Boutzaureanu[2] prepared a monammonate monohydrate of

[1] Abstracted from a portion of a thesis submitted to the Faculty of the Graduate School of the University of Wisconsin in partial fulfilment of the requirements for the degree of Doctor of Philosophy, 1929. This work was started under the direction of the late Victor Lenher, continued under the supervision of the late George Kemmerer, and completed under the guidance of Professor V. W Meloche.

[2] Boutzaureanu, Ann. *chim. phys.*, 6, 18, 346 (1889).

copper selenite. His method of preparation was to dissolve copper selenite in ammonium hydroxide and to allow the resulting dark blue solution to evaporate. The residue was a blue product corresponding in composition to the formula $CuSeO_3 \cdot NH_3 \cdot H_2O$.

Preparation of Copper Selenite **Dihydrate.**—The direct neutralization of selenious acid with copper carbonate or precipitated copper oxide yielded a flocculent green precipitate, the color and composition of which varied with the preparation. Boutzaureanu[2] converted this basic salt to the normal dihydrate by subjecting it to the action of a 5% solution of selenious acid in a closed bomb at a temperature of 250° for two hours. It was found that although this method yielded the normal dihydrate, it was usually contaminated with small amounts of elementary selenium. Inasmuch as almost all of the preparations to be described were checked on the weight conversion basis, it was necessary to devise a method of preparation which would yield pure copper selenite dihydrate in large quantities.

The most satisfactory method for the preparation of copper selenite was to add to a hot 15% solution of selenious acid a saturated solution of copper acetate. The flocculent green precipitate first formed immediately redissolved and precipitated the slightly soluble copper selenite dihydrate. The product was filtered on a sintered glass plate, washed with a 1% solution of selenious acid and then with distilled water. Analysis of the air-dried product yielded results in harmony with the calculated values for the dihydrate. In some cases the water content was slightly higher than the calculated percentage. In such cases the selenium and copper content was correspondingly low. The methods of analysis used through the work have been described in an earlier paper.[3]

The Hydrated Ammonates of Copper Selenite

Copper Selenite Diammonate Monohydrate.—Fifty grams of copper selenite dihydrate was dissolved in 50 cc. of concentrated ammonium hydroxide and the solution transferred to an eight-inch pyrex tube. The tube was placed in a thermostat at 60° and a rapid stream of ammonia gas passed into the solution. Following the evaporation of the bulk of the liquid there remained a mass of blue crystals. The product was removed from the tube, transferred to a sintered glass filter and pressed dry by means of a piece of rubber dental dam tied over the top of the funnel. Following the removal of most of the liquid, the product was placed over freshly ignited time for one hour. Analysis of the material yielded results in accord with the calculated values for $CuSeO_3 \cdot 2NH_3 \cdot H_2O$.

Anal. Calcd. for $CuSeO_3 \cdot 2NH_3 \cdot H_2O$: CuO, 32.76; Se, 32.61; NH_3, 14.02. Found: CuO, 32.42; Se, 32.20; NH_3, 14.45 (all av. of 3 detns.).

Copper selenite diammonate monohydrate was a blue crystalline salt, the color of which was slightly lighter than the B shade of the normal tone of Mulliken's color standards.[4] It was very unstable. Traces of moisture caused a liberation of ammonia with

---

[4] Mulliken, "Identification of Pure Organic Compounds," John Wiley and Sons, Inc., New York, 1904, Color Charts, Vol. I.

the formation of lower ammonates and basic salts. The ammonate was not completely soluble in water but dissolved readily in acids and ammonia solution. It was insoluble in liquid ammonia.

Copper selenite diammonate monohydrate was also prepared by the action of anhydrous ammonia gas on copper selenite dihydrate at 25°. The product was usually slightly moist in spite of prolonged exposure over desiccating agents in an atmosphere of ammonia. The compound when prepared in this manner usually contained slightly more water and ammonia than the calculated amounts.

Passage of ammonia into an ammoniacal solution of copper selenite did not yield a precipitate until the solution was cooled below 10°. Below this temperature a mass of crystals was obtained which when warmed melted to a blue viscous liquid. Analysis of numerous samples did not yield results in harmony with values calculated from any simple formula. Analysis of acid solutions of the product indicated the copper selenite–ammonia ratio to be as 1:3.

Copper Selenite **Monammonate** Monohydrate.—Solutions of copper selenite containing an excess of ammonia were allowed to evaporate slowly at room temperatures. After a short time a green deposit was formed on the sides and bottoms of the crystallizing dishes. Analysis of the product indicated that it consisted essentially of a basic copper carbonate. A few small crystals were deposited over the bulk of the green scale. Analysis of these products yielded results in approximate agreement with values calculated from the formula $CuSeO_3 \cdot NH_3 \cdot H_2O$. However, when solutions of copper selenite in carbon dioxide-free ammonium hydroxide were allowed to evaporate out of contact with air, a large mass of green crystals was obtained. Analysis of this product substantiated the formula assigned by Boutzaureanu.[2]

Anal. Calcd. for $CuSeO_3 \cdot NH_3 \cdot H_2O$: CuO, 35.25; Se. 35.07; NH_3, 7.54 Found: CuO, 35.13; Se, 34.95; NH_3, 7.67 (all av. of 3 detns.).

Copper selenite monammonate monohydrate so prepared was a dark greenish-blue crystalline mass. It was not readily soluble in water but dissolved easily in dilute mineral acids and ammonia solution. It was not altered by prolonged exposure to air and remained unchanged over phosphorus pentoxide. The compound was also prepared by exposing $CuSeO_3 \cdot 2NH_3 \cdot H_2O$ to the air. Ammonia was evolved and analysis of the light green powder remaining indicated that its composition was the same as that of the salt prepared in the manner of Boutzaureanu.[2]

Anal. Calcd. for $CuSeO_3 \cdot NH_3 \cdot H_2O$: CuO, 35.25; Se, 35.07; NH_3, 7.54. Found: CuO, 34.94; Se, 35.05; NH_3, 7.67 (all av. of 3 detns.).

Anhydrous Ammonates of Copper Selenite

Copper Selenite **Diammonate.**—$CuSeO_3 \cdot 2NH_3$ was prepared from $CuSeO_3 \cdot 2NH_3 \cdot H_2O$ in the same manner in which Dennis and Koller[5] prepared $CuSeO_4 \cdot 4NH_3$ from $CuSeO_4 \cdot 4NH_3 \cdot H_2O$. Samples of $CuSeO_3 \cdot 2NH_3 \cdot H_2O$ were placed in a soda lime desiccator and the system held at a pressure of about 15 mm. for six days. Analysis of the residue established the composition of the compound.

Anal. Calcd. for $CuSeO_3 \cdot 2NH_3$: CuO, 35.39; Se, 35.23; NH_3, 15.15. Found: CuO, 35.29; Se, 35.21; NH_3, 15.15 (all av. of 3 detns.).

Copper selenite diammonate is a light blue compound, the color of which matches closely the color GB, tint 1 of Mulliken's charts.[4] The compound is quite stable, samples losing little weight after prolonged desiccation over soda lime or phosphorus pentoxide. When treated with water a basic precipitate was formed and only a small portion of the sample dissolved. It was insoluble in liquid ammonia but reacted with ammonia gas to form higher ammonates.

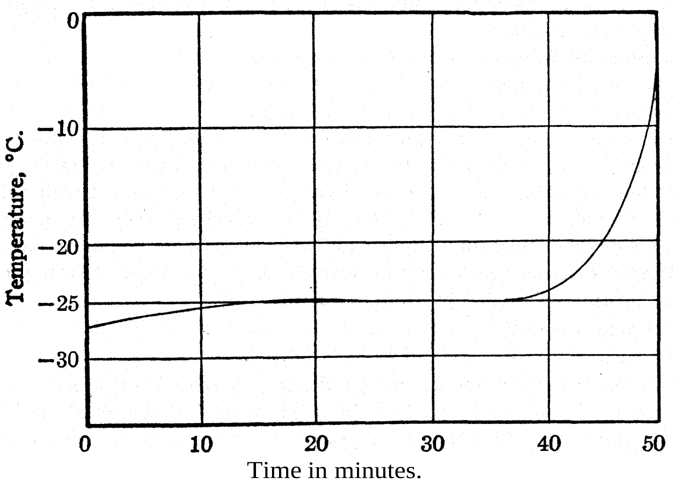
---

[5] Dennis and Koller, THIS JOURNAL, 41, 949 (1919).

Copper Selenite Triammonate.—It was found that either $CuSeO_3\cdot 2NH_3$ or $CuSeO_3\cdot NH_3\cdot H_2O$ would react with ammonia gas at 0° to form an ammonate of higher ammonia content. In the case of $CuSeO_3\cdot NH_3\cdot H_2O$ water was liberated. From the volume of ammonia absorbed by a given weight of the diammonate it was found that the stable phase at 0° was $CuSeO_3\cdot 3NH_3$.

Twenty grams of $CuSeO_3\cdot NH_3\cdot H_2O$ were treated with a rapid stream of anhydrous ammonia gas at 25° to remove the water and form the anhydrous diammonate. Following the removal of the water the reaction tube was immersed in an ice-bath and treatment with ammonia gas continued. Analysis of the product indicated that the formula of the addition compound was $CuSeO_3\cdot 3NH_3$.

Anal. Calcd. for $CuSeO_3\cdot 3NH_3$: CuO, 32.90; Se, 32.75; NH_3, 21.12. Found: CuO, 32.96; Se, 32.69; NH_3, 20.93 (all av. of 2 detns.).



Pig. 1.—$CuSeO_3\cdot 4NH_3$ to $CuSeO_3\cdot 3NH_3$.

Copper selenite triammonate so prepared had a bright blue color midway between the GB and B normal tone colors of Mulliken's charts.' The ammonate was partially soluble in water. It was relatively unstable and decomposed into the diammonate and ammonia when stored at room temperature. The transition point was found to be in the neighborhood of 19.8'.

Copper Selenite Tetrammonate.—Fifty grams of copper selenite dihydrate was placed in an eight-inch pyrex test-tube and treated with ammonia gas at a temperature of 60°. After eight hours' passage of the gas, the product was removed, crushed and the ammonia treatment continued until the last traces of water had been removed. The tube was then cooled and immersed in a Dewar flask containing liquid ammonia. Passage of gas through the mass was continued until there seemed to be no further absorption. Anhydrous liquid ammonia was then condensed in the tube and the suspension thoroughly stirred. Following removal of the liquid, large samples were quickly removed and sealed into tubes. The tubes were weighed, broken under dilute acid and analysis of the solution made in the usual manner.

Anal. Calcd. for $CuSeO_3\cdot 4NH_3$: CuO, 30.74; Se, 30.59; NH_3, 26.31. Found CuO, 30.39, 30.12; Se, 30.25, 30.01; NH_3, 25.50, 25.86.

Inasmuch as analytical results on preparations of the tetrammonate were seldom in good agreement, it was thought advisable to investigate the warming curve of the system $CuSeO_3.4NH_3$–$CuSeO_3.3NH_3$ between the temperature of boiling liquid ammonia and 0". Accordingly approximately 50 g. of the ammonate was prepared in the manner described. When the excess of ammonia had been removed, the material was quickly mixed with 15 g. of $CuSeO_3 \cdot 3NH_3$ and the system allowed to warm slowly. Temperature was indicated by a toluene thermometer and recordings were taken every thirty seconds. Figure 1 shows a plot of the results obtained in a typical run. The transition point for the system fell at $-25 \pm 1°$. It is interesting to note that the product may be warmed to 0° in the absence of decomposition products. Figure 2 is illustrative of the type of curve obtained when the triammonate inoculation was not made.

Copper Selenite Monammonate.—All anhydrous ammonates of copper selenite were found to decompose at or below 120° to yield $CuSeO_3 \cdot NH_3$. The compound was most conveniently prepared by heating $CuSeO_3 \cdot 2H_2O$ in an atmosphere of ammonia at a temperature of 60". When the water had been removed, the temperature was raised to 120" and the passage of gas continued for several hours. Analysis of the residue established the identity of the salt.

Anal. Calcd. for $CuSeO_3 \cdot NH_3$: CuO, 38.29; Se, 38.11; NH_3, 8.19. Found: CuO, 38.20; Se, 37.99; NH_3, 8.17 (all av. of 3 detns.).

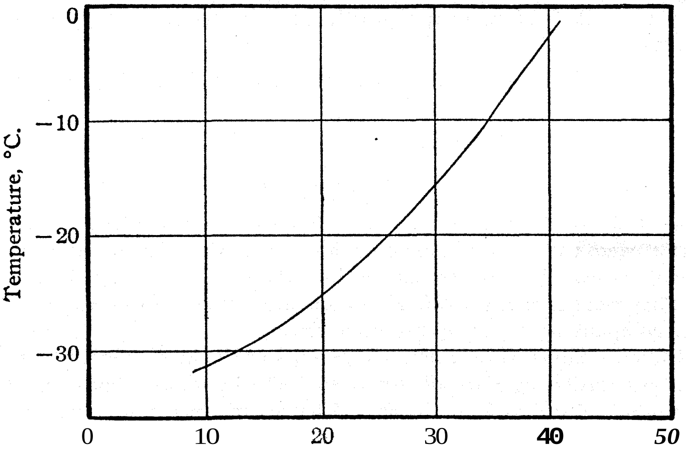


Fig. 2.—Warming curve for $CuSeO_3 \cdot 4NH_3$ in the absence of decomposition products.

$CuSeO_3 \cdot NH_3$ was a green powder when prepared in the manner described. The color was close to the BG, normal tone of Mulliken's charts.' It was insoluble in water and soluble in dilute mineral acids and ammonia solution. $CuSeO_3 \cdot NH_3$ absorbed ammonia below 120° to form higher ammonates. The compound was stable at ordinary temperatures and could be exposed to the air with little alteration. Above 150" $CuSeO_3 \cdot NH_3$ was decomposed with the liberation of ammonia and the production of reduction products of copper selenite.

Summary

1. A new hydrated ammonate of copper selenite, $CuSeO_3 \cdot 2NH_3 \cdot H_2O$, has been prepared and identified.

2. Four new anhydrous ammonates of copper selenite, $CuSeO_3 \cdot NH_3$,

$CuSeO_3 \cdot 2NH_3$, $CuSeO_3 \cdot 3NH_3$ and $CuSeO_3 \cdot 4NH_3$ have been prepared, identified, and their ranges of stability determined.

3. Evidence has been given for the existence of a new hydrated ammonate having the general formula $CuSeO_3 \cdot 3NH_3 \cdot xH_2O$.

4. The work of Boutzaureanu has been checked and the existence of $CuSeO_3 \cdot NH_3 \cdot H_2O$ substantiated.

THE ACTIVITY COEFFICIENTS OF CESIUM CHLORIDE AND HYDROXIDE IN AQUEOUS SOLUTION[1]

BY HERBERT S. HARNED AND ORION E. SCHUPP, JR.

RECEIVED JUNE 30, 1930 PUBLISHED OCTOBER 6, 1930

The present investigation comprises the evaluation of the activity coefficients at 25° of cesium chloride and hydroxide from measurements of the cells

$$Ag \mid AgCl \mid CsCl(m) \mid Cs_xHg \mid CsCl(0.1) \mid AgCl \mid Ag \qquad \text{(Type I)}$$

and

$$H_2 \mid CsOH(m) \mid Cs_xHg \mid CsOH(0.05) \mid H_2 \qquad \text{(Type II)}$$

Experimental

Cells.—Cells of the type developed by MacInnes and Beattie,[2] Harned,[3] Knoble[4] and Åkerlöf[5] were used. A vacuum technique was always employed and all solutions were boiled in *vacuo* before introduction into the cells. Each cell had a capacity of 100 cc. They were carefully dried before each measurement so as to avoid the waste of solution accompanying the usual method of rinsing.

Electrodes.—Silver–silver chloride electrodes of the kind referred to as Type II in a recent investigation by Harned[6] were used. The hydrogen electrodes were of platinized platinum foil 0.7 by 3 cm. in size. The cesium amalgams were made either by electrolysis of the chloride in a vessel containing a porous cup which served to separate the anode and cathode solutions, or by the electrolysis of cesium hydroxide. Some of the measurements of the cells containing cesium chloride were made with a 0.01% amalgam, while others were obtained by employing a 0.1% amalgam. Both strengths yielded good consistent results, although the potentiometer readings were somewhat difficult to obtain with the 0.01% amalgam. On the other hand, it is important to note that although the 0.1% amalgam gave satisfactory results in the hydroxide solutions, the more dilute amalgam did not.

Cesium Chloride.—This was obtained from the mineral pollucite, $H_2O \cdot 2Cs_2O \cdot 2Al_2$-

$O_3 \cdot 9SiO_2$, by slightly modifying the methods of Godeffroy[7] and Wells,[8] so as to obtain readily the pure chloride. The finely ground mineral was treated with strong hydrochloric acid and evaporated to small volume on a hot-plate. This strongly acid solution was somewhat diluted, filtered and poured into three to four times its volume of boiling ammonium hydroxide solution in order to precipitate the aluminum. By adding the acid solution to the ammonium hydroxide instead of the reverse process, the precipitate could be very rapidly filtered onto a large Biichner funnel and readily washed with boiling water. The solution was then evaporated to small volume, the ammonium salts removed by nitric acid and the alkali salts converted to the chloride by repeatedly evaporating with hydrochloric acid. This mixture of cesium and other alkali metal chlorides was concentrated and the strongly acid solution treated with antimony trichloride to precipitate the insoluble double salt, $3CsCl \cdot 2SbCl_3$. This salt was hydrolyzed with several changes of water, giving an acid solution containing the cesium chloride together with a little antimony trichloride, but almost free from other alkali salts. Hydrogen sulfide was used to remove the last of the antimony and the solutions evaporated to dryness to obtain the very nearly pure cesium chloride.

For further purification, a concentrated solution of the practically pure chloride was heated with an equivalent weight of iodine and chlorine bubbled into the solution until precipitation of the $CsCl_2I$ ceased. Recrystallization yielded a salt free from other alkali metals, and it was then decomposed into pure cesium chloride by heating. Chloride analyses on the final product calculated to CsCl varied from 99.85 to 100.06% on different samples of salt.

The cesium chloride prepared as described above was used directly, or was converted to the hydroxide. The chloride and hydroxide used in the measurements were recovered in the form of the chloride in the following manner. The solutions were evaporated to dryness on the hot-plate, making certain that an excess of hydrochloric acid was present when hydroxide had been used. This residue was taken up with water and hydrogen sulfide bubbled into the solution to precipitate any dissolved silver, mercury, etc., and the solution filtered and again evaporated. At this point the solution was sometimes evaporated to dryness, the solid scraped out, ground in a mortar, ignited and used for further experiments. At other times the solution was taken nearly to dryness, and the greater part of the salt remaining in solution precipitated as a fine, crystalline product by the addition of considerable 95% alcohol. The material thus obtained was dried in the oven, and then ignited as in the previous case, to obtain the salt ready for use.

Cesium Hydroxide.—Dilute cesium hydroxide—0.1 and 0.05 molal—was prepared by treating a weighed portion of cesium acid sulfate with just enough half normal barium hydroxide solution to react completely, keeping the solutions at all times out of contact with carbon dioxide. The solution thus prepared was filtered through asbestos, carefully tested for sulfate and barium ions, and either sulfuric acid or barium hydroxide added when necessary. This solution was again filtered, analyzed and diluted with boiled distilled water to the desired concentration.

The cesium acid sulfate was obtained by treating the cesium chloride with sulfuric acid, evaporating until all excess sulfuric acid was removed and the acid sulfate slightly decomposed. The salt thus obtained was dissolved in a minimum of hot water and precipitated by the addition of a very considerable quantity of alcohol. This yielded a material which could be dried in the oven, readily ground and mixed and titrated for acid content. From this single analysis, and the assumption that the salt was a mixture of pure cesium acid sulfate and normal cesium sulfate, the amount of barium hydroxide solution required to react with the sulfate in a given amount of salt was calculated, and

---

[7] Godeffroy, *Ber.*, 7, 375 (1874).

[8] Wells, *Am. Chem. J.*, 26, 265 (1901).

the two quantities of materials allowed to react. The assumption was evidently correct, for tests of the solutions thus obtained showed only faint traces of either barium or sulfate ions.

The more concentrated cesium hydroxide solution was prepared in a similar way. A hot barium hydroxide solution of about 1.5 molal concentration was prepared and analyzed as accurately as possible. To a weighed amount of this solution an equivalent amount of cesium acid sulfate was added and the two allowed to react. After allowing the barium sulfate to settle, the clear hydroxide solution was siphoned off through an asbestos filter into a second flask, where it was treated with additional barium hydroxide or sulfuric acid until the solution was practically free from an excess of either sulfate or barium ions. This solution was filtered through asbestos as before, analyzed and diluted with boiled distilled water to make solutions of the desired concentrations.

The Activity Coefficient of Cesium Chloride.—Table I contains the electromotive forces, E, of cells of Type I. These are the mean of the number of measurements given in Col. 4. Column 5 shows the maximum variation of the readings from the mean. Column 6 contains the activity coefficients computed by Hiickel's equation[9]

TABLE I

THE ACTIVITY COEFFICIENTS OF CESIUM CHLORIDE SOLUTIONS

1 Molality of CsCl	2 Normality of CsCl	3 E	4 No. cells	5 Max. diff.	6 Hückel	7 Obsd	8 Harned	9 Diff., mv.

1.5	1.4078	.11925	2	.01	.507	.507	.505	.00
2.0	1.8405	.13228	2	.02	.488	.491	.486	.32
2.5	2.2538	.14214	2	.16	(.476)	(.476)	.475	.11
3.0	2.6511	.15020	1	...	.467	.464	.470	.33

For Hiickel's equation, $A = 0.52$; $B = 0.0160$. For Harned's equation, $\alpha = 0.063$; $\beta = 0.333$; $\alpha' = 0.400$.

$$\log \gamma = -\frac{0.354\sqrt{2c}}{1 + A\sqrt{2c}} + B(2c) - \log(1 + 0.036m) \qquad (1)$$

The constants A and B given in the table were obtained by the usual method from the electromotive forces of the 0.1, 1 and 2.5 molal cells. Column 7 contains the activity coefficient computed from the reference value of 0.747 at 0.1 M obtained from Hiickel's equation by the well-known equation for the cell, namely

$$E = 0.1183 \log \frac{\gamma m}{0.747 \times 0.1} \qquad (2)$$

---

[9] Hückel, *Phys. Z.*, 26, 123 (1925).

Further, since we desire the vapor pressures of the solutions for further studies, and since Hückel's equation is complicated for this calculation, we include values computed by Harned's[10] equation

$$\log \gamma = -\beta m^{\alpha'} + \alpha m \tag{3}$$

The constants β, α' and α are given at the bottom of the table. It is clear that in the concentration range of 0.05 to 3 M this equation holds satisfactorily.

The agreement between the observed values and those computed by Hückel's equation is very good as evidenced by the differences in mvs. given in Col. 9. That the activity coefficient of cesium chloride falls in the expected place in respect to the other chlorides is shown by Fig. 1, where the results are plotted along with those obtained by Harned for potassium, sodium and lithium chlorides,[11] and by Randall and Young for hydrochloric acid.[12]

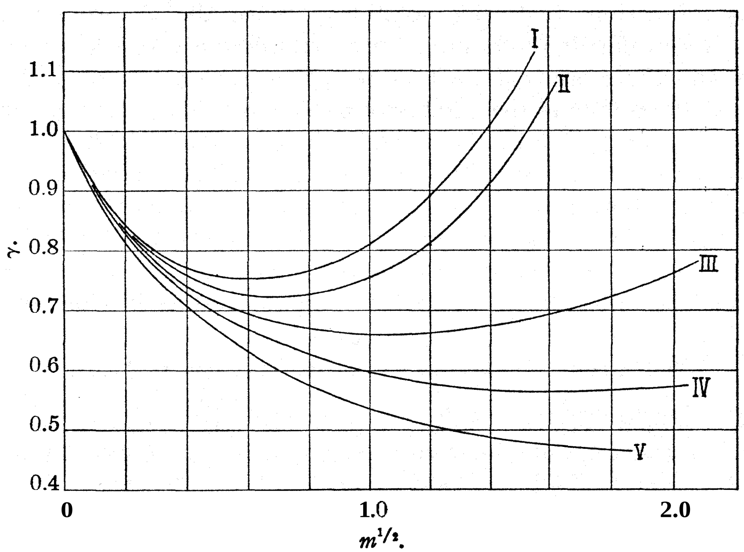

Fig. 1.—The activity coefficients of the alkali chlorides: I, HCl; II, LiCl; III, NaCl; IV, KCl; V, CsCl.

The Activity Coefficient of Cesium Hydroxide in Aqueous Solution.—The electromotive forces of cells of Type II are related to the activity coefficients according to the equation

$$E = 0.1183 \log \frac{\gamma_{\text{CsOH}(m_1)}}{\sqrt{a_{\text{H}_2\text{O}(m_1)}}} \cdot \frac{\sqrt{a_{\text{H}_2\text{O}(m_0)}}}{\gamma_{\text{CsOH}(m_0)}} \times \frac{m_1}{m_0} \tag{4}$$

---

[10] Harned, This Journal, 42, 1080 (1920).

[11] Harned, *ibid.*, 51, 416 (1929).

[12] Randall and Young, *ibid.*, 50, 989 (1928).

Since the activity of water is proportional to its vapor pressure, we may write

$$E + 0.05915 \log \frac{p_{H_2O(m_1)}}{p_{H_2O(m_0)}} = 0.1183 \log \frac{\gamma_{CsOH(m_1)}}{\gamma_{CsOH(m_0)}} \tag{5}$$

We are interested in computing both γ_{CsOH}, and γ'_{CsOH}, or γ_{CsOH}/a_{H_2O}. For the former, we must use Equation 5 and for the latter Equation 4, which may be written

$$E = 0.1183 \log \frac{\gamma'_{CsOH(m_1)}}{\gamma'_{CsOH(m_0)}} \times \frac{m_1}{m_0} \tag{4a}$$

Table II contains the observed electromotive forces, E, and the values of γ' computed by Hückel's equation and from the observed electromotive forces by Equation 4a. Column 2 contains measurements of the density of cesium hydroxide solutions. Since the electromotive force values were difficult to obtain, a curve was drawn through the observed values and the more consistent values given in Col. 5 were read off this plot. Column 6 gives the number of measurements of each cell, and Col. 7 the deviation (+) from the mean. The 0.05, 0.5402 and 1.3205 molal cells were used to evaluate the constants in Hückel's equation which are given at the bottom of the table. Column 8 contains the values of γ' computed by Hückel's equation, Col. 9 the values of γ' calculated by Equation 4a by employing 0.831 as the reference value at 0.05 M, and Column 10 similar values computed from the results in Column 5.

Constants for Hückel's equation: A = 0.94; B = 0.0663.

There remains the calculation of γ according to Equation 5, which necessitates a knowledge of vapor pressures of the solutions. The method employed to determine the corrections to the electromotive forces, AE, corresponding to the second member on the left of Equation 5 was the same as that used by Harned.[13] The constants, a, β and d of Equation 3

---

[13] Harned, THIS JOURNAL, 47,676 (1925).

were evaluated and the logarithms of the vapor pressure ratios were computed by the equation

$$\ln \frac{p_0}{p} = \frac{m}{55.5}\left[2 + 2.303\alpha m - \frac{4.605\ \alpha'\beta}{\alpha' + 1}\ m^{\alpha'}\right] \qquad (6)$$

From the values of p thus obtained, AE was evaluated. Table III contains the results. Column 2 contains the corrections, AE, Col. 3, the corrected electromotive forces obtained by subtracting AE from the corresponding values of E given in Col. 5, Table II. Column 4 contains the values of γ computed by Hiickel's equation, Col. 5 the values of γ

Constants for Hiickel's equation: A = 0.97; B = 0.0604.
Constants for Harned's equation: a = 0.152; β = 0.260; a' = 0.362.

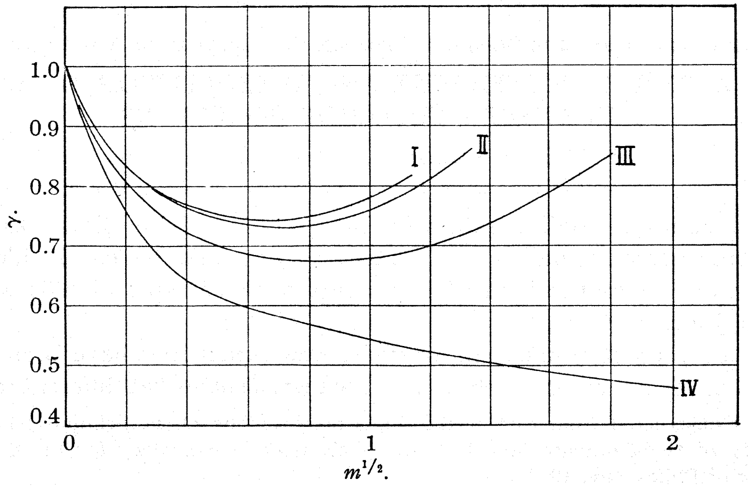

Fig. 2.—The activity coefficients of the alkali hydroxides. I, CsOH; II, KOH; III, NaOH; IV, LiOH.

computed from the observed electromotive forces by employing the reference value of 0.831 at 0.05402 molal concentration. Column 6 contains the values of γ computed by Harned's equation. The constants A, B, α, β and α' are given at the bottom of the table.

In Fig. 2 the activity coefficients of the alkali hydroxides have been plotted against $m^{1/2}$. The activity coefficient of cesium hydroxide lies somewhat higher at all concentrations but close to that of potassium hydroxide. The general rule that the hydroxides show the reverse distribution to the chlorides is verified.

Summary

1. The activity coefficients of cesium chloride and hydroxide in aqueous solution at 25° have been obtained by measurements of the cells,

$$Ag/AgCl/CsCl(m)/Cs_xHg/CsCl(m_0)/AgCl/Ag, \text{ and}$$
$$H_2/CsOH(m)/Cs_xHg/CsOH(m_0)/H_2$$

respectively.

2. The constants of Hückel's equation have been obtained from these results.

3. The constants of Harned's equation have been computed. From these, the vapor pressures of the chloride solutions may be calculated. The vapor pressures of the hydroxide solutions have been computed.

4. Both the chloride and hydroxide activity coefficients are of the expected order of magnitude, and conform with the distribution of the same quantities in the cases of the other alkali chloride and hydroxide solutions

THE ACTIVITY COEFFICIENT AND DISSOCIATION OF WATER IN CESIUM CHLORIDE SOLUTIONS[1]

By Herbert S. Harned and Orion E. Schupp, Jr.

Received June 30, 1930 Published October 6, 1930

In a series of studies, values for the variation of the dissociation and the ionic activity coefficient of water in some uniunivalent halide solutions were computed from measurements of three types of cells without liquid junction.[2]

In the present communication these same quantities have been determined in cesium chloride solutions. Further, a somewhat different method

---

[1] Constructed from part of the thesis presented by O. E. Schupp, Jr., to the Faculty of the Graduate School of Yale University in candidacy for the degree of Doctor of Philosophy, 1930.

[2] (a) Harned, This Journal, 47, 930 (1925); (b) Harned and Swindells, *ibid.*, 48, 126 (1926); (c) Harned and James, *J. Phys. Chem.*, 30, 1060 (1926).

of calculation has been employed which shows that the determined values depend only on strict thermodynamic principles and one experimentally demonstrated proposition. Secondly, as a check, an alternate method has been employed. We shall proceed directly to a consideration of the experimental results, and let the procedure of calculation develop during this discussion.

The Activity Coefficient of Hydrochloric Acid in Cesium Chloride Solutions.—The electromotive forces of the cells

$$\mathrm{Ag} \mid \mathrm{AgCl} \mid \mathrm{HCl}(0.01),\ \mathrm{CsCl}(m) \mid \mathrm{H_2} \mid \mathrm{HCl}(0.01) \mid \mathrm{AgCl} \mid \mathrm{Ag} \qquad \text{(Type I)}$$

are related to the activity coefficients and concentrations involved by the equation

$$E = 0.1183 \log \frac{\gamma_{\mathrm{HCl}}}{0.904} \frac{(m + 0.01)}{0.01} \qquad (1)$$

This double cell was not measured directly but was obtained by subtracting the electromotive force of the cell

$$\mathrm{H_2} \mid \mathrm{HCl}(0.01),\ \mathrm{CsCl}(m) \mid \mathrm{AgCl} \mid \mathrm{Ag} \qquad (E_1)$$

from that, E_0, of the same cell containing 0.01 M hydrochloric acid only. The results are given in Table I. The headings of the columns are self-explanatory. The final column contains the activity coefficients calculated by Equation 1 from the value of 0.904 at 0.01 M given by Randall and Young.[3] The measurements were carried out with the usual type of cell, and the electrodes made in the usual manner. Up to a concentration of 0.7 M cesium chloride the measurements proved to be very satisfactory. At this concentration and above, reproducibility decreases with increasing salt concentration.

[3] Randall and Young, THIS JOURNAL, 50, 989 (1928).

That the results obtained are in accord with expectations is shown by Fig. 1, in which γ of hydrochloric acid in alkali halide solutions is plotted against the square root of the ionic strength. The cesium chloride curve falls in the expected position.

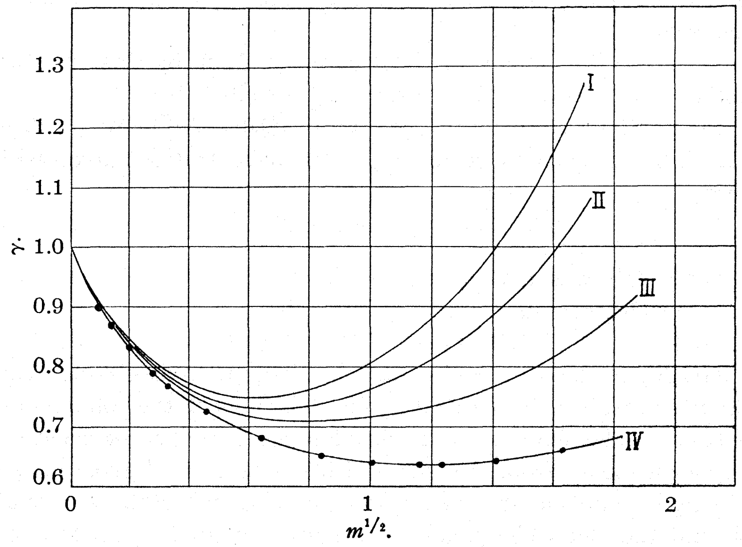

Fig. 1.—The activity coefficient of hydrochloric acid in alkali chloride solutions: I, LiCl; II, NaCl; III, KCl; IV, CsCl.

The Activity Coefficient of Cesium Hydroxide in Cesium Chloride Solutions.—The electromotive forces of the cells

$$H_2 \mid CsOH(m_0),\ CsCl(m) \mid Cs_xHg \mid CsOH(m_0) \mid H_2$$

may be employed to determine the activity coefficient of cesium hydroxide in cesium chloride solutions by means of the equation

$$E = 0.1183 \log \frac{\gamma'}{\gamma'_0} \frac{(m_0 + m)}{m_0} \qquad (2)$$

$$= 0.1183 \log \frac{\gamma}{\gamma_0} \frac{(m_0 + m)}{m_0} + 0.06915 \log \frac{a_{H_2O(0)}}{a_{H_2O}} \qquad (3)$$

γ is equal to $\sqrt{\gamma_{Cs}\gamma_{OH}}$, γ' equals $\sqrt{\gamma_{Cs}\gamma_{OH}/a_{H_2O}}$ in the salt solutions, and γ'_0 and γ_0 are like quantities in the pure hydroxide solution of concentration m_0. To evaluate the second member on the right of Equation 3, we have made use of the method of Harned[4] for evaluating the vapor pressure ratio of cesium chloride solutions. The constants of Harned's equation were obtained from Table I, and the calculations made by Equation 6 of a previous communication.[5] This necessitated the assumption that the vapor pressures of 0.05 and 0.1 M cesium hydroxide solutions

---

[4] Harned, This journal, 44, 252 (1922).

[5] Harned and Schupp, *ibid.*, 52, 3886 (1930).

were the same as those of the corresponding strengths of the chloride solutions. Since the term under consideration is small, this assumption introduces no appreciable error. Two series of results were obtained with cesium hydroxide solutions of **0.05** and **0.1** M, respectively, of which the **0.05** series occurs in Table II. Since it was necessary for further calculation to know γ' at concentrations corresponding to the hydrochloric acid–cesium chloride system, the observed electromotive forces were used to construct a curve from which the results in Col. **3** were obtained. Column 5 contains the vapor pressure ratio from which the second member in the right of Equation **3** was computed.

The Ionic Activity Coefficient and Dissociation of Water in Cesium Chloride Solutions.—It has been shown by Harned[6] that even at high concentrations log γ of hydrochloric acid in a uni-univalent chloride solution at constant total molality varies linearly with the acid concentration. This statement is given by the equation

$$\log \gamma = \alpha m_1 + \log \gamma^0 \tag{4}$$

in which α is a constant, m_1 is the acid concentration and log γ^0 is the logarithm of the activity coefficient of hydrochloric acid at zero concentration in the halide solution of concentration m. Harned and Harris[7]

---

[6] **Harned, THIS JOURNAL, 48,326 (1926).**

[7] **Harned and Harris, *ibid.*, 50,2633 (1928).**

found that in the case of very concentrated sodium and potassium hydroxide solutions there is a small deviation from this law. This makes no theoretical difference since the only information we require is the value of log γ^0, and, consequently, if the results can be extrapolated to zero concentration of hydroxide by a function which fits the experimental material, the data necessary for our calculation are available. In the present instance we make no error greater than the experimental by assuming that Equation 4 represents the correct relationship both in the case of the acid and hydroxide.

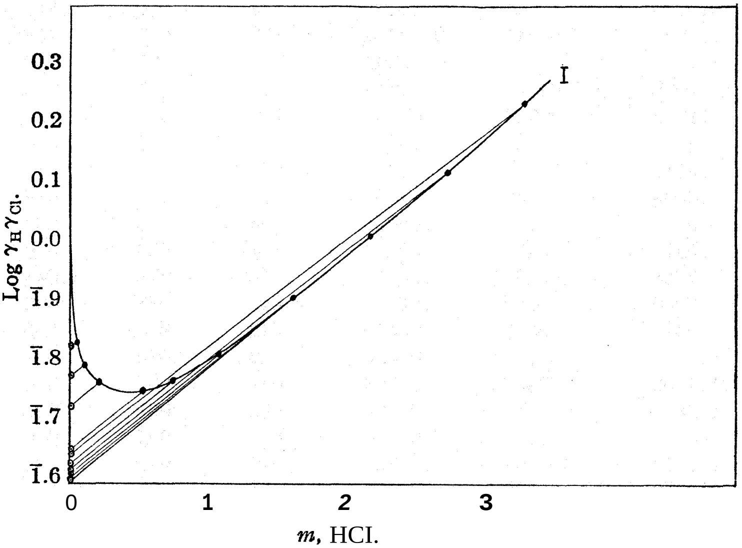

Fig. 2.—m_{HCl}– log $\gamma_H\gamma_{Cl}$ plots at constant total molalities.

In Fig. 2 the logarithm of the square of the activity coefficient of hydrochloric acid in pure aqueous solution (shaded circles) and of 0.01 M hydrochloric acid in cesium chloride solutions of the same total concentration (circles) are plotted against the acid concentration. The straight lines are drawn through the corresponding points at the same constant total molality. The parallel character of these plots leaves nothing to be desired. A short extrapolation to zero acid concentration gives 2 log γ^0 or log $\gamma^0_{H^+}\gamma^0_{Cl^-}$.

In Fig. 3 similar plots have been drawn in the case of cesium hydroxide and the hydroxide–chloride results. The extrapolation gives us the value of 2 log $\gamma^{0\prime}$ or log $\gamma^0_{Cs^+}\gamma^0_{OH^-}/a_{H_2O}$.

It is very important to observe that both $\gamma^0_{H^+}\gamma^0_{Cl^-}$ and $\gamma^0_{Cs^+}\gamma^0_{OH^-}/a_{H_2O}$ are now known in the pure aqueous cesium chloride solutions. Consequently, they may be multiplied to obtain $\gamma^0_{H^+}\gamma^0_{OH^-}\gamma^0_{Cs^+}\gamma^0_{Cl^-}/a_{H_2O}$. If this quantity be divided by $\gamma^0_{Cs^+}\gamma^0_{Cl^-}$ which. we have already evaluated in a previous communication,[5] we obtain $\gamma^0_{H^+}\gamma^0_{OH^-}/a_{H_2O}$, the ionic activity coefficient product of water in cesium chloride solutions, which we shall denote by $K_{\gamma(s)}$. This method is free of all assumptions extraneous to exact thermodynamics other than the use of Equation 4 to extrapolate to zero concentration of acid or hydroxide. The necessary condition for this calculation is that at constant molality the log γ may be extrapolated to zero acid or hydroxide concentration.

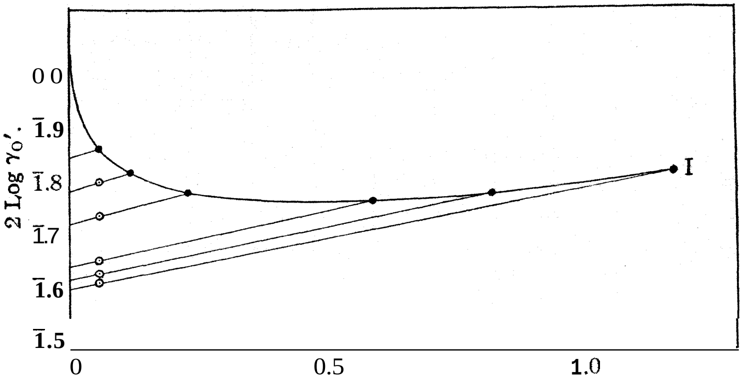

Fig. 3.—m_{CsOH}– **log** $\gamma_{Cs}\gamma_{OH}/a_{H_2O}$ **plots at constant total molalities.**

The thermodynamic equilibrium for the dissociation of water into ions is given by the equation

$$K = K_{\gamma(s)}\, m_{H^+} m_{OH^-} \tag{5}$$

Therefore, since $K_{\gamma(s)}$ has been computed, the variation of the dissociation of water with change in salt concentration may be evaluated. The results are given in Table III. Column 1 contains the total concentration of acid and salt, or hydroxide and salt; Col. 2 the value of γ^0_{HCl},

Column 6 contains the values of the activity of water calculated from the vapor pressures by the method of Harned. Column 7 contains the values of $\sqrt{\gamma_{H^+}\gamma_{OH^-}}$, and Col. 8 the values of the hydrogen- or hydroxyl-ion concentrations computed by Equation 5, and the value of 1.005×10^{-14} for the dissociation constant of water.

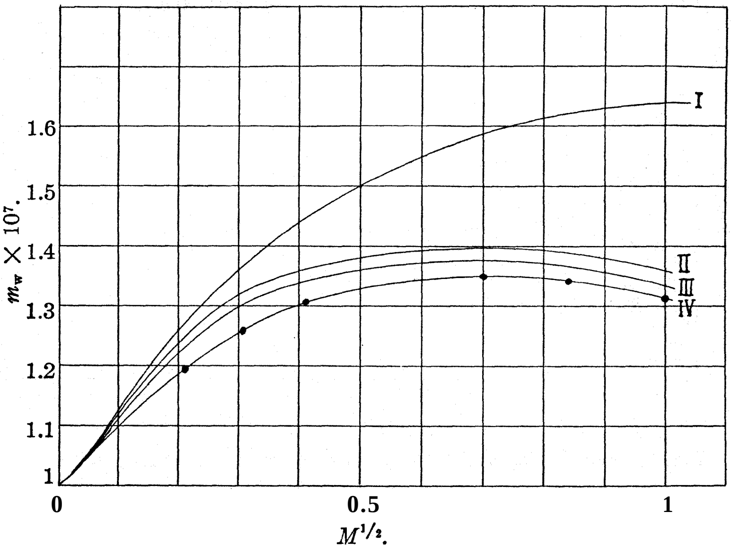

Fig. 4.—The hydrogen- or hydroxyl-ion concentrations in aqueous alkali chloride solutions: I, LiCl; II, NaCl; III, KCl; IV, CsCl.

In Fig, 4 are plotted the values of m_w for the cases of the alkaline chlorides up to 1.0 molal. The results for cesium chloride solutions conform to the expected distribution and show the characteristic maximum.

An Alternate Method of Evaluating the Ionic Activity Coefficient Product in a Salt Solution.—The electromotive force of the cell

$$H_2 \mid CsOH(m_0), CsCl(m) \mid AgCl \mid Ag$$

is given by the equation[8]

$$E = E_0 - 0.05915 \log \gamma_{H^+}\gamma_{Cl^-}m_{H^+}m_{Cl^-} \qquad (6)$$

If we substitute for m_{H^+}, its values derived from the thermodynamic equation for the dissociation of water into ions, namely, $Ka_{H_2O}/\gamma_{H^+}\gamma_{OH^-}m_{OH^-}$, we obtain

$$\left[E + 0.05915 \log \frac{m}{m_0} - E_0\right] = -0.05915 \log Ka_{H_2O} - 0.05915 \log \frac{\gamma_{H^+}\gamma_{Cl^-}}{\mathrm{YE}+\sim \mathrm{OH}-} \qquad (7)$$

E_0 is the standard electromotive force of the cell, which we **take** to be 0.2225, and K is the dissociation constant of water. If we plot the left-

---

[8] The first measurements of this type of cell were made in this Laboratory by Dr. Elliott J. Roberts, This Journal, 52, 3877 (1930).

hand member of this equation against μ, its value at zero μ is equal to 0.05915 log K, since at zero ionic strength a_{H_2O} is unity and by reason of the definition of activity coefficients the second member on the right of the equation vanishes. If we rearrange this equation as follows

$$0.05915 \log \frac{\quad}{a_{H_2O}} = E - E_0 + 0.05915 \left[\log \frac{m}{m_0} + \log K + \log \gamma_{H^+}\gamma_{Cl^-}\right] \qquad (8)$$

it is clear that the ionic activity coefficient product of water, $\gamma_{H^+}\gamma_{OH^-}/a_{H_2O}$, in the cesium chloride solution may be evaluated, since $\gamma_{H^+}\gamma_{Cl^-}$ in this salt solution may be obtained from Table III.

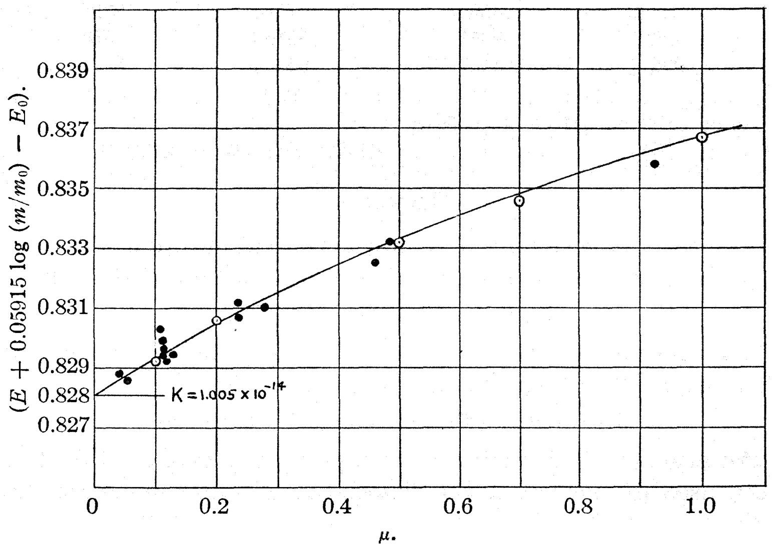

Fig. 5.—Plot of the left side of Equation 7 against the ionic strength.

The cell measurements are given in Table IV, Col. 3. Column 4 contains the values of $(E + 0.05915 \log (m_{Cl^-}/m_{OH^-}) - E_0)$ obtained from them. Even though careful vacuum technique was employed, the measurements were not entirely satisfactory. The electromotive force rose quickly to a maximum and then slowly fell off. The maximum values were recorded. We have, therefore, not employed the results to compute $\gamma_{H^+}\gamma_{OH^-}/a_{H_2O}$. On the other hand, we have computed the value of $(E + 0.05915 \log (m_{Cl^-}/m_{OH^-}) - E_0)$ from the values of $\gamma_{H^+}\gamma_{Cl^-}$ contained in Table I, $\gamma_{H^+}\gamma_{OH^-}/a_{H_2O}$ given in Table III and the value of 10^{-14} for K. In Fig. 5 we have plotted these values which are given in Table IV against the ionic strength, μ (circles). The inked in circles are the results obtained by the second method and given in Col. 4, Table IV. Up to 1.0 *M* the agreement with our previously determined values is good although there is a scattering of ±0.5 mv. in the results.

Summary

1. The activity coefficient of hydrochloric acid in cesium chloride solutions at 25° has been determined from measurements of the cells

$$H_2/HCl(m_0),\ CsCl(m)/AgCl/Ag$$

2. The activity coefficient of cesium hydroxide in cesium chloride solutions at 25° has been obtained from the cells

$$H_2/CsOH(m_0),\ CsCl(m)/Cs_xHg/CsOH(m_0)/H_2$$

3. An exact method, similar to that previously employed by Harned, has been used for computing the dissociation of water in cesium chloride solutions.

4. Another method for determining the ionic activity coefficient product and dissociation of water in salt solutions has been described which employs cells of the type

$$H_2/MOH(m_0),\ MCl(m)/AgCl/Ag$$

Measurements of such cells containing cesium hydroxide and chloride have been made, and it is shown that the results conform with those of the method previously used.

5. The values for the dissociation of water in cesium chloride solutions conform with those previously obtained in the cases of the other alkali halides.

THE ACIDITY OF MONO AND DIAMMONIUM PHOSPHATES

BY T. R. BALL

RECEIVED JUNE 30, 1930 PUBLISHED OCTOBER 6, 1930

It is well known that many samples of diammonium phosphate contain varying amounts of the mono salt. The only test bearing upon the ammonia–phosphate ratio in the diammonium salt which the writer has been able to find is that of the Committee on Analytical Reagents of the American Chemical Society.[1] According to this test, 1 g. of the salt in 10 ml. of water should give a pink color with 2 drops of phenolphthalein solution. This is in no sense a measurement of P_H. The salt effect on the indicator is unknown and the intensity of the color is not specified. The present paper presents data upon the P_H of mono and diammonium phosphates. For both salts in dilute solutions this was obtained by titration of phosphoric acid with ammonia, and in addition the P_H of pure diammonium phosphate at various concentrations was measured with the hydrogen electrode. For higher concentrations, the colorimetric indicator method has been used.

Materials and Procedures

An approximately 0.10 *N* solution of phosphoric acid was made by dilution of a high grade analyzed sample, and its weight normality as a dibasic acid was determined by conversion to magnesium pyrophosphate.

49 915 g. of soln. yielded 0.2854 g. of $Mg_2P_2O_7$; wt n. = 0.1027
49 943 g. of soln. yielded 0.2854 g. of $Mg_2P_2O_7$; wt. n. = 0.1026

A solution of freshly distilled ammonia was used in the titration of the phosphoric acid. It was standardized roughly against hydrochloric acid. In titrating phosphoric acid with ammonia, using a hydrogen–calomel electrode system, the first break in the curve, corresponding to the monoammonium salt, is so sharp as to make the accurate standardization of the ammonia unnecessary. Having determined the volume of reagent required to produce $NH_4H_2PO_4$, it is only necessary to double this to get the point on the curve corresponding to $(NH_4)_2HPO_4$. Because of the volatility of ammonia, this procedure seemed advisable. All e. m. f. measurements were made with a Leeds and Northrup students' potentiometer.

It is impossible to titrate in an open vessel in a stream of hydrogen because of the loss of ammonia in the more alkaline solutions. Consequently a rocking electrode vessel was designed consisting of a pyrex tube 13.5 cm. long and 4.3 cm. in diameter, having a capacity of 160 ml. This tube was sealed at both ends and had three tubulatures in the side for the insertion of a hydrogen electrode, a buret and a salt bridge. It was mounted horizontally on a small shelf attached to a vertical strip of wood 120 cm. long, which served as a pendulum, with its center of oscillation just below the shelf. A strip of sheet brass, with sharpened edges, ran through the wood to serve as a knife-edge which had bearing upon a metal arm clamped to the edge of the laboratory table. A heavy lead weight was attached to the lower end of the pendulum to lower the center of gravity. The huret was supported by clamps to that portion of the strip which projected above the electrode vessel. A hydrogen electrode of platinized platinum was inserted through a

---

[1] *Ind. Eng. Chem.*, 19, 645 (1927).

rubber stopper in tubulature No. 1 and a fine-tipped buret in No. 2. A potassium chloride bridge making contact with the calomel electrode, passed through one hole of a rubber stopper in No. 3. This bridge had a glass stopcock which was kept closed except while the e. m. f. measurement was being taken. A 30.5-cm. length of soft rubber tubing in the bridge and also in the hydrogen line gave sufficient flexibility to cause no interference with the rocking of the electrode. A hydrogen exit tube in the second hole of stopper No. 3 dipped about 1 mm. beneath the surface of mercury in a small vial standing upright on the shelf to prevent back-diffusion of air when the hydrogen stream was cut off. In operating, a weighed quantity of the phosphoric acid solution was placed in the vessel and a rapid stream of purified tank hydrogen was passed for about thirty minutes. By swinging the pendulum the vessel was rocked through an angle sufficiently large to cause complete submersion of the hydrogen electrode. Readings were taken at intervals until equilibrium was established and at this point the hydrogen stream was cut off and the titration started by running in ammonium hydroxide from the buret.

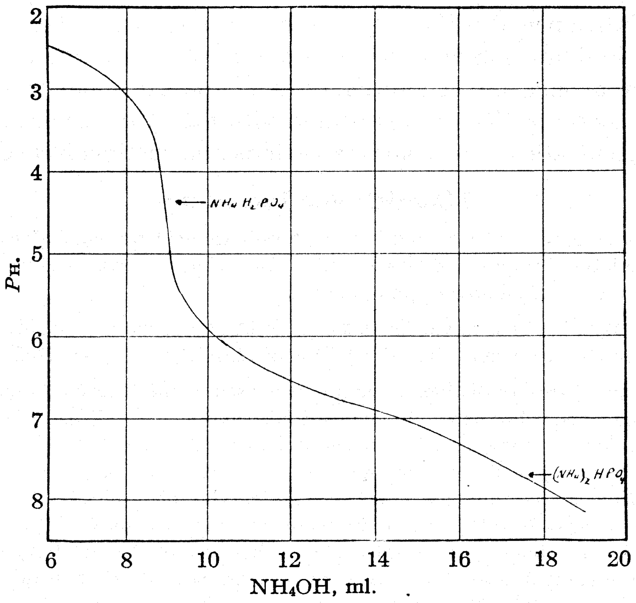

Fig. 1.—Titration curve of phosphoric acid with ammonia.

One source of error that was anticipated with this set-up was the diffusion of ammonia from the buret tip. A very slight upward drift in the potential was observed if the hydrogen electrode was left for some time without intermittent, complete submersion, but by rocking the vessel several times, the original reading could be obtained.

Two curves were run, one of which is shown in Fig. 1. The P_{H} of monoammonium phosphate was found to be 4.35 in each case. It will be noted that there is no break at the equivalence point for diammonium phosphate, because of the hydrolysis of the salt.[2] By finding the point on the curve corresponding to twice the volume of ammonia required to produce the mono salt, the P_{H} of the diammonium salt could be determined. Each curve showed a P_{H} of 7.75 for this salt. The concentrations of the diammonium phosphate were 1.65 and 4.34 g. per liter, respectively, at the end-points

---

[2] Buchanan and Winner, *J Ind.* Eng. *Chem.*, 12,448 (1920).

of the two titrations. These values will be referred to later in connection with the effect of concentration upon the acidity.

The test of the Committee on Analytical Reagents makes use of a solution containing 1 g. of diammonium phosphate in 10 ml. The above titration method could scarcely be applied to such high concentrations. Consequently, a high grade. analyzed, commercial sample of diammonium phosphate was carefully analyzed for ammonia and phosphorus in order to establish the ratio of these two constituents. Difficulty was encountered in getting check results, especially for ammonia, when small samples of the dry salt were taken. This was undoubtedly due to the fact that the salt was not uniform. Finally, a 25-g. sample was diluted to 250 ml. and the solution weighed. Weighed portions of this solution were analyzed for phosphorus by conversion to magnesium pyrophosphate, and for ammonia by distillation into standard acid. Five analyses which did not differ from the mean by more than 0.15% showed 0.007553 mole of phosphorus per gram of salt; calcd. for $(NH_4)_2HPO_4$, 0.007568 mole per gram. Two determinations of ammonia showed 0.01481 and 0.01481 mole per gram; calcd., 0.01514 mole per gram; ratio $NH_4 : P = 1.96:1$. The salt, in addition to being deficient in ammonia, probably contained enough water to lower the percentage of phosphorus.

A solution was made from the original salt by taking a sample of sufficient size to yield exactly 50 g. of pure diammonium phosphate after fortification with the calculated amount of standard ammonia required to make up the deficiency. This solution was then diluted to 500 ml. to give a solution of the concentration used by the Committee. Four other solutions were made from this by successive dilution and the PH of each was determined by the hydrogen electrode in the rocking vessel already described. For these determinations, the apparatus was modified by inserting a two-holed stopper in tubulature No. 2. One hole carried the buret and the other a siphon tube with a pinchcock. This made it possible to remove the solutions through the siphon and replace them by others from the buret without admitting air. The vessel was flushed out with at least three 50-ml. portions of solution before the PH measurements were made. The PH of the most concentrated solution was also determined colorimetrically with cresol red and phenol red. The results are shown in Table I.

TABLE I

THE PH OF DIAMMONIUM PHOSPHATE AT VARIOUS CONCENTRATIONS

Soln.	Concn., g. per liter	Concn., moles per liter	PH Hydrogen elect.	Cresol red	Phenol red
1	100	0.7568	8.01	8.3	8.1
2	40	.3027	7.89		
3	20	.1514	7.84		
3a	4.34	.0328	7.75[a]		
4	4.00	.0303	7.77		
4a	1.65	.01249	7.75[a]		
5	0.80	.00605	7.72		

[a] Solutions 3a and 4a were produced by titration.

The data of Table I are plotted in Fig. 2. The dots on the curve are points found by dilution of the pure salt and the crosses designate titration data. The maximum deviation from the smooth curve is 0.025 unit of PH. From 0.8 to 20 g. per liter the PH is almost a linear function of log $1/C$; above this concentration the PH increases rapidly to 8.01 at 100 g. per liter.

The salt error for cresol red is very marked in the concentrated solution

(100 g. per liter), being +0.29 unit of *P*H. Ramage and Miller[3] have noted an effect of +0.25 unit on this indicator in solutions of alkali chlorides of 2.5% concentration, and Wells'[4] data show errors of the same order. Phenol red shows a salt error of only 0.09 unit. Either of these indicators could be used empirically to test the ammonia–phosphate ratio, but neither gives the correct PH in solutions of the concentration used by the committee.

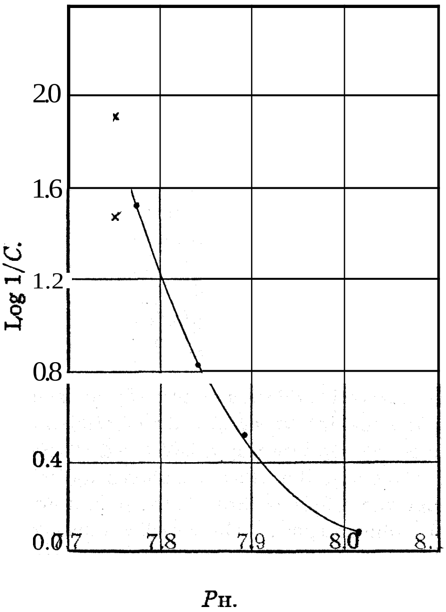

Fig. 2.—The effect of concentration upon the *P*H of $(NH_4)_2HPO_4$ solutions.

Ten ml. of the pure diammonium phosphate solution (1 g. in 10 ml.) gave a pink color with 2 drops of phenolphthalein, (10 g. in 1 liter of 95% alcohol) which was removed by 0.30 ml. of 0.10 *N* sulfuric acid. The solution contained a total of 0.007568 mole of the diammonium salt. Only 0.00003 mole, or 0.38%, would be converted into the mono salt by the acid required to decolorize the solution. The test of the Committee, therefore, appears to be sufficiently accurate for all practical uses. A word might be added regarding the use of diammonium phosphate as a precipitant for zinc. Ball and Agruss[5] have shown that zinc is best precipitated at a *P*H between 6.5 and 6.9. The titration curve of Fig. 1 shows that in this range of acidity from 30 to 50% of the excess phosphate would exist as the monoammonium salt. Obviously the usual precaution of applying the phenolphthalein test is not necessary.

Summary

The *P*H values of diammonium phosphate solutions, ranging in concentration from 0.8 to 100 g. per liter, have been determined.

At concentrations up to 20 g. per liter, the *P*H is almost a linear function of log 1/*C* and increases with the concentration. Above 20 g. per liter the *P*H increases rapidly.

The test of the Committee on Analytical Reagents of the American Chemical Society is accurate, within about 0.4%.

Cresol red shows a salt error of +0.29 unit when applied to the solution used by the Committee. Phenol red shows an error of 0.09 P_H unit,

In dilute solution, monoammonium phosphate has a P_H of 4.35.

A simple, inexpensive type of rocking electrode has been described.

EXPLOSIONS IN DETONATING GAS MIXTURES. I. CALCULATION OF RATES OF EXPLOSIONS IN MIXTURES OF HYDROGEN AND OXYGEN AND THE INFLUENCE OF RARE GASES[1]

BY BERNARD LEWIS[2] AND JAMES B. FRIAUF[3]

RECEIVED JUNE 30, 1930 PUBLISHED OCTOBER 6, 1930

Historical

In the year 1381, Berthelot and Vieille[4] and independently Mallard and Le Chatelier[5] announced the discovery of the propagation of explosions in gas mixtures with speeds enormously greater than had been measured previously. These investigators were able to measure the speeds in a number of different mixtures by means of chronoelectric[6] and photographic[7] methods, respectively. Since then, Dixon and others[8] have continued these studies and have measured the velocity of propagation of the detonation wave in a large number of gas mixtures.

Properties of the Detonation Wave.—When certain inflammable gas mixtures are ignited at one end of a uniform tube, the initial slow movement of the flame is rapidly accelerated to a high speed, which remains constant, regardless of the length of the tube. The term "detonation wave" is applied to the propagation of a disturbance at this constant

speed. The following are among its more important properties. (1) When established, the detonation wave propagates with a constant velocity which depends upon the chemical and. percentage composition of the gas mixture. (2) The speed is independent of the material of which the tube is made. **(3)** The speed is independent of the diameter of the tube, if this is larger than a small limiting value. (4) The speed is practically independent of the initial pressure and temperature of the gas mixture. A three-fold variation in pressure near atmospheric or a variation in temperature from 10 to 100° introduces only a slight alteration in speed. (5) The speed is independent of conditions in the rear of the wave. It is immaterial whether inflammation is started at the closed or open end of the tube and whether ignition is produced by a flame, spark, detonator, shock wave or by some other means.

Therefore, the speed with which a detonation wave propagates is a physical constant of the particular gas mixture. It should be noted, however, that the period of combustion immediately preceding the establishment of the detonation wave is markedly influenced by many factors such as initial pressure, temperature, condition of the interior surface of the tube, diameter of the tube, composition of the mixture or method of ignition.

Theories **of the** Detonation Wave.—Betthelot and Vieille compared the speed of a detonation wave to the mean kinetic velocity of the molecules in the burned gases. This can be computed readily from the temperature attained in the combustion, but in many instances the speed thus calculated differs widely from the experimentally determined velocity of the detonation wave.

Dixon identified the speed of the detonation wave in gas mixtures with the velocity of propagation of sound at the high temperature created by the combustion. Although, for some cases, the calculated velocities agree with those actually found, for others they differ rather widely. It was soon recognized that the "sound-wave theory" was defective and inadequate.[9]

Very recently, Lewis[10] has developed a theory of the propagation by means of reaction chains. The complete reaction consists of a number of steps. The product of any one step is shot forward with a velocity corresponding to the energy of translation acquired by it and it then becomes a reactant in the next step. A similar active product or "carrier" is continually regenerated. The velocity of the "carrier" is shown to increase to a constant value, which is identified with the velocity of the detonation wave in the appropriate mixture. Consider, for example, a series of explosive mixtures of hydrogen and oxygen. It is found experimentally that the velocity of the detonation wave depends upon the concentrations of

[9] H. B. Dixon, *J. Chem. Soc.*, 97, 665 (1910).

[10] Bernard Lewis, THIS JOURNAL, 52, 3120 (1930).

hydrogen and oxygen and reaches a maximum value for a certain optimum composition, $8H_2 + O_2$. The final velocity of the "carrier" as computed by the chain-reaction theory is compared with the velocity of the detonation wave in this mixture of optimum composition. The calculated values agree very well with those found experimentally for a considerable number of different explosive mixtures. Although this picturization of the molecular mechanism in reaction chains is a step in advance, it is not easy to predict quantitatively velocities slower than that corresponding to the optimum composition mentioned above. This theory is, therefore, not to be regarded as complete, but rather as an attempt to visualize the chemical reactions occurring in the detonation wave.

A widely applicable theory was developed independently by Chapman[11] and Jouguet.[12] This theory is essentially hydrodynamical and furnishes no satisfactory explanation of the extreme rapidity with which chemical reactions occur in gaseous explosions. It would seem that a fusion of the chain reaction and the Chapman–Jouguet theories is necessary for an understanding of two striking phenomena in explosions. These are (1) the extreme rapidity of chemical reaction in the wave front, and (2) the high speed of the detonation wave. The view is held[10,13] generally that explosive reactions occur in a series of chains in which an active product of one reaction is continually used and regenerated in succeeding reactions. The chain-reaction theory is able to account rather generally for very high rates of chemical reaction.[13] Granted a high rate of chemical reaction, the Chapman–Jouguet theory is able to predict the velocity of the detonation wave. In this fusion of the two theories it is only necessary to find a "carrier" in a reaction chain that will propagate the chemical reaction through an infinitesimal element of volume in a period not greater than that required for the detonation wave to sweep across this volume. This combination of the two theories will introduce no change in the equations developed in the Chapman–Jouguet theory.

The velocities calculated by Jouguet[12] agreed reasonably well with those found experimentally. However, his more recent calculations[14] using specific heat data given by Kast, in some instances, give velocities in less satisfactory agreement with experiment than the earlier calculations.

In view of the importance of the problem of the mechanism of deto-

nations in gases, it has seemed worth while to repeat these calculations using the best specific heat data of today and taking into account dissociation of the products. Because in this paper we deal solely with the combustion of hydrogen and oxygen mixtures, either by themselves or admixed with inert gases, the dissociations which occur to an appreciable extent at the temperatures developed and which will be considered are

$$2H_2O \rightleftharpoons 2H_2 + O_2 \quad (1)$$
$$2H_2O \rightleftharpoons H_2 + 2OH \quad (2)$$
$$H_2 \rightleftharpoons 2H \quad (3)$$

The Chapman–Jouguet Theory.—To facilitate an understanding of the method used to calculate the velocity of the detonation wave, it seems desirable to give a brief account of the Chapman–Jouguet theory.[15] Consider a plane explosion wave traveling in a tube with velocity V. The coordinate axes will be assumed to move with the wave front, which is consequently stationary in this coördinate system. AB and CD in Fig. 1 are two planes immediately ahead of and behind the wave front. Let p_1, v_1, T_1, u_1 and E_1 be the pressure, specific volume, absolute temperature, velocity with respect to the moving coördinate system, and specific internal energy of the unburned gases, respectively; and p_2, v_2, T_2, u_2 and E_2 the corresponding quantities for the burned gases. Since it is assumed that the unburned gases are at rest in a stationary system of coordinates, $u_1 = -V$. The experimental results indicate that the detonation wave is of permanent type. Assuming that this is the case, it is immediately possible to write the following three equations which state that the mass, momentum and energy of the matter contained between the planes AB and CD do not change with time

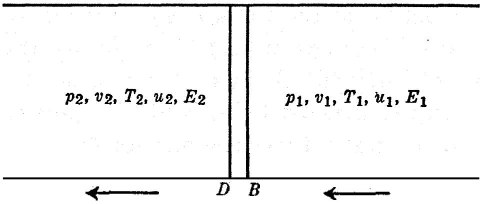

Fig. 1.—Diagram illustrating detonation wave front.

$$\text{Mass} \qquad \frac{u_1}{v_1} = \frac{u_2}{v_2} \quad (1)$$
$$\text{Momentum} \qquad \frac{u_1^2}{v_1} + p_1 = \frac{u_2^2}{v_2} + p_2 \quad (2)$$
$$\text{Energy} \qquad E_1 + \frac{u_1^2}{2} + p_1v_1 = E_2 + \frac{u_2^2}{2} + p_2v_2 \quad (3)$$

It will be initially assumed also that the chemical reaction proceeds to completion and that the composition of the burned gases is consequently

---

[15] In view of the equivalence of the relations developed by Chapman and Jouguet. it seems preferable to refer to the Chapman–Jouguet theory rather than the Jouguet theory, even though Chapman's investigations are less comprehensive, An excellent account of this theory is given by R. Becker, Z. *Physik*, 8,321 (1922).

known. This furnishes the value of n_2, the number of moles per gram to be used in the equation of state

$$p_2v_2 = n_2RT_2 \tag{4}$$

These four equations give four relations between the five unknowns, V (or $-u_1$), u_2, v_2, p_2 and T_2, and an additional relation is consequently needed for their complete determination. Considerations based on mechanics and thermodynamics led jouguet to the conclusion that the required relation is

$$\frac{p_2 - p_1}{v_1 - v_2} = -\left(\frac{\partial p_2}{\partial v_2}\right)_{\text{ad}} \tag{5}$$

The additional relation which was obtained by Chapman from different considerations has been shown to be equivalent to this.

If it is assumed that the internal energy of the burned gases is a function of the temperature only, it follows that

$$E_2 - E_1 = \bar{c}_v(T_2 - T_1) - Q \tag{6}$$

where $\bar{c}_v$ is the mean specific heat of the burned gases between T_2 and T_1 and Q is the heat liberated by the reaction at constant volume, per gram of the explosive mixture. Also

$$\left(\frac{\partial p_2}{\partial v_2}\right)_{\text{ad}} = -\frac{\gamma_2 p_2}{v_2} \tag{7}$$

where γ_2 is the ratio of the specific heats for the burned gases at the temperature T_2. If

$$\mu = \frac{v_1}{v_2} \tag{8}$$

the equations given can be transformed to the forms

$$\mu^2 - \left(1 + \frac{1}{\gamma_2}\right)\mu + \frac{n_1T_1}{n_2T_2\gamma_2} = 0 \tag{9}$$

$$\bar{c}_v(T_2 - T_1) - Q - \frac{R}{2}(\mu - 1)\left(n_2T_2 + \frac{n_1T_1}{\mu}\right) = 0 \tag{10}$$

$$V = \mu\sqrt{\gamma_2 n_2RT_2} \tag{11}$$

$$\frac{p_2}{p_1} = \mu\frac{n_2T_2}{n_1T_1} \tag{12}$$

It will be seen that Equation 11 states that the velocity of the detonation wave is μ times the velocity of sound in the burned gases.

For the computation of V in the case of no dissociation, it is assumed that the combination of hydrogen and oxygen to form water vapor proceeds to completion. A value for T_2 is assumed and γ_2 for this temperature is calculated from the specific heats of the burned gas. These values for T_2 and γ_2, together with the known values of n_1, n_2 and T_1, are substituted in Equation 9, which is solved for μ. This value of μ is introduced in Equation 10, which is then solved to give an improved value of T_2. The calculations are repeated until values of μ and T_2 are found which satisfy both (9) and (10). The velocity of the detonation wave can then be found from (11) and the pressure, p_2, from (12).

The velocities for detonation waves were also calculated on the assumption that the chemical composition of the burned gases corresponds to equilibrium at the temperature and pressure attained in the wave front. The dissociation of water vapor into hydrogen and oxygen and into hydrogen and hydroxyl, and the dissociation of molecular into atomic hydrogen were considered.

Three additional variables are required to specify the chemical composition of the burned gases and three more equations are furnished by the conditions of equilibrium. By an extension of the method[16] of calculation outlined above, values for T_2, μ and the three variables which specify the composition of the burned gases are found which satisfy Equations 9 and 10 and the three conditions of equilibrium. These values can then be used to determine the velocity from Equation 11.

Two interpretations of $(\partial p_2/\partial v_2)_{ad}$ are possible when dissociation is considered. In the first, $(\partial p_2/\partial v_2)_{ad}$ is taken to mean the adiabatic change of pressure divided by change of volume for a gas of the invariable chemical composition found from the conditions of equilibrium. This interpretation leaves unchanged the equations which have been given and is the one which has been used for the calculation of velocities. The other interpretation is that $(\partial p_2/\partial v_2)_{ad}$ is to be taken on the assumption that the chemical composition of the gas changes during the adiabatic compression, so as to be in chemical equilibrium at all stages of the infinitesimal compression.

Consideration of the theory indicates that the second assumption is the one which should be used. The equations which have been given are valid for the first assumption; consequently, a strict interpretation of the theory requires that they be suitably modified in order to be in agreement with the second interpretation of $(\partial p_2/\partial v_2)_{ad}$. We have therefore calculated the velocity of detonation in a mixture of $2H_2 + O_2$ and in mixtures of $2H_2 + O_2$ diluted with six moles of hydrogen or five moles of oxygen, nitrogen, helium or argon, in two different ways. In one we have used the equations that are valid for the first interpretation of $(\partial p_2/\partial v_2)_{ad}$, and in the other, the equations that are valid for the second interpretation. In all these cases the differences between the velocities calculated in these two ways are less than 0.4%. We have therefore made all the other calculations using the first interpretation, because it is much simpler mathematically.

Choice of Data.—Eastman[17] has made an exhaustive critical study of the existing data on the specific heats of gases at high temperatures. The experimental data for diatomic gases are on the whole reasonably satisfactory up to 3000°K. As the calculated temperatures in the detonation

---

[16] Lack of space prevents a detailed description of the method used for dealing with the three-fold dissociation. It may prove desirable to treat this separately in another place.

[17] E. D. Eastman, Tech. Paper 445, U. S. Bureau of Mines, 1929.

wave are often considerably in excess of this temperature a certain amount of extrapolation is necessary. The final equations which we have adapted for the specific heats of hydrogen, oxygen and nitrogen were formulated on the basis that the specific heats at constant volume reach a value of 7 at 3000°K. and remain constant thereafter. The equations used in this investigation are

$$C_{v_{H_2}} = 4.65 + 0.492 \times 10^{-3}T + 0.319 \times 10^{-6}T^2 - 0.074 \times 10^{-9}T^3$$
$$C_{v_{N_2 \text{ or } O_2}} = 4.74 + 0.408 \times 10^{-3}T + 0.486 \times 10^{-6}T^2 - 0.1234 \times 10^{-9}T^3$$

up to 3000°K. For higher temperatures the constant value, 7, is employed. The specific heats obtained from these formulas are in substantial agreement with those given by Eastman's equations.

The experimental data on the specific heat of water vapor at high temperatures are not in as satisfactory a condition. Eastman has made this the subject of a special study and has kindly sent us a copy of his unpublished manuscript. His new equation follows closely the best experimental data up to about 2700°K., reaches a maximum for C_v of 12.18 at 2800°K., and then falls off slowly at higher temperatures. There is no experimental or theoretical basis for the falling off of specific heats at high temperatures. Furthermore, Wohl and von Elbe[18] have made a few new determinations which agree with Pier's results on which Eastman's formula is based mainly, but their numerical values do not agree with Eastman's, due to different considerations in the calculations. There is every indication that the specific heat approaches an asymptotic value. We have, therefore, adopted Eastman's formula and assumed that the maximum value reached at 2800°K. remains constant at higher temperatures. The formula is

$$C_{v_{H_2O}} = 6.33 - 6.53 \times 10^{-4}T + 2.70 \times 10^{-6}T^2 - 6.145 \times 10^{-10}T^3$$

The values for the heat content of water vapor calculated from this equation agree to within less than 6% with the values given by Wohl and von Elbe for temperature up to 5000°K.

Equilibrium Constants.—The equilibrium constant for the dissociation of water vapor into hydrogen and oxygen was recalculated, using the specific heat data given above. The free energy of water vapor has been calculated by several methods by Eastman.[19] His average value at 298°K. is $\Delta F_{298} = -54{,}467$ Cal. The heat of formation of water is $\Delta H_{291} = -57{,}826$ Cal.[20]

Three equations are necessary to cover this temperature range because of the form of the specific heat equations. The final equations used are

[18] K. Wohl and G. von Elbe, *Z. physik. Chem.*, 5B, 241 (1929).

[19] E. D. Eastman, Information Circular 6125, U. S. Bureau of Mines, 1929.

[20] "International Critical Tables," Vol. V, 1929, p. 176. The minus sign represents the evolution of energy.

Valid up to 2800°K.

$$\log K_{H_2O} = +\frac{57,295}{4.573T} - 0.848 \log T - 1.474 \times 10^{-4}T + 7.78 \times 10^{-8}T^2 - 8.72 \times 10^{-12}T^3 + 0.0616$$

Valid between 2800 and 3000°K.

$$\log K_{H_2O} = \frac{14,412}{T} + 2.0975 \log T - 7.610 \times 10^{-5}T - 2.047 \times 10^{-8}T^2 + 2.473 \times 10^{-12}T^3 - 10.4417$$

Valid above 3000°K.

$$\log K_{H_2O} = \frac{13317.3}{T} + 0.34492 \log T - 4.3285$$

The following data have been used to calculate the equilibrium constant for the dissociation of molecular into atomic hydrogen; entropy,[21] $S_{H_2\ (298)} = 31.25$; $S_{H\ (298)} = 27.4$; and $\Delta H_{298} = 103{,}500$ cal.[22]

The following equations are obtained from these data

Valid up to 3000°K.

$$\log K_{H_2} = -\frac{102,534}{4.573T} + 1.673 \log T - 0.5375 \times 10^{-4}T - 1.16 \times 10^{-8}T^2 + 1.350 \times 10^{-12}T^3 + 0.322$$

Valid above 3000°K.

$$\log K_{H_2} = 6.1622 - \frac{23,179}{T} + 0.4885 \log \frac{T}{3000}$$

An equation expressing the equilibrium constants for the dissociation of water vapor into H_2 and OH has been given by Wohl and von Elbe[18] and has been adopted here. F in the following equation is the Einstein function for the free energy of an harmonic oscillator. The figures in brackets are the values of $(h/k)\nu = \beta\nu$ calculated from the frequency of the absorption maxima in the infra-red.[23]

$$\log K_{OH} = -\frac{128,000}{4.573T} + 2.5 \log T + \frac{1}{4.573T}\,[F(6140) + 2F(5100) - 2(F(2280) + 2F(5330))] - 0.44$$

Wohl and von Elbe's equation has not been modified to conform with the specific heats used in this investigation because of the uncertainty in the heat of decomposition into OH and H_2.

It is to be emphasized that the specific heat data used in this investigation have not been calculated from the observed velocities of detonation waves, as was done by Chapman. If specific heats obtained in this way are used, it is to be expected that the calculated and observed velocities will be in close agreement. Our data have been derived from the independent sources mentioned above. Hence, the close agreement which we have found (see below) between the calculated and observed velocities for a number of explosive mixtures would seem to substantiate both the Chapman–Jouguet theory and the specific heat data used.

---

[21] These are unpublished values of Giauque, and were given to us through Dr. Eastman.

Fig. %.—Calculated velocities of detonation wave with excess nitrogen.

$2H_2 + O_2$. The second column contains the calculated velocity assuming that no dissociation occurs in the detonation wave. The third column contains the calculated velocity assuming three-fold dissociation as given above. The fourth column gives the experimental velocity determined by Dixon and others.[24] The fifth column gives the percentage deviation of the values in the third column from the experimental values.

Figures 2 and 3 show the data graphically. The circles represent the experimental points. It is seen that the agreement with the theory is exceptionally good.

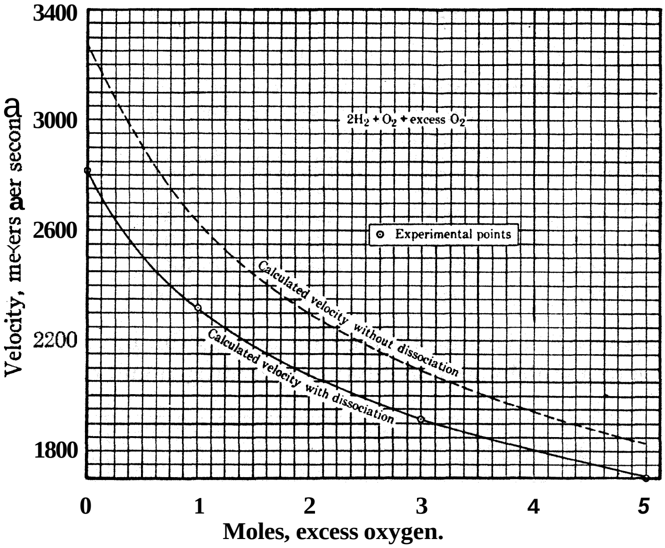

Fig. 3.—Calculated velocities of detonation wave with excess oxygen.

The velocities for the mixtures $2H_2 + O_2$ and $2H_2 + 6O_2$ were also calculated by assuming that equilibrium is attained for the reaction $2H_2 + O_2 \rightleftharpoons 2H_2O$ and neglecting the other two dissociations previously considered. The values calculated in this way are 3023 and 1793 meters per second, which are in much less satisfactory agreement than the values obtained by considering all three dissociations. These results indicate that it is important to consider dissociation in explosion phenomena. If the specific heat and free energy data are correct, the close agreement between the calculated and observed velocities would appear to justify the conclusion that *the explosion occurs as if equilibrium were reached for the three dissociations we have used.*

Table III and Fig. 4 show the results with excess hydrogen.

The agreement in the case of a large excess of hydrogen is not quite as

$+ 4H_2$	3769	3627	3527	+2.83
$+ 6H_2$	3802	3749	3532	+6.15

good. There are several possible reasons for this discrepancy. The experimental values for the mixtures with a large amount of excess hydrogen may be somewhat low. On the other hand, dissociation is almost negligible for these mixtures if equilibrium is assumed. It is quite possible that complete combustion is not realized in the wave front at these high speeds. If this is the case, the calculated values would be lower and more nearly in agreement with the observed. The incompleteness of the reaction may easily be enough to account for the difference. That there is incomplete reaction in the wave front is borne out by some direct photographs we have taken of the explosion with excess hydrogen. The photographs indicate a fair amount of combustion occurring behind the wave front, although not nearly as much as in an explosion of a $2H_2 + 1O_2$ mixture where the equilibrium falls far short of complete reaction.

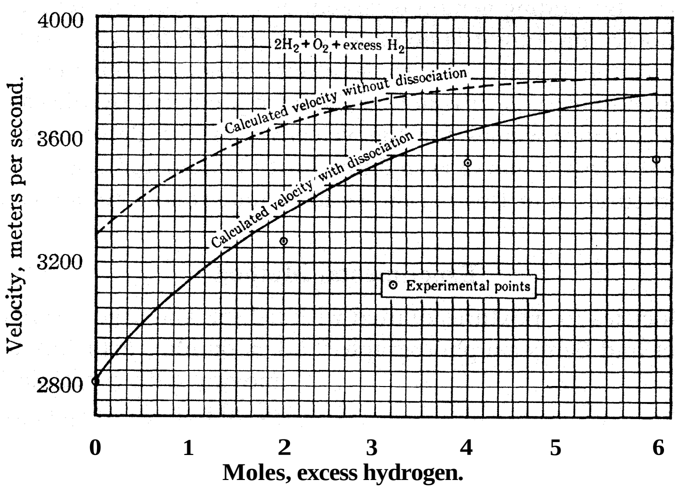

Fig. 4.—Calculated velocities of detonation wave with excess hydrogen.

The Effect of Helium and Argon.—The addition of helium and argon to the explosive mixture furnishes another means of checking the correctness of the Chapman–Jouguet theory. The theory indicates that the velocity of the detonation wave is proportional to the density of the gas mixture after combustion and to the absolute temperature reached in the wave front. If the inert gas helium be added to a mixture of $2H_2$ and $1O_2$, the velocity should increase as a result of the decreased density. On the other hand, argon, because of its greater density, should be expected to effect a decrease in the velocity. We have here the ordinarily unexpected result that two inert monatomic gases differing in atomic weight but identical in every chemical respect affect the velocity of the explosion in opposite directions. For the same quantities of added inert gas, the degree of dissociation and the heat capacities, and consequently T_2, γ_2 and μ, are the same. The calculated velocities for mixtures with an equal number of moles of helium and argon are therefore inversely proportional to the square root of the density of the burned gases.

To test the theory it is highly desirable to eliminate all variable factors except one. By adding helium or argon, or mixtures of helium and argon, to the explosive mixture it is possible to keep all factors constant with the exception of the density and to determine whether the dependence of velocity upon density is, or is not, of the form predicted by the theory.

No experimental values for the velocities of the detonation wave in mixtures of hydrogen and oxygen diluted with helium and argon were found in the literature. For this reason we have undertaken to determine their velocities.

Experimental Method

The velocities for mixtures diluted with helium and argon were obtained from direct and Schlieren photographs[25] taken on films attached to a drum moving with a peripheral speed of about 60 meters a second. Figure 5 is a sketch of the arrangement for the direct photographs. The explosion tube consisted of a thick-walled lead tube with an inside diameter of 19 mm. and of sufficient length to insure setting up the detonation wave of constant velocity. This was joined to a heavy pyrex glass tube of the same bore for the direct photographs and to a steel tube with a slit covered by a cellophane window for the Schlieren photographs. Both ends were closed by rubber stoppers which subsequently were blown out by the force of the explosion. An explosion traveling with constant velocity produces an inclined straight line on the film. The velocity of the detonation wave can be readily computed from the slope of this line, the speed of the drum and the constants of the optical arrangement.

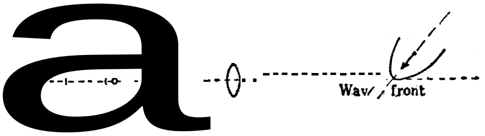

Fig. 5.—Apparatus for obtaining direct photographs of detonation waves.

---

[25] Töpler, *Wid. Ann.*, 131, 33 (1867).

The gases were taken from cylinders and mixed over water. The hydrogen and oxygen were of a high degree of purity, while the helium and argon contained (by analysis) 2.95 and 4.65% nitrogen, respectively, and no combustible gases, carbon dioxide or oxygen.

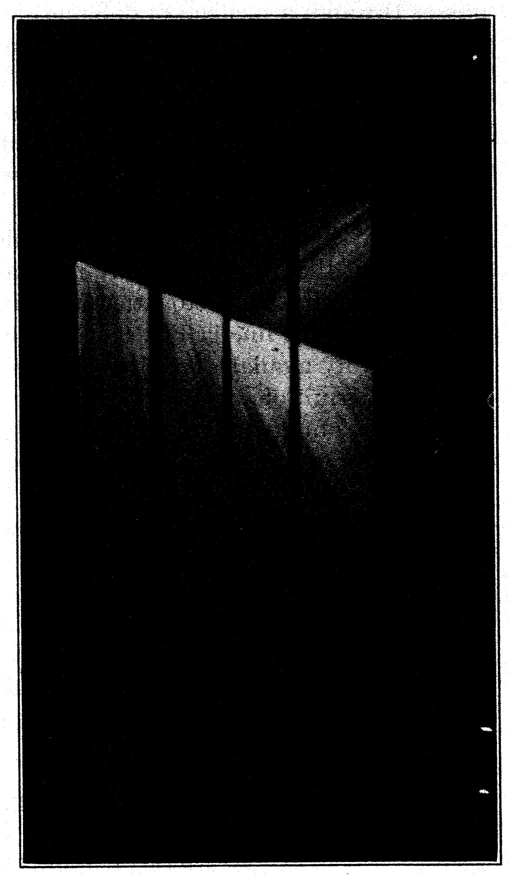

Fig. 6.—Photograph of explosion.

Figure 6 is a reproduction of a typical direct photograph. The dark vertical lines are due to strips of opaque paper placed at certain distances on the explosion tube. The upper inclined straight line represents the movement of the wave front. The lower straight line sloping in the opposite direction represents the wave reflected from the end of the tube. This travels with a reduced velocity in the partly burned medium. The photograph is an interesting one, for it can be used to give an estimate of the velocity of the gases in the rear of the wave. This velocity is obtained from the slope of the striations close to the upper straight line. Although the slope of the striations cannot be measured accurately because of its rapid rate of change, the value found for the velocity of the burned gases agrees reasonably well with the value calculated from the Chapman–Jouguet theory. The theoretical value for the velocity of the burned gases in a fixed coordinate system is

$$D = V - u_2 = \frac{\mu - 1}{} V$$

The passage of the reflected detonation wave causes more intense combustion in the burning gases. The directions of the wave and the burned gases are completely reversed. It will be observed that near the point where the reflection occurs, the velocity of the gases emitted from the reflected wave are nearly zero, due to the balancing effect of velocity of the gases from the original wave traveling in the opposite direction; but as the reflected wave meets gases with smaller and smaller velocities, the velocity of the gases emitted from it increases, as is clearly shown in the photograph. Here again the velocity of the gases falls off with time.

The Schlieren method depends upon the refraction of a beam of light as it passes through a medium of different density. The alteration of the density in the wave front is sufficient to change the direction of the beam from an arc lamp, causing it to enter the camera instead of impinging on a diaphragm. Schlieren photography has been used by W. Payman and his associates[26] in explosion experiments and will not be described in detail here. A steel tube was used, a narrow slit being cut at one end for a length of about 33 cm. to permit passage of the beam of light. The slit was covered with a cellophane window which was strong enough to remain intact until the detonation wave had passed.

The velocity of the detonation wave is determined from the slope of the inclined straight line in Fig. 6. The slopes obtained with the apparatus found readily available were not great enough, especially for the fast mixtures, to permit of any great precision in the determination of the velocity. The values obtained for a stoichiometric mixture of hydrogen and oxygen and also for mixtures containing excess oxygen and excess hydrogen are somewhat lower than those given in the literature. For this reason the results about to be given are to be considered preliminary in character and too great weight should not be attached to the lack of agreement between the calculated and observed velocities for mixtures diluted with helium and argon. With certain changes in technique that are contemplated, better experimental values can be obtained.

The experimental results in Table IV are an average of the velocities determined by both methods. They are compared with the calculated velocities with and without dissociation.

[26] Payman and Robinson, Safety in Mines Research Board Paper No. 18; Payman and Shepherd, *ibid.*, Paper No. 29. Payman, *Proc. Roy. Soc.* (London), 120A, 90 (1928).

It is observed that the predictions of the theory are verified qualitatively. In view of the preliminary nature of the experimental results this is perhaps all that could be expected. It is interesting to note, however, that the differences are in such a direction as to be accounted for by failure to attain equilibrium in the wave front. As more inert gas is added the dissociation is repressed owing to the lower temperature in the explosion. This effect is not as marked as it is with excess hydrogen, but it is possible that the presence of a large amount of inert gas prevents the attainment of equilibrium in the wave front, especially for those mixtures that possess a high velocity.

Acknowledgment.—The writers wish to acknowledge with pleasure their appreciation to W. C. F. Shepherd, investigator from the Safety in Mines Research Board, Great Britain, for his aid in taking these photographs and to D. B. Gawthrop for permission to use the Schlieren apparatus constructed by him and W. Payman of the Safety in Mines Research Board.

Summary

1. Velocities for the detonation wave in explosive mixtures of hydrogen and oxygen diluted with several gases have been calculated on the basis of the Chapman–Jouguet theory. Velocities have been computed for each of the two following assumptions: (a) the composition of the burned gases corresponds to complete combustion; (b) the composition of the burned gases corresponds to chemical equilibrium for the dissociation of water vapor into hydrogen and oxygen, and into hydrogen and hydroxyl, and for the dissociation of molecular into atomic hydrogen.
2. The calculated values for mixtures diluted with nitrogen and oxygen agree exceptionally well with the experimental values when dissociation is considered.
3. The calculated values for mixtures diluted with hydrogen are in good agreement for amounts of excess hydrogen up to four moles, but about 6% high for 6 moles of excess hydrogen. Possible reasons for the difference are suggested.
4. These results indicate the importance of dissociation phenomena in explosions.
5. The satisfactory agreement for these mixtures suggests further tests of the Chapman–Jouguet theory for mixtures diluted with helium and argon.
6. Direct and Schlieren photographs have been taken for mixtures containing various amounts of these inert gases, and the velocity of the detonation wave has been determined from them.
7. There is less satisfactory agreement with the theory than for the other mixtures. Although the predictions of the theory are verified qualitatively, the average difference between observed and calculated velocities

is about 8%. At least a part of this difference may be due to experimental error.

8. Further work is contemplated to obtain better experimental results.

QUENCHING OF THE FLUORESCENCE OF NITROGEN DIOXIDE

BY WARREN P. BAXTER[1]

RECEIVED JULY 5, 1930 PUBLISHED OCTOBER 6, 1930

Of late the photochemical decomposition of nitrogen dioxide into nitric oxide and oxygen has been the object of several investigations.[2] That the absorption spectrum of nitrogen dioxide in the visible and near ultraviolet regions of the spectrum is discrete is well known.[3] Recently, Mecke[4] and Henri[5] have noted that predissociation occurs in this gas, the bands first becoming diffuse between 3800 and 3700 Å. The light absorption process in this region corresponds to the beginning of formation of an excited molecule followed by immediate dissociation into nitric oxide and oxygen. Fluorescence is to be expected in nitrogen dioxide at sufficiently low pressures when one illuminates with wave lengths above the limit of predissociation. Indeed, due to the ineffectiveness of blue light, 4358 Å., in causing photodecomposition, Norrish was led to conclude that all of this light must be reradiated. Norrish[6] succeeded in obtaining the expected fluorescence which appears as a faint yellowish luminescence when nitrogen dioxide is illuminated with the 4358 and 4047 Å. lines of the mercury arc. The spectra emitted are identical under excitation by either λ4358 or 4047, consisting of two wide maxima at 6400 and 5900 Å., except that the intensity of the 5900 band is relatively more intense with the shorter wave length. With λ3660 there is only an extremely feeble fluorescence, also in this same region. The almost complete absence of fluorescence by this light is indeed in keeping with the idea that immediately after light absorption, dissociation of the excited molecule takes place.

The object of the present investigation is the study of the intensity of the fluorescence as a function of the pressure both of nitrogen dioxide itself and of added gases. Such measurements afford quantitative data concerning the efficiencies of deactivating collisions, quantities of considerable importance in chemical kinetics.

Experimental Arrangement

The fluorescence vessel was a pyrex tube, 4 cm. in diameter, with a fused-on plane end window and a side tube for applying liquid air. Connection was made through a stopcock to a reservoir of known volume (213.1 cc.) which led through a second cock to a liquid-air trap and a device for magnetically breaking small bulbs filled with nitrogen dioxide at a known pressure, and finally through another stopcock to a liquid-air trap and mercury diffusion pump. The method of introducing nitrogen dioxide was essentially that used previously.[7] The volume of the fluorescence vessel was 109.3 cc. Thus, once the fluorescence vessel had been filled with a known amount of nitrogen dioxide, the pressure could be reduced in definite steps by expansion into the evacuated reservoir. In this manner a complete set of runs could be made on a single sample of gas over the desired pressure range. Other gases (H_2, N_2, O_2, CO_2) were added from a bulb containing them through a stopcock buret. These gases were taken directly from tanks and purified by drying over phosphorus pentoxide.

The light source was a mercury arc run at atmospheric pressure. After the light had passed through suitable filters, it was collimated by lenses and diaphragms before entering the window of the fluorescence vessel. In order to observe the rather feeble fluorescence it was necessary to enclose the arc and completely darken the room

The intensity of the fluorescence was determined by a method of visual photometry. A beam of light from a small filament passed through two Nicol prisms, one of which could be rotated, and struck a small piece of cardboard placed between the eye of the observer and the path of the irradiating light as outlined by the fluorescence. The point in the beam at which the comparison of intensities was made was 3 cm. from the window the light entered. A yellow filter cut out the small amount of scattered blue and violet light. With this simple photometer it was found possible to obtain quite reproducible matches; an average of at least five settings was taken as representing a fairly accurate measure of the intensity of the fluorescence.

Fluorescence in Pure Nitrogen Dioxide.—When nitrogen dioxide is illuminated with λ4358 or 4047 Å., the incident beam is clearly outlined when viewed at right angles. The fluorescent light appears nearly white or slightly yellowish. No fluorescence was observable when illumination was made with λ3660.

In Table I are given the experimental results on the relative intensities of the fluorescence in pure nitrogen dioxide for the pressures investigated. Illumination was made with the λ4358 and 4047 lines of the mercury arc, used together to secure sufficient intensity. In the first two columns are given the pressures of nitrogen dioxide and nitrogen tetroxide, in the third the observed intensity. The fourth column gives the fractional transmission of light through the 3-cm. layer of nitrogen dioxide up to the point of observation. This was calculated for each of the pressures from Beer's law, $I = I_0e^{-\alpha lp}$, with $\alpha = 0.0192$ per cm. per mm. pressure of nitrogen dioxide. The absorption coefficients of nitrogen dioxide for λ4358 and for λ4047 were obtained incidental to some photochemical experiments and are the same within a few per cent. With the aid of a spectral photometer, Beer's law was found to hold between 4.5 and 0.3 mm. pressure and should presum-

---

[7] Dickinson and Baxter, THIS JOURNAL, 50,774 (1928).

ably hold down to the lowest pressures used here. For small absorption, Beer's law reduces to the form that the absorption is proportional to the pressure. Therefore, the observed intensities, divided by the transmission and by the pressure of nitrogen dioxide, give the relative intensities of the fluorescence for the same quantity of light absorbed.

The excited molecule of nitrogen dioxide produced by light absorption may either fluoresce by dropping back to lower energy levels or, on collision with other molecules, enter into chemical reaction or lose its excitation energy in other ways such as degradation to heat motion. These considerations lead to the expression[8]

$$\frac{I}{I_0} = \frac{1}{\frac{\tau}{t} + 1} = \frac{1}{ap_{NO_2} + 1} \qquad (1)$$

I_0 is the intensity of the fluorescence at zero pressure, I, the intensity at the pressure p_{NO_2} and τ the natural life of the excited molecule before dropping back to a lower level. The mean time between collisions, t, is inversely proportional to the pressure and from kinetic theory has the value

---

[8] Stern and Volmer, *Physik. Z.*, 20, 183 (1919).

$$t = \frac{1}{N\sigma_{12}^2(8\pi kT)^{1/2}\left(\frac{m_1 + m_2}{m_1m_2}\right)^{1/2}} \qquad (2)$$

At 25° this reduces to the numerical form

$$t = \frac{3.90 \times 10^{-23}}{p\left(\frac{M_1 + M_2}{M_1M_2}\right)^{1/2}} \qquad (3)$$

with the pressure, p, in mm. of mercury. Any efficiency factor may be included in σ_{12}, the distance between nuclei for a quenching collision. The constant a in Equation 1 is an abbreviation

$$a = 2.56 \times 10^{22}\left(\frac{M_1 + M_2}{M_1M_2}\right)^{1/2}\sigma_{12}^2\,\tau \qquad (4)$$

A plot of $1/I$ against the pressure gives a straight line with the slope a/I and intercepts $1/I_0$. Run 1 when treated in this manner gives $a = 50$ mm.$^{-1}$. Run 2 similarly results in $a = 47$. These results were checked in the following manner. Values of I_0 were calculated from Equation 1 for each observed point with assumed values of the constant a. With the correct a the set of values of I_0 so obtained should be constant over the whole range. In this manner a was found to be equal to 50 mm.$^{-1}$ for Run 1 and between 45 and 50 mm.$^{-1}$ for Run 2. One run with illumination by λ4047 alone leads to $a = 40$. This latter value is necessarily approximate, due to the difficulties attending the measurement of the feeble intensity of fluoresced light in this case. In the sixth column of Table I are given the values of I calculated from the expression

$$\frac{I}{I_0} = \frac{1}{50p_{NO_2} + 1}$$

with $I_0 = 8.3$ in Run 1 and 5.9 in Run 2. Inspection of the last two columns of the table shows that the functional relationship between the pressure of nitrogen dioxide and the intensity of fluorescence given by Equation 1 holds quantitatively over a pressure range of 12,000-fold with a corresponding variation in the intensity of 850-fold. Such agreement is confirmation of the general idea that the light first produces an excited molecule which may then fluoresce or be damped by collision.

It is evident that at a pressure of nitrogen dioxide of 0.02 mm. the fluorescence is half damped. From the experimental result $a = 50 = 5.35 \times 10^{21}\sigma_{12}^2\tau$ it follows that $\sigma_{12}^2\tau = 9.3 \times 10^{-21}$ cm.^{2} sec. If we assume τ is 10^{-7} sec., σ_{12} must be 30×10^{-8} cm. or about ten times ordinary kinetic theory diameters. On the other hand, if σ_{12} is taken equal to 3×10^{-8} cm., τ must be as long as 10^{-5} second. The lives of excited atoms, investigated by Wien[9] and Kerschbaum,[10] are all of the order of magnitude of 10^{-7} or 10^{-8} seconds. It is natural to suppose that the lives of optically

---

[9] Wien, *Ann. Physik,* 83, 1 *(1927).*

[10] Kerschbaum, *ibid.,* 83, *287* (1927).

excited molecules should be of the same order of magnitude. On the other hand, it is quite common for large diameters to appear in collisions of the second kind. For example, the measurements of Stuart[11] on the quenching of the resonance fluorescence of mercury by hydrogen and carbon monoxide lead to diameters of the excited mercury atom several times that of the normal atom. Also Mannkoff[12] finds similar dimensions in the case of damping of fluorescence in sodium vapor by nitrogen and hydrogen. Kallmann and London[13] have treated on a quantum mechanical basis the problem of abnormally large effective diameters and succeeded in giving a reasonable explanation of their repeated appearance in terms, among other things, of the closeness of resonance between the two systems. Thus, depolarization by sodium vapor of the fluorescence of the D-lines of sodium[14] may occur at distances many thousand-fold ordinary kinetic theory values. Hence we may conclude that the apparently large diameters found here in the quenching of the nitrogen dioxide fluorescence by nitrogen dioxide itself are reasonable and that there is no necessity for assigning an exceptionally long life (10^{-5} second) to the optically excited nitrogen dioxide molecule.

Quenching of Fluorescence by Foreign Gases.—The addition of oxygen, hydrogen, nitrogen or carbon dioxide to the nitrogen dioxide produces a noticeable decrease in the intensity of the fluorescence. Figure 1 illustrates the quenching of the nitrogen dioxide fluorescence in the presence of oxygen. Such an effect is to be expected since in this case more collisions of the second kind should occur. In place of Equation 1 we have

$$\frac{I}{I_0} = \frac{1}{\Sigma_i \frac{\tau}{t_i} + 1} \tag{5}$$

When there is only one added gas this becomes, using the experimental result of the preceding section

$$\frac{I}{I_0} = \frac{1}{50p_{\mathrm{NO_2}} + ap + 1} \tag{6}$$

Calling J_0 the observed intensity in pure nitrogen dioxide at the pressure $p_{\mathrm{NO_2}}$, and J the intensity after the addition of the pressure, p, of foreign gas we obtain the ratio

$$\frac{J}{J_0} = \frac{p_{\mathrm{NO_2}}\,(I)_{p=p}}{p_{\mathrm{NO_2}}\,(I)_{p=0}} = \frac{50p_{\mathrm{NO_2}} + 1}{50p_{\mathrm{NO_2}} + ap + 1} = \frac{1}{cp + 1} \tag{7}$$

where $c = a/(50p_{\mathrm{NO_2}} + 1)$, a constant for any particular pressure of nitrogen dioxide.

Table II contains the experimental results on the quenching of the fluorescence by various gases. The observations are given in full for the

case of nitrogen; the other gases give similar results. The values of c are indeed constant within the experimental error throughout any single run. Moreover, the values of a calculated from each run are in good accord among themselves, as seen from the last column of Table II, thus establishing the general validity of Equation 6, which relates the intensity of fluorescence to the pressure of both nitrogen dioxide itself and the foreign gas. The effect of nitrogen tetroxide has been neglected. In the preceding section this factor comes into question only at the highest pressures,

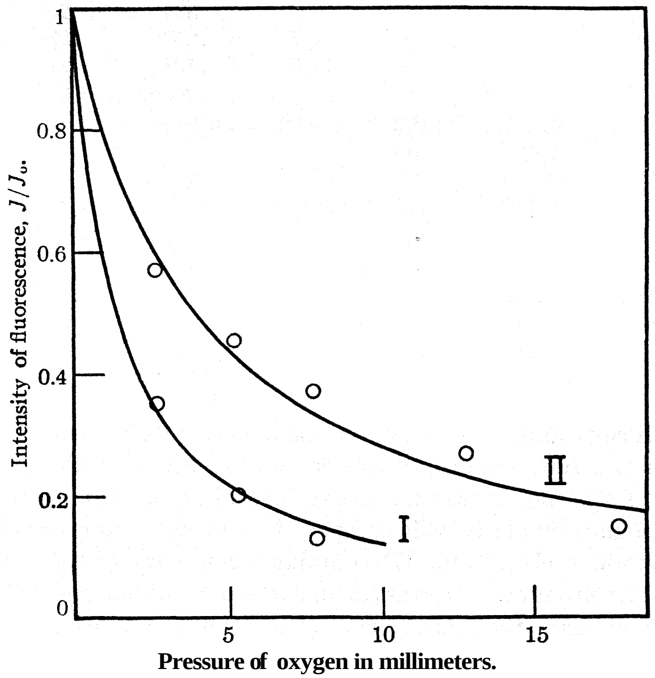

Fig. 1.—Quenching of fluorescence by oxygen. Solid curve from $\frac{J}{J_0} = \frac{1}{\frac{16.5}{50P_{\mathrm{NO}_2} + 1}\,p_{\mathrm{O}_2} + 1}$ I, P_{NO_2}, 0.436 mm.; II, P_{NO_2}, 1.256 mm.

where the observations may already be in error in the correction for light transmission. Since, however, carbon dioxide is practically as efficient in quenching as nitrogen dioxide, we might assume that nitrogen tetroxide has also the same efficiency. The pressure p_{NO_2} should then be replaced by $p_{\mathrm{NO}_2} + p_{\mathrm{N}_2\mathrm{O}_4}$. This would lead to a somewhat better check among the various values of a.

It is to be noticed that the pressure of added gas which damps the fluorescence to one-half is not an immediate measure of the life of excited

nitrogen dioxide and the deactivating diameter, since the ratio of observed intensities is a function also of the pressure of nitrogen dioxide. Rather the value of a is such a measure; its reciprocal gives the pressure at which the fluorescence would be half damped if there were no quenching by nitrogen dioxide itself. Table III contains a summary of the experimental results. The product, $\sigma_{12}^2\tau$, was calculated from a by means of Equation 4. Column 5 contains the relative efficiencies of the various added gases in quenching fluorescence, nitrogen dioxide arbitrarily being set equal to unity. The last column gives the value σ_{12}, the effective deactivational diameter, assuming a mean life of the excited nitrogen dioxide molecule of 10^{-7} second.

The specific nature of collisions of the second kind is shown by Table III. Carbon dioxide is practically as effective as nitrogen dioxide in quenching, while nitrogen, oxygen and hydrogen are only one-quarter or one-fifth as effective in this respect. The molecular complexity of the triatomic molecules, CO_2 and NO_2, implies a greater number of higher energy levels than is possessed by the simpler diatomic molecules. It is known that collisions of the second kind are more effective for those cases in which a small amount only of the excitation energy is to be transformed into kinetic energy. It is therefore not surprising that carbon dioxide and nitrogen dioxide are indeed the more efficient in damping fluorescence.

Summary

The intensity of fluorescence excited in nitrogen dioxide by the 4358 and 4047 Å. lines of the mercury arc has been determined for the pressure range 0.001 to 18 mm. Nitrogen dioxide is very efficient as a quenching agent; the fluorescence is half damped at a pressure of 0.02 mm. The product of the square of the effective diameter for collision and the life of the excited molecule $\sigma_{12}^2\tau$ is 9.3×10^{-21} cm.^{2} sec. This result indicates a deactivational diameter approximately ten times greater than kinetic theory values.

It is shown that the quenching of this fluorescence by foreign gases is in quantitative agreement with Equation 7, which is based on the occurrence of deactivating collisions with these gases as well as with nitrogen dioxide itself. There is specificity in quenching by added gases; the relative deactivational efficiencies of carbon dioxide, nitrogen, oxygen and hydrogen referred to nitrogen dioxide as unity are, respectively, 0.87, 0.29, 0.24 and 0.15.

STUDIES ON THE THERMOCHEMISTRY OF THE COMPOUNDS OCCURRING IN THE SYSTEM $CaO-Al_2O_3-SiO_2$. IV. THE HEAT OF SOLUTION OF TRICALCIUM ALUMINATE AND ITS HYDRATES IN HYDROCHLORIC ACID[1]

BY T. THORVALDSON, WELDON G. BROWN AND C. R. PEAKER

RECEIVED JULY 8, 1930 PUBLISHED OCTOBER 6, 1930

The heats of solution of the compounds occurring in the system $CaO-Al_2O_3-SiO_2$ and of their hydration products are of interest not only for the purpose of calculating the heat of formation of these compounds but also in connection with problems relating to the constitution of hydraulic cements and elucidation of the reactions which take place during their hydration. This applies especially to the aluminates and the silicates of calcium which are rich in lime. The paucity of such data is probably mainly due to the difficulty of preparing sufficient quantities of these substances in a pure

---

state. The present paper describes the determination of the heats of solution of tricalcium aluminate and its hydrates in $HCl \cdot 20H_2O$ and $HCl \cdot 200H_2O$.

Apparatus and Experimental Procedure.—The calorimeter, which was of the Richards adiabatic type with a slight modification, the Beckmann thermometers used, the method of introducing the sample into the calorimeter aad the limits of adiabatic control have been described elsewhere.[2]

The general procedure used was to determine the heat of solution of the aluminate in $HCl \cdot 20H_2O$. The heat of dilution of $HCl \cdot 20H_2O$ and of the resulting solution of aluminate, when diluted to a concentration corresponding to $HCl \cdot 200H_2O$, was determined by the method of Richards, Rowe and Burgess,[3] and the heat of solution of the aluminate in $HCl \cdot 200H_2O$ then calculated according to the usual method.[3]

Preparation of Materials

Calcium Carbonate and Alumina.—The method of purification of the calcium carbonate was similar to that already described.[2a] The aluminum hydroxide was purified by precipitation from a boiling 2% solution of ammonia alum which was free from iron, using redistilled ammonia water; the precipitate was washed thoroughly by decantation, filtered off, washed, redissolved in pure hydrochloric acid, the solution diluted to the original volume and the precipitation as aluminum hydroxide repeated. After thorough washing, the aluminum hydroxide was dried in a covered platinum dish and ground to pass a 200-mesh sieve. The material had an ignition loss of about 30%.

Tricalcium Aluminate. Sample 1.—Calcium carbonate and aluminum hydroxide, prepared as described above, were mixed wet in the proportions $3CaO:Al_2O_3$. The water was then evaporated with constant stimng of the mixture to prevent segregation. When dry. the material was transferred to platinum crucibles, placed in a platinum-wound resistance furnace, the temperature gradually raised to 1300" and kept there for several hours. The sintered mass was then broken up, ground in an agate mortar to pass a 200-mesh sieve, and the heating repeated, the temperature being raised to about 1370°. Microscopic examination showed that even after several heat treatments at 1370" the material contained small amounts of free lime and $5CaO \cdot 3Al_2O_3$. It was found that treating the finely powdered material with water aided combination materially during the subsequent heat treatment due probably to dispersion of the free lime by hydration. The treatment, however, seemed to cause tiny voids to be formed in the crystals of tricalcium aluminate and this made exact microscopic examination more difficult. These voids were eliminated by subsequent heat treatments. The material was repeatedly ground and reheated until White's test* indicated absence of free lime. and careful examination by the petrographical microscope showed that the sample was homogeneous and free from particles of lime and $5CaO \cdot 3Al_2O_3$. It was composed of isotropic crystals, with a refractive index of 1.710 ± 0.002.

Sample 3.—Sample 3 was prepared in the same way as Sample 1. This sample, however, contained a small amount of $5CaO \cdot 3Al_2O_3$ but no free lime. Table I gives the analysis of the two samples.

TABLE I

ANALYSES OF TRICALCIUM ALUMINATE[a]

	Sample 1	Sample 3	Calcd.
Calcium oxide (CaO)	62.31	61.98	62.27
Alumina (Al_2O_3)	37.76	37.98	37.73

Ferric oxide, alumina and silica were absent from both samples.

[a] Analyses by David Wolochow.

$HCl\cdot 20H_2O$.—C. P. acid was redistilled through a partly refluxing quartz condenser, the middle portion of the distillate collected in silica flasks and adjusted to $HCl\cdot 20H_2O$, the concentration being determined both by titration with pure sodium carbonate and by gravimetric determination of chloride.

The Specific Heat of $HCl\cdot 20H_2O$

Recent determinations of the specific heat of hydrochloric acid of various concentrations by Richards, Mair and Hall[5] have given values which differ somewhat from the previously accepted ones. Unfortunately the specific heat of $HCl\cdot 20H_2O$ was not included among those redetermined. It was therefore decided to determine the specific heat of $HCl\cdot 20H_2O$ over both the temperature intervals 16 to 20 and 18 to 20°. The acid used in this determination was purified with special care and gave the composition $HCl\cdot 20.01H_2O$ by titration with sodium carbonate and $HCl\cdot 20.02H_2O$ by gravimetric analyses of chloride.

The method used for the determination of specific heat was that of Richards and Rowe.[6] The calorimeter can was of pure gold, while containers for the sulfuric acid and alkali were made of a gold alloy (80% gold and 20% copper). This alloy was not attacked appreciably during the series of experiments by the solutions in contact with it.

The concentrations of sulfuric acid and sodium hydroxide used for the series for the interval 16 to 20° were: H_2SO_4, 6.928%; NaOH, 27.73%; and for the series for the interval 18 to 20°: H_2SO_4, 4.235%; NaOH, 13.86%. As practically the same weights of the acid and alkali were used for each determination and as both the water standardization and the determinations of specific heat covered exactly the same temperature range it was not necessary to know the specific heats of these solutions with a high degree of accuracy. The following values for specific heats were used: H_2SO_4 (6.928%), 0.94; H_2SO_4 (4.235%), 0.96; NaOH (27.73%), 0.83; NaOH (13.86%), 0.87.

Tables II and III give the experimental data for the determinations over the interval 16 to 20°. In Table 11, Q_{100} represents the heat evolved during the neutralization of 100.0 g. of the solution of sulfuric acid, at 20°.

A similar series of experiments, including water standardization, was made with the same solution of hydrochloric acid over the temperature

[a] The temperature rise is corrected for exposed stem, setting and stirring. [b] As the average final temperature of the water standardization series was 19.99° and the temperature coefficient for the neutralization of sulfuric acid is fairly large, a small correction was applied in Expts. 2, 3, 4 and 6 of Table III for the variation in the final temperature from 19.99°. For this purpose the temperature coefficient given by Richards and Rowe[7] (—49.5 cal. per $^1/_2$ mole H_2SO_4 per °C.) and the average value for the heat of neutralization of 100 g of 6 928% H_2SO_4 obtained in Table II were used.

interval 18–20'. The value obtained for the specific heat of $HCl\cdot 20H_2O$ over this range was 0.8510 (mean calorie 18–20°).

The value 0.8507 for the specific heat of $HCl\cdot 20H_2O$ over the range 16–20° is considerably higher than the preliminary value of 0.8487 given by Richards and Rowe.[7] It may, however, be shown that our result is consistent with those of Richards, Mair and Hall[5] for more dilute solutions of hydrochloric acid by plotting the apparent molal heat capacity with the square root of the molality as Randall and Rossini[8] have done for a number of electrolytes. This provides an extremely sensitive graphical method of comparing the results (Fig. 1).

The Heat of Solution of Tricalcium Aluminate in $HCl \cdot 20H_2O$ and in $HCl \cdot 200H_2O$

The results of the determinations of the heat of solution of tricalcium aluminate, Sample No. 1, in $HCl \cdot 20H_2O$ are given in Table IV. The specific heats used in calculating the heat capacity of the calorimeter system were: gold, 0.031; gold alloy (80% Au, 20% Cu), 0.44; $HCl \cdot 20H_2O$ (16–20°), 0.8507, (18–20°), 0.8510. The specific heat for $HCl \cdot 20H_2O$ is in terms of the specific heat of water over the same temperature interval. All weights were corrected to vacuum.

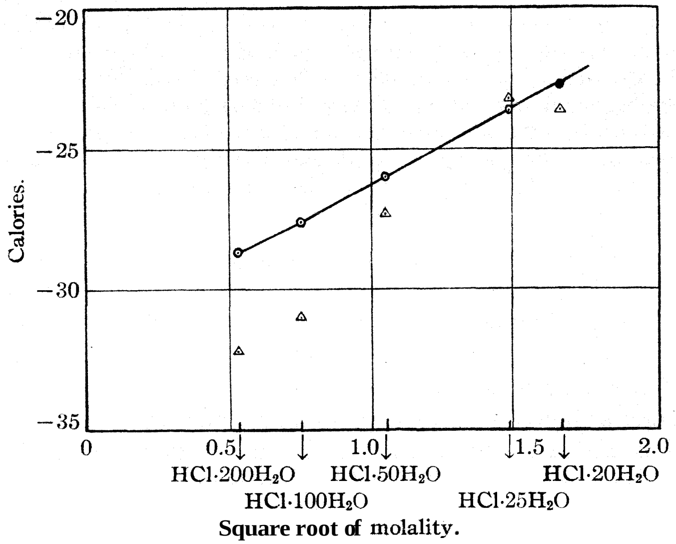

Fig. 1.—Apparent molal heat capacity of HCl at 18°. ⊙, Richards, Mair, and Hall; △, Richards and Rowe; ●, Thorvaldson, Brown and Peaker ($HCl \cdot 20H_2O$).

From Table IV one finds that the average proportion of aluminate to acid is 1 g. to 210.7 g. of $HCl \cdot 20H_2O$. In order to calculate the heat of solution of tricalcium aluminate in $HCl \cdot 200H_2O$ it is necessary to determine the heats of dilution of 210.7 g. of $HCl \cdot 20H_2O$ to $HCl \cdot 200H_2O$ and of 211.7 g. of the aluminate solution to a corresponding dilution. It is also necessary to determine the heat effect of mixing the resulting diluted solutions.

Ten determinations of the heat of dilution of $HCl \cdot 20H_2O$ to $HCl \cdot 200H_2O$ were made. The weight of $HCl \cdot 20H_2O$ used for each experiment was 61.21 g., the total heat capacity was 564 cal. and the final temperature 20.0°. The corrected rise varied from 0.150 to 0.152° with a mean of 0.1509°. The heat of dilution is therefore 85.11 calories for 61.21 g. or 293.0 calories for 210.7 g. of $HCl \cdot 20H_2O$.

In a similar way it was found that 211.7 g. of the aluminate solution gave

TABLE IV

HEAT OF SOLUTION OF $3CaO{\cdot}Al_2O_3$, SAMPLE 1, IN $HCl{\cdot}20H_2O$

Weight of $HCl{\cdot}20H_2O$, 600.4 g.

Expt.	$3CaO{\cdot}Al_2O_3$, g.	Final temp., °C.	Corr. rise,[a] °C.	Heat capacity,[c] 18° cal.	Heat of soln. per gram at 20°, cal.$_{20°}$
1	2.8481	20.01	3.968	528.6	736.8
2	2.8649	19.95	3.991	528.6	736.7
3	2.8766	19.96	4.007	528.6	736.6

5	2.8558	20.05	4.041	519.0	734.7
Mean		19.99			736.1
corrected for evaporation[b]					736.4

[a] Corrected for stem exposed, setting of thermometer and stirring [b] The volume of air in the calorimeter was about 600 cc. This was no doubt saturated with water vapor at the beginning of each run and probably nearly saturated at the end of each run. Three-fourths of the calculated correction for the heat of vaporization is applied. [c] The temperature of the sample of tricalcium aluminate when introduced into the calorimeter was 20°. The heat capacity of the aluminate is therefore not included in the calculated value.

on corresponding dilution the mean value of 289.4 calories. For this determination it was necessary to know the specific heat of the aluminate solution. Determinations, made as for $HCl{\cdot}20H_2O$ described above, gave 0.847 calorie per degree and this value was not found to vary appreciably for the different aluminate solutions used.

Experiments showed that there was no heat effect produced when $HCl{\cdot}200H_2O$ was added to the diluted aluminate solution. Thus the heat of solution of $3CaO{\cdot}Al_2O_3$ in $HCl{\cdot}200H_2O$ is independent of the proportion of aluminate to acid at least for proportions approximating those used. The calculated value for the heat of solution of $3CaO{\cdot}Al_2O_3$ in $HCl{\cdot}200H_2O$ at 20° is therefore 732.8 (736.4 + 289.4 − 293.0) calories (20°) per gram.

The Heat of Solution of $3CaO{\cdot}Al_2O_3{\cdot}6H_2O$ in Hydrochloric Acid.[9]—Thorvaldson and Grace[10] have shown that tricalcium aluminate forms a very stable hydrate of the composition $3CaO{\cdot}Al_2O_3{\cdot}6H_2O$. This hydrate is readily formed when tricalcium aluminate is hydrated in steam under pressure.

Determinations of the heat of solution of two samples of $3CaO{\cdot}Al_2O_3{\cdot}6H_2O$ prepared from $3CaO{\cdot}Al_2O_3$, Sample 1, were made. Sample A was prepared by exposing the freshly ignited aluminate to saturated steam at 150° in an autoclave and drying the resulting hydrate to constant weight over calcium oxide. It was found that the $3CaO{\cdot}Al_2O_3$ had taken up 39.97% of water, which corresponds to a formula of $3CaO{\cdot}Al_2O_3{\cdot}5.99H_2O$

---

[9] The authors are indebted to Mr. Norman S. Grace for preparing the samples of the hydration products of tricalcium aluminate used in the determinations of the heat of solution.

[10] Thorvaldson and Grace, Canadian *J.* Res.. **1**, 36 (1929).

Sample B was prepared by adding water to the anhydrous aluminate and drying to constant weight over calcium oxide, this process of treating with water and drying being repeated several times. The total increase in weight after drying over lime was 40.08%, which corresponds to a formula of $3CaO·Al_2O_3·6.01H_2O$.

Special precautions were taken to prevent access of the carbon dioxide of the air to the samples during the preparation of the hydrate. This could be effectively prevented in the case of the hydrate prepared in steam by taking care that the air and water in all vessels were free from carbon dioxide. There was a somewhat greater chance in the case of the sample prepared at room temperature for contact with ordinary air and there may have been a slight absorption of carbon dioxide. This probably accounts for the slightly lower heat of solution obtained for Sample B. Both samples were entirely isotropic and had an index of refraction,'' N_{Na} 1.604 * 0.002.

Average for Samples A and B.				....	522.1

[a] Corrected for stem exposed, setting of thermometer and stirring. [b] Corrected for evaporation and from the 19° to the 20° calorie. [c] The temperature of the sample of hydrated tricalcium aluminate when introduced into the calorimeter was 20°. The heat capacity of the aluminate is therefore not included in the calculated value for heat capacity.

The heat of dilution of the aluminate solution obtained from the experiments recorded in Table V to a dilution corresponding to $HCl·200H_2O$ at 20° was determined. Four determinations gave exactly the same value, namely, 84.09 calories for the heat of dilution of 61.43 g. of the solution (that is, a temperature rise of 0.149° for a heat capacity of 564.4 cal./deg.). Considering the determinations with Sample A in Table V, the average weight of $HCl·20H_2O$ used per gram of anhydrous tricalcium aluminate was 288.9 g. and the corresponding average weight of aluminate solution pro-

---

[11] Measurements by V. A. Vigfusson.

duced was 290.3 g. The heats of dilution amount to 401.7 and 397.4 calories, respectively.

The value for the heat of solution of $3CaO\cdot Al_2O_3\cdot 6H_2O$ (Sample **A)** in $HCl\cdot 200H_2O$ at 20° is therefore 518.8 $\text{calories}_{20°}$ per gram of anhydrous tricalcium aluminate or 370.6 $\text{calories}_{20°}$ per gram of the hydrate.

The calculated heat of hydration of tricalcium aluminate to the hexahydrate at 20° is 214.0 $\text{calories}_{20°}$ per gram or 57.8 kg. $\text{calories}_{20°}$ per formula weight.

Heats of Solution of Higher Hydrates of $3CaO\cdot Al_2O_3$

A crystalline hydrate of tricalcium aluminate occurring as hexagonal plates, needles and spherulites is well known. Attempts to obtain this hydrate in the pure state and determine its water of hydration have produced results which are apparently very discordant, Gallo,[12] Klein and Phillips[13] and Pulfrich and Linck[14] reporting a water content varying from 5.5 to 10.5 molecules. Later experimental work[15] has shown that special precautions must be taken in order to obtain this hydrate free from admixture of the isotropic hydrate $3CaO\cdot Al_2O_3\cdot 6H_2O$. Further, it appears that on drying, the crystalline hexagonal plates, which when formed in equilibrium with water near its freezing point probably have the composition $3CaO\cdot Al_2O_3\cdot 12H_2O$, give up their water of hydration in several steps without a material change in the crystalline form until exposure over calcium oxide produces a material of the composition $3CaO\cdot Al_2O_3\cdot 8H_2O$.

There seems, however, to be some doubt as to the existence of several anisotropic hydrates of tricalcium aluminate. It was thought that determinations of the heat of solution of hydrated material containing varying amounts of water might give an indication as to the way in which the water is held. In determining the heat of solution of calcium hydroxide in $HCl\cdot 200H_2O$ it was found[2b] that this substance is capable of taking up large quantities of water with only a very slight decrease in the heat of solution. As it is generally accepted that calcium hydroxide does not form a higher hydrate, a similar change in the heat of solution of hydrated tricalcium aluminate with increasing water content would suggest that the water is not bound chemically.

The higher hydrates of tricalcium aluminate were formed by the gradual addition of anhydrous tricalcium aluminate to carbon dioxide-free water, the mixture being cooled by ice. The hydrate was then kept in contact with water below 21° for about two weeks, after which portions were dried at 21° over saturated solutions of various salts. The method is described in detail elsewhere.[15]

[14] Pulfrich and Linck, *Kolloid-Z.*, 34, 117 (1924).

[15] Thorvaldson, Grace and Vigfusson, *Canadian J. Res.*, 1, 201 (1929).

The hydrates used for this series of determinations were prepared from $3CaO{\cdot}Al_2O_3$, Sample **3.** This sample is slightly low in lime and contains therefore a small quantity of the aluminate next lower in lime, namely, $5CaO{\cdot}3Al_2O_3$. On hydration this substance forms hydrated tricalcium aluminate with liberation of the excess of alumina as hydrate. It was found that the heat of solution of Sample **3** in $HCl{\cdot}200H_2O$ was 9.3 calories per gram lower than that obtained with the purer Sample No. 1, but the heat of solution of the hydrate ($3CaO{\cdot}Al_2O_3{\cdot}6H_2O$) obtained by exposing Sample No. **3** to steam under pressure was also 9.3 calories lower than that for the corresponding product from Sample 1, giving a calculated heat of hydration of 214.1 for Sample 3 against 214.0 calories for Sample 1. There was therefore good reason to expect that the *differences* in the heat of solution of the various hydrates prepared from Sample **3** would not differ materially from those which would have been obtained with hydrates from the purer Sample, No. 1. Table VI gives the calculated heats of hydration of tricalcium aluminate to hydrates containing four different amounts of water.

TABLE VI

HEAT OF HYDRATION OF TRICALCIUM ALUMINATE CALCULATED FROM VALUES FOR HEATS OF SOLUTION OF THE HYDRATES IN $HCl{\cdot}200H_2O$

Hydration of $3CaO\ Al_2O_3$	Hwt effect calories per gram of anhydrous aluminate
$3CaO{\cdot}Al_2O_3{\cdot}6.00H_2O$	**214**
$3CaO{\cdot}Al_2O_3{\cdot}8.00H_2O$	**235**
$3CaO{\cdot}Al_2O_3{\cdot}10.2H_2O$	**251**
$3CaO{\cdot}Al_2O_3{\cdot}11.6H_2O$	**261**

The values given in Table VI can be considered only as preliminary. The changes in the heat effect are rather larger than one would expect were the water adsorbed by $3CaO{\cdot}Al_2O_3{\cdot}8H_2O$, but are approximately proportional to the increase in H_2O in the material. The results can hardly be considered to give conclusive evidence as to the existence of several anisotropic hydrates of tricalcium aluminate.

The Heat of Formation of Tricalcium Aluminate.—The heat of formation of tricalcium aluminate from calcium oxide and aluminum oxide may be calculated from the heats of solution of these substances in hydrochloric acid. As no experimental value for the heat of solution of aluminum oxide in hydrochloric acid is available, this must also be calculated from other thermochemical data. Using the value 68.4 kg. cal. per mole for the heat of formation of water,[16] 127 kg. cal. per gram atom as the heat of solution of aluminum in $HCl{\cdot}200H_2O$,[3] and 190.0 kg. cal. per gram atom as the heat of combustion of aluminum,[17] we obtain 79.2 kg. cal. per mole for the heat of

[17] **Roth and** Müller, *Z. phys. Chem.*, **144,** *257* (1929).

solution of Al_2O_3 in $HCl\cdot200H_2O$. Combining this value with 46.5 kg. cal. per mole as the heat of solution of calcium oxide2" and 198 kg. cal. per mole as the heat of solution of tricalcium aluminate in $HCl\cdot200H_2O$, one obtains 20.7 kg. cal. per mole for the heat of formation of $3CaO\cdot Al_2O_3$ from CaO and Al_2O_3 at 20°.

Summary

1. The heat of solution of tricalcium aluminate in hydrochloric acid (1 g. of $3CaO\cdot Al_2O_3$ to 19.4 g. of HCl) was found to be 736.4 $cal._{20}$ per gram of $3CaO\cdot Al_2O_3$ in $HCl\cdot20H_2O$ or 732.8 $cal._{20}$ per gram in $HCl\cdot200H_2O$ at 20°.

2. The heat of solution of the isotropic (regular) hydrate of tricalcium aluminate ($3CaO\cdot Al_2O\cdot6H_2O$) in hydrochloric acid (1 g. of anhydrous $3CaO\cdot Al_2O_3$ to 26.5 g. of HCl) was found to be 523.1 $cal._{20}$ per gram of anhydrous aluminate in $HCl.20H_2O$ or 518.8 $cal._{20}$ per gram in $HCl\cdot200H_2O$ at 20°.

3. The heat of solution of tricalcium aluminate in $HCl\cdot200H_2O$ was found to be independent of the amount of acid of this concentration used in excess of the above ratio of aluminate to acid.

4. The calculated heat of hydration of tricalcium aluminate to the hexahydrate is 214 $cal._{20}$ per gram at 20°.

5. Preliminary values were obtained for the heat of solution in $HCl\cdot20H_2O$ of samples of anisotropic (hexagonal) hydrates of tricalcium aluminate containing 8, 10.2 and 11.6 moles of water of hydration per formula weight of $3CaO\cdot Al_2O_3$.

6. The specific heat of hydrochloric acid of the concentration $HCl\cdot20H_2O$ was determined between 16 and 20° as compared with water over the same temperature interval and the value 0.8507 was obtained.

7. The value of 77 calories per gram was obtained for the calculated heat of formation of tricalcium aluminate from lime (CaO) and alumina (Al_2O_3) at 20°.

STUDIES IN DIFFUSION. 11. A KINETIC THEORY OF DIFFUSION IN LIQUID SYSTEMS

BY J. HOWARD ARNOLD

RECEIVED JULY 16, 1430 PUBLISHED OCTOBER 6, 1930

The experimental study of diffusion in liquid systems was begun by Graham about 1850. A few years later Fick,[1] from analogy with Fourier's law of thermal conduction, enunciated the basic law of diffusion. In 1879 Stefan[2] showed that the data of Graham harmonized with Fick's Law, and developed the theory of liquid diffusion further along the same lines as his theory of diffusion in gaseous systems.[3] The equation given

$$dN/d\Theta = DA\,dc/dx$$

by Fick rests upon the assumption that the driving force causing diffusion is proportional to the concentration gradient. The use of the equation requires the evaluation, by measurement or estimation, of the proportionality constant D, usually termed the diffusion coefficient or diffusivity.

TABLE OF NOMENCLATURE

(1) — Subscript referring to diffusing substance (solute)
(2) — Subscript referring to solvent medium
A — Area of contact; abnormality factor for compounds containing active oxygen or nitrogen
a, A', B' — Proportionality constants
B — Universal constant in the equation for D
b — Temperature coefficient
c — Concentration, in moles per cubic centimeter
D — Diffusion coefficient (diffusivity), $\text{cm.}^2/\text{sec.}$ or $\text{cm.}^2/\text{day}$
d — Differential operator
F — Factor used to allow for resistance due to intermolecular forces
M — Molecular weight
m — Weight of a single molecule
N — Number of moles of substance transferred
R — Gas constant, in $pV = RT$
r — Radius of diffusing particle
S — $V_1^{1/3} + V_2^{1/3}$; represents the sum of the molecular diameters
T — Absolute temperature, degrees Kelvin
t — Temperature, degrees centigrade
u — Net forward velocity of diffusion
V — Volume of one mole of liquid; refers to b. p. for the calculation of S
v — Specific volume
w — Molecular velocity of thermal agitation
x — Distance, measured in the direction of diffusive flow
Z — Solvent viscosity, in centipoises
Θ — Time, in seconds or days

Numerous attempts to correlate the values of D obtained experimentally and the properties of the substances involved have been made during the past fifty years; none has been a pronounced success, and all have lacked generality. The principal difficulty in the way of the development of a rational theory of diffusion in liquid systems has been the absence of a kinetic theory of liquids corresponding to that of gases. Attempts at correlation have proceeded along two diametrically opposite lines, the kinetic and the hydrodynamic, as represented by the Exner Rule and the Stokes–Einstein Equation.

From kinetic theory it is known that in any gaseous system the average kinetic energy of a molecule is a function of temperature only

$$mw^2 = \text{constant}$$

It is seen from this that the translational velocity of the molecule is inversely proportional to the square root of the molecular weight; if we make the simple assumption that the rate of diffusion varies directly as the translational velocity, the diffusivity varies inversely as the square root of the molecular weight (Graham's Law). In 1875 Exner[4] applied this rule to the diffusion of gases through liquids, and showed that it is in agreement, approximately, with the experimental data. This work was continued by Hüfner,[5] who later extended it to substances other than dissolved gases, as did Euler[6] and Pickering.[7] The rule has been exploited by a number of other investigators, among them Thovert,[8] Öholm,[9] and Carlson.[10] More recently, Smith,[11] using Öholm's data, defined D/M as the "ideal diffusion coefficient," which was then shown proportional inversely to the $3/2$ power of M.

In 1858, Wiedemann[12] found that D varied inversely as the solvent viscosity, thereby laying the foundation for numerous attempts at correlation along hydrodynamical lines. This fact was combined by Walden[13] with the Exner Rule, giving the relation

$$DZM^{1/2} = \text{constant}$$

The equations of Wiedemann and Walden were tested for a large number of systems by Thovert,[14] and found to conform approximately to the observed facts.

In 1905 Sutherland[15] and Einstein[16] independently derived what is now known as the Stokes–Einstein equation. Sutherland applied the relation

$$D = \frac{RT}{6\pi NZr}$$

(N here is Avogadro's number) to the existing data, but finding the agreement poor, discarded it in favor of the empirical equation

$$V = A'/V + B'/V^{1/3}$$

Einstein, who derived the relation in the course of his investigation of the Brownian movement of colloidal particles, indicated its possible usefulness in molecular diffusion, but did not apply it to the existing data; this has been done by von Wogau,[17] Groh and Kelp, Svedberg[18] and Miller, resulting in the conclusion that the equation is only approximately true for the diffusion of molecules, though accurate for colloidal particles. Its breakdown is due to the inapplicability of Stokes' law, which assumes the solvent to be a continuum, a postulate no longer satisfied when the diffusing particle approaches the solvent molecules in size. It also possesses the obvious fault of including only the viscosity of the solvent and the radius of the diffusing particle, which are certainly insufficient to specify the behavior of the system; similar objections apply to the Exner Rule. It may be noted that Gapon and Muchin[19] have derived an equation similar to the Stokes–Einstein, but including other variables than r and z.

Riecke[20] found a relation between the diffusivity and the mean free path of the diffusing molecule, but as he did not evaluate the free path length, the theory is incomplete. His theory is essentially the same as the usual kinetic theory of diffusion in gases. Enskog[21] has also made a preliminary attempt to apply gas theory to liquid diffusion.

In the absence of a classical kinetic theory of liquids, there has arisen in recent years a tendency to apply the kinetic theory of gases directly to liquid systems, usually with the introduction of a free space factor to take account of the fact that the close packing of the molecules must necessarily interfere with their freedom of motion. In this manner Christiansen,[22] Norrish and Smith[23] and Jowett[24] have made use of the gas theory expression for collision rate in their studies of reaction velocity

in liquid systems. Lenard[25] follows a similar course in his consideration of ionic mobility.

It is the purpose of this paper to demonstrate that the classical kinetic theory expression for gaseous diffusivity may be applied to liquid systems, provided that due regard be taken of the complications introduced by the close packing of the molecules. We shall first apply gas theory directly to liquid diffusion, later modifying the equation so obtained to allow for the failure of several assumptions made for gases. The derivation which follows closely parallels that of Stefan[26] for gaseous diffusion.

Fick's law states that the diffusion rate is proportional to the concentration gradient

$$\mathrm{d}N_1/A\mathrm{d}\Theta = D\mathrm{d}c_1/\mathrm{d}x$$

If we represent by u_1 the net forward velocity of a molecule in the diffusion stream

$$\mathrm{d}N_1/A\mathrm{d}\Theta = c_1u_1$$

It may easily be shown by calculation that the acceleration of the diffusing molecules is negligibly small; in the absence of external forces, the driving force $\mathrm{d}c/\mathrm{d}x$ is used solely to overcome the resistance to diffusion, measured in terms of the momentum transferred from the diffusing solute to the solvent. This momentum transfer is equal to the product of the total number of collisions of unlike molecules by the momentum loss per collision. From gas theory the number of collisions per second is proportional to the concentration of each type of molecule, to an "average" molecular cross-sectional area, and to the root mean square molecular velocity; that is, to

$$c_1c_2\,S^2\sqrt{w_1^2 + w_2^2} \tag{3}$$

where S^2 represents the square of the sum of the molecular diameters. At constant temperature, all the molecules in the system have, on the average, the same kinetic energy; w^2 therefore varies inversely as the molecular weight, since Mw^2 is constant, and Expression 3 becomes

$$c_1c_2\,S^2\sqrt{\frac{1}{M_1} + \frac{1}{M_2}} \tag{4}$$

For forceless spheres, the momentum loss per collision is

$$2/3\,\frac{m_1m_2}{m_1 + m_2}\,(u_1 + u_2) \tag{5}$$

Since the mass of a single molecule, m, is proportional to the molecular weight, M, Expression 5 may be written

$$\frac{(u_1 + u_2)}{\frac{1}{M_1} + \frac{1}{M_2}} \tag{6}$$

$u_1 + u_2$ being the relative velocity of unlike molecules.

---

[25] Lenard, Ann. *Physik,* 61,665 (1920).

[26] Stefan, *Wien.* Ber., 65, 323 (1872); cf. Sutherland, Phil. Mag., 38, 1 (1884).

Assuming no volume change on mixing, we may write the equation of continuity to express the constancy of volume

$$c_1V_1u_1 - c_2V_2u_2 = 0 \tag{7}$$

since the sum of the partial volumes equals the total volume

$$c_1V_1 + c_2V_2 = 1 \tag{8}$$

Combining Equations 7 and 8

$$(u_1 + u_2) = u_1\left(1 + \frac{c_1V_1}{c_2V_2}\right) \tag{9}$$

From 4, 6 and 9 the resistance to diffusion is found to be proportional to

$$\frac{c_1c_2\, S^2\, u_1}{c_2V_2\sqrt{\dfrac{1}{M_1} + \dfrac{1}{M_2}}} \tag{10}$$

From Equations 1 and 2

$$\mathrm{d}c_1/\mathrm{d}x = c_1u_1/D \tag{11}$$

On setting the driving force $\mathrm{d}c_1/\mathrm{d}x$ equal to the resistance and solving for D we have

$$D = \frac{B\sqrt{\dfrac{1}{M_1} + \dfrac{1}{M_2}}}{S^2}\,(V_2) \tag{12}$$

where B is a proportionality constant. Except for the V_2, this is identical with the expression derived by Stefan for gaseous diffusion.

In the derivation of Equation 12 three assumptions relative to the collision rate have been made, *viz.*, (1) that all collisions are binary, involving two molecules only; (2) that the collision rate is unaffected by the volume occupied by the molecules, which in a gas is negligibly small compared to the total volume; and (3) that the intermolecular attractions do not come into play. While in the kinetic theory of gases these assumptions may be allowable, in the treatment of liquid diffusion none of them can be considered valid because of the greater molecular density in the liquid state. As far as the writer is aware, no molecular analysis of the problem of collision rate in liquid systems has been made; in this paper we shall take account of the failure of the three assumptions mentioned in a semi-empirical way, by means of a factor F to be inserted in the denominator of Equation 12, this factor being evaluated by a study of the available data on liquid diffusion.

Since roughly one-third of the volume of a liquid is occupied by the molecules themselves, it is apparent that a fairly large fraction of the collisions will be of an order higher than the second, on account of the very close packing. It has been shown by Syrkin[27] that the expression for the rate of higher order collisions is of a form similar to Equation 4; as will be seen later, we may assume to a sufficient approximation that the simpler expression (4) is applicable.

---

[27] Syrkin, *Physik. Z.*, 24, 236 (1923).

The effect on collision rate of the volume occupied by the molecules was first evaluated for gases by van der Waals[28] in developing his equation of state. For gases, the correction factor obtained is always a function of the ratio b/V, where b is proportional to the actual volume of the molecules and V is the apparent volume. In the gaseous state, b/V is very small, while for a liquid it is roughly unity; however, in a liquid, V is no longer constant as required by Avogadro's law, but varies from liquid to liquid over a wide range. At the boiling points, or other corresponding temperatures, the actual volume of the molecules is the same fraction of V for all liquids, hence b/V becomes the same for all liquids. The correction factor therefore varies from liquid to liquid only in so far as V at the given temperature differs from V at the boiling point; because of the low coefficients of expansion of liquids, this variation will not be large. Moreover, the correction factor is probably quite insensitive to moderate variations in b/V, and, since most liquids are not far removed from their boiling points at ordinary temperatures, we may safely suppose that this factor is constant for all systems, as a working approximation; exceptions will be met with in the case of high-boiling solvents.

The third assumption, that intermolecular forces may be neglected, is not tenable even in the theory of gaseous diffusion, and much less so in the case of liquids. Presumably because of induced curvature in the molecular paths, such forces cause a very considerable increase in the collision rate; the effect is a specific one, depending on the nature of the molecules composing the system, and varying over an extremely wide range. The effect of molecular forces on gaseous viscosity and diffusion was considered by Sutherland,[29] who arrived at a dynamical solution of the problem; the application of Sutherland's equations to gaseous diffusion is treated in the first paper of this series.[30] In the present state of liquid kinetic theory, a dynamical analysis of the problem is impossible; we shall therefore evaluate the factor F in terms of other properties of the system as parameters, thereby avoiding the necessity for such an analysis. Since F is intimately connected with the total transfer of momentum within the fluid, it is logical to relate it to the viscosity of the medium, which is a measure of such transfer.

By the empirical examination of the existing data on the diffusion of non-electrolytes, several rules for the variation of F with the nature of the system have been determined. In this paper we shall be concerned only with the data for low concentrations of diffusing substance, *i. e.*, for dilute systems, a condition satisfied by practically all the existing data.

---

[28] Jeans, "Dynamical Theory of Gases," pp. 125 ff.; Loeb, "Kinetic Theory of Gases," pp. 130 ff.

[29] Sutherland, *Phil. Mag.*, 36, 507 (1893); 38, 1 (1894).

[30] Arnold, *Ind. Eng. Chem.*, 22, 1091 (1930).

1. For dilute systems, F is essentially a function of the solvent properties only, being nearly independent of the nature of the diffusing substance; thus the diffusion data for a number of solutes in any given solvent obey the same law found for gaseous diffusion, except for the proportionality constant. This rule is not strictly true, some dependence of F on solute properties being noted, but the meagerness of the available accurate data prevents the more accurate determination of the nature of this dependence.

2. F is directly proportional to the square root of the solvent viscosity. For high-boiling solvents indications are that some modification of this rule is necessary; this also is hampered by scarcity of data.

3. When either solvent or solute, or both, belongs to the class of substances commonly regarded as "associated," factors A_1 and A_2 (for solute and solvent, respectively) must be inserted in the expression for F. Such substances are those containing an unsaturated oxygen or nitrogen atom, *e.* g., water, alcohols, acids, amines, etc., whose molecules as a result of this unsaturation possess unduly large attractive forces, and consequently show anomalies in many physical properties. With such substances the resistance to diffusion is found to be higher than can be accounted for by the first two rules, necessitating the use of the "abnormality factor," A.

The complete expression for F is therefore

$$F = A_1A_2V_2Z_2^{1/2} \tag{13}$$

the V_2 in this expression canceling that in Equation 12, as is found necessary for proper correlation. The final equation for D to be tested is then

$$D = \frac{B\sqrt{\frac{1}{M_1} + \frac{1}{M_2}}}{A_1A_2Z_2^{1/2}S^2} \tag{14}$$

As a standard temperature of comparison, we shall use 20°, conversions to this temperature being made with the aid of the coefficients discussed later. Z_2 is expressed in centipoises at 20°; S is the sum of the cube roots of the molecular volumes of solute and solvent, found with the aid of the Kopp–Le Bas system of calculation as described in the previous paper.

To test the first rule governing F, we require data on the diffusion of normal substances in a single solvent; these are supplied by the experiments of Thovert,[31] using benzene as the solvent. Table I contains values observed at 15°, in cm.^{2}/sec., X 10^{-5} together with D_{calcd} found with the aid of a graphically determined value of B of 0.00918 at 15°, or 0.0100 at 20°. The agreement is not exact, the ratio of calculated to observed D tending to rise with increasing molecular weight; the median deviation is 8%, which is not to be considered serious inasmuch as the probable

---

[31] Thovert, *Ann. phys.*, [9] **2, 415 (1914).**

experimental error is about 5% or even more. We shall therefore assume that F is approximately independent of solute nature, for normal solutes.

Dinitronaphthalene	202.6	109.4	.1320	1.38	1.23

The relation of *F* to solvent viscosity is well shown by the data of Miller[32] on the diffusion of iodine (Table II). The values for diffusion in ether and ethyl alcohol are due to Groh and Kelp,[33] whose values for benzene, carbon disulfide, and chloroform agree closely with those of Miller. The units of D are cm.^{2}/day, at 20°; converted to these units, the B found from Thovert's data is (0.01) (86400) or 864, which is found to be satisfactory for the correlation of Miller's data as well. The last column of Table II contains the ratio of calculated to observed D, assuming A_1 and A_2 of Equation 14 to be unity; for most of the solvents the ratio is seen to be nearly unity, indicating the correctness of our theory. Heptane is anomalous, for no apparent reason, while the high-boiling solvents anisole, phenetole, ethylene dibromide and acetylene tetrabromide show rather large deviations which will be mentioned further below. For

---

[33] Groh and Kelp, *Z. anorg.* Chem., 147, 321 (1925).

acetic acid, methanol, ethyl alcohol and water, the ratio is much larger, since these substances are abnormal and A_2 is greater than unity. As will be shown below, A_2 is a constant characteristic of the solvent, paralleling in magnitude the familiar "association factor" found from surface tension or similar anomalous properties of abnormal liquids.

Table V contains data from Thovert[31] for the diffusion of normal solutes in methanol, in cm.^{2}/sec. X 10^{-5} at 15°. Using the abnormality factor 2.0 found from Dummer's data for methanol, satisfactory correlation is obtained, the deviations being of the same nature and magnitude as in Table I. It may be noted here that Thovert's results are somewhat erratic, with considerable errors in some instances; the general accuracy of his work is quite uncertain.

TABLE V

DIFFUSION OF NORMAL SOLUTES IN METHANOL (THOVERT)

Substance	*V*	S^2	$\sqrt{\frac{1}{M_1}+\frac{1}{M_2}}$	D_{calcd}	$D_{\text{obs.}}$

Iodobenzene	129 4	70 5	.1903	1.59	1.65

As noted above, when the solvent is abnormal, the calculated D must be brought into agreement with the observed ***D*** by the use of the abnormality factor A_2; it is also found that abnormal ***diffusing substances*** require the introduction of a factor A_1, quite independently of the abnormal or normal nature of the solvent. This is clearly shown by Table VI, the values of ***D*** calculated on the assumption of an A_1 of unity being uniformly too high; the ratio $D_{\text{calcd.}}/D_{\text{obs}}$ is then equal to the factor A_1. The last column contains values of A_1 found similarly from Thovert's data on diffusion in methanol; in most cases these agree closely with the values for benzene solution, indicating that the abnormal diffusional behavior of the solute is not greatly influenced by the nature of the solvent (see, however, the discussion of Table X).

Table VII contains data by Öholm[34] for the diffusion of both normal and abnormal solutes in ethyl alcohol; values of D are given in cm.²/day, at 20°, extrapolated to zero concentration. To a close approximation, the A_2 for ethyl alcohol may be taken as 2.0, as for methanol. The last column gives, for the abnormal solutes, the values of A_1 calculated from Thovert's data on diffusion in methanol, as in Table VI.

We have next to consider the data for diffusion in aqueous solution. In order to arrive at an abnormality factor A_2 for water, we are limited to the consideration of normal solutes only; unfortunately, nearly all substances which are water-soluble are also abnormal. In Table III

an A_2 of 4.70 was found, which on further trial proves to be correct, giving excellent agreement with the experimental results for the diffusion of the fixed gases (Table VIII). The molecular volumes used in this table have been taken from the previous paper on gaseous diffusion, and were calculated from gaseous viscosity data; Kopp's law is rather difficultly applicable to substances of low molecular complexity. The values of $D_{\text{obs.}}$ are taken as the most reliable of those cited in Table VIII-A, which was compiled from data given by Tammann[36] in his recent review of the subject, together with values for oxygen and carbon dioxide given by

[36] Tammann, *Z. anorg. Chem.*, 179, 125 (1929).

Carlson,[37] all data being reduced to 20° with the aid of a temperature coefficient of 0.030, and expressed in $cm.^2$/day. Especially in the case of hydrogen, disagreements among the various experimenters are apparent, and are traceable to the difficult technique involved and the low solubility of most of the gases.

Representative of the diffusion of abnormal solutes in aqueous solution, Table IX contains the data of Thovert. The dependence of A on the functional groups in the molecule is clearly shown; the aliphatic alcohols show nearly the same value of A throughout, as do formic and acetic acids. In the multiple-functioned compounds such as tartaric acid, glycerin and the sugars, internal neutralization of the abnormal forces operates to give a lower A than would be expected. When such neutralization becomes complete, an A of unity is to be expected; this is the case for

[37] Carlson, *Medd.* Nobelinst., 2, 2 (1913).

aniline hydrochloride, trinitrobenzene and acetonitrile. A similar effect is noted with phthalic acid and salicylic aldehyde (Table VI).

Because of the cumulative errors in experiment and theory, accurate generalizations concerning the abnormality factor A are difficult to formulate. For a given substance, A_2 is greater than A_1; that is, the abnormality is more pronounced when the substance is the solvent than when it is the solute. Thus, methyl and ethyl alcohols have an A_2 of 2.0, and an A_1 in aqueous solution of only 1.2; acetone and nitrobenzene show an A_2 of 1.15 and 1.35, respectively, but as diffusing substances are apparently nearly normal. The magnitude of A_1 is dependent to some extent on the solvent, as shown in Table X; it is seen that the tendency is for A_1 to increase as the A_2 for the solvent decreases, A_1 being generally smallest in aqueous solution. Pyridinc, however, shows the opposite tendency. The usual behavior is in accord with the Nernst–Thomson rule,[38] which is based on the diminution of molecular forces when the molecule is surrounded by a medium of high dielectric constant; as commonly expressed, good ionizing media, such as water, have high dielectric constants, while solvents with low constants favor association. Thus, intermolecular attractions will be weak, and A_1 consequently low, when the solvent dielectric constant is high.

TABLE X

SOLUTE ABNORMALITY FACTORS (A_1)

Solute	Water	Methanol	Ethyl alcohol	Benzene
Phenol	1.21	1.35	..	1.32
Amyl alcohol	1.16	1 29	1.31	1.29
Hydroquinone	1.27	1.43	2.14	..
Chloral	1.33	1.40	1.53	..

Formic acid	1.32	1.53	..	1.29
Acetic acid	1.27	1.53	..	1.38
Acetamide	1.15	1.54	2.08	..
Pyridine	1.60	1 26	1.07	..

It is to be emphasized that much better correlation is obtainable by the use of the factors A_1 and A_2 than by the use of an "association factor" as a multiplier for M and V in Equation 12, as would be required by the usual concept of the association of abnormal substances. For example, to fit the value of 1.22 for Cl_2 in Table VIII, an association factor for water of 12.6 would be required—far higher than any such factor found heretofore by other methods; using this factor for bromoform (Table III) gives a $D_{\text{calcd.}}$ of 0.68, with 0.85 observed, while for H_2 (Table VIII) the calculated value is 8.33, the observed average 5.13, and the value using our A factor, 5.34. Thus, granting the fundamental soundness of the present method of correlation, it appears that the hypothesis of molecular asso-

---

[38] Turner, "Molecular Association," Longmans, Green and Co., 1915, p. 42.

ciation is insufficient to explain the data. In this connection, it is noteworthy that Longinescu[39] has apparently abandoned the concept of an actual physical combination of molecules, replacing it by the idea of an abnormally high "molecular concentration" in abnormal liquids. In the opinion of the present writer, all the anomalous properties of abnormal substances are fully as readily explainable by the concept of an abnormally strong force field around the molecule as by the assumption of association.

It is noteworthy that evidence of such association is usually very indirect, and that the several available methods for the quantitative estimation of degree of association give widely differing values of this quantity. It is hardly to be expected that such relationships as, for instance, the familiar Eötvös–Ramsay–Shields equation, will give a true value of molecular weight when the surface tension and critical temperature used in the equation are themselves abnormally high because of excessive intermolecular attraction; attempts to balance the equation by assuming an abnormal molecular weight can be productive of nothing more than empirical correlations, since a new, non-existent abnormality is assumed to compensate for the two existing ones. Similar criticisms may be applied to the related hypothesis of solvation. Inspection of Table II shows the absence of complications due to solvation, which is often assumed to be the cause of the diverse colors of iodine solutions. For instance, Hildebrand[40] has even determined equilibrium constants of solvation reactions from colorimetric data. It is evident that any actual attachment of solvent molecules to the diffusing iodine molecules would be shown by the failure of the diffusion equation to apply when the normal molecular weights and volumes are used.

The variation of diffusivity with temperature has never received a thorough investigation over a wide range. It is usual to assume D a linear function of t, according to the Nernst equation

$$D = D_0(1 + bt) \tag{15}$$

where b is the usual temperature coefficient. This relation is sufficiently accurate over short ranges, but for wide variation in temperature D is not linear in t. The Stokes–Einstein equation provides the relation

$$D \propto T/Z \tag{16}$$

Cohen and Bruins,[41] investigating the diffusion of acetylene tetrabromide in acetylene tetrachloride, found the relation to be true over the range 0–50°; Scheffer,[42] for mannitol diffusing in water, verified it from 0 to 70°.

Taking the logarithm of both sides of the last equation and differentiating gives

$$\frac{1}{D}\frac{dD}{dT} = \frac{1}{T} - \frac{1}{Z}\frac{dZ}{dT} \qquad (17)$$

whence, by definition

$$b = 1/T - b_z \qquad (18)$$

where b_z is the corresponding temperature coefficient of viscosity. Also if instead of using the Stokes–Einstein equation, we choose to express the variation of D solely in terms of the change in Z, let

$$D = aZ^n \qquad (19)$$

from which

$$b = -nb_z \qquad (20)$$

To test these relations, we may use the data of Miller, over the range 10–20°. In Table XI the first column shows values of b_z calculated from the solvent viscosities. The second column gives values of b found from the Stokes–Einstein, relation, Equation 18, taking T to correspond to 15°, while the third column gives values of b from Equation 20, taking n as $3/2$. The fourth column contains values of b given by the empirical equation

$$b = 0.020(Zv^{2/3})^{1/2} \qquad (21)$$

Z and v both being at 20°. A study of this table indicates that the relation last given is the most satisfactory, and the Stokes–Einstein the least, though all agree fairly well with the observed values.

A study of the temperature coefficients found by Öholm[43] for diffusion in aqueous solution indicates that, like the factor F, b is (for dilute solutions) a function of the solvent properties only, converging to a value of **0.030** as solute concentration approaches zero. For concentrated solutions, b becomes greater or less than **0.030**, depending on the nature of the

---

[43] Öholm, *Z. physik. Chem.*, 70, 378 (1910); *Medd. Nobelinst.*, 2, 23, 24 (1913).

Z–c curve. For dilute solutions, since b is independent of solute nature, the relations deduced from Miller's data may be used for any diffusing substance.

It is apparent from an inspection of the tables given that the theory here presented is still incomplete, and can make no claim to mathematical exactness; nevertheless, the agreement with experiment is considerably better than any hitherto attained, and indicates that the method of approach is fundamentally sound and practicable. We have now to consider the several causes to which the deviations noted may be attributed.

Experimental errors in diffusion measurements are considerable, of the order of 5% for ordinary work, and undoubtedly are responsible for much of the disagreement. The use of a Kopp law V as representing the cube of the molecular diameter is open to some criticism; it has, however, been shown in the previous paper of this series that this volume corresponds closely with that calculated from gas viscosity, and is therefore probably satisfactory for diffusion calculations. The importance of errors in V is lessened by the fact that it appears in the equation for D as a cube root. The selection of 20° as a standard reference temperature is quite arbitrary, but in the absence of a more definite knowledge of the variation of D with T, it seems advisable to choose a constant temperature near that used experimentally. The further development of the present theory will undoubtedly require the expression of F as a function of T; it is to be noted that Equation 14 is correct only at 20°, and does not completely express the variation of D with T. The factor F is analogous to the $(1 + C/T)$ of the Sutherland theory of gaseous diffusion, both representing the effect of intermolecular forces on diffusional resistance.

The greater part of the observed discrepancy is probably traceable to three causes: (1) the assumption of binary, elastic collisions in a liquid system is inexact; (2) the van der Waals correction factor is not, as assumed, constant for all systems; (3) the functional relation between F and Z is not accurately given over a wide range by Equation 13. Of these, (1) and (2) are not remediable except by further analysis of the problem, while (3) awaits further data on diffusion in viscous, high-boiling solvents. Further, neglect of the dependence of F on the solute nature introduces some error, comparable in magnitude with the experimental errors and hence not yet subject to exact evaluation. It is also to be mentioned that F may be a function of molecular volume as well as molecular force, allowing for the mean free path shortening due to the space occupied by the molecules as well as that due to intermolecular attractions. Macleod[44] has shown that liquid viscosity is very simply related to the free space within the liquid, while Equation 13 is seen to contain the solvent molecular volume as a variable affecting F. The more exact

[44] *Macleod. Trans. Faraday Soc., 19,* 6 (1923); 21, 151 (1925).

evaluation of this factor, together with the applications of the principles above discussed, to the closely related problems of diffusion in mixed solvents, ionic mobility and the diffusion of electrolytes, will be considered in a later paper.

The writer is indebted to Mr. James J. Hogan for his careful reading of the manuscript and his many helpful suggestions; to Professor Warren K. Lewis for his continued interest in the work; and to the host of experimental investigators in this field during the past eighty years, whose contributions of painstaking and accurate work have made possible the present correlation.

Summary

The classical kinetic theory of gases has been applied to diffusion in liquid systems, assuming that the resistance to diffusion is due wholly to binary collisions, and that the mean free path shortening due to the volume occupied by the molecules is the same for all systems. Allowance is made for the retarding effect of intermolecular forces by introducing a factor F, which has been found empirically to be essentially independent of the nature of the diffusing substance and directly proportional to the square root of the solvent viscosity. "Associated" substances are found to require the use of abnormality factors in the expression for F; it is found that the usual hypothesis of molecular association is incapable of explaining the diffusional behavior of these substances, and that the related hypothesis of solvation of certain substances is unnecessary for good agreement with theory. The variation of diffusivity with temperature is discussed, and several rules are given for the prediction of temperature coefficients. Comparison of the observed diffusion coefficients with those calculated from the theory shows good agreement over a wide range of molecular weights and viscosities; the sources of the deviations observed are discussed.

THE HIGH TEMPERATURE EQUILIBRIUM OF TITANIUM DIOXIDE AND CARBON WITH TITANIUM CARBIDE AND CARBON MONOXIDE

BY L. REED BRANTLEY AND ARNOLD O. BECKMAN

RECEIVED AUGUST 4, 1930 PUBLISHED OCTOBER 6, 1930

Introduction

This investigation is a continuation of the researches on high temperature equilibria which have been carried out in this Laboratory.[1] The high pressure apparatus previously used in studying the equilibria between zirconium oxide and carbon,[1a] thorium oxide and carbon,[1c] and aluminum oxide and carbon[1d] was employed. The method consists in electrically heating a small graphite tube furnace which contains the solid reaction mixture, determining the temperature by an optical pyrometer, and measuring the gas pressure on a mercury manometer. The measurements described in this article include the pressures of carbon monoxide in equilibrium with the solid phases TiO_2, TiC and C over the pressure range 0.8 to 2.0 atmospheres and the temperature range 1000 to 1150°. The composition of the solid reaction mixture was determined by x-ray powder photographs.

The authors wish to express their thanks to Dr. W. B. Hincke for his suggestions and interest in this work and to Mr. F. J. Ewing for his assistance in obtaining the x-ray photographs.

Apparatus and Procedure

The apparatus was substantially the same as that used in the previous high pressure investigations.[1a,c,d] A more convenient furnace assembly was used, however, which had been developed by Dr. Hincke and one of us during the course of the investigation (unpublished) of the calcium oxide–carbon equilibrium. As is shown in Fig. 1A the graphite furnace A was supported by tungsten leads which were, in turn, connected through flexible copper cable to the water-cooled copper tubes B and C which were held rigidly co-linear by attachment to the heavy rod D. Electrode B was held in place by a micarta insulating support E; electrode C was held by a similar brass support F fitted with a thumbscrew H. The pyrex furnace bulb was sealed to the electrodes at G with sealing wax. A side tube with an inverted cup connection, also sealed with sealing wax, connected the furnace bulb with the manometer and auxiliary gas apparatus. Since the entire furnace was immersed in a water thermostat, it was necessary to protect the exposed sealing wax with paraffin.

To insert a furnace tube, the glass bulb was slipped over the lowered electrode C, which was then raised to allow the insertion of the furnace tube, after which thumbscrew H was tightened and the glass furnace bulb raised and sealed in position. It was found

that the sealing wax seals were gas tight even at two atmospheres' pressure and a furnace temperature of 2000°K.

The furnace tubes, Fig. 1B, were turned from Acheson graphite with a groove near each end to provide a central region of nearly uniform temperature within which the charge was held by graphite plugs. Two types of charge were used, one consisting of TiC and the other consisting of stoichiometric quantities of TiO_2 and graphite. In each case the materials were ground to pass through a 200-mesh sieve. The TiC was prepared by heating in *vacuo* an equimolal mixture of powdered titanium and graphite to a temperature (1950°K.) sufficiently high to volatilize any uncombined titanium metal. The TiO_2 and the metal were Eimer and Amend C. P. preparations.

When the charge consisted of TiC, the furnace was baked out in *vacuo* at a high temperature, after which the temperature was lowered to 1275 to 1350°K., and the heating continued for six to seven hours with carbon monoxide present at a pressure of about two atmospheres. When the charge consisted of TiO_2 and graphite, the furnace was heated in *vacuo* at a dull red heat for a few seconds. The apparatus was then filled with carbon monoxide at a pressure of about two atmospheres and the furnace heated to about 1750°K. for half an hour to drive off adsorbed oxygen. The furnace was then evacuated and refilled with fresh carbon monoxide at the desired pressure for the equilibrium measurements. It was found that under these conditions reaction mixtures were produced which gave satisfactory rates of reaction for the equilibrium measurements.

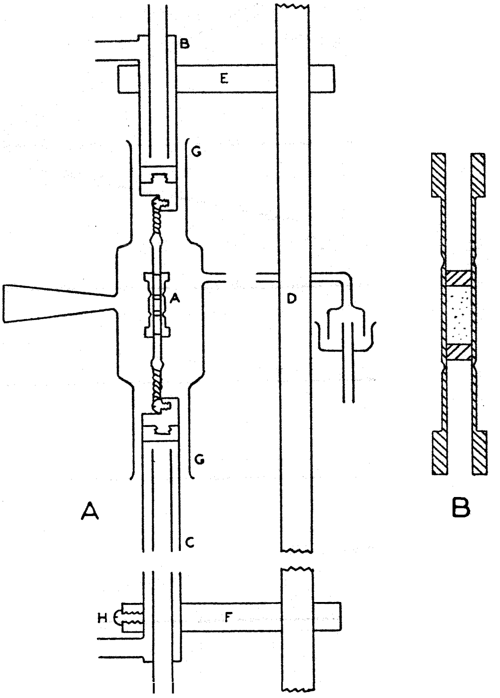

Fig. 1.—Furnace bulb and graphite furnace.

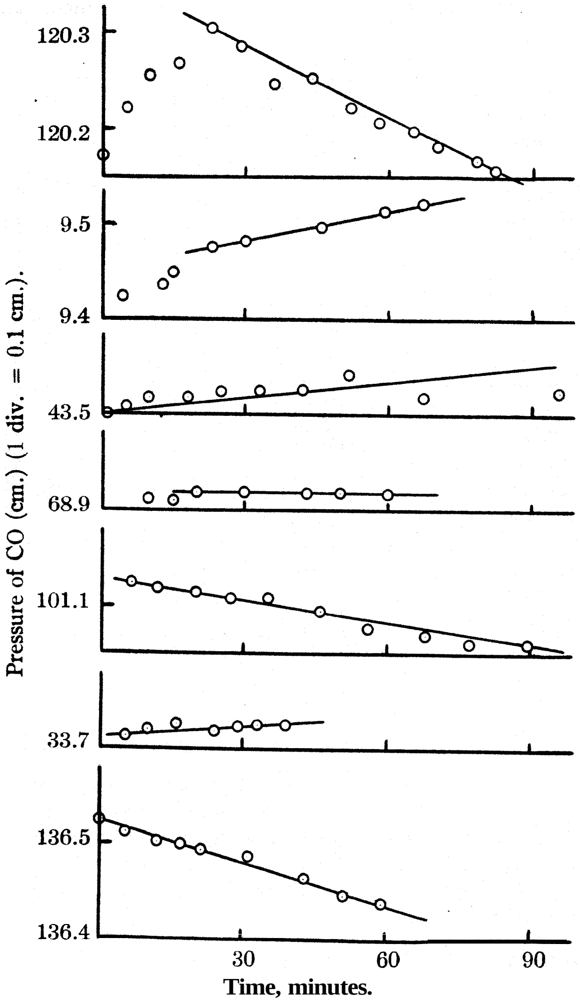
For preliminary work the furnace was heated by an alternating current from a low-voltage one-kilowatt transformer, but for the final measurements a direct current from storage batteries was used. To maintain a temperature of 1330°K. a current of about 70 amperes at 6 volts was required.

The Equilibrium Measurements

The equilibrium pressures were determined by measuring the rate of reaction (*i.* e., the rate of change of carbon monoxide pressure) at constant temperature for different pressures of carbon monoxide. By obtaining a series of both forward and reverse rates with the same furnace charge, the equilibrium pressure was found graphically as the pressure corresponding to zero rate. Typical graphs are shown in Figs. 2 and 3. In Fig. 2 are shown the carbon monoxide pressures plotted as ordinates against the time as abscissas for six successive runs at the temperature 1278°K. with different initial carbon monoxide pressures. For each run the average rate of pressure change was determined, rejecting values which were obtained during the first thirty to forty minutes of the run when the system was attaining equilibrium. These six rates are shown as ordinates in Fig. 3 with the average pressure during the run as abscissas. The intersection with the zero rate ordinate of the best straight line through these points shows the equilibrium pressure to be 60.5 cm. at this temperature.



Run	Pressure, cm.	Reaction rate (cm. X 10^3/min.)
A	120.2	−2.360
B	9.5	+1.080
C	43.5	+0.424
D	68.9	0.000
E	101.1	−0.737
F	33.7	+0.385
G	136.5	−1.473

Fig. 2.—Change of pressure with time during a typical experiment (1278°K.).

Six sets of runs of this kind were made over the temperature range 1278 to 1428°K. and pressure range from a few centimeters to two atmospheres. In some cases the initial furnace charge consisted of TiO_2 and C, and in other cases of TiC. The equilibrium pressures and corresponding temperatures are given in Table I, where Θ is the observed temperature and T is the true temperature after corrections have been made for the transmission of the window and the emissivity of carbon as in the previous work.

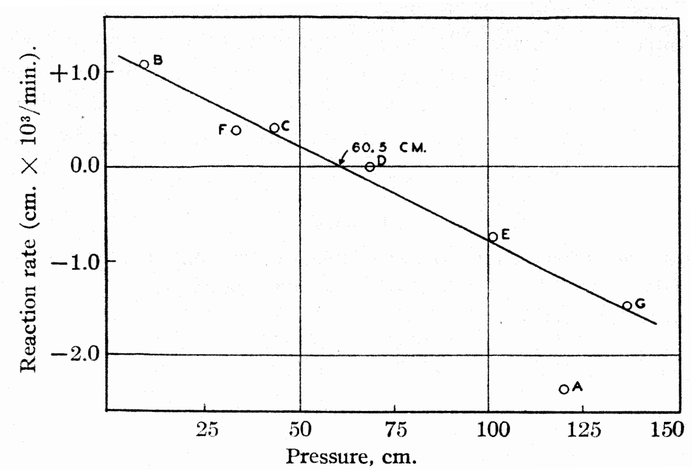


Fig. 3.—Change of reaction rate with pressure for a typical experiment (1278°K.); equilibrium pressure = 60.5 cm.

In Fig. 4 the logarithms of the equilibrium pressures are shown plotted against the reciprocals of the absolute temperatures, and it will be seen that all of the points fall upon a straight line within the experimental error.

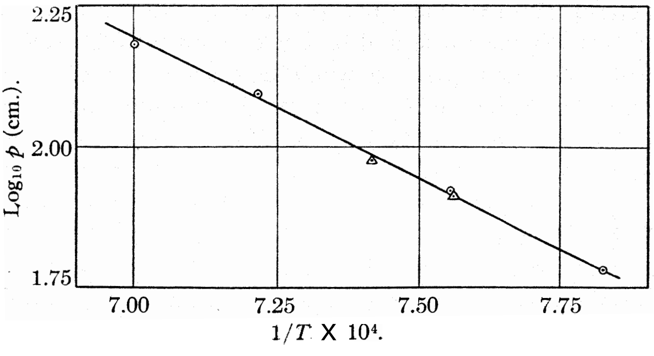

Fig. 4.—Relation between absolute temperature and equilibrium pressure of CO; circles, furnace charge initially consisted of TiO_2 + C; triangles, furnace charge initially consisted of TiC.

The relation between the equilibrium pressures and absolute temperature is given by the equation

$$\log_{10} p_{\text{atm.}} = 3.829 - 5024/T$$

A furnace charge was never used for more than two, and usually for only one, equilibrium pressure determinations. One run was attempted at 1246°K., but the reaction rates were too slow to measure accurately.

The dissociation of carbon monoxide into carbon dioxide and carbon is appreciable in this temperature range, being approximately 0.6% at 1278°K. and 0.1% at 1428°K. It is well known, however, that equilibrium is attained only very slowly. In blank experiments, using an entirely empty graphite furnace at temperatures, with carbon monoxide pressures, and over time intervals similar to those used in the equilibrium measurements, no measurable rates were observed, showing that the carbon monoxide dissociation could be entirely neglected.

TABLE I

EQUILIBRIUM PRESSURES AND FREE ENERGIES AT VARIOUS TEMPERATURES

1393	1428	7.003	1.995	.2999	−3916

The Nature of the Solid Phases

To determine the nature of the solid phases an analytical method was attempted, but the small quantities of materials available and the lack of information regarding the chemistry of the lower oxides of titanium led to the abandonment of this method. X-Ray powder photographs were finally taken of the reaction mixtures and of the various substances, namely, TiO_2 (both the rutile and brookite modifications), TiC, graphite, Ti metal and TiO, whose presence would be suspected in the reaction mixtures. The TiO was prepared by heating in the graphite furnace to 1775°K. for half an hour *in vacuo* a mixture of finely ground TiO_2 and Ti in approximately stoichiometric proportions. The work of Billy[2] has shown that TiO is formed under these conditions, although perhaps there may be some uncombined TiO_2 or Ti as well. The diameters of the rings (*i.e.*, the distances between corresponding lines on either side of the position of zero deflection) obtained on the eight photographs are represented in Fig. 5. Photographs were taken of two reaction mixtures, one (Fig. 5a) in which the initial charge was TiO_2 and graphite, and one (Fig. 5b) in which the initial charge was TiC.

The results of this investigation showed that the solid phases in the reaction mixture were TiO_2 (rutile modification), TiC and graphite. Metallic titanium, the brookite modification of TiO_2, and the lower oxide TiO were definitely shown to be absent.

---

[2] Billy, Ann. *Chim.*, 16, 23 (1921).

Thermodynamic Calculations

From the results of the x-ray investigation the equilibrium studied is undoubtedly that expressed by the equation

$$TiO_2 + 3C = TiC + 2CO$$

The value of ΔF, the free energy increase attending this reaction, may be derived from the thermodynamic equation $\Delta F = -RT \ln K$, where $K = p^2$. The values of ΔF corresponding to the equilibrium pressures at various temperatures are given in the last column of Table I.

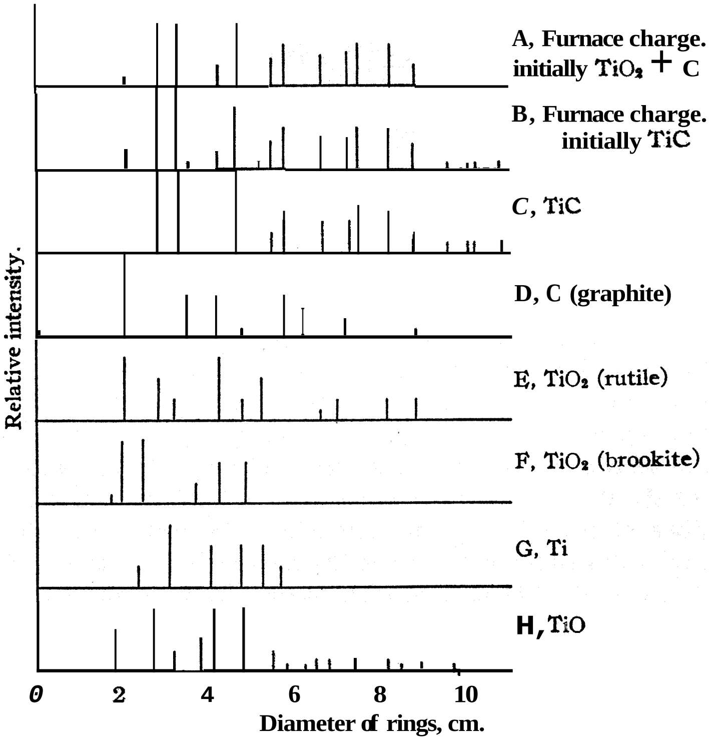

Fig. 5.—Results of x-ray powder photographs.

From the expression for $\log_{10} p$ given in the previous section, the relation

$$\Delta F = 45{,}930 - 35.01T$$

may be obtained for the temperature range 1278 to 1428°K. From this it follows that the increase in heat content, ΔH, is 45,930 calories. At 1312°K. the free energy is zero and the equilibrium pressure is one atmosphere.

Summary

Determinations have been made of the equilibrium pressures of carbon monoxide for the reaction

$$TiO_2 + 3C = TiC + 2CO$$

in the temperature range 1278 to 1428°K. The solid phases were identified by x-ray powder photographs.

Within this temperature range the increases in free energy and heat content that attend this reaction at one atmosphere pressure were found to be given by the expression A F = 45,930 − 35.01 T calories and A H = 45,930 calories. The equilibrium pressure is one atmosphere at 1312°K.

THE EFFECT OF ADDED SALTS UPON THE SOLUBILITY OF OTHER SALTS IN ETHYL ALCOHOL

BY RALPH P. SEWARD WITH WALTER C. SCHUMB

RECEIVED AUGUST 19, 1930 PUBLISHED OCTOBER 6, 1930

Introduction

The measurement of the relative solubility of a salt in a pure solvent and in the presence of other salts gives a ready measure of the change of potential or of the activity coefficient of the saturating salt These changes should be quantitatively accounted for by any adequate theory of solutions. The inter-ionic theory of Debye and Hückel[1] has achieved considerable success in describing the properties of strong electrolytes, particularly in aqueous solutions. As the inter-ionic forces vary inversely with the dielectric constant of the solvent, we may expect a more sensitive test of the theory in the case of solvents of lower dielectric constant. The number of investigations in non-aqueous solutions by which the theory may be tested is small. Solubility measurements have been made in methyl alcohol by Williams,[2] in ethyl alcohol by King and Partington,[3] in acetone by Robinson[4] and by Kraus and Seward,[5] in isopropyl alcohol by Kraus and Seward,[5] and in ethyl alcohol–water mixtures by Hansen and Williams.[6] These measurements indicate that marked deviations from the original Debye–Hückel approximation are found in aqueous and methyl alcohol solutions only in the case of higher valence salts. La Mer and Mason[7] have discussed these deviations. In solvents of lower dielectric constant, however, marked deviations have been observed in the case of univalent salts even in the most dilute solutions.

The present investigation consists of the determination of the solubility

of potassium chloride in ethyl alcohol in the presence of ammonium nitrate; the solubility of potassium perchlorate in ethyl alcohol in the presence of ammonium nitrate, ammonium perchlorate and ammonium iodide; the solubility of barium nitrate in ethyl alcohol in the presence of ammonium bromide; and the comparison of the results with those predicted by the inter-ionic attraction theory.

As the inter-ionic relations should be most simple in dilute solutions, it is of importance to select salts, the saturated solutions of which are the most dilute in which their solubility may be determined with a reasonable degree of accuracy. The selection of the salts used as saturating salts was therefore determined by this consideration and that of their analytical determination. For the added or solvent salt one which was considerably more soluble and did not interfere with the analysis was selected

Preparation of Materials.—Part of the solvent used was 92% ethyl alcohol dehydrated with lime by the method recommended by W. A. Noyes;[8] part was a commercial anhydrous alcohol which was given one treatment with lime and subsequent distillation. Both samples had a density of 0.7852 at 25°.

The salts used were the purest available, further purified by recrystallization and carefully dried.

Determination of Solubilities.—The method was that used by Kraus and Seward.[6] A quantity of solvent containing a known amount of the added salt was agitated with an excess of the saturating salt until equilibrium was reached and the concentration of the saturating salt in the resulting solution determined analytically. About five grams—a large excess—of finely ground saturating salt was introduced into a cylindrical bottle having a length of approximately 38 cm., a diameter of 10 cm., and a capacity of 3 liters. A known weight of the second salt was then introduced into the bottle and a known weight, 1.5 to 2 liters, of pure solvent added.

The bottles were provided with narrow necks and closed with ground stoppers which were covered by rubber caps when in use. Four bottles were rotated at one time in a horizontal position in a water thermostat. The bottles were rotated initially for sixteen hours at a temperature of 28–30°, after which the temperature was lowered to 25 ± 0.01° and the rotation continued for six hours. The bottles were then set upright without being removed from the thermostat and allowed to settle for four hours or more. Two samples of 500 cc. or more were then removed from each bottle and the amounts of solution determined by weighing in glass-stoppered Erlenmeyer flasks. The solvent was then removed by distillation and the residue containing the salts transferred to a beaker or small dish. The amount of the saturating salt was then determined gravimetrically in all cases. With potassium chloride as the saturating salt the chloride was determined by weighing as silver chloride in a Gooch crucible. With potassium perchlorate as the saturating salt, the potassium was determined as potassium sulfate by adding an excess of sulfuric acid to the residue left by distillation of the solution after transferring it to a silica or platinum dish and heating to constant weight. This method was tested with known mixtures of potassium perchlorate with ammonium salts and found to be sufficiently accurate. The solubility of barium nitrate was determined by weighing the barium as barium sulfate. Due to the very slight solubility of the nitrate and consequent small weight of barium sulfate, the analyses were not very satisfactory. The mean values obtained, however, lie on a fairly smooth curve.

---

[8] W. A. Noyes, THIS JOURNAL, 45, 860 (1923).

Experimental Results

The solubilities of the different saturating salts in solutions with known amounts of a second salt are shown in the tables. All concentrations are expressed in moles per liter. The density of the pure solvent was used in calculating the concentrations. In addition, for the purpose of com-

paring with the theory, the square roots of the ionic strengths and the calculated values of $-\ ^1/_2 \log P_{i_0}/P_i$ are given. In the case of the biunivalent salt, barium nitrate, the function used is $-\ ^1/_3 \log P_{i_0}/P_i$.

Discussion

The results in general resemble those in other solvents: there is a uniform increase in solubility on the addition of a salt without a common ion and a decrease on the addition of a salt with a common ion.

The Debye–Hückel theory leads to the equation

$$-\log f = \frac{2.72\, Z_1 Z_2 \sqrt{\mu}}{1 + (0.576 \times 10^8)a\sqrt{\mu}} \tag{1}$$

for ethyl alcohol at 25°, where f is the activity coefficient of the salt, Z_1 and Z_2 are the valences of the ions, a is the average ion diameter and μ the ionic strength. Inasmuch as, for a uni-univalent salt

$$-\log f = -1/2 \log P_{i_0}/P_i - \log f_0 \tag{2}$$

where the quantity P_i indicates the product of the ion concentrations of the salt, P_{i_0} indicates this product for the salt in the pure solvent, and f_0, the activity coefficient of the salt in the pure solvent, is a constant, the values of $-1/2 \log P_{i_0}/P_i$ plotted against the square root of the ionic strengths should give a curve which is very nearly a straight line with a slope of 2.72 for dilute solutions.

Figures 1 and 2 show how the curves from the solubility measurements compare with the limiting line from Equation 1.

Examination of these curves shows considerable deviation from the Debye–Hückel limiting slope. The experimental curves all have a greater slope than the theoretical. This could be accounted for only by assuming negative values of a in (1). The relative deviations from the Debye–Huckel limiting slope are slightly less in the potassium perchlorate solutions than in the potassium chloride solutions where the concentrations are somewhat greater. Comparison of the curves with those obtained for similar solutions in isopropyl alcohol and acetone by Kraus and Seward[5] shows that the relative deviations from the theoretical limiting slope are much less in ethyl alcohol solutions than in isopropyl alcohol and acetone.

It has been pointed out that the treatment of Debye and Hückel in arriving at Equation 1 involves certain approximations which cause considerable error with ions of higher valence in water and even with univalent ions in solvents of low dielectric constant. Gronwall, La Mer and Sandved[9] by calculating the influence of the neglected higher terms of the Debye–Hückel equation have derived corrections to account for such deviations as those observed. Bjerrum,[10] by calculating the probability of the existence of associated ion pairs and treating them as uncharged, was able to explain such deviations while giving reasonable values for ion

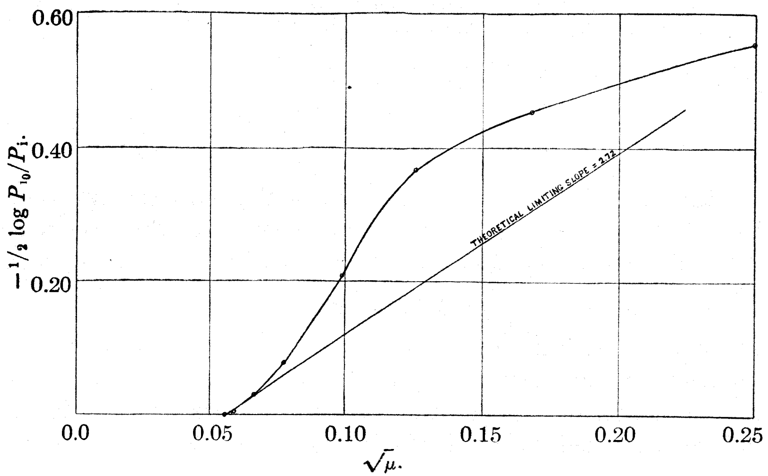

Fig. I.—KCl + NH_4NO_3.

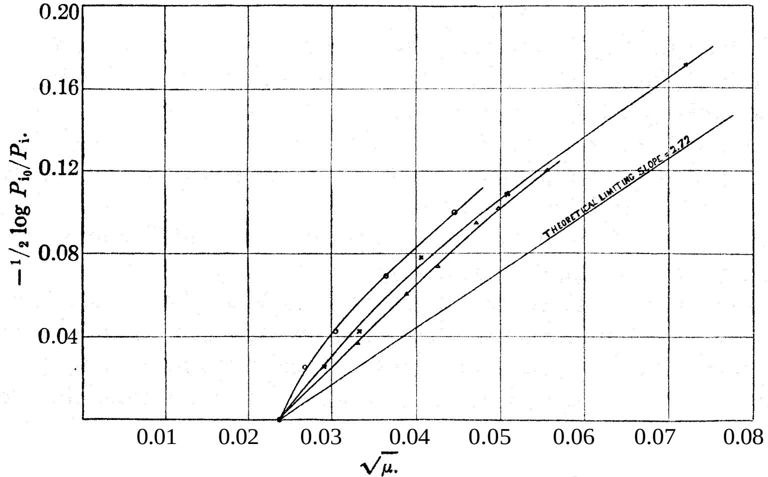

Fig. 2.—0, $KClO_4$ + NH_4ClO_4; ×, $KClO_4$ + NH_4NO_3; △, $KClO_4$ + NH_4I.

[10] Bjerrum, *Det. Kgl. Danske Videnskab Selskab, Math.-fys. Medd.*, [9] 7, 1 (1926).

diameters. Both the treatment of Gronwall, La Mer and Sandved and that of Bjerrum lead to the same conclusion, namely, that deviations from the Debye–Hückel limiting slope are to be expected in solutions of lower dielectric constant even in very dilute solutions and the smaller the average ion diameter the greater the positive deviation from the limiting slope.

By applying the results of Bjerrum's calculations a value of 2.5 Å. is obtained for the average ion diameter in the potassium perchlorate–ammonium nitrate mixtures in ethyl alcohol. This appears to be a reasonable value. Moreover, taking different points on the curve, the average diameters obtained are fairly constant.

Summary

The solubilities of potassium chloride, potassium perchlorate and barium nitrate in the presence of other salts in ethyl alcohol have been measured and the results compared with those predicted by the inter-ionic attraction theory.

While the solubility results in ethyl alcohol show marked deviations from those predicted on the basis of the original Debye–Hückel approximation, they seem to be, qualitatively at least, in agreement with the inter-ionic attraction theory as developed by Gronwall, La Mer and Sandved or by Bjerrum.

THE FREE ENERGY OF STANNOUS HYDROXYL CHLORIDE AND THE ACTIVITY COEFFICIENT OF STANNOUS CHLORIDE AND STANNOUS ION

BY MERLE RANDALL AND SENZO MURAKAMI

RECEIVED SEPTEMBER 2, 1930 PUBLISHED OCTOBER 6, 1930

The hydrolysis product of stannous ion is the basic stannous hydroxyl chloride $SnOHCl \cdot H_2O$, which is a stable white insoluble solid.[1] The determination of the equilibrium of the hydrolysis reaction

$$Sn^{++} + Cl^- + 2H_2O(l) = SnOHCl \cdot H_2O(s) + H^+; \; K_m = m(H^+)/m(Sn^{++})m(Cl^-) \quad (1)$$

enables us, by combination with the known free energies of the other substances occuring in Equation 1, to determine the free energy of the solid hydrolysis product. Furthermore, from the rather unusual way in which the activity coefficients of H^+ and Cl^- occur in the expression for the equilibrium constant, the individual activity coefficient of the stannous ion

---

[1] The simplest formula of the basic salt is used. The amount of hydration is uncertain. See (a) Proust, *J. Phys.*, 61, 338 (1804); Ann. *chim.*, 28, 213 (1798); (b) Davy, *Trans. Roy. Soc.* (London), 102A, 169 (1912); (c) Ditte, *Compt.* rend., 94, 792, 1114 (1882); Ann. chim., [5] 27, 145 (1882); Comfit, rend., 97, 42 (1883).

is obtained by means of assumptions which are less uncertain than those usually employed.

The Solubility of Stannous Hydroxyl Chloride in Aqueous Hydrochloric Acid at 25°.—The stannous hydroxyl chloride was prepared in two ways. (1) In the first series of experiments an approximately 0.5 M solution of stannous chloride was prepared by dissolving c. p. $SnCl_2\cdot2H_2O$ in conductivity water with the addition of just enough c. p. hydrochloric acid (0.006–0.008 M) to give a clear solution. Pure metallic tin was then added. The air was displaced and the solution agitated by a stream of pure nitrogen which was bubbled through. The solution was then added, in the absence of air, to a large volume of air-free conductivity water. The precipitate formed was washed several times by decantation with air-free water. The suspension of the solid in water was used for the solubility experiments. (2) In the remaining experiments the stock solution of acid stannous chloride was precipitated by adding an air-free solution of sodium chloride and hydroxide, the chloride being in large excess. The precipitate was washed free from sodium ion by decantation, as before. On analysis our salt corresponded to the formula $SnOHCl\cdot(1.00 \pm 0.01)H_2O$.

A portion of the paste containing about 10 g. of the solid phase was transferred, in the absence of air, to a 250-ml. pyrex distilling flask body which had been swept free of air by nitrogen. Dilute air-free hydrochloric acid

solution or water was added, the flasks were sealed and rotated in the thermostat at 25 ± 0.02.[2]

After the time of rotation indicated in Col. 2 of Table I, the solution was filtered[2] and analyzed (moles per 1000 g. of water in vacuum). The stannous-ion constituent (Col. 3) was determined by titration with potassium permanganate solution. Dilute nitric acid was added to give a sufficient hydrogen-ion concentration for the titration. After titration the chloride-ion constituent (Col. 4) was determined as silver chloride by precipitation The hydrogen-ion constituent was determined by difference. In Expts. 7 to 13 in which the stannous ion was very small the hydrogen-ion constituent was determined by titration with sodium hydroxide solution (phenolphthalein indicator) and chloride-ion constituent was taken equal to twice the stannous ion plus the hydrogen-ion constituent.

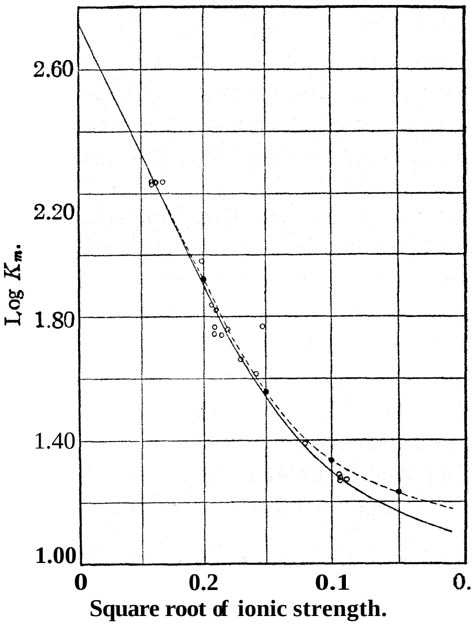

Fig. 1.—$Sn^{++} + Cl^- + 2H_2O(l) = SnOHCl{\cdot}H_2O(s) + H^+(25°)$.

In plotting Fig 1, the scale of the square root of the ionic strength (Cot. 7) was made the same, and the scale of log K (Equation 1, Col. 6) was made one-fourth that of Fig. 2 of Randall and Vietti,[2] for the following reason. If we again consider Equation 1, the expression for the equilibrium constant is

$$K = m\gamma(H^+)/m\gamma(Sn^{++})m\gamma(Cl^-) \qquad (2)$$

The individual activity coefficient of H^+ is very nearly the same as that of Cl^-, especially in the more dilute solutions. Furthermore, we should expect the activity coefficient of these ions to be more nearly alike in mixtures with stannous ion, and in the presence of the large excess of chloride ion.[3] We also find as a consequence of the Debye–Hückel treatment of dilute solutions that at near zero molality[3,4]

---

[4] Debye and Hückel, *Physik. Z.*, 24, 185 (1923).

$$\log \gamma = -z^2 A \mu^{1/2} = -z_1 z_2 A \mu^{1/2} \qquad (3)$$

where z is the valence of an ion, A is a constant $= 0.503$ at 25°, and μ is the ionic strength. In the case of the mean activity coefficient z^2 is replaced by 2 for uni-bivalent salts. In order, therefore, to have the plot of the logarithm of the activity coefficient of a bivalent ion, or its value plus a constant superimpose on our standard plot, we must make the scale one-fourth that of a univalent salt. By comparison with the standard curves2 we find $\log K = 2.75$, or

$$\mathrm{Sn^{++} + Cl^- + 2H_2O(l) = SnOHCl{\cdot}H_2O(s) + H^+};\quad \Delta F^\circ_{298\cdot1} = -3750\ \text{cal.} \qquad (4)$$

Using the values of the free energy of chloride ion given by Randall and Young[5] and the value of —6276 cal. for the free energy of stannous ion[a] we find for the free energy of formation of stannous hydroxyl chloride

$$\mathrm{Sn(s) + {}^1\!/_2Cl_2(g) + 1{}^1\!/_2H_2(g) + O_2(g) = SnOHCl{\cdot}H_2O(s)};$$
$$\Delta F^\circ_{298\cdot1} = -154{,}491\ \text{cal.} \qquad (5)$$

If we assume the individual-ion activity coefficients given by Lewis and Randall,[6] we find at four molalities the values for $\log \gamma\ (\mathrm{Sn^{++}}) + \log K$ indicated on the dotted curve. The values of the activity coefficient of stannous ion found by subtracting $\log K$ from the values of $\log K_m$ are, however, probably more nearly the correct values than those found by using the individual-ion activities which are based on the values in pure hydrochloric acid. The values of the activity coefficient of stannous ion are smaller than those of the alkali earth bivalent ions.

We may also write Equation 1 in the form

$$\mathrm{Sn^{++} + 2Cl^- + 2H_2O(l) = SnOHCl{\cdot}H_2O(s) + H^+ + Cl^-};$$
$$K = m\gamma(\mathrm{H^+})m\gamma(\mathrm{Cl^-})/m\gamma(\mathrm{Sn^{++}})m^2\gamma^2(\mathrm{Cl^-}) \qquad (6)$$

where the numerical value of K is obviously identical with that in Equation 1. We may also write

$$\log K = \log K_m + \log \gamma^2_\pm(\mathrm{HCl}) - \log \gamma^3_\pm\ (\mathrm{SnCl_2})$$

whence, rearranging

$$\log \gamma_\pm(\mathrm{SnCl_2}) + {}^1\!/_3 \log K = {}^1\!/_3 \log K_m + {}^2\!/_3 \log \gamma_\pm(\mathrm{HCl}) \qquad (7)$$

TABLE II

[6] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances." McGraw-Hill Book Co., New York and London, 1923.

The values of log $\gamma_{\pm}$ $(SnCl_2)$ given by this procedure will be those in the presence of hydrochloric acid, and the values of log $\gamma_{\pm}(HCl)$ which should be used are those in the presence of stannous chloride, We give in Table I along with the values of $^1/_3$ log K_m (Col. 9), the values for the ratio of the molality of the hydrochloric acid to that of stannous chloride, and the values of $^1/_3$ log K_m + $^2/_3$ log $\gamma_{\pm}(HCl)$ = log $\gamma_{\pm}(SnCl_2)$ + const., where the value of $^2/_3$ log $\gamma_{\pm}(HCl)$ is taken from the curves of Randall and Breckenridge in mixtures of hydrochloric acid and barium chloride at the same ratio and same ionic strength. This approximation is not entirely justified as the stannous chloride is a "weaker" salt than barium chloride, but the approximation is better than taking the activity coefficient in pure hydrochloric acid. The values of $^1/_3$ log K_m and of $^1/_3$ log K_m + $^2/_3$ log $\gamma_{\pm}(HCl)$ are plotted against $\mu^{1/2}$ in Fig. 2 and lead to an extrapolated value of $^1/_3$ log K which is identical with $^1/_3$ log K, as was found from Fig. 1. The values of log $\gamma_{\pm}(Sn^{++})$ and of log $\gamma_{\pm}(SnCl_2)$ at round molalities, as determined by substituting log K in Equations *2* and 7, are given in Table II.

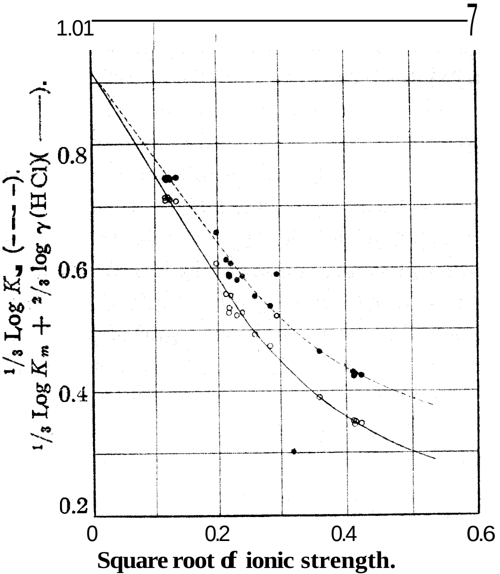

Fig. 2.—$Sn^{++} + 2Cl^- + 2H_2O(l) = SnOHCl \cdot H_2O(s) + H^+ + Cl^-(25°)$.

Summary

The equilibrium in the hydrolysis of stannous chloride has been measured at 25°. The free energy of the solid stannous hydroxyl chloride and the activity coefficient of stannous chloride and of stannous ion have been calculated,

Berkeley, California

NOTES

The Molecular Diameters of Nitrogen Pentoxide.—Eyring and Van Valkenburgh[1] have just published a determination of the viscosity of nitrogen pentoxide; from this viscosity they calculate a molecular diameter of 8.53×10^{-8} cm. I should like to make a few comments on the application of this value to reaction rate calculations. It is common to all modern theories of unimolecular reaction that the rate of production of activated molecules is calculated by assuming that it is equal to the rate at which these activated molecules would enter into collision if they were present at the Maxwell–Boltzmann equilibrium concentration. In this usage a collision is an interaction which leads to a redistribution of internal energy; the diameter which is appropriate to the calculation of the number of such collisions is not the ordinary kinetic theory diameter, though it must be of the same order of magnitude, if grave difficulties are to be avoided. Thus the 8.53×10^{-8} cm. of Eyring and Van Valkenburgh is of no *direct* significance for the theory of the unimolecular decomposition of nitrogen pentoxide.

The statement of Eyring and Van Valkenburgh that recent calculations[2] show that a diameter of 6×10^{-6} cm. must be used to obtain sufficient activations is hardly correct. When these calculations were made, three years ago, they referred to the particular form of theory proposed by Fowler and Rideal.[3] Since that time more satisfactory theories have been proposed, and also considerable new work has been done on the actual measurement of the reaction rate at low pressures.[4] It now appears that the true homogeneous reaction rate falls off to half its high-pressure value at about 0.005 mm. Reference to the calculations made by the writer[5] before these new data were available shows that, on one particular form of theory, they may be accounted for by using a diameter of about 17×10^{-8} cm., which must be considered a permissible value. The details of the theory are so uncertain that one cannot assert the true diameter for collisional deactivation to be greater than that determined by Eyring and Van Valkenburgh; there is, however, no reason why it should not be.

Note on Bimolecular Reactions.—In homogeneous bimolecular reactions, integration of the two velocity expressions, $dx/dt = k(a - x)^2$, when the two reacting molecules are alike or of the same initial concentrations, and $dx/dt = k(a - x)(b - x)$, when the reacting molecules are unlike, leads to the following familiar equations

$$k = \frac{1}{ta} \times \frac{x}{(a - x)}, \text{ and} \tag{1}$$

$$k = \frac{1}{t(a - b)} \times \log \frac{b(a - x)}{a(b - x)} \tag{2}$$

where the symbols have their usual significance. It is a physical necessity that expression (2) reduce to (1) if $b = a$. Yet it is obvious that (2) assumes the form 0/0 when $b = a$.

It has been shown in several places[1] that (2) does become equal to (1) under this condition, by expanding the logarithm term in (2) in series and evaluating the resulting expression. However, the methods quoted require a page or more of mathematical simplification to obtain the desired result. On the other hand, making use of the customary way of evaluating 0/0, we have been able to find in a very simple manner the limiting value of the ratio as $b \longrightarrow a$, and from this to show the identity of the two expressions. It proves to be a rather interesting situation, and since it does not appear in any of the ordinary textbooks on the subject, we thought that it might be worth while to pass it on.

From (2)

$$k = \frac{\log b + \log (a - x) - \log a - \log (b - x)}{t(a - b)} = \frac{0}{0}$$

when $b = a$. Now since this would be 0/0 for all finite values of x and t, for our purpose we may treat these as constants and take

$$\lim_{b \longrightarrow a} \frac{f(b)}{F(b)}$$

Treating b as the variable, and differentiating numerator and denominator separately[2] we get[a]

$$\frac{\frac{1}{b} - \frac{1}{b - x}}{-t}$$

THE SKRAUP REACTION WITH CERTAIN AZO COMPOUNDS

BY KONOMU MATSUMURA

RECEIVED FEBRUARY 27, 1930 PUBLISHED OCTOBER 6, 1930

In the course of an investigation of the possible explanation of the reaction mechanism of the formation of p-phenanthroline in the Skraup reaction with p-aminoresorcin dimethyl ether, p-benzene-azo-resorcin dimethyl ether was subjected to the Skraup reaction and the product was found unexpectedly to be also p-phenanthroline; the yield in this case was three times as good as in the same reaction with p-aminoresorcin dimethyl ether. The formation of *p*-phenanthroline was also established, in the same way, from *p*-benzene-azo-resorcin, whereas from p-aminoresorcin, no crystalline matter could be isolated, on working under the same conditions.

From these facts it seemed that in case of the Skraup reaction with rather unstable amines, better results might follow if the corresponding azo compounds were used as reactants: and here I have extended this study to several azo compounds.

Concerning the study of the Skraup reaction with azo compounds, work has been reported by Claus and Stegelitz[1] and later by Lellmann and Lippert.[2] They established the formation of the corresponding ring compounds in this reaction, but the yield in each case was reported to be very poor. In the present investigation the reactions were carried out with the addition of arsenic acid, this being the only difference from the methods of previous investigations.

TABLE I

EFFECT OF ARSENIC ACID IN THE SKRAUP REACTION WITH AZO COMPOUNDS

Reactants	Products	Yield, g.	
		Presence of H_3AsO_4	Absence of H_3AsO_4
Azobenzene, 10 g.	Quinoline picrate	0.5	0.65
	6,6′-Diquinolyl	5.7	1.2
p-Benzene-azo-resorcin dimethyl ether	Quinoline	2.0–2.5	1.4
	p-Phenanthroline	1.35–1.5	0.3

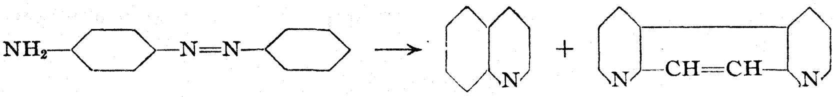
---

[1] Claus and Stegelitz, *Ber.*, 17, 2380 (1884).

[2] Lellmann and Lippert, *ibid.*, 24, 2623 (1891).

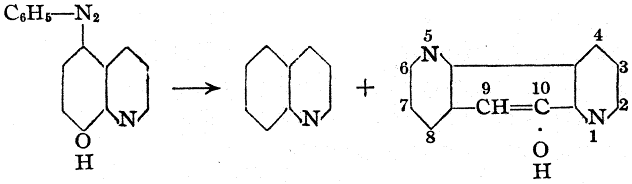
First of all, in order to find the influence of the presence of arsenic acid in the reaction, the following two pairs of experiments were performed for the sake of comparison, with the result that, in the Skraup reaction with azo compounds, the presence of arsenic acid gave far better yields (Table I).

In view of this fact, it seems that the action of arsenic acid in the Skraup reaction may be other than it has previously been thought to be. In the Skraup reaction with p-amino-azobenzene, p-phenanthroline could he isolated in a satisfactory yield in accordance with the scheme



The preparation of p-phenanthroline was reported by Kaufmann and Radošević[3] by the Skraup reaction with 6-aminoquinoline and recently by Smith by the same reaction with *p*-phenylenediamine.[4] The Skraup reaction with p-amino-azobenzene, however, appears to be the most suitable for preparing it in quantity, because *p*-amino-azobenzene is more easily accessible than 6-amonoquinoline or *p*-phenylenediamine.

In the Skraup reaction with benzene-azo-5-hydroxy-8-quinoline, the yield of 10-hydroxy-*m*-phenanthroline was very poor on working up under a variety of conditions.



La Coste,[5] in the Skraup reaction with *m*-nitraniline, could isolate an hydroxy-m-phenanthroline (m. p. 159–60°) as a by-product and, as to the position of the hydroxyl group, he concluded, under his reasonable interpretation, that the substance might be 2-hydroxy-m-phenanthroline.

The hydroxy-m-phenanthroline he had obtained appears to be very near in its properties to 10-hydroxy-m-phenanthroline (m. p. 157–158°), which I have now obtained.

Pictet and his co-worker[6] obtained phenotripyridine in good yields in the Skraup reaction with 1,3,5-triaminobenzene. Chrysoidin was now submitted to the Skraup reaction, with the expectation of obtaining one of its structural isomers in accordance with the equation

After a tedious process of separation, a minute amount of colorless needles (m. p. 155–156°) could be isolated by means of petroleum ether but the scarcity of the material has rendered its further characterization impossible.

Experimental

General Procedure for the Skraup Reaction with Azo Compounds.—A mixture of monoazo compound ($^1/_{20}$ mole), glycerin (18 g.), concd. sulfuric acid (18 g.) and arsenic acid (9 g.) was gently refluxed in an oil-bath (bath temperature 160–195°) for two to thirty hours. The flask contents, which consisted of a hard black lump on cooling, was digested with hot water and the filtered liquid, after being made alkaline, was distilled with steam. The distillate was shaken with ether. On evaporating the solvent, after thorough drying with sodium sulfate, quinoline could be isolated. It was identified by converting it into its picrate.

From the residue of the steam distillation, by means of benzene, another component of the products could be isolated. Further purification was effected by recrystallization of its sulfate from hot alcohol.

In the case of 10-hydroxy-*m*-phenanthroline, instead of benzene extraction, the material was extracted first with cold alcohol, then with benzene, ether and petroleum ether successively.

I desire to express my best thanks to Professor Hata for the interest which he has kindly taken in this work.

Summary

1. It has been reported that in the Skraup reaction with azo compounds, the presence of arsenic acid gives better results.

2. In connection with this fact, the following quinoline compounds have been prepared; quinoline, *p*-phenanthroline, 6,6′-diquinolyl, 6-chloroquinoline and 10-hydroxy-m-phenanthroline, of which the last is a new compound.

MERCURY DERIVATIVES OF ACETYLAMINOCRESOLS[1]

BY A. PROSKOURIAKOFF AND R. J. TITHERINGTON

RECEIVED APRIL 23, 1930 PUBLISHED OCTOBER 6, 1930

Introduction

Organic compounds of mercury have gained considerable prominence during the last few years in the field of pharmaceutical chemistry as general antiseptics. In almost every field of application, they have displaced their inorganic precursor, mercuric bichloride, and have established for themselves a very important position among modem synthetic drugs. The value of the new organic mercurials in the treatment of syphilis and the importance of their use in conjunction with the well-known arsenicals are at present well recognized. Further investigation in this field, however, seemed to be especially desirable in view of the fact that comparatively few organic mercury compounds suitable for therapeutic use have been synthesized and still fewer were thoroughly studied and tried clinically. Among these, phenol derivatives and dyestuffs were given much attention and large groups of their mercury derivatives were synthesized and investigated therapeutically.

In 1906 Hantsch and Auld[2] prepared mercury derivatives of various nitrophenols. In 1919 Schamberg, Kolmer and Raiziss[3] studied the toxicity and bactericidal effect of mercurated nitrophenols and found that sodium hydroxymercury-o-nitrophenolate exhibited interesting therapeutic properties. Later, Raiziss and Proskouriakoff[4] synthesized a number of mercury derivatives of nitrophenols, nitroresorcinols and nitrosalicylic acids for their chemotherapeutic study, assuming that nitro groups enhance the bactericidal influence and the stability of the organic mercurials. Most of the compounds prepared were amorphous and analyses indicated that they were mixtures of mono- and di-mercury compounds and were separable only with considerable difficulty. Of the dyestuff group, mercury derivatives of phthaleins and azo dyes were more thoroughly investigated and some valuable germicidal compounds were discovered, in the first group mentioned. The di-sodium salt of dibromo-hydroxymercurifluorescein is the most successful of this group.[5] In 1925 Proskouriakoff and Raiziss[6]

prepared and studied a group of azo dyestuffs and found that mercury can be detoxicated considerably by modifying the organic compound to which it is attached. Mercury derivatives of nitrocresols were studied by Raiziss, Proskouriakoff and Fisher[7] and among them the mono-mercury derivative of 6-nitro-o-cresol and the di-mercury derivative of 5-nitro-o-cresol were found to possess superior germicidal properties.

Several isomers of aminocresols were prepared and mercurated by the authors. These compounds, however, were amorphous and their sodium salts, as one would expect, were not sufficiently stable in solution, depositing on standing a fine gray powder of metallic mercury. The instability of mercurated aminocresols was probably due to the presence of the open amino groups, and the protection of these groups seemed to be desirable in order to render the compounds more stable. It would also diminish the possibility of mercury reacting directly with the amino groups, forming the complex and still more unstable compounds.

With this in mind, the authors undertook the preparation and subsequent mercuration of different isomers of acetylaminocresols. On studying the literature we were unable to find any data on properties and methods of preparation of certain amino- and acetylaminocresols. Some, apparently, never have been prepared. Most of those that have been known were prepared by reducing the corresponding nitrocresol with zinc or tin and hydrochloric acid[8] and acetylating the amino compound thus obtained by boiling it with acetic anhydride in an acetic acid solution.[9] This method of reduction was long and tedious, as it involved the precipitation of the metal and evaporation of the solution for the precipitation of the amino compounds. The yield in our hands was very poor. The acetylation of the aminocresols in glacial acetic acid medium in many cases also presented considerable difficulty, due to the ready solubility of acetylaminocresols in dilute acids, and the yields obtained were very poor, also.

Our attempts to find a better and simpler method for the preparation of aminocresols gave us very satisfactory results when we tried to reduce the nitrocresols with sodium hydrosulfite in alkaline solution. After some experimentation we have adopted the following procedure. The nitrocresol was dissolved in dilute alkali and the boiling solution was then treated with small portions of solid sodium hydrosulfite until the liquid became colorless or slightly yellow. The theoretical amount of hydrosulfite was required. The solution was then cooled and the amino compound came down in almost pure crystalline form, which, after a single

[7] Raiziss, Proskouriakoff and Fisher, paper read at the spring meeting of the American Chemical Society in Washington, D. C., 1924.

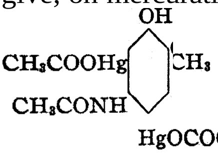
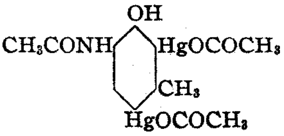
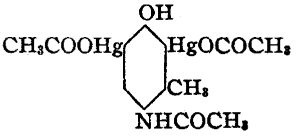
crystallization from water or dilute alcohol, was obtained as a perfectly pure compound suitable for our purposes. The method of the preparation of acetylated aminocresols was considerably improved by carrying on the reaction in aqueous medium. This is a very quick and simple method; the water medium fully protects the hydroxy groups from being involved in the reaction, even though an excess of acetic anhydride be used. The final product is pure and the yield excellent.

The aminocresol is suspended in a small amount of water and treated with a slight excess of acetic anhydride by shaking it for a few minutes in a glass-stoppered Erlenmeyer flask. The compound goes into solution and the acetyl derivative quickly crystallizes on cooling. The acetylaminocresols are thus obtained in a very pure state after the first crystallization.

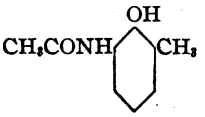
The mercuration of the aminocresols was carried out by treating an alkaline solution of acetylaminocresol with a solution of mercuric acetate in dilute acetic acid solution. The final acid concentration of the solution is in this case an important factor in obtaining uniform yields of a pure crystalline compound of definite structure. The crystalline diacetoxymercury derivatives, apparently, partly hydrolyze on heating in a neutral or insufficiently acid solution, turning into the corresponding amorphous hydroxy-mercury compounds. On boiling with water the compounds produce highly colloidal solutions, acid to litmus. All the compounds were obtained from the reaction mixtures in the form of beautifully uniform crystals of high purity. They were recrystallized once from a 10% solution of acetic acid, dried at 110° in the oven and analyzed for nitrogen and mercury. The analyses showed that in the isomers of acetylaminocresols with ortho and para positions to hydroxyl open, mercury always enters all the positions thus open, leaving the meta positions unsubstituted. Thus 5-acetylamino-o-cresol, 6-acetylamino-m-cresol and 4-acetylamino-m-cresol give, on mercuration, dimercurated compounds



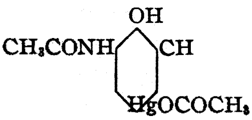




We have attempted to mercurate, with excess of mercuric acetate, 6-acetylamino-o-cresol, which has only para position to hydroxyl open, both ortho positions being already occupied **(A).** As a result we have obtained a good yield of crystalline mono-mercury derivative identical with that



A



B

obtained by mercuration of this compound with the theoretical amount of mercuric acetate (one mole) (B).

All the mercurated acetylaminocresols prepared by us are soluble in dilute solutions of alkalies. The results of the investigation of their therapeutical activity will be published elsewhere.

The mercury in these compounds was determined by decomposing the compounds with sulfuric acid and potassium permanganate and estimating mercury gravimetrically as sulfide.

Experimental Part

Preparation of 5-Amino-*o*-cresol.—Thirty-four grams of **5-nitro-*o*-cresol** (m. p. 117°) was dissolved in 600 cc. of a 3% solution of sodium hydroxide. The solution was brought to boiling and to the boiling solution was gradually added in small portions about 135 g. of sodium hydrosulfite. The reduction was completed when the solution was almost colorless and the addition of sodium hydroxide to a portion of it gave no red color. The solution was then filtered hot and allowed to cool for twenty-four hours. The crystalline precipitate was then filtered off, washed with a small amount of ice-cold water and dried in a desiccator. It could then be recrystallized from water, giving plates of m. p. 161°.

Preparation of 5-Acetylamino-*o*-cresol.—Eight grams of 5-amino-*o*-cresol (m. p. 161°) was suspended in 150 cc. of water in a glass-stoppered Erlenmeyer flask. To this was added 20 cc. of acetic anhydride and the flask was shaken for about a half hour. It was then cooled and allowed to stand for four hours. The precipitate was filtered off, washed with water and dried in the oven at about 70°; yield, 9.5 g. (88%). The compound was then recrystallized from 350 cc. of 50% ethyl alcohol; yield. 8 g. It can also be purified by dissolving it in dilute alkali and precipitating the compound from the filtered solution by dilute hydrochloric acid. It gives colorless crystals (prisms); melting point, 225°. It is soluble in dilute alkalies and hot water.

Preparation of **4,6-Diacetoxymercuri-5-acetylamino-*o*-cresol.**—Two grams of 5-acetylamino-*o*-cresol (m. p. 225°) was dissolved in 50 cc. of water and 15 cc. of a 4% solution of sodium hydroxide. To this was added 7.8 g. of mercuric acetate dissolved in 60 cc. of warm 15% acetic acid. The whole was warmed until the precipitate dissolved. The solution was then cooled. A voluminous white precipitate formed which under the microscope appeared as colorless long needles radiating from centers.

The compound was washed with a small amount of cold water and dried in the oven at 110° for twelve hours; yield, 4.5 g. It is soluble in dilute alkali, sodium carbonate, glacial acetic acid and dilute acetic acid (on warming). It is insoluble in methyl alcohol, benzene, ether and ethyl acetate. The compound darkens and apparently begins to decompose at about 210°.

Anal. Calcd. for $C_{13}H_{15}O_6NHg_2$: Hg, 50.80; N, 2.05. Found: Hg, 59.10; N, 2.03.

Preparation of 6-Amino-*o*-cresol.—Twenty-five grams of 6-nitro-*o*-cresol was dissolved in 500 cc. of 3% solution of sodium hydroxide. The solution was heated to 90°, heating was discontinued and with rapid stirring solid sodium hydrosulfite was added in 2-g. portions at such a rate as to keep the temperature below 100°. The reduction was completed when 100 g. of sodium hydrosulfite had been added. Five grams of norit was then added and stirring was continued for a few minutes. The solution was filtered and the filtrate was cooled in ice water. The crystallized compound was filtered off and dried in the oven at 60°.

The crude dry compound was recrystallized from carbon tetrachloride. Colorless plates were obtained from water. It is soluble in methyl and ethyl alcohol, acetone, ether, chloroform, hot water, hot benzene and hot carbon tetrachloride; insoluble in petroleum ether; m. p. 89° (uncorr.). It gives a red color with ferric chloride.

Anal. Calcd. for C_7H_9ON: N, 11.38. Found: N, 11.25, 11.27.

The hydrochloride was obtained by dissolving the amino compound in dilute hydrochloric acid and precipitating the hydrochloride by adding an equal amount of concentrated hydrochloric acid (colorless crystals).

Preparation of **6-Acetylamino-*o*-cresol.**—Six grams of 6-amino-o-cresol (m. p. 89°) was suspended in 200 cc. of water in a glass-stoppered Erlenmeyer flask. To this was added 4 cc. of acetic anhydride and the mixture was shaken vigorously. A dark solution resulted which with continued shaking quickly became lighter in color with the separation of dark semi-solid substance. This was filtered off and the filtrate was cooled in ice water. The 3-acetylamino-o-cresol crystallized with the help of stirring and scratching. The crystals were filtered off, washed with water and dried in the oven at 60°.

The compound recrystallized from carbon tetrachloride melted at 78–79° (uncorr.) (long prisms). It is soluble in methyl and ethyl alcohol, acetone, benzene, chloroform, ether, hot water and hot carbon tetrachloride; insoluble in petroleum ether. It gives a blue color with ferric chloride. (The corresponding amino compound gives a red color with the same reagent.)

Anal. Calcd. for $C_9H_{11}O_2N$: N, 8.49. Found: N, 8.36, 8.35.

Preparation of **4-Acetoxymercuri-6-acetylamino-*o*-cresol.**—Two grams of 6-acetylamino-o-cresol was dissolved in 20 cc. of 3% solution of sodium hydroxide. To the warm solution was added 4 g. of mercuric acetate dissolved in 30 cc. of 15% warm acetic acid.

The mixture was heated over a low flame until the precipitate formed at first redissolved. The hot solution was filtered and then cooled in ice water. The crystalline precipitate was filtered off, washed with a little 10% acetic acid and then with water and dried in the oven at 60°; yield, 2.2 g. It can be recrystallized from 10% acetic acid. The compound is soluble in dilute alkalies, acetone, ethyl and methyl alcohol and dilute acetic acid. It is insoluble in benzene, ether and carbon tetrachloride. It melts at 122'.

Anal. Calcd. for $C_{11}H_{13}O_4NHg$: Hg, 47.34; N, 3.31. Found: Hg, 47.42, 47.68; N, 3.26.

Preparation of **6-Amino-*m*-cresol.**—Ten grams of 6-nitro-m-cresol (m. p. 56°) was dissolved in 225 cc. of a 3% solution of sodium hydroxide and the boiling solution was treated with small portions of solid sodium hydrosulfite (about 40 g.) until the solution became almost colorless and a portion of it in a test-tube did not give a red color with sodium hydroxide. It was then allowed to cool, whereupon an amino compound crystallized out. It was filtered off and recrystallized from 50% ethyl alcohol; yield, 4.8 g.

It forms colorless long prismatic needles which melt with decomposition at 162'. An aqueous solution of the compound gives with ferric chloride a red color, while the corresponding nitrocresol and acetylaminocresol do not give this reaction.

The compound is soluble in hot water, dilute acids, methyl and ethyl alcohol, acetone, benzene and ether. It is insoluble in petroleum ether.

Anal. Calcd. for C_7H_9ON: N, 11.38. Found: N, 11.27.

Preparation of **6-Acetylamino-*m*-cresol.**—Five grams of 6-amino-m-cresol was suspended in 75 cc. of water and treated with 7 cc. of acetic anhydride in a glass-stoppered Erlenmeyer flask. The change occurred almost immediately; all went into solution and soon after the precipitate came down. The flask was shaken for about a half hour and then well cooled with ice water. The precipitate was then filtered off, washed with cold water and dried in the oven at about 70°; yield, 5 g.

The compound, recrystallized from 50% ethyl alcohol, forms colorless hexagonal plates. It melts at 171° (uncorr.).

The solution of 6-acetylamino-m-cresol gives no color with ferric chloride. (By this reaction it can be distinguished from the corresponding aminocresol.) It dissolves in alkali with a bluish-green color.

The compound can be dissolved in sodium hydroxide or sodium carbonate and precipitated from the solution by neutralizing it with acetic or hydrochloric acid. It is soluble in hot water, easily soluble in methyl and ethyl alcohol and acetone, much less so in benzene and ether. It is insoluble in petroleum ether and carbon tetrachloride.

Anal. Calcd. for $C_9H_{11}O_2N$: N, 8.49. Found: N, 8.38.

Preparation of **2,4-Diacetoxymercuri-6-acetylamino-*m*-cresol.**—Ten and one-half grams of 6-acetylamino-m-cresol (m. p. 171°) was dissolved in 250 cc. of a 1.5% solution of sodium hydroxide. To this was added, with stirring, a hot solution of 40.2 g. (2 moles) of mercuric acetate in 210 cc. of 20% acetic acid.

The whole was then warmed until the precipitate formed went into solution. The solution was then cooled and allowed to stand for twelve hours. The precipitate was filtered off, washed with water, alcohol and ether and dried in the oven at 60°. This yellowish crystalline precipitate was recrystallized from 10% acetic acid, whereupon colorless long needles were obtained.

The compound dissolves in dilute alkalies, forming a colorless solution. It melts with decomposition at 178°. It was dried in the oven at 110° for fifteen hours and analyzed.

Anal. Calcd. for $C_{13}H_{15}O_6NHg_2$: Hg, 58.80; N, 2.05. Found: Hg, 58.70; N, 2.01.

Preparation of **4-Amino-*m*-cresol.**—Sixteen grams of 4-nitro-m-cresol (m. p. 129°) was dissolved in 350 cc. of a 3% solution of sodium hydroxide. To the boiling solution was gradually added 65 g. of solid sodium hydrosulfite. The reduction was completed when the solution became almost colorless and the amino compound began to precipitate. The mixture was then well cooled, the precipitate filtered off and recrystallized from 100 cc. of 50% ethyl alcohol; yield, 7 g.; colorless prisms, m. p. 179°. Nolting and Kohn[8b] give the melting point for this compound as 174°.

Preparation of **4-Acetylamino-*m*-cresol.**—Six grams of 4-amino-m-cresol (m. p. 179°) was suspended in 50 cc. of water in a glass-stoppered Erlenmeyer flask. To this was added 10 cc. of acetic anhydride and the mixture vigorously shaken. The aminocresol went into solution. On cooling a crystalline precipitate of acetylaminocresol came down. This was filtered off, washed with cold water and recrystallized from water; yield, 5 g. of needles. The compound when dried in the oven at 110° for six hours melts at 130° (incorr.). Staedel and Kolb[10] give for this compound (free from water of crystallization) m. p. 125°. It can be dissolved in dilute alkali and reprecipitated by acidifying with hydrochloric acid.

Preparation of **2,6-Diacetoxymercuri-4-acetylamino-*m*-cresol.**—Two grams of 4-acetylamino-*m*-cresol (m. p. 130°) was dissolved in 20 cc. of a 3% solution of sodium hydroxide. To the warm solution was gradually added, with stirring, a solution of 7.7 g. of mercuric acetate in 30 cc. of 15% acetic acid. The mixture was allowed to stand in a cool place for twenty-four hours. The white crystalline precipitate was filtered off, washed first with cold water, then with alcohol and finally with ether and dried in the air. It was recrystallized from 10% acetic acid and dried at 110° for fifteen hours; yield, 3 g. of colorless crystals (prisms). On heating; in the melting point tube,

---

[10] Staedal and Kolb, Ann., 259, 217 (1890).

the compound darkens and gradually decomposes, but does not melt below 250°. It is soluble in dilute alkalies. The solutions are colorless.

Anal. Calcd. for $C_{13}H_{16}O_6NHg_2$: Hg, 58.80; N, 2.05. Found: Hg, 58.69; N, 2.06.

Summary

1. A simple method of preparation of aminocresols from corresponding nitrocresols by reduction with sodium hydrosulfite is described.

2. 6-Amino-o-cresol, 6-acetylamino-o-cresol, 6-amino-m-cresol and 6-acetylamino-m-cresol were prepared and studied.

3. The following mercury derivatives of acetylaminocresols were synthesized and studied: 4-acetoxymercuri-6-acetylamino-o-cresol, 4,6-diacetoxymercuri-5-acetylamino-o-cresol, 2,4-diacetoxymercuri-6-acetylamino-m-cresol and 2,6-diacetoxymercuri-4-acetylamino-*m*-cresol.

BENZOHYDRYLMAGNESIUM CHLORIDE AND THE APPARENT PRIOR FORMATION OF FREE BENZOHYDRYL RADICALS

BY HENRY GILMAN AND E. A. ZOELLNER

RECEIVED JUNE 6, 1930 PUBLISHED OCTOBER 6, 1930

Introduction

In the preparation of all Grignard reagents, there are side-reactions, and chief among these is the coupling reaction to give R·R compounds.[1] The extent of this coupling reaction varies between extreme limits,[2] and until recently it was essentially impossible, for example, to prepare allylmagnesium bromide because of the unusually high yield of diallyl.[3]

Perhaps the most unusual preparation of this type is that of benzohydrylmagnesium chloride, $(C_6H_5)_2CHMgCl$. Under ordinary conditions the yield of coupling product, *sym.*-tetraphenylethane, is astonishingly high and has reached 95.5%.[4] For this reason, the application of this RMgX compound in synthesis has followed the procedure of Barbier. This involves the preparation of the benzohydrylmagnesium halide in the presence of the reactant.[5] Ordinarily this procedure has two serious disadvantages:

---

[1] Gilman and Fothergill, THIS JOURNAL, 50, 3334 (1928).

[2] See Giman, Zoellner and Dickey, *ibid.*, 51, 1576 (1929), for the yields of some RMgX compounds. Some typical RMgX compounds like phenylmagnesium bromide and *n*-butylmagnesium bromide can be prepared in essentially quantitative yields when an excess of magnesium is used.

[3] It is now possible to prepare allylmagnesium bromide in yields greater than 93%. See Giman and McGlumphy, Bull. *soc. chim.*, 43, 1322 (1928).

[4] Gilman and Kirby, THIS JOURNAL, 48, 1733 (1926).

first, the yields are low; second, the formation of the Grignard reagent may be retarded and, in some cases, actually inhibited.'"

We needed benzohydrylmagnesium chloride in connection with the extension of studies on the so-called abnormal reactions of Grignard reagents having α,β-unsaturation.[6] As a result of the present study, it is now possible to prepare this RMgX compound independently (and not in accordance with the Barbier procedure) and the yields are satisfactory (70%). Excellent yields of the corresponding carboxylic acid, diphenylacetic acid, have been realized by the customary procedure of carbonation.

Perhaps of greater significance than the development of a method for the preparation of this unusual Grignard reagent in satisfactory yields, is the direct observation of what appear to be transiently formed free radicals. During the addition of the benzohydryl chloride in ether to magnesium in ether, it was noted that a reddish color formed where the chloride came in contact with the ether containing magnesium and Grignard reagent. The same phenomenon was observed when the benzohydryl chloride was added to an ether solution of benzohydrylmagnesium chloride free of magnesium. With the rapid addition of halide to the Grignard solution, it was possible (in small containers) to have the color throughout the solution. The color disappears very shortly after its formation, and it is impossible to get the color when the Grignard reagent is used up.

It has already been suggested by Gomberg and Bachmann[7] that free radicals are formed initially in the *preparation* of Grignard reagents when iodine is used as a catalyst, as follows

$$\mathrm{Mg} + \mathrm{I_2} \longrightarrow \mathrm{MgI_2} \qquad (1)$$
$$\mathrm{MgI_2} + \mathrm{Mg} \longrightarrow 2\,\text{—MgI} \qquad (2)$$
$$\mathrm{RX} + \text{—MgI} \longrightarrow \mathrm{R}\text{—} + \mathrm{XMgI} \qquad (3)$$
$$\mathrm{XMgI} + \mathrm{Mg} \longrightarrow \text{—MgI} + \text{—MgX} \qquad (4)$$
$$\mathrm{R}\text{—} + \text{—MgX} \longrightarrow \mathrm{RMgX} \qquad (5)$$

In the absence of a catalyst, like iodine, it has been suggested[7] that the first step in the reaction is

$$2\mathrm{RX} + \mathrm{Mg} \longrightarrow \mathrm{R{\cdot}R} + \mathrm{MgX_2} \qquad (6)$$

and that the $\mathrm{MgX_2}$ so formed then reacts with magnesium in accordance with Reaction 1 to give —MgX which subsequently combines with the free radical to give the RMgX compound. However, we[1] are of the opinion that the formation of free radicals is the *first* step in the preparation of the Grignard reagent, even in the absence of any catalyst

$$2\mathrm{RX} + \mathrm{Mg} \longrightarrow 2\mathrm{R}\text{—} + \mathrm{MgX_2} \qquad (7)$$

[7] Gomberg and Bachmann, *ibid.*, 49, 236 (1927). This article contains leading references to explanations for the catalytic influence of some reagents for initiating the preparation of organomagnesium halides.

and that then the MgX_2 reacts with magnesium (Reaction 2) to give the —MgX, which subsequently combines with the free radical (Reaction 5). Possibly both reactions occur.

Whatever may be the correct explanation, and both mechanisms as well as others may be correct, there is experimental evidence by Gilman and Fothergill[1] and Gilman and Kirby[8] in support of the intermediate formation of free radicals incidental to the preparation of Grignard reagents.

The transitory color observed on the addition of benzohydryl chloride to benzohydrylmagnesium chloride indicates that free radicals are also formed ***subsequent*** to the preparation of RMgX compounds. The free radicals so formed might account in part at least for the side reactions of coupling and disproportionation described by Gilman and Fothergill.[1]

$$(C_6H_5)_2CHMgCl + (C_6H_5)_2CHCl \longrightarrow 2(C_6H_5)_2CH— + MgCl_2 \qquad (8)$$

$$2(C_6H_5)_2CH— \longrightarrow (C_6H_5)_2CHCH(C_6H_5)_2 \qquad (9)$$

and, where disproportionation can occur, the following general reaction[1] might be written

$$2R— \longrightarrow R(+H) + R(—H) \qquad (10)$$

It is interesting to note that apparently the same color phenomena are observed on the addition of benzohydryl chloride to some RMgX compounds other than benzohydrylmagnesium chloride. This is not entirely unexpected in view of the studies by Fuson,[9] who showed that the coupling reaction is best interpreted under certain conditions, as follows

$$2RX + 2R'MgX \longrightarrow R{\cdot}R + R'{\cdot}R' + 2MgX_2 \qquad (11)$$

In accordance with this reaction it is readily understandable that the formation of R·R compound from the RX compound might have taken place as indicated in Reaction 9, written above. Actually, Späth[10] has suggested such a general mechanism, but this is the first case where we have observed the apparent intermediate formation of free radicals other than those of *tri*-arylmethyls[11] and related compounds. It should be possible to capture[12] these radicals and extend our knowledge of free radicals to new types.

[8] Gilman and Kirby, THIS JOURNAL, 51, 1571 (1929). Another interpretation does not involve —MgX, and consists in the direct union of $2R— + Mg \longrightarrow R_2Mg$. See Gilman and Brown, ibid., 52, November, 1930.

After the manuscript was submitted for publication, it was found that benzohydrylmagnesium chloride reacted with benzophenone to give benzopinacol and tetraphenylethylene. This is evidence for the dissociation of this RMgCl compound. and for the disproportionation of benzohydryl radicals.

Experimental Part

The benzohydryl chloride used in these studies may not have been as pure as that prepared previously by Gilman and Kirby.[4] Two fractions were used. One of them boiled at 147–148° (6 mm.) (m. p. 9–11"), and the other at 148–150° *(6* mm.) (m. p. 13–15") The apparatus and method of analysis were those described by Gilman, Zoellner and Dickey.[2] However, the procedure had the following slight variations: ten drops of halide were used to initiate the reaction; heat was applied by means of a microburner under a wire gauze; as soon as reaction set in (two to three minutes), stirring was commenced; then, refluxing and stirring were continued for ten minutes prior to addition of the remaining halide in ether. There was no difficulty in starting the reaction when the customary small quantity (0.03–0.05 g.) of iodine was used as a catalyst.

Without going into details of a series of experiments, it may be stated at once that the yield is markedly affected by the quantity of fine magnesium (30–80-mesh). In an experiment using 5.07 g. (0.025 mole) of benzohydryl chloride, 6.1 g. (0.25 atom) of magnesium and a total of 74 cc. (0.74 mole) of ether, the yield was 51%. The time of addition of the halide was one hour, and with a two-hour period of addition the yield was 53%. It was noted that the formation of precipitate was slightly progressive. In contrast with this, the precipitation is more pronounced at the beginning of the preparation of *tert.*-butyl- and *tert.*-amylmagnesium chlorides,[13] and in these cases the precipitate (under optimal conditions) disappears when the preparation is about one-half completed.

When the ratio of magnesium and ether to the chloride was doubled, so that for each mole equivalent of benzohydryl chloride 20 atom equivalents of magnesium and 60 mole equivalents of ether were used, the yield was 57%. Here there was less precipitate and its formation was not progressive.

When 30 atom equivalents (9.12 g.) of magnesium and 60 equivalents (74 cc.) of ether were used with one mole equivalent (2.53 g.) of benzohydryl chloride boiling at 148–150° (6 mm.), and when the time of addition was one and one-half hours, the yield was 71%. In a like experiment with the halide boiling at 147–148° (6 mm.), the yield was 68%. In these experiments the smallest quantity of precipitate formed. It appears altogether reasonable that with a still higher ratio of magnesium, pure halide and slow addition, the yield can be significantly increased.

A larger-sized run was made in order to prepare the corresponding carboxylic acid. In this experiment the conditions were those described for the 51% yield preparation: 10.14 g. (0.05 mole) of the chloride was used and the time of addition was two hours. The yield by titration was 50%. After cooling the RMgCl solution to −15°, carbon dioxide was added[14] rapidly and was taken up almost instantly. The yield of diphenylacetic acid, $(C_6H_5)_2CHCOOH$, was 84% (based on the quantity of available RMgCl compound).[15] The identity of the acid was confirmed by a mixed melting point determination with an authentic specimen. In addition to the acid, there was isolated 2.5 g or 30% of *sym*-tetraphenylethane.

Summary

Under ordinary conditions it is practically impossible to prepare benzohydrylmagnesium chloride, $(C_6H_5)_2CHMgCl$, because of an extreme tend-

[15] This high yield is remindful of the very high yield of triphenylacetic acid obtained by the carbonation of triphenylmethylmagnesium chloride.''

ency for coupling which results in a 95% yield of R·R compound. Directions are now available for the preparation of this unusual Grignard reagent in yields upwards of 70%. The coupling reaction is apparently due to the prior formation of free benzohydryl radicals, which are of red color and of short life.

ALIPHATIC ACYLOINS. I. PREPARATION[1]

BY B. B. CORSON, W. L. BENSON AND T. T. GOODWIN

RECEIVED JUNE 9, 1930 PUBLISHED OCTOBER 6, 1930

The most promising method which has been described for the preparation of aliphatic acyloins involves the action of sodium on ethereal or benzene solutions of aliphatic esters. This reaction was first described by Bouveault and Locquin[2] and the following mechanism was assumed

$$\begin{gathered}2\mathrm{RCOOR'} + 4\mathrm{Na} \longrightarrow 2\mathrm{NaOR'} + \mathrm{RC(ONa){=}C(ONa)R}\\ \mathrm{RC(ONa){=}C(ONa)R} + 2\mathrm{H_2O} \longrightarrow \mathrm{RC(OH){=}C(OH)R} + 2\mathrm{NaOH}\\ \mathrm{RC(OH){=}C(OH)R} \longrightarrow \mathrm{RCHOHCOR}\end{gathered}$$

Other mechanisms have been suggested.[3]

According to the original directions the reaction was run at 0° except in one case, pivaloin (2,2,5,5-tetramethylhexanol-3-one-4), where the reaction temperature was that of the room. The implication was that the acetoacetic ester condensation would result at higher temperatures and it was suggested that acyloins represented an intermediate step in the acetoacetic ester condensation.[4] Other investigators, however, have used higher temperatures, with equally good results.[5]

When the original directions are followed the reaction proceeds very slowly. In preparing pivaloin at room temperature Bouveault found it necessary to allow the reaction mixture to stand for eight to ten days. The use of a higher reaction temperature cuts down the time from days to hours. It has been suggested that the slowness of reaction in this particular case was due to the highly branched chain and the absence of enolizable hydrogen in the starting material, ethyl trimethylacetate.[5a] However, following the original directions the reaction also goes very slowly

---

with straight chain esters such as ethyl butyrate, We have not applied the modified directions to the preparation of pivaloin but we have prepared a very similar substance, 3,3,6,6-tetramethyl-octanol-4-one-5 from ethyl dimethylethylacetate and, as far as we could see, the reaction proceeded as smoothly with the latter as with simpler esters. In the course of this work we have prepared propionoin, the two isomeric butyroins, two valeroins and four capronoins at the reflux temperature of the ether solutions.

For solvent, Bouveault used either dry ether or dry benzene, but from our experience, ether is much superior to benzene. Scheibler[3a] found the same to be true in a similar reaction, the preparation of ester enolates from aliphatic esters.

The yield of once-distilled product (25° boiling point range) is around 50% of the theoretical amount. The yield of pure product (1–3° boiling point range) is considerably smaller owing to the necessity of repeated vacuum fractionation. At least two substances are always obtained, the acyloin proper and a higher-boiling liquid of approximately twice the molecular weight and of unknown structure. Certainiy, part of this second substance is formed during distillation and according to Bouveault the elevated temperature of distillation is responsible for all of it. A subsequent paper from this Laboratory will deal with this high-boiling by-product.

Also, a third substance is usually present, the 1,2-diketone (RCOCOR) corresponding to the acyloin (RCHOHCOR). Presumably autoxidation of the enediolate, $RC(ONa){=}C(ONa)R$,[5a] accounts for the presence of the diketone, although some mechanisms of acyloin formation envisage the diketone as an intermediate step. The greater part of the diketone can be removed from the once-distilled product by shaking with saturated sodium bisulfite but the last traces must be removed by distillation. Since the diketones are deep yellow and the acyloins pale yellow, the depth of color in the distilling column is a useful guide as to the progress of fractionation.

It is our experience that acyloins as obtained by distillation are always slightly yellow. Butyroin was fractionated in a vacuum six times in succession in the attempt to obtain a colorless product. The film of liquid flowing down the column appeared to be colorless but the butyroin which collected in the receiver had a tinge of yellow. Although it seemed impossible to remove the last traces of yellow by distillation, we finally discovered that exposure to sunlight quickly brought about that result. Usually, a one-hour exposure was sufficient. In only one case, that of a sample of isobutyroin made from ethyl isobutyrate, were we unable to remove the color; on the other hand, a sample of isobutyroin made from isobutyl isobutyrate decolorized easily. When these colorless acyloins are kept in the dark or in diffused light, the yellow color returns in several days. This color change can be repeated several times by alternately exposing to sunlight and keeping in the dark.

Scheibler[3b] has recorded the extreme light sensitivity of an aromatic substituted aliphatic diketone, tetrabenzyldiacetyl, the photo-reaction being to some extent reversible.

$$(C_6H_5CH_2)_2CHCOCOCH(CH_2C_6H_5)_2 \rightleftharpoons (C_6H_5CH_2)_2CHCHOHCOCH(CH_2C_6H_5)_2$$

It has long been known that aromatic 1,2-diketones are light sensitive and the best known example of this reaction is the conversion of yellow benzil into colorless benzil-benzoin.

It may be that the yellow color of aliphatic acyloins is due to a small amount of the corresponding yellow diketone and by analogy with Scheibler's findings it may be that the reversible color change is due to the reversible reduction–oxidation of the diketone–hydroxyketone system. Further work is now in progress in this Laboratory on the photochemical decomposition products of aliphatic acyloins.

For some time we did not realize that this color change was indicative of alteration in composition, since the refractive index and the density were identical in colored and colorless samples. Finally, it was discovered that the colorless samples had a considerably different carbon–hydrogen composition. Up to this time exposure of the acyloins to light had never Seen avoided, with the result that after a few weeks in the laboratory the acyloins were far from pure. After this discovery all the acyloins were redistilled and a low-boiling fore-run was found in every case. There was very little, if any, high-boiling residue. With these acyloins, refractive index and density are merely rough criteria of purity, e. g., a sample of n-valeroin which had been exposed to light still had the identical refractive index and density within 2 parts per 1000 although its carbon and hydrogen percentages had fallen 1.2 and 1.1%, respectively.

In the preparation of acyloins it is advisable to start with the methyl or ethyl ester of the acid in question. Although the reaction proceeds at least as fast and possibly faster[3"] with the higher esters such as iso-amyl, etc., it is difficult to obtain a pure product, due to contamination by the resulting high-boiling alcohol.

About 10% of the sodium becomes so thickly encrusted with sodium derivative that it is unable to react. Following these modified directions, satisfactory yields of acyloins are obtained with esters of acids from propionic up through caproic, but the limit has been reached in an acid of twelve carbons. With ethyl laurate and ethyl myristate only 20–30% of the sodium reacted in ten hours of heating followed by thirty-six hours of standing. The reaction was so incomplete that no attempt was made to isolate the products. Very likely potassium would extend the limits of the reaction. Acetoin cannot be prepared successfully by this method, due partly to its solubility in water and partly to its extreme sensitivity to alkali.

Aromatic acyloins have recently been prepared by Gomberg[3d] from both esters and acids by means of magnesious halide. With sodium, the free acid does not result in acyloin, the only product being the sodium salt of the acid. It may be that, under suitable conditions, the reaction would proceed, but at any rate, mere substitution of free acid for ester in the following directions results only in the sodium salt of the acid.

Experimental Part

General Procedure.—In a three-necked 2-liter round-bottomed flask were placed 1000 cc. of dry ether and 92 g. of sodium cut into small slices. We did not find it practicable to convert such large quantities of sodium into wire; thin slices were found quite suitable. First, the sodium was cut into sticks 10–13 cm. long and about 2.5 sq. cm. in cross section and stored in wide-mouthed, rubber-stoppered bottles. Just before using, the sodium was freed from oxide, weighed and cut under dry ether with a thin knife, into 5-mm. slices (thinner if possible). The middle neck of the flask was fitted with a mechanical stirrer (propeller type) and mercury seal combination. In one of the side necks was placed a reflux condenser and in the other a 125-cc. dropping funnel. The stirrer was started and the ether heated to the reflux temperature by means of a jet of steam impinging on the bottom of the flask. A pan was placed under the flask to catch the drip. The heating necessary to keep the ether refluxing varied with the ester used—with ethyl *n*-caproate and ethyl propionate considerable steam heating was required, whereas with iso-amyl isovalerate and isobutyl isobutyrate very little heating was required. Two-gram molecules of the ester in question was added at the rate of two drops per second to the stirred, hot mixture. Addition required two hours. The mixture was then stirred and steam-heated for an additional hour. A yellowish (occasionally reddish to light brown) solid began to appear in fifteen to thirty minutes and gradually increased in amount until practically all of the sodium had been converted into it and the contents of the flask was a thick mush. With ethyl butyrate 1000 cc. of ether was sufficient but with ethyl valerate and iso-amyl isovalerate it was necessary to introduce another 500 cc. of ether after half the ester had been added in order to keep the mixture sufficiently liquid to stir.

After standing for twenty-four hours the sodium salt was ready to be decomposed. Longer standing does no harm. If the mixture is to be allowed to stand for several days, the flask should be stoppered to prevent evaporation of ether and also to exclude air. The reaction mixture was poured (small amount at a time) into a 2-liter battery jar containing about 8 cm. of water full of cracked ice and layered with 5 cm. of ordinary ether. Each portion was brought into solution by stirring with a rod before another addition; excess of ice was maintained throughout the process. Pieces of unreacted sodium were removed with a wire skimmer, rinsed in a small dish of ether and finally dropped into a beaker of alcohol. Sometimes the mixture was fluid and poured nicely; sometimes it was thick and had to be removed by means of a long spatula. The layer of ether prevents the sodium from igniting; most of the sodium pops up and down at the ether–water interface. Although this decomposition is surprisingly free from fire hazard it is advisable to have wet towels and fire extinguishers handy.

In several runs toluene was substituted for ether. The reaction proceeded nicely in the boiling toluene but it was impossible to work up the product in the usual manner by pouring into water without frequent fires. Possibly the excess sodium could have been decomposed with alcohol or acetic acid.

After the sodium salt had been added and both the water and ether had become clear, the ether was separated. The water layer was extracted with two 250-cc. portions of ether and then discarded. The discarded water contains about 6 g. of organic acid as sodium salt. In the preparation of butyroin the greater part of this acid was butyric but there was a certain amount of a higher-boiling liquid which seemed to be dipropylglycolic acid. The combined ether was washed twice with strong sodium chloride solution. The ether was then distilled through a 30-cm. column until the residue was about 250 cc., the temperature at the top of the column being 42–44°. The ether should be distilled rapidly with a free flame since prolonged heating increases the yield of the high-boiling product at the expense of the acyloin. The residue was distilled in a vacuum and collected over a wide range, the object being to remove ether. The distillate was thoroughly shaken (occasionally over a period of one hour) with 100 cc. of saturated bisulfite solution to remove diketone. In most cases a solid separated, necessitating suction filtration. Finally, the product was redistilled in a vacuum, the yield being about 50% of the theoretical amount.

[a] The ethyl butyrate used in the preparation of n-butyroin was kindly furnished by the Waukegan Chemical Co. The ethyl esters of isobutyric, *n*-valeric, isovaleric, n-caproic, isocaproic and β-methylvaleric acids were obtained by the oxidation of the corresponding primary alcohols [Robertson, "Organic Syntheses," John Wiley and Sons, Inc., New York, *1925*, Vol. V, *p.* 23]. The resulting esters (isobutyl isobutyrate, n-amyl n-valerate, etc.) were saponified. The free acids were liberated, purified by distillation and finally esterified with ethyl alcohol. The ethyl ester of dimethylethylacetic acid was prepared from *tert.*-amyl magnesium chloride plus carbon dioxide [Corson, Thomas and Waugh, THIS JOURNAL, 51, 1950 (1929)]. The amyl alcohols used in the synthesis of the four caproic acids were generously furnished by the Sharples Solvent Co. [b] Anderlini, *Gazz.* chim. *ital.*, 25, II, 51, 128 (1895). Isocapronoin	101–103 (3 mm.)	1.4326	.8865	58.69	58.60	97.4	97.6
3,8-Dimethyldecanol-5-one-6	102–104 (3 mm.)	1.4330	.8880	58.69	58.51	97.4	97.5
3,3,6,6-Tetramethyloctanol-4-one-5[a]	96–97 (3 mm.) (m. p., ±12°)	1.4471	.9300	58.69	57.58	97.4	96.2

[a] In this one case it should be noted that the actual molecular refraction did not check the theoretical. The carbon–hydrogen analysis, however, was satisfactory.

Carbon-hydrogen Analysis of Acyloins.—Aliphatic acyloins are difficult substances to burn properly. In order to obtain consistent analytical results the combustion must be slow and more oxygen than usual must be passed through the combustion tube. These substances are too volatile to be weighed in the usual combustion boat. Using Pregl's method of weighing the substance in small tubes containing a little potassium chlorate and ending in capillary tips, there were often small explosions during the combustion and finally one explosion was so violent that it wrecked the combustion tube. These explosions were due to the fact that the liquid did not vaporize from the tip but was forced out in drops by the pressure within. Finally, small ground-glass stoppered pyrex tubes (50 × 9 mm.) were used. These were ignited, cooled in a desiccator and weighed in a little wire frame which sat on the balance pan. The tube was then transferred to another wire frame and two drops of liquid were dropped into the tube from a small pipet. The tube was then half filled with previously ignited copper oxide powder, the ground-glass stopper was inserted and the tube was re-weighed. These tubes are easily handled by means of steel tweezers with curved tips.

Sodium Bisulfite Addition Product of Diketones.—Usually the amount of solid obtained on treatment of the crude acyloin with sodium bisulfite was small and was not further investigated. Bouveault removed diketone by means of bisulfite solution but he did not observe the formation of any solid product. Incidentally, we substantiated Bouveault's finding that ether interferes with the removal of diketone by means of bisulfite. With one run of isovaleroin which had stood for two weeks before it was worked up, bisulfite occasioned an appreciable warming and a considerable quantity of solid was obtained. The air-dried salt was analyzed and almost the theoretical figure was obtained for the sodium bisulfite addition product of the diketone. Later, the solids from n-capronoin and isobutyroin were analyzed and about twice the theoretical sodium percentage found; but there was this difference in procedure—the first salt was merely air-dried, whereas the last two were dried at 100° in a vacuum over concentrated sulfuric acid. The first analysis was therefore repeated on a sample which had been thoroughly dried, and the sodium percentage was then found to be about twice the theoretical. During the drying of the isovaleroin product considerable yellow oil came out of the solid and slowly evaporated into the sulfuric acid which was the drying agent. No oil was noticed in the drying of the other two salts.

Solid from Crude Isovaleroin.—*Anal.* Calcd. for $C_{10}H_{20}O_8Na_2S_2$: Na, 12.4. Found: Na, 12.8 (air-dried); 28.5 (dried at 100°).

Solid from Crude *n*-**Capronoin.**—*Anal.* Calcd. for $C_{12}H_{24}O_8S_2Na_2$: Na, 11.3. Found: Na, 24.4.

Solid from Crude **Isobutyroin.**—*Anal.* Calcd. for $C_8H_{16}O_8S_2Na_2$: Na, 13.1. Found: Na, 24.8.

These values are very close to that of sodium bisulfite (Na, 22.1) and sodium pyrosulfite (Na, 24.2). Possibly these addition products decompose at 100° into diketone and bisulfite.

Photochemical Decomposition.—Many analyses were made on acyloins which had been exposed to light for various lengths of time but in Table III are listed only those values which are farthest from the percentages of the original acyloins. The acyloins whose analyses are recorded below were exposed to sunlight for about two weeks. However, a much shorter exposure causes a decided change in the carbon and hydrogen percentages. This change seems to be least with the two capronoins, 3,8-dimethyl-decanol-5-one-6 and 3,3,6,6-tetramethyl-octanol-4-one-5. In every case the percentage of carbon and hydrogen dropped except with isocapronoin, where exposure to light resulted in raising the figures for both carbon and hydrogen.

TABLE III

ANALYTICAL DATA

Acyloin exposed to sunlight	Taken, mg.	CO_2, mg.	H_2O, mg.	Carbon, % Calcd.	Carbon, % Found	Hydrogen, % Calcd.	Hydrogen, % Found
Propionoin	21.66	46.63	18.13	62.02	58.71	10.42	9.36
n-Butyroin	22 07	49 75	19 73	66 61	81 48	11.18	10.00
Isobutyroin	18.43	43.33	17.53	66.61	64.12	11.18	10.64
n-Valeroin	21.20	53.14	20.14	69.70	68.36	11.71	10.63
Isovaleroin	17.65	44.59	17.45	69.70	68.90	11.71	11.06
n-Capronoin	22.34	56.58	22.35	71.93	69.07	12.08	11.19
Isocapronoin	18.60	49.48	20.60	71.93	72.55	12.08	12.39
3,8-Dimethyldecanol-5-one-6	17.43	45.83	17.17	71.93	71.70	12.08	11.03
3,3,6,6-Tetramethyl-octanol-4-one-5	22.49	58.62	23.43	71.93	71.09	12.08	11.66

Identification of **Butyroin.**—At first erratic analyses forced us to doubt that these substances were really acyloins. At this time we did not realize that aliphatic acyloins are difficult substances to burn and that they also undergo photochemical decomposition. Two derivatives of butyroin were prepared following Bouveault's directions.

Butyroin Acetate.—The boiling point was 113–115° (21 mm.), which is in agreement with Bouveault's figures, 117–118" at 21 mm.

Anal. Calcd. for $C_{10}H_{18}O_3$: C, 64.47; H, 9.75. Found: C, 65.06; H, 10.11.

Butyroin Osazone.—A good yield of yellow crystalline solid resulted. The compound melted at 140.5–141° (corr.), which agrees as well as can be expected with the uncorrected values given in the literature, 135°,[6] and 138°.[7]

Reaction between Sodium and *n*-**Valeric** Acid.—The reaction was carried out in the usual manner except that free acid was substituted for ester. A white solid quickly appeared which did not turn yellow or red as is the case when the reactant is ester. After standing for the usual length of time, a sample of this solid was removed, washed with dry ether, dried between filter paper and analyzed. The product was sodium valerate.

Anal. Calcd. for $C_5H_9O_2Na$: Na, 18.6. Found: Na, 16.9.

---

[6] Klinger and Schmitz, Ber., 24, 1271 (1891).

[7] Basse and Klinger, ibid., 31, 1219 (1898).

When the run was worked up in the usual manner no valeroin was found. On the other hand, 50% of the valeric acid was recovered from the alkaline water layer.

Summary

Detailed directions are given for the preparation of aliphatic acyloins. Approximately 50% yields of the following acyloins were obtained: propionoin, n-butyroin, isobutyroin, *n*-valeroin, isovaleroin, *n*-capronoin, isocapronoin, 3,8-dimethyldecanol-5-one-6 and 3,3,6,6-tetramethyl-octanol-4-one-5. The last three substances are new.

Aliphatic acyloins easily undergo photochemical decomposition.

STUDIES ON REACTIONS RELATING TO CARBOHYDRATES AND POLYSACCHARIDES. XXX. THE COMPARATIVE HYDROLYSIS OF SOME DISACCHARIDES AND POLYSACCWARIDES

BY HAROLD HIBBERT AND EDMUND G. V. PERCIVAL[1]

RECEIVED JUNE 18, 1930 PUBLISHED OCTOBER 6, 1930

Introduction

The problem of the relative ease of hydrolysis of disaccharides and of polysaccharides such as starch and cellulose is an important one, not only from the scientific, but also from the industrial standpoint. Thus its solution is of great importance for a thorough understanding not only of the role played by starch as a "reserve material" in the vegetable kingdom but also of the close inter-relationship existing between starch and cellulose in plant metabolism. Also since it may be assumed that the structure of cellulose as a long chain of cellobiose units is now established on a reasonably firm basis, and that starch is presumably derived in a similar manner from maltose, the inter-relation of the reactions involving both analysis and synthesis of these products is of considerable interest.

It would also seem that a more intimate knowledge of the relative ease of hydrolysis of these products into glucose might throw some light on their relative stability and the bearing of the latter on the mode of linkage in the long-chain polysaccharides. Many of these hydrolytic changes, as shown in other researches to be published later, can be readily brought about under the influence of bacterial action as well as by the enzyme isolated from such organisms. There thus exists the possibility of co-relating two widely different types of hydrolytic agents.

Part I. Hydrolysis of Derivatives of Glucopyranose

The hydrolysis of starch by dilute acids has been investigated by Nanji and Beazeley,[2] Defren,[3] Meyer, Hopff and Mark[4] and others. Similarly Sherrard and Gauger,[5] Ost and Wilkening[6] and Simonsen[7] have studied the hydrolysis of cellulose by dilute acid. Since heat has to be applied, however, there is extensive decomposition of the glucose formed and the results are of no interest for comparing the two polysaccharides, the more so as cellulose is not dispersed in dilute acid.

Willstatter and Zechmeister[8] dissolved cotton cellulose in 41% hydrochloric acid and followed the course of the hydrolysis by observing the change in the specific rotation of the solution, and its reducing power. A discontinuity in the curve after about three hours was taken to indicate the presence of cellobiose. Sherrard and Froehlke[9] and Cunningham[10] employed a similar method, and Konig and Hühn[11] used a solution of zinc chloride in hydrochloric acid to disperse and hydrolyze cellulose.

Daish[12] investigated the hydrolysis of starch and maltose using fuming and concentrated hydrochloric acid, and he compared his results with those of Willstatter and Zechmeister.[8] Although his values indicate that starch hydrolyzes much more rapidly than cellulose, the fact that the experiments were not conducted under comparable conditions detracts from their value for purposes of comparison. Daish[12] indeed showed that maltose was hydrolyzed at about the same speed as starch itself, but as to how far the hydrolysis of cellulose is concerned with the breakdown of cellobiose was still left undecided. Freudenberg, Wolf, Knopf and Zaheer,[13] carrying out hydrolyses with *N* sulfuric acid at 70°, showed that cellobiose is much more difficult to break down than maltose. Willstatter and Zechmeister[8] had also called attention to the resistance towards hydrolysis of this disaccharide.

Selection of Reaction Medium

Instead of the inconvenient, fuming hydrochloric acid, it was decided to use zinc chloride, dissolved in hydrochloric acid, for the experiments on glucopyranose derivatives.

In the case of certain anhydrofructose compounds which were to be investigated, it was found advisable, owing to the rapidity of the hydrolysis and the decomposition of the fructose, to employ 0.1 N oxalic acid at 65°.

Preparation of Materials

Cellulose.—The material used was a pure absorbent cotton, having an a-cellulose value of 99.1%; ash, 0.05%, after drying at 60° (15 mm.).

β-Cellobiose.—This disaccharide was prepared from cellobiose octa-acetate (m. p. 227°), by the method of Maquenne and Goodwin,[14] as modified by Haworth and Hirst.[15] The product after purification had $[\alpha]^{20}_{D}$ 35°; m. p. 215°.

Cellodextrin (Cellobiosan) was prepared by Mr. J. G. Morazain, of this Laboratory, according to the method of Hess and Friese[16] (see also Meyer and Hopff);[17] $[\alpha]^{20}_{D}$ in 2 *N* NaOH, −4.1°.

Starch.—This was Kahlbaum's pure soluble starch for analysis, dried at 60° (15 mm.).

Inulin.—"Kiliani inulin" was "recrystallized" according to the method of Drew and Haworth[18] and dried at 60° (15 mm.).

Levan.—This was supplied by Mr. R. S. Tipson[19] of this Laboratory, and obtained by the action of *Bacillus mesentericus* on sucrose; after electrodialysis it was precipitated twice with alcohol; $[\alpha]^{20}_{D}$ −40°, dried at 60° (15 mm.).

The maltose, lactose, glucose, fructose, sucrose and galactose used in these experiments were authentic samples as shown by their physical constants, and were dried over phosphoric oxide in a vacuum.

The solvent, hereafter called (A), used in the experiments on the glucopyranose derivatives was a solution of anhydrous zinc chloride (1 part) in concentrated hydrochloric acid (d, 1.180) (2 parts) and was of d_4^{23} 1.464.

For the anhydrofructose derivatives 0.105 N oxalic acid (solution B) was used as the hydrolyzing agent.

The optical measurements were made with the Frič polarimeter recommended by the U. S. Bureau of Standards." All solutions were kept at 23 ± 0.1° by the use of a jacketed tube, except when oxalic acid was employed as hydrolyzing agent, in which case the temperature was 65 ± 0.2°.

Throughout these experiments *K* is calculated from the formula

$$K = \frac{1}{0.4343t} \log_{10} \cdot \frac{\alpha_\infty - \alpha_0}{\alpha_\infty - \alpha_t}$$

derived from the equation for *a* monomolecular reaction, in which *t* is time in seconds, α_0 is initial value of specific rotation (extrapolated), a, is final value of specific rotation and α_t is rotation at time *t*.

Experimental

For purposes of comparison it is necessary to have the cellulose completely dispersed prior to the hydrolysis and to carry out the experiments

under identical conditions of temperature, because the velocity of a reaction is so markedly influenced by that factor.

The Hydrolysis of Cotton Cellulose at 23°.—About 0.25 g. of the dry material was weighed out accurately into a dry stoppered bottle, and 50 cc. of the solvent (A), at 23°, was added by means of a pipet. The mixture was shaken vigorously for five minutes and then carefully filtered through a weighed asbestos Gooch crucible, taking care to avoid loss of hydrogen chloride by employing the minimum amount of suction. The clear solution was transferred to the polarimeter tube and readings were taken at convenient times until the rotation became constant.

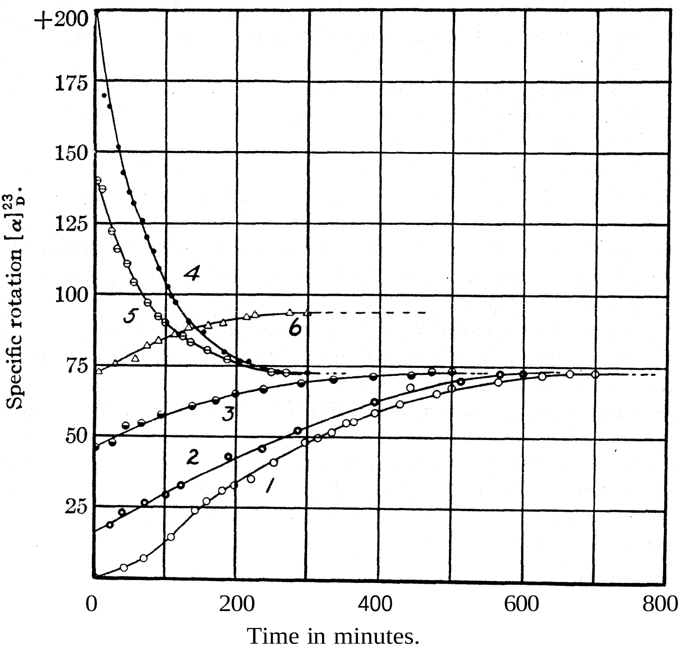

Fig. 1.—Rate of hydrolysis in zinc chloride–hydrochloric acid solution at 23°: 1, cellulose, ○; 2, cellodextrin O; 3, cellobiose, ◒; 4, starch, ●; 5, maltose, ⊖; 6, lactose, Δ.

The Gooch crucible was washed with distilled water and alcohol, dried at 105°, weighed and the increase in weight subtracted from the original weight of cellulose. This method was adopted because otherwise a slight cloudiness obscured the rotation. The amount of insoluble material after five minutes was usually about 7%. $[\alpha]^{23}_{D}$ was calculated on the basis of glucose, *i.* e., $[\alpha]^{23}_{D}$ observed X (162/180).

The rotation of anhydrous glucose in the same solvent (*A*) gave $[\alpha]^{23}_{D}$ +73.1 for $C = 1$.

The results are to be found in Table I and are plotted as Curve 1, Fig. 1.

The Hydrolysis of β-Cellobiose at 23°.—This disaccharide is completely soluble in solvent (A) to give a clear solution. The results are to be found in Table II and are plotted in Curve 3, Fig. 1.

TABLE I

THE HYDROLYSIS OF CELLULOSE AT 23°

Concentration, 0.454 g. of cellulose in 100 cc. of solvent (A)

Time, min.	$[\alpha]^{23}_{D}$	K X 10^4	Time, min.	$[\alpha]^{23}_{D}$	K X 10^4
0	0	...	335	51.5	0.61
42	+ 3.4	0.18	355	54.9	.66
75	6.9	.22	365	55.6	.66
105	14.4	.35	392	58.3	.69
156	24.0	.47	429	61.7	.73
160	27.4	.49	479	65.2	.79
182	30.9	.51	502	67.2	.83
199	32.9	.50	565	69.9	.96
223	35.0	.49	625	72.0	1.24
255	41.0	.54	665	72.7	...
298	48 0	.60	700	\$72.7	...
315	49.4	.60			

The reaction is thus shown not to be of the monomolecular type. Mean value of $K = 0.61 \times 10^{-4}$.

TABLE II

EXPERIMENTAL RESULTS

Concentration, 0.574 g. of cellobiose in 100 cc. of solvent (A)

Time, min.	$[\alpha]^{23}_{D}$	K × 10^4	Time, min.	$[\alpha]^{23}_{D}$	K × 104
0	+46.1	..	136	60.2	0.91
2	46.4	0.90	180	63.0	.93
10	46.5	.89	250	66.5	.95
16	48.7	1.05	296	68.7	1.02
21	49.9	1.20	339	69.3	0.96
37	52.1	1.13	388	70.5	1.00
61	54.4	1.10	449	71 6	1.07
94	56.3	0.95	508	73.1	..
113	59.0	.96	560	+73.1	..

Mean value of $K = 1.0 \times 10^{-4}$. The reaction is of the monomolecular type.

The Hydrolysis of Cellodextrin at 23°.—The results (Table III) indicate that the hydrolysis is not monomolecular, and that the polysaccharide occupies an intermediate position between cellulose on the one hand and cellobiose on the other. The values are plotted in Curve 2, Fig. 1.

TABLE III

EXPERIMENTAL RESULTS

Concentration, 0.550 g. of cellodextrin in 100 cc. of solvent (A)

Time, min.	$[\alpha]^{23}_{D}$	K X 10^4	Time, min.	$[\alpha]^{23}_{D}$	K X 10^4
0	\$16.5	..	238	46.0	0.52

123	32.8	.46	573	72.5	..
190	43.0	.56	600	+72.5	..

The Hydrolysis of Starch at 23°.—Using the same technique, the hydrolysis of starch was investigated. The results are to be found in Table IV and are plotted on Curve 4, Fig. 1.

TABLE IV

EXPERIMENTAL RESULTS

Concentration, 0.448 g. of starch per 100 cc. of solution

Time, min.	$[\alpha]^{23}_D$	$K \times 10^4$	Time, min.	$[\alpha]^{23}_D$	$K \times 10^4$
0	+200.0	..	102	103.0	2.36
12	169.7	3.79	109	98.6	2.05
19	165.6	2.77	114	97.4	2.41
32	151.7	2.49	133	90.4	2.46
39	142.6	2.58	155	87.0	2.58
47	136.0	2.49	185	80.0	2.40
55	132.1	2.32	205	77.0	2.49
66	126.0	2.27	219	76.5	2.73
73	120.0	2.29	258	73.0	..
82	115.6	2.25	300	+73.0	..
90	109.2	2.33			

Mean value of $K = 2.45 \times 10^{-4}$. The reaction is apparently monomolecular after the first half hour.

The Hydrolysis of Maltose at 23°.—The results depicted in Table V and plotted in Curve 5, Fig. 1, indicate that the reaction is monomolecular.

TABLE V

EXPERIMENTAL RESULTS

Concentration, 0.552 g. of maltose in 100 cc. of (A)

Time, min.	$[\alpha]^{23}_D$	$K \times 10^4$	Time, min.	$[\alpha]^{23}_D$	$K \times 10^4$
0	+142.8	..	100	90.0	2.36

75	97.2	2.37	270	+72.8	..
90	92.3	2.44			

Mean $K = 2.40 \times 10^{-4}$.

TABLE VI

THE HYDROLYSIS OF LACTOSE AT 23°

Concentration, 1.560 g. of lactose in 100 cc. of solvent (A)

Time, min.	$[\alpha]^{23}_D$	$K \times 10^4$	Time, min.	$[\alpha]^{23}_D$	$K \times 10^4$
0	+72.4	..	133	87.7	2.49
4	72.8	..	161	88.8	2.78
28	73.0	..	182	89.9	2.67
56	76.9	2.80	216	92.0	2.57
73	81.7	2.90	247	92.8	2.83
90	83.4	2.63	275	93.5	..
113	85.4	2.43	300	+93.5	..

Mean value of $K = 2.84 \times 10^{-4}$. The reaction again is of the monomolecular type.

Since the results seemed to indicate that a β-biose is hydrolyzed much more slowly than an a-biose, it appeared of interest to determine whether lactose (which is a β-galactoside) hydrolyzes as slowly as cellobiose. The results are to be found in Table VI and are plotted in Curve 6, Fig. 1.

Discussion of Results

Table VII shows the mean values of the hydrolysis constant K for the substances indicated.

TABLE VII

VALUES OF THE HYDROLYSIS CONSTANT

Substance	Cellobiose	Starch	Maltose	Lactose
$K \times 10^4$	1.00	2.45	2.40	2.84

These experiments establish the fact that no generalization can be made as to the rate of hydrolysis of a disaccharide, and the mode of union of the building units with one another. This was also emphasized by Freudenberg, Wolf, Knopf and Zaheer,[13] who carried out the hydrolyses at 70° in N sulfuric acid solution for a large number of glucosides and disaccharides. These workers showed that under their experimental conditions, maltose (a-linkage) is hydrolyzed more than twice as rapidly as cellobiose (β-linkage) and that lactose (β-linkage) is hydrolyzed a little faster than maltose; this is confirmed by the present results.

The conclusions of Willstatter and Zechmeister[8] with regard to the discontinuity in their curve for the hydrolysis of cellulose are not confirmed in the present instance and it is suggested their results are possibly due to temperature variations. There would appear to be no theoretical significance whatever to the discontinuity as found by these authors. It would mean either that the hydrolysis had stopped, or that a substance of zero or negative rotation was being formed, whereas cellobiose was shown to have a positive equilibrium rotation value in their solvent. It is noteworthy that these authors in their determination of the reducing power found no such steps in the curve, and the same may be said of the results of Sherrard and Froehlke.[9]

The slow hydrolysis of cellulose is due to a great extent to the slow hydrolysis of cellobiose. The reaction is not monomolecular and the hydrolysis constants tend toward the value experimentally found for cellobiose under the same conditions.

If cellobiose is a reversion product as Hess[21] suggests, the time for the hydrolysis would be abnormally long because the following chain of reactions must, in this case, take place

$$\text{Cellulose} \longrightarrow \text{Glucose} \longrightarrow \text{Cellobiose} \longrightarrow \text{Glucose}$$

The fact that the cellobiosan of Hess and Friese[16] (which is regarded as a cellulosedextrin in the recent paper by Meyer and Hopff)[17] occupies an

[21] Hess, "Die Chemie der Zellulose," Leipzig, Germany, 1928, p. 494.

intermediate position between cellulose and cellobiose is further evidence against Hess' viewpoint.

The observations of Konig and Hühn, who found maxima in the case of the hydrolysis of different celluloses using solvent (A), are not confirmed except that it is apparent that the maxima they refer to are due to the destruction of glucose on standing, the solution becoming yellow and diminishing in $[\alpha]^t_D$ after thirty hours.

Willstatter and Zechmeister[8] considered that the amount of isomaltose formed in a 1% solution of glucose in fuming hydrochloric acid was negligible. This has been contested by Irvine and Soutar[22] but there seems to be little doubt that in the dilute solution used for these experiments (0.5%) the amount of isomaltose present at equilibrium would not affect the conclusions.

The difference in the rate of hydrolysis of starch and cellulose under identical conditions is shown to be due mainly to the difference in the rates of hydrolysis of the corresponding disaccharides, maltose and cellobiose, respectively. There would seem to be, therefore, no foundation for the belief that the glucose units in these polysaccharides possess a different ring system; the only difference between starch and cellulose, as far as hydrolysis is concerned, would seem to be due to the mode of linking of the glucose residues and the physical nature of the substances (see also Haworth[23] and Meyer, Hopff and Mark[4]).

It has been shown (Table III) that after the first half hour the hydrolysis of starch is practically monomolecular. Daish, using both concentrated and fuming hydrochloric acid, concluded that the hydrolysis of starch was not monomolecular but varied about 20% from that condition. He showed, however, that maltose did follow a monomolecular course and indicated that the two substances were hydrolyzed at almost the same rate. This is confirmed by the present series of observations.

The great influence of concentrated hydrochloric acid on the equilibrium rotation value was pointed out by Daish and has been observed repeatedly by other workers.

In the particular case of the zinc chloride–hydrochloric acid solvent (A) used, the equilibrium rotation between α- and β-glucose is shifted from +52.5 to +73.1°.

Part II

The Hydrolysis of Derivatives of Anhydrofructose.—It was of particular interest to determine the relation of levan to inulin. The former, as shown by Hibbert and Tipson,[19] consists of γ-fructose units linked together in the 2,6-positions. On the other hand, Haworth and Learner[24] provide con-

---

[22] Irvine and Soutar, *J. Chem. Soc.*, 117, 1489 (1920).

[24] Haworth and Learner, *J. Chem. Soc.*, 133, 619 (1928).

clusive evidence that inulin consists of fructofuranose units joined in the 1,2-positions.

Experiments on the comparative hydrolyses of these polysaccharides were carried out at 65 ± 0.2° using $N/10$ oxalic acid solution (B).

Experimental

The solutions were made up at 70° and rapidly transferred to the jacketed polarimeter tube. Corrections for the expansion of the glass, pipet and contained liquid were applied and all the results are calculated with the volumes reduced to 20°.

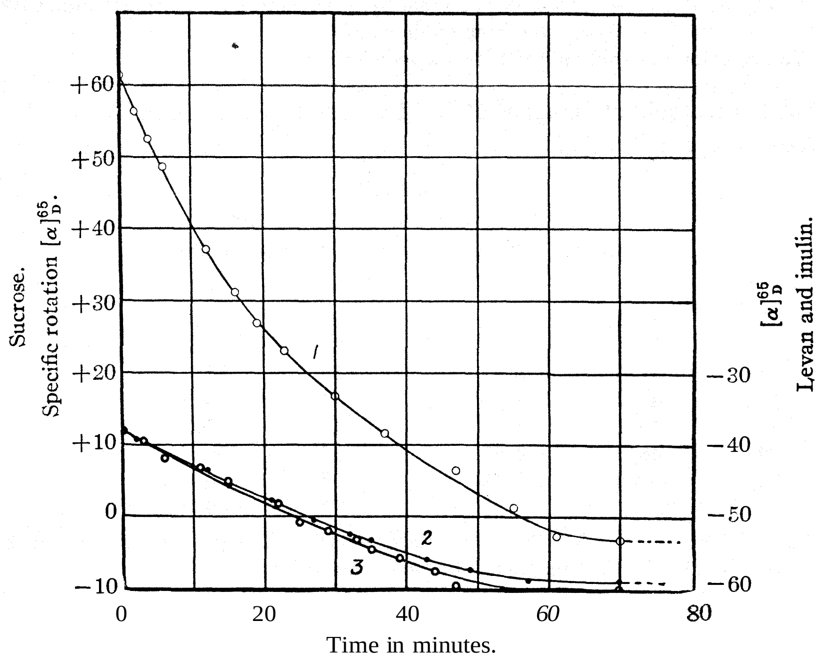

Fig. 2.—Rate of hydrolysis in N oxalic acid solution at 65°: *1*, sucrose, O; 2. inulin, ●; 3, levan, O.

The specific rotation of fructose at 65° may be calculated from the equation of Jungfleisch and Grimbert.[25]

$$[\alpha]^t_D = -[101.38 - 0.56t + 0.108(c - 10)]$$

where t is temperature in °C., and c is concentration in grams per 100 cc. Thus for a 1% solution at 65° $[\alpha]^{65}_D = -64.0$ in water; found, $[\alpha]^{65}_D$ −64.9 in solvent (B) for fructose.

The Hydrolysis of Inulin at 65°.—The results are given in Table VIII and plotted in Curve 2, Fig. 2.

22	48.3	4.77	47	59.7	..
25	50.8	5.72	52	60.0	..
			70	-60.0	..

Mean value of $K = 5.66 \times 10^{-4}$. $[\alpha]^{26}_D$ $-83.0°$. Calcd., $-85.8°$. % fructose from levan = 96.7%. The reaction is not monomolecular.

The Inversion of Cane Sugar at 65°.—The results are given in Table X and plotted in Curve 1, Fig. 2.

TABLE X

THE INVERSION OF CANE SUGAR AT 65°

Concentration, 1.258 g. of sucrose in 100 cc. of solvent (B)

Time, min.	$[\alpha]^{65}_D$	$K \times 10^4$	Time. min.	$[\alpha]^{65}_D$	$K \times 10^4$
0	+61.5	..	23	23.1	6.62
2	56.4	5.49	30	16.6	6.71
4	52.5	6.30	37	11.5	6.81
6	48.7	6.19	47	6.4	6.95
12	37.1	6.65	55	+1.3	..
16	31.3	6.63	61	-2.6	..
19	26.9	6.80	70	-2.6	..

Mean value of $K = 6.50 \times 10^{-4}$. These figures indicate a monomolecular reaction.

Discussion of Results

It is to be noticed that inulin yields only 94% while levan yields 97% of its weight as fructose according to the values of the specific rotations.

This has been noted repeatedly in the case of inulin and is attributed to a difructose anhydride by Jackson and Goergen.[26]

It appears that the three anhydrofructose derivatives studied hydrolyze under the experimental conditions at about the same speed. This is illustrated in Table XI, showing the mean velocity constants.

TABLE XI

MEAN HYDROLYSIS CONSTANT AT 65°

Substance	Sucrose	Levan	Inulin
$K \times 10^4$	6.50	5.66	5.01

The constants in the case of levan and inulin (Tables IX and X) indicate that the process is not monomolecular, since the values of K, in general, rise. They are sufficiently close, however, to indicate that these two polysaccharides belong to the same group of substances.

Summary

1. The rates of hydrolysis of cellulose, cellobiose, cellodextrin, starch, maltose and lactose, in a zinc chloride–hydrochloric acid solution, are compared at 23°.
2. It is concluded that the slow hydrolysis of cellulose is, in a large part, due to the slow hydrolysis of cellobiose; that cellobiose is not a reversion product, and that there seem to be no grounds to suppose that starch and cellulose are essentially different, except for the a-linkages in the former and the 8-unions in the latter.
3. The rates of hydrolysis of sucrose, levan and inulin in 0.1 *N* oxalic acid solution at 65° have been measured.
4. It is established that these anhydrofructose derivatives hydrolyze at almost the same rate and it is concluded that this behavior is related to the γ-fructose residue present in each.
5. The technique developed is of possible application in the determination of the configurations of unknown polysaccharides.

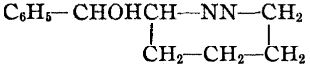
PIPERIDINE DERIVATIVES
X. THE PHENYLPIPERIDYLCARBINOLS

BY KENNETH E. CROOK AND S. M. McELVAIN

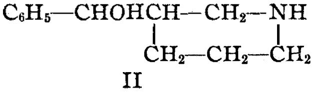
RECEIVED JUNE 20, 1930 PUBLISHED OCTOBER 6, 1930

Since the publication[1] of the summarized work of Chen and others on the pharmacological properties of ephedrine, a number of papers have appeared in the chemical literature in which the preparation and properties of certain synthetic homologs of this important drug have been described.[2] These synthetic compounds in general have been of the type $ArCHOH\text{-}CHR_1NHR_2$, where Ar is a phenyl or alkyl substituted phenyl radical and R_1 and R_2 are various alkyl radicals. In certain cases R_1 is a phenylalkyl radical.

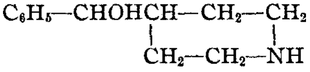
This paper describes the preparation and properties of the three phenylpiperidylcarbinols (I, II, III) as an effort to extend the synthetic ephedrine-like compounds to other types of structure. The relationship between the structure of these carbinols and ephedrine (IV) seemed interesting on account of the fact that the secondary amino group could be placed at different positions relative to the secondary alcohol group without increasing the carbon content of the molecule or altering materially the characteristic ephedrine-like structure.



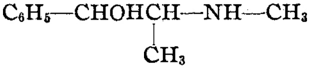
I



II



III



IV

The phenyl-2-, -3- and -4-piperidylcarbinols were obtained by the catalytic reduction of 2-, 3- and 4-benzoylpyridine hydrochlorides using Adams' platinum-oxide platinum black catalyst. The 2-benzoylpyridine was so weakly basic that due to the hydrolysis of its hydrochloride the catalyst was rendered inactive by the precipitation of the free base upon it. This difficulty was overcome by carrying out the reduction with an excess of hydrochloric acid in the solution. No similar difficulty was encountered in the reduction of the 3- and 4-benzoylpyridine hydrochlorides.

The reduction of 2-benzoylpyridine produced both diastereoisomeric racemic phenyl-2-piperidylcarbinols. One isomer (A) melted at 141–142°

---

[1] Chen and Kao, *J. Am. Pharm. Assocn.*, 15, 625 (1926).

[2] Adams, Hyde and Browning, THIS JOURNAL, 50, 2287 (1928); Johnson and Manske, *ibid.*, 51, 1906 (1929); Fourneau and Barrelet, *C. A.*, 24, 352 (1930); de Buruaga, *C. A.* 24,596 (1930)

and the other (B) melted at 171–173°. Both isomers were isolated as the free bases and in the ratio of about three parts of A to one part of B. It was found that isomer A could be changed into isomer B to some extent by heating at 100° for forty-eight hours with 25% hydrochloric acid. The separation and purification of these racemic diastereoisomers are made possible by the fact that the hydrochloride of B is much more soluble in an alcohol-ether mixture than the hydrochloride of A, while the free base, B, is considerably less soluble than the free base A in water containing 4% alcohol. The details of the isolation and the conversion of the lower-melting into the higher-melting isomer are given in the experimental part of the paper. The amount of material that was available did not allow for any extended search to be made for the diastereoisomeric phenyl-3-piperidylcarbinols; consequently only one of these racemic mixtures was obtained. Obviously such isomerism would not be present in a structure such as phenyl-4-piperidylcarbinol.

The 2- and 4-benzoylpyridines were prepared by the oxidation of 2- and 4-benzylpyridines. 3-Benzoylpyridine was prepared from nicotinic acid by the method of LaForge.[3]

Pharmacological Properties.—The isomeric phenylpiperidyl carbinols are being studied pharmacologically by Messrs. Edward E. Swanson and Charles L. Rose of The Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana. They have reported that each of these carbinols has the same pharmacological properties as ephedrine, but is somewhat less active. The details of this pharmacological investigation will be published by them elsewhere.

Experimental

All melting points and boiling points herein given are corrected.

The 2- and 4-benzyl- and benzoylpyridines were prepared by a modification and, it is believed, an improvement of the methods which have been described by Tschitschibabin[4] and LaForge[3] for these compounds. Since specific directions were not found in the available literature, the procedures which proved most satisfactory are given below in considerable detail.

2-Benzylpyridine.—A mixture of 300 g. of benzyl chloride, 200 g. of dry pyridine and 3 g. of powdered copper was placed in a 2-liter flask fitted with a reflux water condenser and thermometer dipping into the contents of the flask. The mixture was slowly heated to 70°, after which the heat of the reaction caused the temperature to continue to rise to about 115°, when the liquid began to boil. At the first indication of boiling, the flask was surrounded by an ice-bath and cooled for three to five minutes until the violent reaction was over. The water condenser was then replaced by an air reflux condenser and the flask contents heated rapidly in an oil-bath to 225–230°, then slowly to 240–245°. A small amount of liquid distilling out of the top of the flask was discarded. The temperature was held at 240–245° for three hours, after which time the reaction

[3] LaForge, THIS JOURNAL, 50, 2484 (1928).

[4] Tschitschibabin, *Chem. Centr.*, 72, II, 127 (1901); 73, I, 206 (1902); 87, II, 146

mixture was cooled to 75–100°, poured into 750 cc. of warm water which contained 50 cc. of concd. hydrochloric acid and chilled in an ice-bath. The black solution was poured off from a small amount of tar, made alkaline with sodium hydroxide, extracted with benzene, and the benzene solution dried over potassium hydroxide. After evaporation of the solvent, the material was distilled,' giving about 175 g. of crude benzylpyridines boiling between 260 and 310°, together with some higher-boiling material which was discarded. The 260–310° fraction was carefully fractionally distilled at atmospheric pressure through a 6-inch Vigreaux column sealed onto a flask. After three fractionations, the following fractions were obtained

279–282°	65–75 g.	285–288°	17–23 g.
282–285°	28–31 g.	288–299°	12–20 g.

The fractions boiling between 282 and 299" were used in the preparation of 4-benzoylpyridine (see below).

Fifty grams of the 279–282° fraction was added to a solution of 105 g. of picric acid in 3 liters of alcohol and refluxed for thirty minutes. The solution was then quickly cooled to about 32° in an ice-bath with stirring and the impure 2-benzylpyridine picrate which precipitated quickly filtered off. This crude picrate was dissolved in 3 liters of hot alcohol, cooled in an ice-bath with stirring to about 32" and again rapidly filtered. A second recrystallization from the same quantity of alcohol, but cooled to 20" before filtering, yielded 57–59 g. of pure 2-benzylpyridine picrate, m. p. 139.5–140.5°. If the relative amount of alcohol used in recrystallization was decreased or the solutions cooled to lower temperatures than indicated, additional recrystallizations were found to be necessary.

A suspension of 40 g. of 2-benzylpyridine picrate in about 1 liter of hot water was made strongly alkaline with ammonium hydroxide. The 2-benzylpyridine separated as an oil and, after cooling to 40°, was extracted with benzene. After drying over potash, the benzene was distilled off, leaving 16 g. of 2-benzylpyridine which boiled at 276.8–277.2° (737 mm.).

2-Benzoylpyridine.—Eighty-eight grams of 2-benzylpyridine was suspended in about 2 liters of water contained in a 3-necked flask fitted with reflux condenser, mechanical stirrer and thermometer which dipped below the surface of the liquid. To this suspension 115.5 g. of potassium permanganate was added in five or six portions. each portion being added only after the preceding ohe was practically decolorized. The temperature was held at 70° until after addition of the last portion of the oxidizing agent, and then raised to 100° until all the permanganate had reacted. After cooling, the liquid was layered over with benzene, stirred vigorously and the benzene solution of 2-benzoylpyridine drawn off, dried over potassium hydroxide and the solvent evaporated. The residue on distillation yielded 85–89.5 g. of 2-benzoylpyridine that boiled at 170–172° (10 mm.).[5]

This 2-benzoylpyridine gave a picrate from alcoholic solution that melted at 121–123°. After two recrystallizations from alcohol, the melting point of this picrate was 122–123°. Tschitschibabin[4] reports the melting point of this particular picrate as 130°. Further recrystallization, however, did not change the melting point. The purity of the compound obtained in the present work was checked by preparing some 2-benzoylpyridine from pure picolinic acid by the procedure described below for the preparation of 3-benzoylpyridine from nicotinic acid. The 2-benzoylpyridine so obtained gave a picrate which also melted at 122–123° and a mixture of the picrates prepared by the two methods melted at the same temperature.

2-Benzoylpyridine Hydrochloride.—When 2-benzoylpyridine was dissolved in

---

[5] *Cf.* Wolffenstein and Hartwich, *Ber.*, 48,2043 (1915).

ether and dry hydrogen chloride passed in, a liquid hydrochloride separated that was difficult to crystallize. After solution in acetone and evaporation under diminished pressure to remove excess hydrochloric acid, the thick liquid was allowed to stand for three weeks, when about half had crystallized. One recrystallization from anhydrous acetone gave a white, crystalline hydrochloride, m. p. 126–128°.

Anal. Subs., 0.4567, 0.3917: AgCl, 0.2987, 0.2563. Calcd. for $C_{12}H_{10}ONCl$: Cl, 16.15 Found: Cl, 16.18, 16.19.

4-Benzoylpyridine.—The fractions of the benzylpyridine boiling between 282 and 299° were oxidized with potassium permanganate in a similar manner to that described above in the preparation of 2-benzoylpyridine. The crude 4-benzoylpyridine was added to a solution of double its weight of picric acid in sufficient alcohol to retain the picrate in solution at the boiling point. On cooling, nearly pure 4-benzoylpyridine picrate separated. One to two recrystallizations from the minimum quantity of boiling alcohol necessary for solution gave pure 4-benzoylpyridine picrate which melted at 159–160°. This picrate was decomposed as in the case of the 2-benzylpyridine picrate, yielding 4-benzoylpyridine, b. p. 313.5–314° (742 mm.), which solidified immediately to a white solid that melted without recrystallization, at 71.5–72.5°. In one run the three higher-boiling fractions of crude benzylpyridines were oxidized and purified separately, the yields of 4-benzoylpyridine being

75 g. of the 282–285° fraction gave 22.5 g. of 4-benzoylpyridine
38.5 g. of the 285–288° fraction gave 17.0 g. of 4-benzoylpyridine
31.5 g. of the 288–299° fraction gave 15.6 g. of 4-benzoylpyridine

In other runs the three fractions were combined before oxidation and there was obtained 32–33 g. of 4-benzoylpyridine for each 100 g. of material boiling between 282–299°.

4-Benzoylpyridine Hydrochloride.—Dry hydrogen chloride was passed into a solution of 10 g. of 4-benzoylpyridine in 250 cc. ether. The white, crystalline hydrochloride was recrystallized once from alcohol–ether, yielding 10 g. of the hydrochloride, m. p. 195–197°.

Anal. Subs., 0.6494, 0.7821: . AgCl, 0.3575, 0.5097. Calcd. for $C_{12}H_{10}ONCl$: Cl, 16.15. Found: Cl, 16.10, 16.12.

3-Benzoylpyridine was made by the method given by LaForge.[3] The only variation from his procedure was that the 3-benzoylpyridine was purified as the hydrochloride instead of as the picrate. The purified hydrochloride melted at 160–162°.

Anal. Subs., 0.3581, 0.4013: AgCl, 0.2321, 0.2598. Calcd. far $C_{12}H_{10}ONCl$: Cl, 16.15. Found: Cl, 16.03, 16.01.

Phenyl-2-piperidylcarbinol.—The 2-benzoylpyridine is very weakly basic and a solution of its hydrochloride in water appears cloudy due to hydrolysis. On attempting to reduce a solution of the hydrochloride in water with platinum-oxide platinum black catalyst which had previously been reduced in water, the eatalyst collected in small clumps and no hydrogen was absorbed. The addition of a 75% excess of hydrochloric acid would usually cause the catalyst to whip up into suspension and reduction then proceeded normally. To determine the optimum conditions for reduction in hydrochloric acid solution, the following experiments were made. In each case 0.100 g. of platinum-oxide catalyst was placed in 10 cc. of water and shaken with hydrogen until the brown oxide was reduced to black platinum. Then 5 g. of 2-benzoylpyridine, together with the indicated excess of hydrochloric acid was added, with enough water to make the total volume given in the table. Each sample of catalyst was taken from the same lot of freshly prepared catalyst, and the same initial hydrogen pressure (41 lb.) was used in each case. The results that were obtained are shown in Table I.

TABLE I

THE REDUCTION OF 2-BENZOYLPYRIDINE WITH VARYING AMOUNTS OF HYDROCHLORIC ACID

Excess of hydrochloric acid, %	Total volume of solution. cc.	Time of reduction. hours
10	45	13
10	75	No reduction
25	75	7.5
50	75	5.5
75	75	5
100	75	4
125	75	4
150	75	11.5

It is seen from the above data that 100–125% excess of hydrochloric acid over that necessary to form the hydrochloride is the optimum amount of acid for the reduction of this concentration of 2-benzoylpyridine. It is also apparent from the first two runs that a dilution from 45 cc. to 75 cc. of the benzoylpyridine hydrochloride solution containing a 10% excess of hydrochloric acid causes sufficient hydrolysis of the hydrochloride to the free base to prevent the reduction. In this connection it may be of interest to point out that Craig and Hixon[6] found that pyrrole could be more efficiently reduced to pyrrolidine in the presence of an excess of hydrochloric acid.

The two diastereoisomeric phenyl-2-piperidylcarbinols designated as A and B were separated as follows: 10 g. of 2-benzoylpyridine was reduced in 100% excess of hydrochloric acid, the catalyst filtered off and the water removed by evaporation under diminished pressure. The residual hydrochloride was recrystallized by dissolving in 5 cc. of absolute alcohol for each gram of hydrochloride and precipitating with 6 cc. of dry ether for each cc. of alcohol used. Four such recrystallizations gave 4.04 g. of the hydrochloride of A, m. p. 200–202°. On dissolving in a small amount of water and making alkaline with sodium hydroxide, 3.26 g. of the free base was obtained. One recrystallization from water containing 4% of alcohol gave 2.5 g. of A, m. p. 141–142°.

Anal. Subs., 0.2377, 0.2000: CO_2, 0.6544. 0.5514: H_2O, 0.1921, 0.1617. Calcd. for $C_{12}H_{17}ON$: C, 75.39; H, 8.90. Found: C, 75.08, 75.19; H, 8.98, 8.98. 0.6119 g. (1 mol) of this carbinol reacted with 0.6555 g. (2.01 mols) of acetic anhydride.?

The alcohol-ether filtrate from the first recrystallization of the hydrochloride of A contains most of the hydrochloride of B, the latter of which is the more soluble. On evaporation of the solvent and conversion to the free base, there remained 3.75 g. of base. After three recrystallizations of the free base from the minimum quantity of water containing 4% of alcohol, 0.81 g. of B, m. p. 171–173°, was obtained.

Anal. Subs., 0.2210, 0.2098: CO_2, 0.6086, 0.5805: H_2O, 0.1808. 0.1700. Calcd. for $C_{12}H_{17}ON$: C, 75.39; H, 8.90. Found: C, 75.10, 75.46; H, 9.09, 9.00. 0.4865 g. (1 mol) of the carbinol reacted with 0.4899 g. (1.89 mols) of acetic anhydride.

Evaporation of all filtrates from the purification of A and B and conversion to the free base gave 4.6 g., from which an additional quantity of A and B could be recovered by a repetition of the above method of separation.

Conversion of A into B.—One-half gram of A was heated at 100° for forty-eight

---

[6] Craig and Hixon, THIS JOURNAL, 52, 804 (1930).

[7] The carbinol and a 3- to 4-fold excess of acetic anhydride contained in a sealed tube were heated overnight on a steam-bath, then dissolved in water and the excess acetic acid titrated with standard potassium hydroxide.

hours in 5 cc. of 25% hydrochloric acid. The solvent was removed under diminished pressure and the hydrochloride converted to the free base with sodium hydroxide. After three recrystallizations from water containing 4% of alcohol, there remained 0.032 g. of the B isomer that melted at 171–173°.

Phenyl-3-piperidylcarbinol Hydrochloride.—Ten grams 3-benzoylpyridine hydrochloride was reduced in aqueous solution with 0.5 g. of platinum-oxide platinum black catalyst. The reduction required fifteen hours for completion. After filtering off the catalyst and removing water under diminished pressure, the hydrochloride was purified by recrystallization from an alcohol–ether mixture. After five recrystallizations, 3 g. of product, m. p. 190–192°, was obtained.

Anal. Subs., 0.3558, 0.4267: AgCl, 0.2241, 0.2680. Subs., 0.2715: CO_2, 0.6338; H_2O, 0.1805. Calcd. for $C_{12}H_{18}ONCl$: Cl, 15.58; C, 63.30; H, 7.91. Found: Cl, 15.58, 15.54; C, 63.67; H, 7.56.

Phenyl-4-piperidylcarbinol Hydrochloride.—A solution of 10 g. of 4-benzoylpyridine hydrochloride in water absorbed the theoretical quantity of hydrogen in five hours when shaken with 0.5 g. of catalyst. After removal of solvent and one recrystallization from an alcohol–ether mixture, 10.2 g. of phenyl-4-piperidylcarbinol was obtained; m. p. 191–193°.

Anal. Subs., 0.2821, 0.3207: AgCl, 0.1768, 0.2016. Calcd. for $C_{12}H_{18}ONCl$: Cl, 15.58. Found: Cl, 15.50, 15.55.

Phenyl-4-piperidylcarbinol.—Ten grams of **phenyl-4-piperidylcarhinol** hydrochloride on conversion to the free base gave, after one recrystallization from water containing 4% of alcohol, 6.4 g. of the free base, m. p. 166–167°.

Anal. Subs., 0.2469, 0.2150: CO_2, 0.6805, 0.5936: H_2O, 0.2005, 0.1736. Calcd. for $C_{12}H_{17}ON$: C, 75.39; H, 8.90. Found: C, 75.17, 75.30; H, 9.02, 8.97. 0.9545 g. (1 mol) of the carbinol reacted with 1.004 g. (1.97 mols) of acetic anhydride.

Summary

1. The isomeric phenylpiperidylcarbinols have been prepared and described. In the case of the phenyl-2-piperidylcarbinol the two diastereoisomers have been isolated.

2. These carbinols have structures analogous to ephedrine and it has been found that although they are somewhat less active they all possess the same pharmacological properties as this important drug.

A NEW METHYLATION PROCESS

BY M. NIERENSTEIN

RECEIVED JUNE 23, 1930 PUBLISHED OCTOBER 6, 1930

The catechins are remarkable for their well-crystallizing and sharp-melting penta-acetyl derivatives.[1] On the other hand, the corresponding methoxy derivatives, if prepared in the usual way by the action of dimethyl sulfate and alkali, either on the catechins themselves, or on the penta-acetyl derivatives, are contaminated with by-products, formed through fission of the chromane-ring.[2] It was therefore desirable to evolve a reliable method for the conversion of these well-defined penta-acetyl derivatives into the corresponding methoxy derivatives; such a method has now been elaborated. It consists in the interaction in the cold of diazomethane with these penta-acetyl derivatives in the presence of piperidine. The reaction proceeds smoothly and is easily controlled, each molecular proportion of piperidine removing one acetyl group, which is then replaced by the methyl group. The results obtained with the penta-acetyl catechins will be dealt with later on, a few representative cases being meanwhile described.

Experimental

The acetyl derivatives used in the following experiments were dissolved in alcohol and to this solution was added piperidine, also in alcoholic solution. Into this solution was then distilled an ethereal solution of diazomethane prepared from nitrosomethylurethan, the reaction being carried out in the apparatus previously described.[3] After standing for twenty-four hours the alcohol was removed, the solid dissolved in warm aqueous alkali and refluxed for thirty minutes on a water-bath. The methoxy derivatives were obtained by acidifying the cold solution, which had previously been freed from piperidine by exhaustive extraction with ether.

(1) Veratric Acid.—One gram of diacetyl-protocatechuic acid (m. p. 162°)[4] was reacted on with diazomethane from 5 cc. of nitrosomethylurethan in the presence of 1 g. of piperidine (excess); yield, 0.6 g.; m. p. and mixed m. p., 180°.

Anal. Subs., 2.107, 6.302 mg.: AgI, 5.365, 16.267 mg. Calcd. for $C_9H_{10}O_4$: OCH_3, 34.07. Found: OCH_3, 33.61.34.06.

(2) Isovanillic Acid—The same proportions as given above were used, with the exception of piperidine, when 0.4 g. (1 mol) was added; yield, 0.7 g.; m. p. 249°.

Anal. Subs. 4.085 mg.: AgI, 5.667 mg. Calcd. for $C_8H_8O_4$: OCH_3, 18.45. Found: OCH, 18.32.

(3) Dimethyl-β-resorcylic Acid.—One gram of diacetyl-β-resorcylic acid (m. p.

137°)[5] was reacted on with diazomethane in the presence of 0.8 g. (2 mols) of piperidine; yield, 0.5 g.; m. p. 109°, which is in agreement with the melting point given by Liebermann and Lindenbaum.[6]

Anal. Subs., 3.314 mg.: AgI, 8.533 mg. Calcd. for $C_9H_{10}O_4$: OCH_3, 34.07. Found: OCH_3, 33.99.

(4) **Monomethyl-β-resorcylic** Acid.—When using one molecule of piperidine a mixture of the two monomethyl-β-resorcylic acids was obtained. This mixture melted gradually between 169 and 174°, and gave with ferric chloride a violet coloration which had a distinctly greenish tint. The two isomers in question show the following properties: 2-hydroxy-4-methoxybenzoic acid melts at 160-161°, and gives a violet coloration with ferric chloride, whereas 2-methoxy-4-hydroxybenzoic acid melts at 187-189°, and gives a red-brown coloration with ferric chloride. The former substance therefore predominated in the mixture.

Anal. Subs., 7.310 mg.: AgI, 10.571 mg. Calcd. for $C_8H_8O_4$: OCH_3, 18.45. Found: OCH_3, 19.08.

(5) **Trimethylgallic** Acid.—One gram of triacetylgallic acid (m. p. 175°)[7] was methylated in the presence of an excess of piperidine; yield, 0.8 g.; m. p. 169°, with slight evolution of carbon dioxide.

Anal. Subs., 4.017 mg.: AgI, 13.303 mg. Calcd. for $C_{10}H_{12}O_5$: OCH_3, 43.86. Found: OCH_3, 43.72.

Summary

A method is described for the replacement of acetyl groups by methyl groups, using diazomethane and piperidine.

LOCAL ANESTHETICS DERIVED FROM QUINOLINE AND ISOQUINOLINE

BY C. F. BAILEY AND S. M. MCELVAIN

RECEIVED JUNE 23, 1930 PUBLISHED OCTOBER 6, 1930

Several previous communications[1] from this Laboratory have described the preparation of substituted piperidino-alkyl benzoates and substituted piperidino-alkyl cinnamates. Since these compounds possessed local anesthetic action, some of them to a marked degree, it seemed desirable to prepare for pharmacological study a series of hydroquinolino-alkyl benzoates in which the nitrogen, instead of being a member of a piperidine ring, is incorporated in a bicyclic structure such as that present in certain of the reduced forms of quinoline and isoquinoline. It seemed of par-

ticular interest to ascertain whether or not there would be any marked pharmacological difference in the anesthetics derived from the stereoisomeric decahydroquinolines. Also an anesthetic derived from tetrahydroisoquinoline would possess a phenylene-dialkylamino structure and would be an interesting type to compare with those anesthetics containing phenyl alkyl groups which have been previously reported[2] as being unusually potent pharmacologically.

This paper describes the preparation, properties and pharmacological action of the hydrochlorides of the following amino esters: (1) β-tetrahydroquinolino-ethyl benzoate, (2) γ-tetrahydroquinolinopropyl benzoate, (3) *trans*-β-decahydroquinolino-ethyl benzoate, (4) *trans*-γ-decahydroquinolinopropyl benzoate, (5) *cis*-β-decahydroquinolino-ethyl benzoate, (6) cis-y-decahydroquinolinopropyl benzoate, (7) γ-tetrahydroisoquinolinopropyl benzoate. These compounds were prepared by the condensation of the corresponding secondary amines with (3-chloro-ethyl benzoate and γ-chloropropyl benzoate.

Tetrahydroquinoline was prepared by the catalytic reduction of quinoline. The cis and trans isomers of decahydroquinoline were prepared by the complete catalytic reduction of quinoline; the reduced material obtained in this manner was separated into the pure isomeric forms by a modification of the method of Hiickel and Stepf.[3] The literature contains numerous references to the trans isomer (m. p. 48°)[4] but the existence of the cis isomer, which is a liquid at ordinary temperatures, had not been demonstrated previous to the work of Hiickel and Stepf.

Tetrahydroisoquinoline was prepared by the method of Pictet and Spengler,[5] which involves the condensation of methylal and β-phenylethylamine in concentrated hydrochloric acid solution. The tetrahydroisoquinoline so obtained was not entirely pure, and it was observed that the strength of the hydrochloric acid used in the condensation plays an important part in determining the course of the reaction. In dilute acid solution methyl-(3-phenylethylamine, instead of tetrahydroisoquinoline, is formed.

Experimental

Tetrahydroquinoline.—This compound was prepared by the catalytic reduction of quinoline, using a nickel catalyst at a temperature of 150° and at pressures of 150–170 atmospheres of hydrogen.6 The boiling point of the product was 122–124° (10 mm.)

[6] The reduction of quinoline was carried out by Mr. Howard Cramer under the direction of Professor Homer Adkins and will be described in detail by them in a forthcoming paper.

***Trans*- and *Cis*-decahydroquinoline.**—Quinoline was completely reduced catalytically, using a nickel catalyst at a temperature of 200° and at pressures of 150–200 atmospheres of hydrogen. The relative proportions of cis and trans isomers varied in different runs. By chilling with ice–salt mixture the trans isomer crystallized and, after filtering with suction and pressing on a clay plate to remove adhering liquid, it melted at 48°.[4] The hydrochloride melted at 278–279°; Hiickel and Stepf report 275' as the melting point of this compound.

The crude cis-demhydroquinoline remaining after removal of the *trans* isomer was converted to the benzoyl derivative by treatment with benzoyl chloride and dilute alkali. Hiickel and Stepf[3] recommended partial purification of the hydrochloride before preparation of the benzoyl derivative, but it was found that better yields were obtained by making the benzoyl derivative directly from the crude base. After two recrystallizations from ligroin (b. p. 90–150°) the material was pure, melting at 969 From 97 g. of crude base there was obtained 45.3 g. of the pure benzoyl-*cis*-decahydroquinoline.

Continued refluxing with 15% sodium hydroxide solution did not hydrolyze benzoyl-cis-decahydroquinoline, but it was found that by refluxing with 20% hydrochloric acid, hydrolysis was complete after sixty to seventy hours. At the end of this time the solution was cooled, after which benzoic acid was filtered off and the filtrate was evaporated on a steam-bath. The free base was liberated with 10% sodium hydroxide and extracted with ether. After drying the ethereal solution with sodium sulfate, the ether was evaporated and the amine was distilled under diminished pressure. By such treatment of 45 g. of benzoyl-*cis*-decahydroquinoline there was obtained 21.9 g. (85% of the theoretical) of cis-decahydroquinoline which boiled at 83–83.5° (16 mm.). The hydrochloride was prepared and found to melt at 222–224°; Hiickel and Stepf reported 226° as the melting point of this compound.

Tetrahydroisoquinoline.—This compound was prepared by a modification of the method of Pictet and Spengler.[5] To a solution of 20 g. of β-phenylethylamine (b. p. 85–88° at 14 mm.) in 120 cc. of concentrated hydrochloric acid, 20 g. of methylal (b. p 41–45°) was slowly added through a separatory funnel. During the addition the reaction mixture was warmed on a steam-bath. Heating was continued for five hours, after which the solution was evaporated to dryness. The residue was dissolved in 90 cc. of water; to this solution, cooled to 7°, was added a solution of 23 g. of sodium nitrite in 40 cc. of water. The mixture was warmed and extracted with ether. After evaporation of the ether, the nitrosamine was reduced with 33 g. of zinc and 90 cc. of concentrated hydrochloric acid. The mixture was made alkaline with 60 g. of sodium hydroxide and steam distilled until all of the oily layer had passed over. The distillate was acidified and evaporated to dryness; the residue was made alkaline, and the free base was extracted with ether. After drying with sodium sulfate and evaporating the ether, the amine was distilled. The yields were 2.2–3 g. (10–14% of the theoretical) of material boiling at 220–233°. The picrate after two recrystallizations from alcohol melted at 199–200°; Helfer[7] reported 197–198° as the melting point of tetrahydroisoquinoline picrate. The hydrochloride after five recrystallizations from alcohol–ether melted at 194–195"; Helfer[7] reported 195–196°.

In an attempt to improve the yield of tetrahydroisoquinoline a run was made using 120 cc. of dilute hydrochloric acid containing only slightly more hydrogen chloride than the amount required to dissolve the β-phenylethylamine. The time of heating was seventeen hours; the rest of the procedure was that described above; 3 g. (14%) of material boiling at 88–95' (16 mm.) was obtained. This was shown to be methyl-β-

---

[7] Helfer, *Helv. Chim. Acta*, 6, 794 (1923).

phenylethylamine.[8] The picrate was prepared and found to melt at 140–141°;[9] a mixed melting point with an authentic specimen of methyl-β-phenylethylamine picrate showed no depression.

Hydroquinolino-alkyl Benzoates.—These compounds were prepared by the general procedure of heating two moles of the secondary amine with one mole of β-chloro-ethyl benzoate or γ-chloropropyl benzoate. In the case of the decahydroquinolines a temperature of 140–150° for two to three hours was sufficient to cause a satisfactory reaction; in the case of tetrahydroquinoline and tetrahydroisoquinoline a somewhat higher temperature (190–200°) for the same period of time was required. The tertiary amino esters were isolated as the hydrochlorides by the procedure commonly employed for compounds of this type.[1] These hydrochlorides are summarized in Table I.

In the case of *trans*-β-decahydroquinolino-ethyl benzoate hydrochloride two apparently isomeric substances appeared to be formed. One of them was obtained pure, while the other could not be caused to attain a constant melting point. Theoretical chlorine analyses for samples melting over a wide temperature range was the evidence upon which the formation of isomers was based.

TABLE I

HYDROQUINOLINO-ALKYL BENZOATE HYDROCHLORIDES

	Hydroquinolino-alkyl group	M. p., °C.	Analyses, Cl, % Calcd.	Found
1	β-Tetrahydroquinolino-ethyl[a]	129–131	11.18	11.18
2	γ-Tetrahydroquinolinopropyl[a]	122–124	10.71	11.04
3	*Trans*-β-decahydroquinolino-ethyl[b]	155–157	10.97	10.87
4	*Trans*-γ-decahydroquinolinopropyl	171–173	10.52	10.51
5	*Cis*-β-decahydroquinolino-ethyl[b]	159–160	10.97	10.82
6	*Cis*-γ-decahydroquinolinopropyl	155–156.5	10.52	10.38
7	γ-Tetrahydroisoquinolinopropyl[c]	188–189	10.71	10.64

[a] These hydrochlorides are sufficiently hydrolyzed in aqueous solution to cause oily globules of free base to appear. [b] A mixed melting point on Nos. 3 and 5 was 135–141°. [c] The corresponding propyl benzoate derived from methyl-β-phenylethylamine melts at 128°; this compound has been prepared by Mr. A. C. Cope in this Laboratory and will be described in a future communication.

Pharmacological Report.—These compounds are being studied pharmacologically by Mr. Charles L. Rose of The Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana. Table II contains a brief summary of this work. Each compound is designated by the number which is associated with it in Table I. Anesthetic efficiencies were determined by application of a 2% solution of the hydrochloride to the rabbit's cornea and noting the duration of anesthesia and also by the method of infiltration anesthesia, which involves the intracutaneous injection of a 1% solution of the hydrochloride into the guinea pig. Subcutaneous toxicity to white mice and intravenous toxicity to white rats were determined; these values are reported in terms of the median lethal dose (M. L. D.), which is that amount of material necessary to cause the death

of 50% of a large number of animals.[10] The values for cocaine and procaine are included in Table II for comparison.

β-Tetrahydroquinolino-ethyl benzoate (1) and γ-tetrahydroquinolinopropyl benzoate (2) were hydrolyzed to such an extent that a solution could not he prepared for pharmacological tests. Hence there are no data for these compounds in Table II.

TABLE II

PHARMACOLOGICAL DATA

Compound	Av. duration of anesthesia, min. Rabbit's cornea	Infiltration	Subcutaneous toxicity to white mice mg./kg. M. L. D.	No of mice used	Intravenous toxicity to white rats mg./kg. M. L. D.	No. of rats used
3	5	36	1000	25	25	7
4	27	81	500	40	20	24
5	21	55	700	36	30	14
6	30	60	500	25	20	15
7	7	187	1600	31	40	10
Cocaine	29	..	150	..	17.5	..
Procaine	0	..	800	..	53	..

Discussion of the Pharmacological Data.—The decahydroquinolinoalkyl benzoates are in general more satisfactory anesthetics than cocaine, since the anesthetic efficiencies of three of them are equal, or nearly equal, to that of cocaine, while the toxicities are considerably less than that of cocaine. Compounds 4 and 6, which are geometric isomers, have quite similar properties. However, 3 and 5, which are also geometric isomers, differ from each other considerably—5, the cis compound, being more active than 3, its *trans* isomer, both as regards anesthetic action and toxicity.

γ-Tetrahydroisoquinolinopropyl benzoate[7] has quite a low toxicity combined with high anesthetic efficiency when measured by the infiltration method. However, when measured by the corneal method, the anesthetic efficiency is quite low. The compound contains a phenylene-dialkylamino structure, and would therefore be expected to be a rather powerful anesthetic on account of its structural relationship to those anesthetics containing phenyl alkyl groups.[2] It is reported as being highly irritating to the rabbit's cornea, and it is quite probable that it is this property rather than its structure, which causes the low corneal anesthesia value.

Summary

1. A series of hydroquinolino-alkyl benzoates has been prepared and described.
2. A discussion of the pharmacological properties of these compounds is given.

DI-IODOTHYMOL AND THE DECOMPOSITION OF ITS SALTS[1]

BY G. H. WOOLLETT AND CARL H. EVERETT

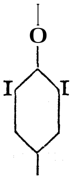
RECEIVED JUNE 25, 1930 PUBLISHED OCTOBER 6, 1930

Colored products obtained by the action of iodine and alkali upon phenols have been described by various investigators.[2] The deep red product formed from common phenol[2d] has been shown to consist largely of material having a high apparent molecular weight and quinonoid characteristics. Its formation from phenol takes place according to the equations

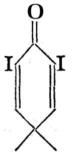
$$C_6H_5OH + 4NaOH + 3I_2 = C_6H_2I_3ONa + 3NaI + 4H_2O \qquad (I)$$

$$n\,C_6H_2I_3ONa + I_2 = (C_6H_2I_2O)_n + n NaI + I_2 \qquad (II)$$

During the action represented by Equation II, divalent radicals such as



or



or the ortho isomers are probably formed, the final product being made by their polymerization. Substances of this type are amorphous, soluble in carbon disulfide or bromoform, and insoluble in alcohol, water and ligroin, lose their color on reduction and regain it upon re-oxidation. They will be referred to here as chromo-resinoids.

Probably the best known of these substances is the one obtained from thymol, as it is, in an unpurified state, used as the pharmaceutical now called thymol iodide. The similarity in preparation and properties strongly suggest for the thymol chromo-resinoid a genesis similar to that of its phenol analog. This would require the formation and subsequent decomposition of di-iodothymol. Previous work[3] also pointed in this direction. As no description of a di-iodothymol could be found in the literature, an attempt was made to prepare it.

Willgerodt and Kornblum[4] and later Rasik Lal Datta and Nogendra Prosad[5] have iodinated phenols in ammoniacal solution, the former using alcohol as a solvent and the latter the alkali salts of the phenols.

It was found possible to introduce a second iodine atom into *p*-iodothymol by a modification of these methods using no solvent other than the

---

[1] A portion of this work formed part of a thesis presented to the Faculty of the Graduate School of the University of Mississippi by Carl H. Everett in partial fulfilment of the requirements for the degree of Master of Science.

[4] Willgerodt and Kornblum, *J. prakt.* Chem., [2] 39,290 (1889).

[5] Rasik Lal Datta and Nogendra Prosad, THIS JOURNAL, 39,441 (1917).

ammonia solution. The di-iodothymol made thus is a straw-colored liquid which did not solidify at −17°. It forms a crystalline benzoate (m. p. 112°). The second iodine atom is presumably ortho to the hydroxyl. Because of the repeated reports of dimolecular structures for iodothymol derivatives, the molecular weight of the benzoate was taken and found to be normal.

Di-iodothymol decomposes spontaneously, giving the expected red resinoid when treated with sodium hydroxide solution. The decomposition appears to start at the surface of undissolved droplets of the phenol and once initiated goes a great way toward completion. As alcohol, acetone, sulfites or other substances which react easily with iodine prevent the decomposition, and as free iodine in catalytic quantity will cause decomposition in undecomposed alkaline solutions, the spontaneous decomposition is believed to be due to traces of free iodine in the di-iodothymol.

Potassium ferricyanide also will cause the formation of a chromo-resinoid apparently identical with the above. The action in this case is not catalytic but requires molecular quantities of ferricyanide and will take place in the presence of considerable antagonistic material such as sulfites.

As might be expected from its method of preparation, U. S. P. thymol iodide contains a demonstrable amount of di-iodothymol, as shown by the action of potassium ferricyanide on alcoholic extracts from it.

While tri-iodophenol seldom decomposes on mere contact with alkali, its behavior otherwise is remarkably like that of di-iodothymol.

Experimental

Preparation of *p*-Iodothymol.—Eight hundred cc. of 0.25 molecular sodium thymolate and 0.25 molecular I_2–KI solution were run slowly and at approximately equal rates into a 12-cm. funnel filled with cracked ice. The funnel discharged into a 3-liter beaker containing cracked ice and 500 cc. of water, mechanically stirred.

When about one-tenth of the reactants had been added, the product was seeded with iodothymol and addition was interrupted until crystallization started. Excess of iodine present at the end was removed by sodium bisulfite.

The white crystalline p-iodothymol (51.5g.) was filtered off and purified by dissolving twice in alkali, treating with norit, and precipitating by dilute sulfuric acid; then by twice dissolving in alcohol, treating with norit, filtering and precipitating by water; and finally by two crystallizations from heptane (m. p. 69°). Willgerodt[4] gives the melting point as 69°.

Preparation of Di-iodothymol.—One gram of pure p-iodothymol was dissolved in 800 cc. of concd. ammonia. To this was added rapidly and with shaking 20 cc. of 0.2 *M* iodine–potassium iodide solution. After one minute 1 cc. of 20% sodium bisulfite was added and the mixture was poured into a previously prepared bottle containing 500 cc. of ice water and 150 cc. of ether. The di-iodothymol was extracted twice and the ether allowed to evaporate spontaneously. Steam was passed through the remaining yellowish oil to remove iodothymol. The non-volatile residue was taken up in a small amount of acetone and then added to 200 cc. of water containing 5 cc. of 4 *N* sodium hydroxide, boiled to remove acetone, cooled, 1 g. of norit added and filtered. The filtrate contained nearly pure di-iodothymol, which was precipitated by dilute sulfuric acid, extracted with ether and dried over sodium sulfate. After evaporation of the ether, a light yellow oil was left which failed to solidify after several days at −17°; average yield, 0.63 g. or 43%.

Anal. (Carius). Calcd. for $C_{10}H_{12}I_2O$: I, 63.17. Found: I, 62.92, 62.85. 62.92.

Preparation of Di-iodothymol Benzoate.—A solution of 2 g. of di-iodothymol was made as above. cooled and shaken with 20 cc. of benzoyl chloride and 70 cc. of 4 *N* alkali. The insoluble material was washed with alkali and water, dried and crystallized three times from alcohol and four times from heptane. The last two crystallizations gave colorless crystals of constant melting point (112").

Anal. (Carius). Calcd. for $C_{17}H_{16}I_2O_2$: I, 50.18. Found: I, 50.03, 49.97. *Mol. wt.* (cryoscopically in benzene). Calcd. for $C_{17}H_{16}I_2O_2$: 506.05. Found: 429,447.

Decomposition by Alkali.—Samples I to IV of di-iodothymol were stirred up with sodium hydroxide solution. They turned red and became semi-solid. Water was then added, and the precipitates were filtered off, washed. dried and extracted with alcohol to remove undecomposed di-iodothymol. The chromo-resinoid, alcoholic extract and silver iodide precipitated from the filtrate with silver nitrate were all weighed. The chromo-resinoid was analyzed for iodine.

Di-iodothymol from U. S. P. Thymol Iodide.—A sample was extracted with methanol. Water and a little sodium bisulfite were added to the alcoholic extract and steam was passed through to remove methanol, thymol and iodothymol. The residue was dissolved in 5 cc. of acetone and dilute sodium hydroxide added. The acetone was removed by boiling, the alkaline solution treated with norit and filtered. A solution containing 2 g. of potassium ferricyanide was added to the cold filtrate and the typical red resinoid was filtered off, dried and weighed: sample, 4.372 g.; chromo-resinoid 0.113 g., corresponding to 3.7% di-iodothymol.

Anal. (Carius). Calcd. for $(C_{10}H_{11}IO)_n$: I, 46.32. Found: 1, 44.75.

Summary

Di-iodothymol and its benzoate have been prepared.

Di-iodothymol salts have been shown to be precursors of the chromo-resinoid formed when iodine acts on alkaline solutions of thymol according to the equation $nC_{10}H_{11}I_2ONa = (C_{10}H_{11}IO)_n + n\ NaI$.

Di-iodothymol has been shown to be present in U. S. P. thymol iodide.

THE POLYMERIZATION OF ASYMMETRICAL DIPHENYLETHYLENE. THE PREPARATION OF 1,1,3-TRIPHENYL-3-METHYLHYDRINDENE

BY C. S. SCHOEPFLE AND J. D. RYAN[1]

RECEIVED JUNE 30, 1930 PUBLISHED OCTOBER 6, 1930

Bergrnann and Weiss, in a paper recently published,[2] have shown that the saturated dimer of asymmetrical diphenylethylene is 1,1,3-triphenyl-3-methylhydrindene and not tetraphenylcyclobutane, as previously supposed, and have stressed the importance of this fact in connection with the views of Staudinger and others on the mechanism of polymerization and the structure of high molecular weight compounds. In a study of the properties of this saturated dimer in this Laboratory, its identity has been established, independently, from its oxidation products. Our investigation, which is still in progress, is concerned chiefly with the mechanism of the reaction by which triphenylmethylhydrindene and other indenes are formed, but the work has paralleled that of Bergmann and Weiss in many respects and therefore it is considered advisable to publish the results which have been obtained at this time.

Polymerization of asymmetrical diphenylethylene (I) by the use of catalysts yields two dimeric compounds, one unsaturated (III) and the other saturated (XII). The unsaturated dimer, m. p. 113°, was prepared first by Hildebrand[3] and shown by Lebedev[4] to be 1,1,3,3-tetraphenyl-1-butene,

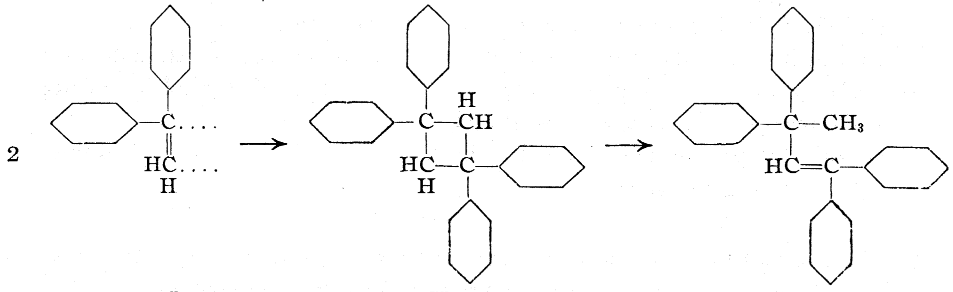
which structure was confirmed by Schlenk and Bergmann.[5] The formation of this compound may be explained by assuming that two molecules of asymmetrical diphenylethylene combine under the influence of catalysts such as sulfuric acid, iodine, stannic chloride, etc., to give 1,1,3,3-tetraphenylcyclobutane (11), which being unstable rearranges to 1,1,3,3-tetraphenyl-1-butene (III). The intermediate product cannot be 1,1,4,4-tetraphenylcyclobutane, since it appears from the work of Schlenk and Bergmann[6] that this compound, prepared by the action of mercury on 1,4-disodium-1,1,4,4-tetraphenylbutane, reverts to diphenylethylene.



I II III

The saturated dimer, m. p. 143°, was prepared first by Lebedev,[4] who obtained a mixture of the two isomers by treating diphenylethylene with concentrated sulfuric acid or with fuller's earth. He concluded that this compound was tetraphenylcyclobutane, since it did not add bromine nor react with ozone, and gave only benzophenone on oxidation. The compound is very stable toward oxidation and Bergmann and Weiss state that long treatment with a considerable excess of chromic acid in acetic acid oxidized only a part of the material and that this part was completely destroyed. By regulating the conditions of the oxidation, however, it is possible to control the reaction so that over a 40% yield of the crude oxidation product is obtained. This product contains a large number of acids and ketones of which about ten have been isolated in pure form. Only two of these were readily identified, namely, benzoic acid and o-dibenzoylbenzene. In addition, benzophenone was isolated as the oxime in small amounts, substantiating the observation of Lebedev. The two latter oxidation products were sufficient to establish the identity of the hydrocarbon, since of the various structures which might be assigned to a dimer of diphenylethylene, only one, namely, 1,1,3-triphenyl-3-methylhydrindene could give both *o*-dibenzoylbenzene and benzophenone on oxidation and could readily be formed by the rearrangement of 1,1,3,3-tetraphenyl-1-butene, which rearrangement had been effected by Lebedev[4]

with fuller's earth at high temperature and with stannic chloride plus hydrochloric acid at room temperature in our work. A synthesis of this hydrindene was in progress at the time when Bergmann and Weiss[2] reported their excellent synthesis, which removed any possible doubt concerning its structure.

1,1,3-Triphenyl-3-methylhydrindene can be readily prepared in practically quantitative yield by adding anhydrous stannic chloride to a benzene solution of methyldiphenylchloromethane, obtained by the action of dry hydrogen chloride on the corresponding carbinol, and allowing the mixture to stand at room temperature for one week. The reaction is apparently a general one and has been extended to several other carbinol chlorides. For example, dimethylphenylchloromethane gave the dimer, m. p. 52.5°, first described by Grignard,[7] and dimethyl-*p*-tolylchloromethane and dimethyl-a-naphthylchloromethane gave compounds melting at 122 and 199°, respectively.[8] The structures of these compounds remain to be proved. Zinc chloride, ferric chloride, antimony pentachloride and aluminum chloride have been used in the reaction in place of stannic chloride, and it is probable that other agents such as boron trichloride and titanium tetrachloride will also be effective.

Inasmuch as tetraphenylbutene can be rearranged to the hydrindene by concentrated sulfuric acid at room temperature, it seems probable that the former is an intermediate step in the preparation of the latter compound from diphenylethylene. As suggested by Bergmann and Weiss, the rearrangement of the unsaturated dimer would consist in the addition of the sulfuric acid to the double bond and the subsequent removal of the acid to form the stable five-membered ring. The unsaturated dimer may also be rearranged by means of stannic chloride, provided hydrogen chloride is present. A benzene solution of this compound in the presence of stannic chloride showed no appreciable rearrangement after one week at room temperature, but when the solution was partially saturated with hydrogen chloride, the rearrangement to the saturated dimer was practically complete in the same period of time. Again, diphenylethylene in benzene solution under the influence of stannic chloride polymerized almost exclusively to the unsaturated dimer, while in the presence of hydrogen chloride the saturated isomer was formed. These results apparently favor the theory that an intermediate compound is formed by the addition of hydrogen chloride to the unsaturated dimer, which compound then reacts to give the hydrindene, but there is some evidence which points to a different mechanism of reaction when stannic chloride is used.

If the preparation of 1,1,3-triphenyl-3-methylhydrindene from methyl-

[8] These compounds were prepared by R. F. Ruthruff.

diphenylchloromethane is compared with the preparation of fluorenes from triarylmethyl halides, it is found that the two reactions have much in common. In each case the product is an indene derivative, and in each case the same reagents may be used to bring about the reaction, namely, stannic chloride, aluminum chloride, zinc chloride, etc. These reagents incidentally give definite colored addition products with the triarylmethyl halides which have been shown to be quinonoid in character.[9] The ease with which fluorenes are formed from triarylmethyl halides varies greatly with different individuals. Triphenylmethyl chloride and bromide give phenylfluorene (VIII) only upon heating above 200°.[10] Phenyl-α-naphthofluorene, however, may be prepared by refluxing an acetic acid solution of α-naphthyldiphenylcarbinol in the presence of a small amount of hydrochloric acid, sulfuric acid, zinc chloride, etc.;[11] the solution first acquires a dark green color which rapidly disappears, indicating that the intermediate product is a quinonoid chloride, sulfate, etc. Di-α-naphthylphenylmethyl chloride or bromide is still more reactive. These halides give addition products of a deep purple color with stannic, aluminum, ferric, zinc and mercuric chlorides, which are unstable and decompose within a short time at room temperature with the formation of di-α-naphthofluorene.[12]

The reaction, for example, in the case of triphenylchloromethane, probably takes place by splitting off the chlorine atom and a hydrogen atom

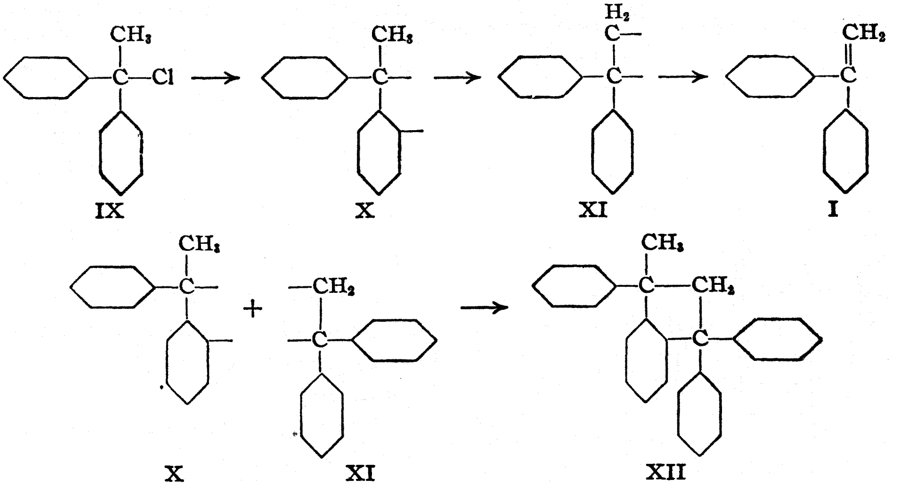
[12] Schoepfle, THIS JOURNAL, 44, 188 (1922).

from an ortho position in the ring to give an unstable intermediate product (VII) which rearranges to the stable fluorene (VIII). Since the reagents or the conditions used in the reaction result in quinoidation of the triarylmethyl halide, the formation of the intermediate compound (VII) may be postulated as being due to splitting off hydrogen chloride from the ortho quinonoid compound, (V), to give the quinonoid residue (VI), which would, of course, rearrange to the benzenoid configuration (VII). In general, the triarylmethyl halides assume the para-quinonoid form but some of the ortho-quinonoid form may also be present, and, indeed, certain compounds would be expected to assume the ortho-quinonoid form more readily than others, which might account for the greater ease with which naphthyl derivatives react in comparison with phenyl derivatives.

In the case of methyldiphenylchloromethane (IX), hydrogen chloride may be split off in accordance with the mechanism proposed above to give



the intermediate product (X), which then tends to rearrange not to methylfluorene but to asymmetrical diphenylethylene, a rearrangement which is not possible in the case of the triarylmethyl derivatives. Actually, however, the rearrangement does not proceed thus far, due to the coupling of the two intermediate products (X) and (XI) to give the stable triphenylmethylhydrindene.

Methyldiphenylcarbinol and concentrated sulfuric acid give a red color which is also characteristic of the addition compounds of methyldiphenylchloromethane with stannic chloride, aluminum chloride, ferric chloride, etc. In the polymerization of diphenylethylene to the hydrindene in the presence of stannic chloride and hydrochloric acid, and in the rearrangement of the unsaturated dimer under these conditions, the same red color always appears. In the absence of hydrochloric acid, the ethylene and the unsaturated dimer give a light green color instead of the red color and in each case practically no hydrindene is obtained. In other words, it seems that the preparation of the hydrindene may be dependent on the formation of methyldiphenylchloromethane as the intermediate product. The formation of this compound is readily explainable with the ethylene which may add hydrochloric acid under the influence of the stannic chloride, and is also plausible in the case of the unsaturated dimer, which evidently dissociates readily to the ethylene, since Hildebrand[8] found that bromine and nitric acid in boiling acetic acid react with the unsaturated dimer to give dibromodiphenylethylene and diphenylvinyl nitrite, respectively, while Lebedev[4] found that with excess of ozone at 0°, diphenylethylene ozonide was obtained from the dimer. Moreover, it was observed that the unsaturated dimer in benzene solution and in the presence of stannic chloride depolymerized to an appreciable extent at room temperature.

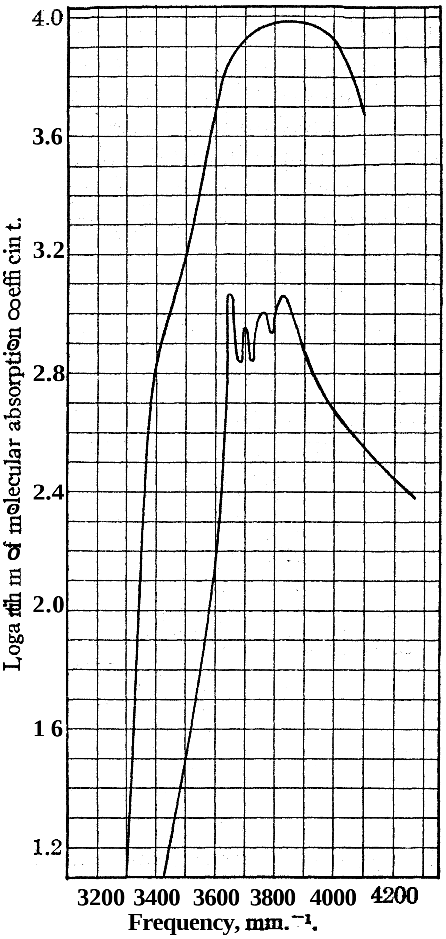


Fig. 1.—Upper curve, 1,1,3,3-tetraphenyl-1-butene; lower curve, 1,1,3-triphenyl-3-methylhydrindene.

An attempt was made to establish the identity of the red intermediate compound formed in the various reactions by means of absorption spectra in the visible region, using a Nutting photometer and a Hilger wave length spectrometer. The following solutions were investigated: (1) methyldiphenylcarbinol in concentrated sulfuric acid, (2) methyldiphenylchloromethane and stannic chloride in benzene, (3) diphenylethylene, stannic chloride and hydrochloric acid in benzene, and (4) tetraphenylbutene, stannic chloride and hydrochloric acid in benzene. All showed a rapid increase in absorption in the violet region and gave an indication of a band with its peak near the edge of the visible part of the spectrum. The location of this peak could not be definitely determined, due to the limitations of the apparatus at wave lengths below 4500 Å. Spectrographic measurements of the absorption spectra of these solutions are to be undertaken in order to obtain this information.

In many of our preliminary experiments mixtures of the unsaturated and saturated dimexs of diphenylethylene were obtained and it was desirable to determine the amount of each isomer present, but the separation by means of fractional crystallization was tedious and unsatisfactory. The mixtures did not melt sharply and did not crystallize readily on cooling, so that the melting point and solidification point were of no value for this purpose. The index of refraction of a concentrated solution of the material could not be used, due to the fact that the indices of refraction of the pure isomers were too nearly alike. The absorption curves of the two dimers are quite different though, as will be seen from Fig. 1, and therefore the composition of a mixture could be quite accurately determined from the molecular absorption coefficient at frequencies between 3425 and 3600. The absorption curves should also prove of value in establishing the structure of other indene derivatives which are not readily synthesized.

The measurements of the absorption spectra were made with a Judd-Lewis sector photometer and a Hilger quartz spectrograph, size C, by Dr. L. C. Anderson of this Laboratory, for whose assistance we wish to express our appreciation.

Experimental

Methyldiphenylchloromethane.—This compound was prepared by treating a benzene solution of the carbinol with dry hydrochloric acid gas at a temperature below 10° in the presence of anhydrous calcium chloride to remove the water formed in the reaction. Attempts to isolate the chloride by concentrating the solution gave a colorless oil which could not be crystallized, although an analysis for chlorine showed that no appreciable decomposition had taken place. A sample of the chloride was prepared in low-boiling petroleum ether, the solvent removed under reduced pressure at 0° and a stream of dry air passed through the residual oil to remove traces of hydrochloric acid. On analysis, 16.0% of chlorine was obtained, the calculated value being 16.4%. At room temperature the chloride decomposes slowly to give the ethylene and hydrochloric acid, a small amount of the unsaturated dimer of diphenylethylene being formed.[13]

1,1,3-Triphenyl-3-methylhydrindene.—Twenty-five grams of methyldiphenylcarbinol was dissolved in 250 cc. of benzene and converted into the chloride as described above. Ten grams of anhydrous stannic chloride was then added and the solution maintained below 10° for several hours, after which it was allowed to stand at room temperature. Upon the addition of the stannic chloride, the solution acquired a deep red color which gradually faded to a light brown. After one week it was washed thoroughly with water, dried and concentrated, and the residue dissolved in absolute alcohol. from which the triphenylmethylhydrindene was obtained in colorless crystals melting at 143'; yield, 95–97%. If the reaction is stopped after one day at room temperature. the yield is about 80%. An attempt to accelerate the reaction by heating on the steam-bath gave a decreased yield due to the formation of diphenylethylene and the unsaturated dimer.

[13] Blicke and Powers, THIS JOURNAL, 51,3383 (1929).

Saturated Dimer of α-Methylstyrene.—This compound was prepared from dimethylphenylcarbinol by the method described above. The oily product from the concentration of the solution was rubbed with a small amount of alcohol, whereby a solid separated which was filtered and recrystallized. An additional amount of the product was obtained by distilling the oily residue and crystallizing the fraction which boiled at 128–135° at 3 mm. from alcohol. The combined yield of the dimer was 88% and the melting point 52°. The same compound is obtained if the stannic chloride used in the reaction is replaced by ferric chloride, aluminum chloride, antimony pentachloride or zinc chloride; stannic chloride and antimonic chloride have the advantage over the other reagents in that they are soluble in benzene. Staudinger and Breusch[14] have previously prepared this compound in 72% yield by the action of stannic chloride on α-methylstyrene.

Oxidation of 1,1,3-Triphenyl-3-methylhydrindene.—Five grams of the hydrocarbon was dissolved in 100 cc. of glacial acetic acid and 25 g. of chromic acid was cautiously added. The reaction was allowed to proceed rapidly with just enough cooling to prevent it from becoming violent, and was usually complete in about half an hour. After one hour the solution was poured into water, cooled to 0° with ice and partially neutralized by adding a solution of 50 g. of sodium hydroxide, which seemed to change the character of the precipitate so that it was easier to filter. The product was washed with water on the filter and air dried. No further material could be recovered from the filtrate by extraction with ether.

The crude oxidation products obtained from a number of runs were combined and extracted with hot water. From the water solution a small amount of oil was obtained by extraction with ether and evaporation of the solvent. Crystallization of the oil from alcohol gave a mixture of colorless, thin plates which after recrystallization melted at 95°, and colorless serrated tables which melted at 146°. A small amount of benzoic acid was obtained by sublimation of that portion of oil which failed to crystallize.

The residual oxidation product was then treated under rapid stirring with warm 25% sodium hydroxide solution and the mixture allowed to settle. The supernatant liquid was decanted or siphoned off and the operation repeated twice to insure removal of all of the alkali-soluble material. The product which was insoluble in alkali was steam distilled and the distillate extracted with ether. A small amount of oil was obtained from the ether solution which upon crystallization from alcohol gave the 146° compound along with long thin colorless needles which melted after recrystallization at 279°. The portion of oil which did not crystallize was treated with hydroxylamine hydrochloride and deposited benzophenone-oxime, which was identified by a mixed melting point. Extraction with ether of the non-volatile residue from the steam distillation, evaporation of the solvent and crystallization of the product from alcohol gave an additional quantity of the 146° compound.

The material soluble in 25% sodium hydroxide solution was precipitated with dilute hydrochloric acid, and the precipitate washed with water and air dried. The yield of this product was 40% of the weight of hydrocarbon oxidized. The material was stirred with a slight excess of dilute sodium hydroxide solution in which about 20% remained insoluble. This was filtered, washed with water, air dried and dissolved in alcohol. Two compounds were recovered from the solution, the 146° compound and large colorless needles which after recrystallization melted at 120°. The solution obtained by redissolving the oxidation product in dilute sodium hydroxide solution was treated with ether and the extracted material crystallized from alcohol. More of the 120° compound was obtained and also a small amount of small colorless needles which melted at 295° after recrystallization. The alkaline solution was then precipitated with dilute hydro-

---

[14] Staudinger and Breusch, Ber., 62, 450 (1929).

chloric acid and the precipitate dissolved in alcohol. The solution deposited a considerable amount of colorless prisms melting at 225°. Since most of this product failed to crystallize, it was dissolved in excess of ammonium hydroxide, the solution diluted several times and then concentrated to its original volume on the hot-plate, when part of the material separated as an oil. The fraction which remained in solution was precipitated with dilute hydrochloric acid and the precipitate dissolved in ethyl alcohol, from which colorless needles were obtained which melted at 245° after recrystallization. The fraction which was precipitated was also dissolved in alcohol and gave very fine colorless needles which after recrystallization melted at 285°. The portion which did not crystallize was then dissolved in ether and extracted with 0.25 *N* ammonium hydroxide solution, The extracted material was precipitated from the ammoniacal solution by dilute hydrochloric acid and dissolved in alcohol from which a considerable quantity of colorless rhombohedral prisms melting at 190° was deposited. From the ether solution. more of the 285° compound was obtained.

The compounds melting at 95 and 295°, respectively, were not obtained in sufficient quantities for macro analysis. The analyses of the other compounds and the solubility in hot 5% sodium hydroxide solution and hot 5% ammonium hydroxide solution are given in Table I. It will be seen that in general the oxidation products which were isolated have a complex structure. Only traces of benzoic acid and benzophenone were obtained. The compound melting at 146° was identified as o-dibenzoylbenzene, and gave no depression in melting point when mixed with a sample of this compound prepared by the oxidation of *o*-dibenzylbenzene. The other compounds have not as yet been identified.

[a] The sodium salt is insoluble in concentrated NaOH solution. [b] Dissolves slowly in hot concentrated NaOH solution. [c] This compound may be α-methyl-α,γ,γ-triphenylglutaric acid. [d] The properties of this compound agree with those described for an anhydro derivative of β-benzoyl-α-phenylpropionic acid. Anschütz and Montfort, *Ann.*, 284, 5 (1895); Hann and Lapworth, J. *Chem. Soc.*, 85, 1362 (1904).

Polymerization of Asymmetrical Diphenylethylene.—Ten grams of the ethylene was dissolved in 75 cc. of benzene and treated with 4 g. of anhydrous stannic chloride at room temperature. The solution developed a light green color which faded to a light brown during the course of a day or two. After seven days at room temperature the solution was washed thoroughly with water, dried and concentrated. The product was diolved in alcohol, from which the unsaturated dimer, 1,1,3,3-tetraphenyl-1-butene was obtained in 77% yield, the residue being unchanged ethylene. Heating the reaction mixture on the steam-bath decreased the yield.

A similar reaction was carried out at room temperature using benzene which had been partially saturated with dry hydrochloric acid. The same light green color appeared initially, but after two hours the solution had become dark red, which color persisted for about a day and then faded to a light brown. Crystallization of the product from absolute alcohol gave a 90% yield of the saturated dimer, 1,1,3-triphenyl-3-methylhydrindene.

Rearrangement and Depolymerization of 1,1,3,3-Tetraphenyl-1-butene.—This compound in benzene solution is not rearranged under the influence of stannic chloride but is partially depolymerized. Five grams of the butene in 40 cc. of benzene was treated with 2 g. of stannic chloride, whereupon the solution acquired a light green color which persisted for about a day. After seven days at room temperature the solution was washed with water, dried and concentrated, and the product dissolved in alcohol, from which 80% of the butene was recovered. The residue was distilled in vacuum and gave 0.7 g. of asymmetrical diphenylethylene. No appreciable rearrangement was observed with stannic chloride in boilimg benzene, toluene or xylene, but when 5 g. of the butene was added to 50 cc. of stannic chloride and the solution refluxed for one week, a 90% yield of the saturated isomer was obtained.

The rearrangement is effected readily at room temperature provided hydrochloric acid is present. Five grams of the butene was dissolved in 40 cc. of benzene which was partially saturated with dry hydrochloric acid gas and 2 g. of stannic chloride was added. The solution first became light green and then dark red, the latter color fading after a day to a light brown. The solution was allowed to stand for a week at room temperature and was then washed with water, dried and concentrated. The residue was crystallized from absolute alcohol and gave a 90% yield of the saturated isomer, triphenylmethylhydrindene.

Summary

The saturated dimer of asymmetrical diphenylethylene has been identified as 1,1,3-triphenyl-3-methylhydrindene by means of its oxidation products.

The preparation of triphenylmethylhydrindene from methyldiphenylchloromethane has been described, and the method shown to be of general application.

The influence of stannic chloride on the polymerization of diphenylethylene and on the rearrangement and depolymerization of 1,1,3,3-tetraphenyl-1-butene has been described.

A reaction mechanism has been postulated for the formation of fluorene derivatives from triarylmethyl halides and for the formation of hydrindene derivatives from alkylarylmethyl halides.

STUDIES RELATING TO ORGANIC GERMANIUM DERIVATIVES. IV. DIPHENYL GERMANIUM AND OCTAPHENYL GERMANOPROPAEJE

BY CHARLES A. KRAUS AND CECIL L. BROWN

RECEIVED JULY 1, 1930 PUBLISHED OCTOBER 6, 1930

I. Diphenyl Germanium

It might be expected that diphenyl germanium could be prepared by the reduction of diphenyl germanium dihalides. The reduction of the corresponding tin[1] derivatives is readily effected by means of the alkali metals in liquid ammonia. In the case of germanium, however, a corresponding reduction cannot be accomplished because of the tendency of the dihalides to ammonolyze. However, since diphenyl germanium dichloride is not ammonolyzed in ethylamine, it was thought that reduction might be effected by means of lithium in that solvent. Lithium is used in preference to sodium or potassium since it is readily soluble in ethylamine.

The reduction of diphenyl germanium dichloride in ethylamine proved impractical as will be shown below. Accordingly, the attempt was made to reduce it by means of metallic sodium in xylene. Morgan and Drew[d] have effected the reduction of the triphenyl germanium halide by this means. This method proved successful although the yields obtained were disappointingly low.

Action of Ethylamine upon Diphenyl Germanium Dichloride.—In a preceding article of this series it was shown that diphenyl germanium dichloride is completely ammonolyzed in liquid ammonia.[3] It was thought, however, that the chloride might be dissolved in ethylamine without ammonolysis. Accordingly, a weighed quantity of the dichloride was treated with ethylamine in a weighed reaction tube. On initial addition of the amine, a solid was formed which dissolved readily in an excess of the solvent. A similar result was obtained when ethylamine was passed through a solution of the dichloride in dry benzene. A precipitate was initially formed which dissolved on further addition of amine.

On removing the ethylamine after solution of the dichloride, a definite compound could not be isolated. At 90 to 100°, at low pressures, the dichloride began to distil to the colder parts of the tube, although all the amine had not been removed. The amount of amine left in the reaction product varied with the conditions of the experiment. In one instance 0.94 millimole of the dichloride retained 5.17 millimoles of amine at 20°

---

[3] Kraus and Brown, This Journal, 52,3690 (1930).

and 38 mm. pressure. After pumping for one hour at 20°, 3.0 millimoles were retained and, after pumping for two hours at 100°, 0.43 millimole.

It was not possible to separate the initial solid in pure condition. On evaporating the solution, a liquid remained which retained amine with great tenacity and from which a solid could not be separated. The small quantity of amine retained at 100° indicates that ammonolysis does not take place.

Reduction of Diphenyl Germanium Dichloride in Ethylamine.—Since the dichloride does not ammonolyze in ethylamine, it was thought that it might be reduced to free diphenyl germanium by means of lithium in ethylamine solution. For this purpose, a weighed quantity of the dichloride was dissolved in ethylamine, cooled in a bath of liquid ammonia, and an equivalent quantity of lithium was added. The metal reacted readily with the dichloride, yielding a pale yellow solution. Only an insignificant quantity of hydrogen was evolved, which showed that the dichloride was not appreaably ammonolyzed. The solvent was evaporated and the two-legged tube was exhausted at a temperature of 100°, dry ether was condensed on the reaction product and the soluble materials were separated from the lithium chloride by decanting the supernatant liquid into the second leg of the reaction tube. After removing the ether, the tube was exhausted at 100° and finally at 200°. The product left in the second leg of the tube was a resinous material which could not be crystallized. Crystals of lithium chloride remained in the first leg.

It was hoped that reaction would occur according to the equation

$$(C_6H_5)_2GeCl_2 + 2Li = (C_6H_5)_2Ge + 2LiCl$$

In spite of the high temperature at which the tube was exhausted, the weight of the reaction tube and its contents indicated the presence of ethylamine. In four experiments the amount of ethylamine retained varied from 0.14 to 0.39 mole of amine per mole of dichloride. Analysis of the resinous product obtained in different reactions gave a germanium content varying from 29.2 to 31.2%. The germanium content of diphenyl germanium is 32.03%. It is evident that the product consisted largely of diphenyl germanium contaminated by some ethylamine and probably some other substances. It has since been found that certain of the metallo-organic free groups are capable of forming stable compounds with ethylamine. Thus Eatough[4] has shown that triphenyl silicon forms a compound $(C_6H_5)_3Si\cdot C_2H_5NH_2$. It is not improbable that ethylamine is retained in combination with the diphenyl germanium group and that the crystalline product cannot be obtained for this reason.

Reduction of Diphenyl Germanium Dichloride in Xylene.—Morgan and Drew[2] reduced triphenyl germanium halides by means of sodium in boiling xylene. It was thought that diphenyl germanium dichloride might be reduced according to the same method. The reduction was carried out in a 100-cc. flask with a long neck which was provided with a condenser jacket. An atmosphere of nitrogen was maintained in the flask throughout the process of reduction. The xylene used was digested with metallic sodium for a considerable period of time and was distilled directly into the reduction

---

[4] Eatough, Thesis, Brown University, 1929.

flask under an atmosphere of nitrogen. Three grams of diphenyl germanium dichloride was added to 30 cc. of xylene, followed by thin slices of sodium freshly cut under xylene. The mixture was boiled for six hours and fresh sodium was added from time to time to insure the presence of a fresh metallic surface. As reduction proceeded, the solution took on a red color which gave way to yellow. At the end of the process, only a faint yellow color remained. The solution was rapidly decanted and filtered not and the brown residue left behind in the flask was washed several times with boiling xylene. On cooling the xylene solution, a small quantity of white crystals separated. These were thrown on a filter, while the filtrate was concentrated. Only a small quantity of crystalline material was obtained on further concentration. When the solvent was completely removed, a viscous yellow liquid remained which, on cooling, solidified to a resinous substance that could be chipped and ground to a powder. Attempts to crystallize this material from benzene, chloroform and xylene yielded only minute quantities of solid. The crystalline product amounted to from 10 to 20% of the theoretical yield. This was analyzed for germanium by the usual methods.

Anal. Subs., 0.1098, 0.0693: GeO_2, 0.0507, 0.0319. Calcd. for $(C_6H_5)_2Ge$: Ge, 32.03. Found: Ge, 32.05, 31.95; mean, 32.00,

The molecular weight of the crystalline product was determined in benzene by the boiling point method, using a modified Cottrell apparatus.

Mol. wt. Solvent, 13.18; solute, 0.5476, 0.7590; Δt 0.123, 0.170°; mol. wt. found, 902, 904; mean, 903.

The molecular weight of diphenyl germanium is 226.7. If four molecules of diphenyl germanium were polymerized, the molecular weight would be 907, which value is in close agreement with that found.

Properties of Diphenyl Germanium.—The crystalline material is readily soluble in benzene so long as the original yellow resin is present but, once separated from this resin, it is only slightly soluble in cold benzene, toluene or chloroform. Its solubility in hot solvents is limited and it is insoluble in petroleum ether. On slow crystallization from benzene, fine white crystals were obtained melting at 294–295° (corr.). These crystals undergo no change on exposure to the atmosphere.

The Resinous Reduction Product.—Analyses of the resinous material varied, depending upon the sample. The germanium content was found to range from 29.6 to 30.4% as against 32.03% for pure diphenyl germanium. The molecular weight of the resinous material, as determined in benzene by the cryoscopic method, was found to be 900 and 930 in two determinations, respectively.

The analyses and the molecular weight determinations indicate that the resin is an impure polymer. In many respects it resembles the product of reduction in ethylamine. No crystals could be obtained from this resinous material although numerous solvents were tried under varying conditions.

Disodium Diphenyl Germanide.—Disodium diphenyl germanide is readily prepared by treating diphenyl germanium with an equivalent quantity of sodium in liquid ammonia. For this purpose a reaction tube is used of the type outlined in the accompanying figure. The diphenyl germanium is introduced into the reaction tube A. The top of this tube is provided with a ground joint B which carries a stirring tube C that reaches to the bottom of the reaction tube. The stirring tube is provided with a stopcock D. The neck of the reaction tube is provided with a second stopcock E. The tubes F and G are connected with the system by means of de Khotinsky cement. The system makes connection with a source of pure ammonia, a manometer. a vacuum pump and with an adjustable mercury trap. The reaction tube is provided with a side arm J which carries a tube K, the end of which projects into the side arm and is fitted to J by means of a ground joint L. The sodium which is to be used in reducing the diphenyl germanium is weighed out under Nujol, washed with petroleum ether and introduced into tube K, which is then inserted into the ground joint. The reaction tube is then evacuated.

The reaction tube A is now surrounded by a bath of boiling ammonia and ammonia vapor is introduced through the stopcock D under a pressure about 20 cm. above that of the atmosphere. This pressure is regulated by the height of mercury in the mercury trap. When a sufficient quantity of ammonia has been condensed in the reaction tube, stopcock E is closed and, by turning the tube K about its axis in the ground joint, sodium is introduced into the reaction tube piece by piece.

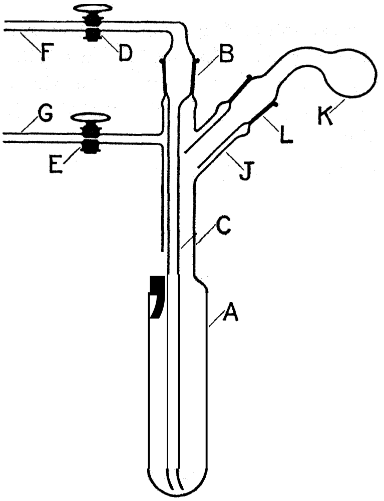

Fig. 1.—Reaction tube.

The sodium goes into a solution and reacts readily with the diphenyl germanium. The blue color, characteristic of the free metal, disappears and a yellow color replaces it. The reaction takes place in two steps, in which respect it resembles the corresponding reaction of dimethyl tin described by Kraus and Greer.[1] On the initial addition of sodium, the solution exhibits a yellow color and, when approximately one-half the equivalent amount of sodium has been added, the diphenyl germanium has been completely dissolved. This stage of the process corresponds to the formation of disodium tetraphenyl germanoethane. On further addition of sodium, the germanium bond is broken and disodium diphenyl germanide is formed. The latter compound is also soluble in liquid ammonia and imparts a deep red color to the solution. At higher concentrations the solutions are almost opaque.

Attempts were made to prepare a diphenyl germane by treating the solution of disodium diphenyl germanide with ammonium bromide. While in certain experiments evidence was found that the dihydride may have been formed initially, the compound could not be isolated. Seemingly, hydrogen is lost and more complex derivatives are formed. The final product was in all cases a viscous liquid.

II. Octaphenyl Germanopropane

Octaphenyl germanopropane could doubtless be prepared by treating disodium diphenyl germanide with triphenyl germanium halide in ammonia or other solvents. However, in view of the difficulty of preparing diphenyl germanium, it seemed preferable to prepare the germanopropane by treating sodium triphenyl germanide with diphenyl germanium dihalide in a suitable solvent. Reaction takes place according to the equation

$$2(C_6H_5)_3GeNa + (C_6H_5)_2GeCl_2 = 2NaCl + (C_6H_5)_8Ge_3$$

Preparation.—Sodium triphenyl germanide was prepared by adding 0.1437 g. (5.876 m. atoms) of sodium to 1.779 g. (2.93 m. moles) of hexaphenyl germano-ethane in liquid ammonia. The ammonia was allowed to evaporate and the tube containing the product was evacuated for twelve hours. The yellow color of the sodium salt gave way to white as the residual ammonia was removed. Dry benzene was then distilled onto the sodium triphenyl germanide, the tube was filled with nitrogen and 0.873 g. (2.93 m. moles) of diphenyl germanium dichloride was added. The reaction mixture was heated with occasional shaking for eight hours. The contents of the tube were then rapidly filtered and most of the solvent was removed by distillation. On cooling. a small crop of crystals appeared. These were separated by filtration and, by their melting point, identified as hexaphenyl germano-ethane. On further concentration of the filtrate, a second crop of crystals was obtained in the form of large flakes. These were removed, washed with cold chloroform and recrystallized from that solvent prior to analysis. On further evaporation of the original solution, a viscous liquid was left behind.

Anal. Subs., **0.1354,** 0.2023: GeO_2, **0.0506, 0.0762.** Calcd. for $Ge_3(C_6H_5)_8$: Ge. **26.11.** Found: Ge, 25.94, 26.14; mean, 26.04.

The molecular weight of the germanopropane was determined in benzene by the boiling point method.

Mol. wt. Solvent, **16.05, 15.67;** solute, **0.7071, 0.9811;** *At,* 0.135°, 0.195°; **mol. wt.** found, **871,875;** mean, **864;** calcd. for $Ge_3(C_6H_5)_8$: 834.

Properties.—Octaphenyl germanopropane is stable toward air and moisture. On rapid crystallization from chloroform, a fine white crystalline powder is obtained, while on slow crystallization plate-like crystals are formed. The compound is readily soluble in warm benzene and chloroform. It melts at 247–248° (corr.).

Action of Bromine on **Octaphenyl Germanopropane.**—As a further check on the structure of the germanopropane and in order to test the resistance of the Ge–Ge bond toward bromine, the compound was treated with bromine in carbon tetrachloride. Reaction took place at ordinary temperatures, the intensity of the color due to bromine gradually diminishing until, at the end of eighteen hours, the solution was but faintly yellow. This color disappeared entirely on warming the solution. On evaporation of the solvent, a crystalline mass resulted in which traces of a viscous liquid were present. The reaction product was extracted with petroleum ether and upon evaporation crystals were obtained that melted at 138°. This corresponds to the melting point of triphenyl germanium bromide. A small quantity of a viscous liquid was also obtained and, when this was treated with a drop of water, a white film was formed. This is characteristic of diphenyl germanium dibromide, the white film being due to the oxide formed on hydrolysis. The remainder of the crystalline product was unchanged octaphenyl germanopropane. It is evident that the Ge–Ge bond is less stable toward bromine than is the phenyl germanium bond. On bromination in carbon tetrachloride, the Ge–Ge linkage is broken down.

Summary

Diphenyl germanium dichloride is not ammonolyzed in ethylamine. The reduction of diphenyl germanium dihalide by means of lithium in ethylamine proved unsuccessful. The reduction product was a resinous material whose composition approximated that of diphenyl germanium but which could not be purified.

Diphenyl germanium, in crystalline form, was obtained by the reduction of diphenyl germanium dichloride by means of sodium in xylene. The yields were small, the greater proportion of the product consisting of a resinous material resembling that obtained on reduction in ethylamine.

Disodium diphenyl germanide was prepared by the action of sodium on diphenyl germanium in liquid ammonia.

Octaphenyl germanopropane was prepared by the action of sodium triphenyl germanide on diphenyl germanium dichloride in benzene solution.

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY
OF WISCONSIN]

THE CLEAVAGE OF CERTAIN UNSYMMETRICAL 193-DIKETONES

BY WALTER M. KUTZ AND HOMER ADKINS

RECEIVED JULY 3, 1930 PUBLISHED OCTOBER 6, 1930

A diketone of the type $R'C(O)CR_2C(O)R''$ may undergo alcoholysis to form either the ester $R'COOEt$ or $R''COOEt$, together with the corresponding ketones. Bradley and Robinson[1] found in the case of 18 out of 20 aryl 1,3-diketones that alkaline hydrolysis took place in such a way that the stronger of the two possible acids was produced in the larger amount. It was shown in a previous paper[2] that acetylbenzoylmethane and benzylacetylbenzoylmethane underwent alcoholysis in the presence of hydrogen chloride to give ethyl acetate unmixed with any ethyl benzoate. Having these facts in mind, the alcoholysis and hydrolysis of certain unsymmetrical 1,3-diketones were carried out with the view to ascertain to what extent structural factors and experimental conditions determine the point of cleavage. The ratios of products in the hydrolysis and alcoholysis of the following list of 1,3-diketones have been determined

$CH_3C(O)CH_2C(O)C_4H_9$-*n*
$CH_3C(O)CH_2C(O)C_5H_{11}$-*n*
$CH_3C(O)CH_2C(O)C_5H_{11}$-*iso*
$CH_3C(O)CH_2C(O)C_5H_{11}$-*sec.*
$CH_3C(O)CH_2C(O)C_5H_{11}$-*tert.*
$CH_3C(O)CH_2C(O)C_6H_5$(phenyl)
$CH_3C(O)CH(CH_2C_6H_5)C(O)C_6H_5$(phenyl)
$CH_3C(O)CH_2C(O)C_6H_{11}$(cyclohexyl)
$CH_3C(O)CH_2C(O)C_4H_3O$(furyl)

Alcoholysis was carried out by placing the desired amount of diketone, together with a one-half molar ratio of hydrogen chloride in ethanol, in a thermostat at 60° for four days. The volume of the alcoholysis mixture was approximately 25 ml. per 0.01 mole of diketone. Two ml. of phenylhydrazine per 0.01 mole of sample was then added to combine with the hydrogen chloride and ketones. After standing for two hours, the reaction mixture was distilled from an oil-bath at a temperature of 110–120°. At this stage the reaction mixtures from the five aliphatic diketones were treated with four successive portions (15 ml.) of butanol, each portion being distilled out under a pressure of 100 mm. before the addition of the next. This procedure was necessary in order to distil out the esters of the various butyric and valeric acids. The ester in the distillate was saponified with 0.1 N sodium hydroxide and the excess back titrated with sulfuric acid of the same concentration, phenolphthalein being used as an indicator. The mixture was evaporated to dryness and an amount of 0.3 N sulfuric acid, equivalent to the sodium salts of the fatty acids present, added. This solution was diluted with water until 50 ml. contained approximately 7.5 millimoles of acid.

In the case of four of the diketones, one of the esters which could be formed was too high boiling to be conveniently distilled out in the presence of phenylhydrazine. After completion of alcoholysis, the mixture was divided into two equal portions. To one phenylhydrazine was added and the ethyl acetate present distilled out with ethanol. The other half was analyzed for acetone by the sodium sulfite method as previously

[1] Bradley and Robinson, J. *Chem. Soc.*, 129, 2356 (1926).

[2] Adkins, Kutz and Coffman, THIS JOURNAL, 52,3212 (1930).

described.[3] The alcoholysis sample was distilled, giving a distillate which contained ethyl acetate, ethanol, hydrogen chloride and any acetone; aqueous sodium hydroxide was then added to neutralize the acid and to saponify the ester. This mixture was distilled, any acetone present being thus obtained in an ethanol–water solution.

The method of analysis for the ratio of acids (or esters) produced in the cleavage of the diketones involved the partition of the acids between water and benzene, the titration of each layer with standard alkali and the calculation of the ratios of the acids present from the result of this titration and a knowledge of the partition of the acids involved between water and benzene.

Behrens[4] described the determination of a number of acids by the partition between ether and water. The greater insolubility in each other of benzene and water and the greater differences in the partition coefficients of the aliphatic acids for this pair of solvents[5] indicated that benzene was to be preferred to ether as the organic solvent.[6]

The results of the determination of the partition of the various acids (except acetic) at various concentrations between equal volumes of benzene and water is shown in Fig. 1. The concentration of acetic acid in the benzene layer was found to be from 1.9 to 2.2 millimoles per liter when the concentration in the water layer was from 75 to 110 millimoles per liter. In the later calculations the concentration of acetic acid in the benzene layer was taken as 2 millimoles per liter. Since all of the samples to be analyzed contained approximately 1.5×10^{-1} moles of sodium sulfate per liter, that concentration of the salt was always present in the water layer during the determination of the partition of the acids. The titrations were made on 25-ml. samples with 0.1 N sodium hydroxide, using phenolphthalein as an indicator, after partition had taken place over a two-hour period, the samples being shaken frequently while they were held in a thermostat at 25°.

The acid solutions obtained by the alcoholysis and hydrolysis of the various diketones were analyzed for the two acids present. Fifty ml. of the solution prepared as described above was placed in a separatory funnel and shaken with 50 ml. of benzene. After shaking for a few minutes it was placed in a thermostat at 25° and shaken at intervals of fifteen minutes over a period of two hours. The layers were separated and titrated with carbonate-free 0.1 N sodium hydroxide. From the previously determined partition ratios the amount of each acid present and consequently the amount of split was calculated. Using the data which were found in the analysis for the acids formed in the hydrolysis of acetylbutyrylmethane, a calculation of the percentage of acetyl split as compared to the total amount of hydrolysis is shown below. After partition of the aqueous acid solution with benzene, 63.0 ml. of 0.1 *N* alkali was required to neutralize 50 ml. of the water layer and 18.5 ml. of 0.1 N alkali for the same volume of the benzene layer. Therefore the amount of acid in the water layer was 6.3 millimoles and in the benzene layer 1.85 millimoles. The concentration of acetic acid in the benzene layer under the conditions used here had been determined to be approximately 2.0

millimoles per liter or 0.1 millimole in 50 ml. of solution. The concentration of butyric acid in the benzene layer was accordingly 35 millimoles per liter. From the graph on which the partition data for the various acids had been plotted, the corresponding concentration of the butyric acid in the water layer was shown to be 48 millimoles per liter or 2.4 millimoles in 50 ml. The total amount of acetic acid was equal to the amount of acid in the water layer plus the amount of acetic acid in the benzene layer minus the amount of butyric acid in the water layer, i. e., 6.3 + 0.1 – 2.4 = 4.0 millimoles. The amount of butyric acid was determined by difference, the total acidity of the water and benzene layers less the amount of acetic acid, *i.* e., 8.15 – 4.0 = 4.15 millimoles. The percentage of "acetyl" cleavage was therefore 49% (4.0/8.15 × 100).

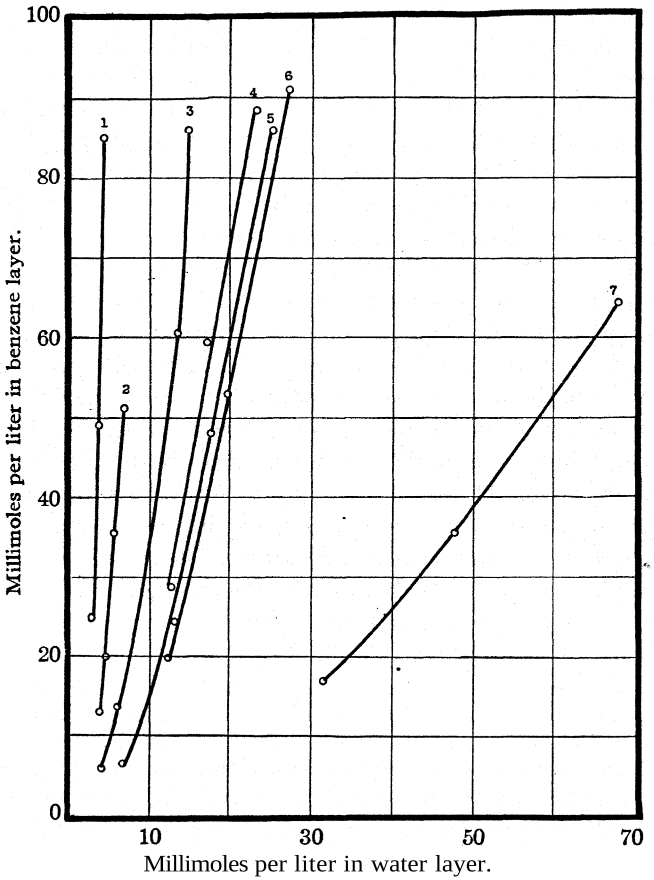

Fig. 1.—Distribution of (1) cyclohexanoic, (2) benzoic, (3) trimethylacetic, (4) *n*-valeric, (5) methylethylacetic, (6) isovaleric, and (7) a-butyric acids at various concentrations between equal volumes of benzene and water containing 0.15 mole of sodium sulfate per liter.

The accuracy of the method of analysis was tested by the analysis of mixtures of known composition of acetic and butyric acids, of acetic and valeric acids, of ethyl acetate and ethyl butyrate, and of ethyl acetate and ethyl valerate. The results were as follows. A solution containing the acids in the ratio 51.5% acetic acid and 49.5% butyric acid was found to contain 50 and 50% acetic acid in two analyses. A solution containing 52.4% acetic and 47.6% valeric acids showed by analysis 53 and 53% acetic acid. A mixture of esters containing 49.8% ethyl acetate and 50.2% ethyl butyrate showed 47 and 46% acetic acid upon analysis. A mixture of ethyl acetate (56.7%) and ethyl valerate (43.3%) showed 55% acetic acid after saponification and partition. Another sample containing 74.9% of ethyl acetate showed by analysis 77%.

The determination of the products formed in hydrolysis was very similar to the method just described. The diketone was placed in a thermostat at 60° with an excess of 0.1 N sodium hydroxide. Twenty-four hours were sufficient to give practically complete hydrolysis, except in the case of acetyltrimethylacetylmethane, which required at least twice that length of time. The hydrolysis sample was back titrated with standard sulfuric acid and then evaporated to dryness. The procedure from this point on was the same as for the alcoholysis samples, *i. e.*, the addition of a calculated quantity of standard sulfuric acid, partition, titration and calculation.

In the hydrolysis of acetylbenzoylmethane, benzylacetylbenzoylmethane, acetylcyclohexoylmethane and acetylfuroylmethane, one of the acids which could be formed is only slightly soluble in water at 25°, so in these cases the whole of an hydrolysis sample was subjected to partition rather than an aliquot portion. The aqueous acid solution was not homogeneous and a representative sample could not be secured.

The amounts of acids, expressed in millimoles, from the esters formed in the alcoholysis of five diketones are given below: from acetylbutyrylmethane, acetic acid 4.15 and 4.30, butyric acid 5.47 and 5.35; from acetylvalerylmethane, acetic acid 6.26 and 5.53, valeric acid 4.06 and 3.37; from acetylisovalerylmethane, acetic acid 4.04 and 5.25. isovaleric acid 2.55 and 2.75; from acetyl-*sec.*-valerylmethane, acetic acid 5.80 and 5.90, *sec.*-valeric acid 1.38 and 1.38; from acetyltrimethylacetylmethane, acetic acid 6.04, 6.14 and 6.44, trimethylacetic acid 0.56, 0.56 and 0.80.

The amounts of ethyl acetate and acetone expressed in millimoles formed in the alcoholysis of four diketones (which might split to give high-boiling esters) are given below: from acetylbenzoylmethane, ethyl acetate 8.66 and 8.66, acetone, none; from acetylcyclohexanoylmethane, ethyl acetate 5.80 and 6.02, acetone 4.3 and 4.0; from benzylacetylbenzoylmethane, ethyl acetate 7.70 and 8.30, ethyl benzoate, none; from acetylfuroylmethane, ethyl acetate 13.1 and 12.4, acetone, none.

The amounts of acids, expressed in millimoles, from the alkaline hydrolysis of nine diketones are given below: from acetylbutyrylmethane, acetic acid 4.00 and 4.04, butyric acid 4.15 and 4.15; from acetylvalerylmethane, acetic acid 4.38 and 4.42, valeric acid 3.58 and 3.66; from acetylisovalerylmethane, acetic acid 5.52 and 5.80, isovaleric acid 271 and 2.87; from acetyl-*sec.*-valerylmethane, acetic acid 4.85 and 4.90, *sec.*-valeric acid 2.95 and 2.95; from acetyltrimethylacetylmethane, acetic acid 4.25, 4.35 and 4.93, trimethylacetic acid 3.15, 3.15 and 3.35; from acetylbenzoylmethane, acetic acid 5.09 and 5.67, benzoic acid 0.82 and 0.93. From acetylcyclohexanoylmethane, acetic acid 4.69 and 4.74, cyclohexanoic acid 3.71 and 3.76; from benzylacetylbenzoylmethane, acetic acid 5.25 and 5.90, benzoic acid 2.35 and 2.70; from acetylfuroylmethane, acetic acid 8.62 and 8.78, furoic acid, none.

There is given in Table I a summary calculated from the above data which indicates the extent to which the linkage on the one side or the other of the "methane" carbon atom was split by alcoholysis or hydrolysis.

There does not appear to be a close agreement between the strength of the acids and the ratio in which they were produced through hydrolysis,

TABLE I

THE RATIO OF PRODUCTS IN THE CLEAVAGE OF CERTAIN 1,3-DIKETONES

Diketone	Alcoholysis		Hydrolysis	
	$CH_3\text{—}\underset{\vert}{C}\text{=}O$, %	$R\text{—}\underset{\vert}{C}\text{=}O$, %	$CH_3\text{—}\underset{\vert}{C}\text{=}O$, %	$R\text{—}\underset{\vert}{C}\text{=}O$, %
Acetylbutyrylmethane	43.5	56.5	49	51
Acetylvalerylmethane	61	39	55	45
Acetylisovalerylmethane	65.5	34.5	67	33
Acetyl-*sec.*-valerylmethane	81	19	62	38
Acetyltrimethylacetylmethane	91	9	58	42
Acetylbenzoylmethane	100	0	86	14
Acetylcyclohexanoylmethane	58.5	41.5	56	44
Benzylacetylbenzoylmethane	100	0	69	31
Acetylfuroylmethane	100	0	100	0

although in the case of the hydrolysis of four of the five aliphatic diketones the stronger acid was produced in the larger amount. Furoic acid is forty times as strong as acetic acid, yet none was produced in the hydrolysis of acetylfuroylmethane. Benzoic acid is three to four times stronger than acetic acid yet over five times as much acetic as benzoic acid was produced in the hydrolysis of acetylbenzoylmethane, while when one of the hydrogens on the "methane" carbon atom had been replaced by a benzyl group the ratio of acetic to benzoic acid was slightly more than 2 to 1. Butyric and acetic acids were produced in almost equal amounts by the hydrolysis of acetylbutyrylmethane, while twice as much acetic acid as isovaleric acid was produced in the hydrolysis of acetylisovalerylmethane despite the fact that isovaleric acid is stronger than butyric acid.

In the case of three of the nine diketones (acetylisovalerylmethane, acetylcyclohexanoylmethane and acetylfuroylmethane) there was no essential difference between the ratio of the products produced in hydrolysis and alcoholysis. In one case (acetylbutyrylmethane) the cleavage to produce an acetyl compound was slightly less in alcohol than in water, but in this determination (acetic and butyric acids) the experimental error was largest. In the other five cases there was from 10 to 45% greater production of the acetyl compound in acid alcoholysis than in alkaline hydrolysis. In general it would seem that the ratio of products is less modified by changes in structure in the case of alkaline hydrolysis than in acid alcoholysis.

The data for the four diketones which have a butyl group at one end of the diketone molecule show clearly that increased branching in the radical greatly slows up the rate of alcoholysis (both actually and relatively) at that side of the molecule. The diketone having the n-butyl group breaks to give 39% of the five-carbon acid, the diketone having the isobutyl group gives 34.5% of the corresponding acid, the *sec.*-butyl group gives 19% of the acid while with the *tert.*-butyl group the production of the five-carbon acid has dropped to 9%. In contrast with this is the fact that the alkaline hydrolysis was but little affected by these changes in structure. In this connection it should be pointed out that the alcoholysis of the diketones containing the *sec.*-butyl and *tert.*-butyl groups was very slow and did not go more than 20 to 30% to completion in 150 hours, while in the case of all the other diketones (except benzylacetylbenzoylmethane) alcoholysis was 100% in less than 100 hours. These facts might be explained on the basis of steric hindrance were it not for the fact that the unsaturated cyclic radicals phenyl and furyl decreased alcoholysis on that side of the diketone to the vanishing point while the cyclohexyl radical permitted a 41.5% cleavage to form ethyl cyclohexanoate. It appears then that the factors which are operating in these cases to determine the point of cleavage are probably constitutional rather than steric.

It has been pointed out[2] that there is a correlation between the extent of enolization of a diketone and the rate of alcoholysis in the presence of hydrogen chloride. Thus it is possible that the ratio of the products in the acid alcoholysis of an unsymmetrical diketone represents approximately the ratio of the extent of the enolization of the two carbonyl groups.

The authors wish to emphasize that in their opinion the ratios of products formed in the solvolysis of the 1,3-diketones as reported in this paper are simply a measure of the relative rates of two competitive reactions and are in no sense measures of the strength or thermodynamic stability of the linkages involved. As noted in another paper they have so far failed in all attempts to determine the latter values for any 1,3-diketones. Such values are as much a characteristic of a given structure as its absorption spectra, while the ratio of the rates of two alternative modes of reaction are modifiable almost without limit. It is interesting to note that the experimental work reported in this paper shows that increased branching in the butyl radical decreases the rate of cleavage of the acyl radical containing it from the remainder of the molecule to which it is attached, while Conant, Small and Sloan[7] have shown that increased branching in the butyl group increases the extent of dissociation of hexasubstituted ethanes. This latter determination is, of course, a measurement of the thermodynamic stability of the carbon to carbon linkage.

Preparation and Purity of Reagents.—Acetylbutyrylmethane, acetylvalerylmethane, acetylisovalerylmethane, acetyl-*sec.*-valerylmethane, acetyltrimethylacetylmethane, acetylbenzoylmethane and acetylcyclohexanolmethane were prepared by the method previously described,''. e., by condensing ethyl acetate with the proper methyl ketone in the presence of metallic sodium. Acetylfuroylmethane was prepared by condensing ethyl furoate with acetone in the presence of sodium ethoxide, the method being the same as for diacetylmethane, except that toluene was substituted for the excess ester used as a solvent in that preparation. The preparation of benzylacetylbenzoylmethane was described in the previous paper. There is given below a summary showing the physical constants, yields and analyses where necessary of the various reagents used in this investigation. Acetylbutyrylmethane: yield 48%, b. p. 173–175°, d_{25}^{25} 0.9375

Summary

The ratio of esters and of salts of acids produced in the acid alcoholysis and the alkaline hydrolysis, respectively, of nine unsymmetrical 1,3-diketones has been determined and the results summarized in tabular form. There was not found to be a close correlation between the amounts and the strength of the acids produced in hydrolysis such as had previously been observed in the case of certain diaryl 1,3-diketones. The ratio of products was less modified by changes in structure in the case of alkaline hydrolysis than in acid alcoholysis. Increased branching in the radical at one end of the diketone molecule decreased the cleavage on that side but this does not appear to be due entirely to steric effects, for the cyclohexyl group was much less effective in this regard than the phenyl or furyl radical. It has been suggested that the ratio of products is a measure of the relative extent of enolization of the two carbonyl groups in these unsymmetrical diketones.

The preparation of acetyl-*sec.*-valerylmethane and acetylfuroylmethane is reported for the first time.

STUDIES OF CONJUGATED SYSTEMS. V. THE PREPARATION AND CHLORINATION OF BUTADIENE

BY IRVING E. MUSKAT AND HERBERT E. NORTHRUP

RECEIVED JULY 7, 1930 PUBLISHED OCTOBER 6, 1930

The addition reactions of conjugated systems have been for some time the subject of an investigation in this Laboratory.[1] In our earlier work we were mainly concerned with the addition reactions of a-substituted conjugated compounds, $RCH{=}CHCH{=}CH_2$, but in order to ascertain the effect of conjugation, free from the influence of substituent groups, we undertook an investigation of the addition reactions of butadiene, $CH_2{=}CHCH{=}CH_2$. The present paper contains the results of a study of the preparation and chlorination of butadiene.

The preparation of butadiene was first reported by Caventou,[2] who obtained it by passing the vapors of fusel oil through a hot tube. Since then it has been found in varying amounts (usually very small) in the pyrogenic decompositions of a large number of organic compounds. The possibility of using butadiene as a raw material for the production of rubber stimulated a great deal of work on the preparation of this hydrocarbon. Harries,[3] one of the pioneers of rubber chemistry, has shown that while excellent rubber is obtained by the polymerization of isoprene, rubber of still better quality is produced by the polymerization of butadiene. Most of the methods that have been patented for the preparation of butadiene are based on the pyrogenic decomposition and cracking of different petroleum products.[4] However, the yields of butadiene obtained by these methods invariably have been low.

A different method for the preparation of butadiene was suggested by Perkin[5] based on the method he developed for the preparation of isoprene. This method may be formulated as follows

$$\underset{\text{Butyl alcohol}}{CH_3CH_2CH_2CH_2OH} \xrightarrow{\text{Dry HCl}} \underset{\text{Butyl chloride}}{CH_3CH_2CH_2CH_2Cl}$$

$$\text{Butyl chloride} \xrightarrow{Cl_2} \underset{\text{butane dichlorides}}{\text{Mixture of } \alpha,\beta\text{-}, \alpha,\gamma\text{- and } \alpha,\delta\text{-}}$$

$$\text{Butane dichlorides} \xrightarrow[\text{at } 470^\circ]{\text{Soda lime}} \underset{\text{Butadiene}}{CH_2{=}CHCH{=}CH_2}$$

He states that he tried this method once and that the yield appeared to be good, but he gave no actual figures.

Since this 1912 paper Perkin has not published further concerning the preparation of butadiene or the development of the process he suggested. It is also of interest that of the many research investigations published since 1912 in which butadiene was used, not any of the investigators prepared the butadiene according to the method suggested by Perkin. We must, therefore, conclude that the method of preparing butadiene devised by Perkin was not considered successful.

Since we intended to make an extended study of butadiene and its addition reactions we made a preliminary investigation of the various methods suggested for its preparation. The method devised by Perkin appeared the most promising and we have developed this method so that it gives a much better yield of butadiene than that obtained by any of the other methods.

n-Butyl alcohol was converted into n-butyl chloride according to the method of Norris[6] by heating the alcohol with concentrated hydrochloric acid and anhydrous zinc chloride. The pure chloride was then further chlorinated to the dichloride. In order to insure the complete conversion, as far as possible, of the monochloride to the dichloride without the formation of any higher chlorinated products, a specially designed apparatus was used. This was modeled after a similar apparatus used by Perkin in his work on the chlorination of isoamyl chloride. A detailed description of the apparatus will follow in the Experimental Part. It was possible to chlorinate in this apparatus two liters of butyl chloride to the dichloride in about six hours.

The chlorinated reaction mixture was then distilled through a fractionating column. From the distillation temperatures of the fractions collected it appeared that the chlorinated product consisted of a mixture of some unreacted butyl chloride and the α,β-, α,γ- and α,δ-dichlorobutanes (possibly also some α,α-dichlorobutane). Detailed data concerning the yields of these fractions will be found in the Experimental Part.

Each of the fractions of the dichlorobutanes was distilled over coarse soda lime contained in an iron tube heated at a temperature of about 700–730°. The volatile products coming from the hot tube were passed through several condensers and wash bottles and finally absorbed in chloroform or ligroin to be treated as desired. A diagram of this cracking apparatus is included in the Experimental Part with the yields of butadiene obtained from each fraction of the dichlorobutane mixture. The best yield was obtained from the α,γ-dichlorobutane, which was about 30 mole per cent. of the theoreti-

cal. This is considerably higher than the yield of butadiene reported from other methods,

The addition of bromine to butadiene was first studied by Griner,[7] then by Thiele[8] and more recently by Farmer and his students.[9] The latter have definitely shown that butadiene unites with bromine to form a mixture of two dibromides. One of these, a liquid, is the 1,2-dibromide, $CH_2BrCHBrCH{=}CH_2$, its structure being proved by ozonization. The other is a solid compound, m. p. 53–54°, proved by Thiele to possess the 1,4-structure, $CH_2BrCH{=}CHCH_2Br$. Farmer further showed that when either the 1,2- or 1,4-dibromide is heated for a few minutes at 100°, the product is a mixture in which the two isomerides appear to be in equilibrium, the equilibrium mixture consisting of 20% of the 1,2- to 80% of the 1,4-isomer. At room temperature the change is very slow. The equilibrium depended in a large measure on the solvent used. Previous to the publication of Farmer's work one of us (M) had determined the same equilibrium between the two dibromide isomers of butadiene and found the equilibrium mixture of the pure compounds to consist of 18% of the 1,2-dibromide to 82% of the 1,4-isomer.

The addition of hydrogen bromide to butadiene was studied by Ipatiew,[10] who obtained an unsaturated bromide, C_4H_7Br, but he was not able to determine its structure.

Lebedev[11] studied the catalytic reduction of butadiene and found that both double bonds are attacked but not at the same rate.

Diels and Alder[12] have found that butadiene will add maleic anhydride, and similar compounds containing the group $C{=}C{-}C{=}O$, in the 1,4-position. The exact mechanism of this reaction is not yet fully understood.

These are the only investigations of the addition reactions of butadiene which have been reported in the literature. As a continuation of our studies on the addition reactions of conjugated systems we have investigated the chlorination of butadiene.

On chlorinating butadiene in carbon disulfide, ligroin or chloroform solution, a mixture of two dichlorides and two tetrachlorides was obtained. The pure dichlorides are colorless oils and distil, under 40 mm. pressure, at 45–45.5° and at 75–76°, respectively. One of the tetrachlorides is an oil, b. p. 110–111° under 40 mm. pressure, while the second tetrachloride, which distilled at 130–134° under 40 mm. pressure, crystallized to a solid, m. p. 72°, which is the same melting point recorded by Henninger[13] for the

tetrachlorobutane he obtained on treating erythritol with phosphorus pentachloride.

The structures of the two dichlorides were proved by oxidation. Three dichlorides are theoretically possible, one 1,2-addition compound and two 1,4-addition compounds, the cis and trans isomers. On ozonizing the lower-boiling dichloride it was possible to isolate α,β-dichloropropionic aldehyde. This proves that the lower-boiling dichloride has the structure $CH_2ClCHClCH{=}CH_2$, and was formed by the 1,2-addition of chlorine to butadiene. The 1,2-structure of the dichloride was further confirmed by oxidizing it with potassium permanganate in dilute alcoholic solution. α,β-Dichloropropionic acid was isolated from the reaction product.

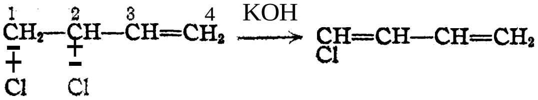
On oxidizing the higher-boiling dichloride with ozone or potassium permanganate in dilute alcoholic solution, it was possible to isolate in each case chloro-acetic acid. This proves that the higher-boiling dichloride has the 1,4-structure, $CH_2ClCH{=}CHCH_2Cl$.

When the lower-boiling dichloride is further chlorinated to the tetrachloride, the liquid tetrachloride is formed to the exclusion of the solid isomer. On the other hand, the higher-boiling dichloride absorbs a molecule of chlorine to give a preponderance of the solid tetrachloride with some of the liquid isomer.

Samples of the two dichlorides and of the two tetrachlorides were reduced with powdered zinc in alcohol. In each case butadiene was formed; this was identified as the tetrabromide, m. p. 114°.

It was possible to control the chlorination of butadiene so that the dichlorides were formed almost exclusively. The detailed procedure will be found in the Experimental Part. From the results of a large number of such chlorinations it appeared that about twice as much of the 1,2-dichloride was formed as of the 1,4-dichloride.

If either of the dichlorides, the 1,2- or 1,4-isomer, is heated to about 90° with twice its weight of dry powdered potassium hydroxide, a vigorous reaction occurs, and a lower-boiling dichloride distils over. After several fractionations a colorless liquid was obtained, b. p. 85° under ordinary pressure, which proved to be monochlorobutadiene, $CHCl{=}CHCH{=}CH_2$. It polymerized on standing to a dark resinous mass. Since the 1,2-dichloride gives the same monochloride as does the 1,4-dichloride, we must conclude that the chlorine atom on carbon atom 2 must be relatively electronegative with respect to the chlorine atom on carbon atom 1, and therefore the terminal carbon atom, 1, must be electronegative relative to carbon atom 2.



$$\underset{\underset{Cl}{\mp}}{\overset{1}{CH_2}}-\underset{\underset{Cl}{\pm}}{\overset{2}{CH}}-\overset{3}{CH}=\overset{4}{CH_2}\xrightarrow{KOH}\underset{Cl}{CH}=CH-CH=CH_2$$

Since many of the more recent interpretations of the addition reactions of conjugated systems are based on the assumption that the formation of 1,4 addition compounds is not due to a direct addition in the 1,4-position but rather to a rearrangement from the 1,2- or 3,4-compound, it was of considerable importance to determine whether the 1,2-dichloride was spontaneously converted into the 1,4-dichloride. In the first part of this paper reference was made to the fact that the 1,2- and 1,4-dibromides of butadiene were actually in equilibrium with each other, the change of one isomer to the other occurring slowly at room temperature but very rapidly at 100°. The change of the dichlorides into each other, if it occurred, could be followed readily by means of their refractive indices: the refractive index of the 1,2-dichloride is 1.4550 at 30.5°, and of the 1,4-dichloride, 1.4745 at 30.5°.

There was no change in the refractive indices of either of the dichlorides even after they were heated to 90° in a sealed tube for four hours, and we must therefore conclude that even under these conditions the dichlorides are stable and do not rearrange into one another.

In attempting to explain addition reactions to conjugated systems in which 1,2- 1,4- and 3,4-addition takes place, some chemists have suggested an extension of Thiele's theory from the point of view of electronic theories of polarization. According to this theory a conjugated system may polarize in two ways, $\overset{+}{C}—\overset{-}{C}—C—C$ and $\overset{+}{C}—C—C—C$, leading to reaction at adjacent (1,2 or 3,4) or terminal (1,4) carbon atoms of the chain. This theory is little more than a translation of Thiele's partial valencies into more modern terminology.

Gillet[14] has applied the principles of α,γ-rearrangements to conjugated systems and has suggested that the formation of 1,4-addition compounds is preceded by the formation of 1,2-addition compounds, as follows

$$\overset{1}{C}=\overset{2}{C}—\overset{3}{C}=\overset{4}{C} + AB \longrightarrow \underset{A}{\overset{1}{C}}—\underset{B}{\overset{2}{C}}—\overset{3}{C}=\overset{4}{C} \longrightarrow \underset{A}{\overset{1}{C}}—\overset{2}{C}=\overset{3}{C}—\underset{B}{\overset{4}{C}}$$

That this theory is not applicable to all 1,4-addition reactions of conjugated systems has been clearly shown above in the chlorination of butadiene, since the formation of 1,4-butadiene dichloride certainly could not have resulted from the rearrangement of the 1,2-isomer.

Prevost,[15] as a result of his work on conjugated systems, has included both of these possibilities in his interpretation of the addition reactions of conjugated systems, and his views are therefore open to the same criticism.

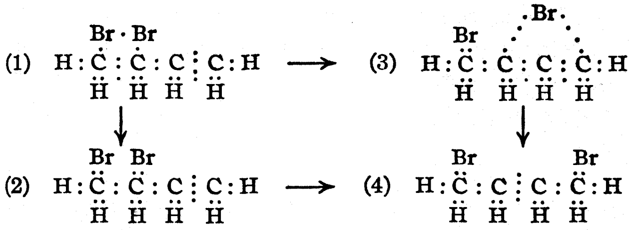
Farmer,[16] who has made an extended investigation of the addition reactions of conjugated systems, suggests the following mechanism for the bromination of butadiene

---

[14] Gillet, *Bull. soc. chim. Belg.*, *31*, 366 (1922).

[15] Prevost, Ann. chim., [10] 10, 113 (1928).

[16] Farmer, *J. Chem. Soc*, 729 (1928).



in which he assumes that the first step in the reaction is the molecular addition of bromine to one of the double bonds in butadiene with the formation of the intermediate compound (1). "This has only transient existence, and breaking of the single linkage between the bromine atoms allows activity in two ways: (a) taking the course normal in the bromination of ethylenes, yielding (2), (b) bringing into action the tautomeric capacity of the propene system and passing through (3) to (4)."

Ingold[17] has classified the addenda in conjugated systems "into three categories'according to whether (Case I) both parts are stable as anions (e. g., Br_2), (Case II) one part is stable as an anion and the other as a kation (e. g., HBr, HCN), or (Case III) both parts are stable as kations (e. g., H_2)." In discussing Case I he states that in the addition of halogens to a conjugated system in a non-ionizing medium, the *initial* product formed could only be a 1,2-addition compound; the formation of any 1,4-compound would, therefore, result from the rearrangement of the 1,2-compound.

In our studies on the chlorination of butadiene, the chlorination was carried out in non-ionizing solvents (carbon disulfide, chloroform and ligroin) and in each case considerable 1,4-dichloride was formed. Since we have shown that the two dichlorides do not rearrange into one another, it is clear that the interpretation advanced by Ingold cannot explain the formation of 1,4-butadiene dichloride in a non-ionizing solvent.

One of the principal objects in this investigation of the addition reactions of conjugated systems has been to show that these addition reactions could be interpreted without recourse to any special hypothesis of conjugation. Conjugated systems differ from non-conjugated systems only in so far as the former may exhibit α,γ-rearrangements, while the latter cannot exhibit this phenomenon.

It has been quite definitely established that the addition of both components of the addendum to an ethylenic double bond does not occur simultaneously. It is more likely, as has been suggested by Stieglitz,[18] that the essential feature is the attraction of the positive substituting group to the negative carbon valencies irrespective of complete saturation. Confirmatory evidence for this hypothesis has been brought by Terry and Eichel-

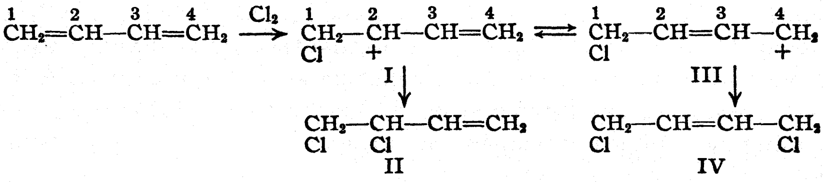
---

[17] Ingold, *J. Chem. Soc.*, 910 (1928); 2022 (1929).

[18] Stieglitz, THIS JOURNAL. 44, 1304 (1922).

berger[19] and by Francis,[20] who have shown that in the addition of halogens to unsaturated compounds the halogen molecule initially supplies only one halogen atom, the positively charged halogen atom, to the unsaturated substance.

Applying these same principles to the chlorination of butadiene we would have as the first step of the reaction the addition of the positive chlorine atom to the terminal carbon atom (see equation on page 4046 to give I).



$$\overset{1}{CH_2}{=}\overset{2}{CH}{-}\overset{3}{CH}{=}\overset{4}{CH_2} \xrightarrow{Cl_2} \underset{Cl}{\overset{1}{CH_2}}{-}\underset{+}{\overset{2}{CH}}{-}\overset{3}{CH}{=}\overset{4}{CH_2} \rightleftharpoons \underset{Cl}{\overset{1}{CH_2}}{-}\overset{2}{CH}{=}\overset{3}{CH}{-}\underset{+}{\overset{4}{CH_2}}$$

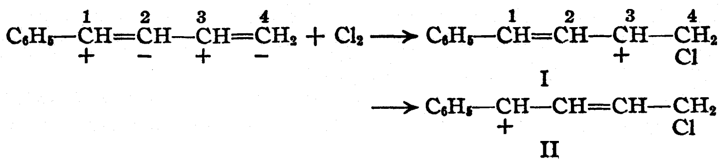
$$\text{I} \downarrow \qquad \text{III} \downarrow$$

$$\underset{Cl}{CH_2}{-}\underset{Cl}{CH}{-}CH{=}CH_2 \;(\text{II}) \qquad \underset{Cl}{CH_2}{-}CH{=}CH{-}\underset{Cl}{CH_2} \;(\text{IV})$$

In the second phase of this reaction the negative chlorine atom either may satisfy the positive charge on carbon atom 2 to give II, 1,2-butadiene dichloride, in a manner normal to ordinary ethylenic compounds; or this intermediate I may undergo a typical α,γ-rearrangement to III, and the negative chlorine atom would now add to the 4 carbon atom to give IV, 1,4-butadiene dichloride.

The formation of either the 1,2- or 1,4-isomer would then depend on the equilibrium of the two intermediates, I and III. This equilibrium would in turn depend on the effect of the group CH_2Cl, in this case, and upon the experimental environment, such as solvent, etc., in promoting or hindering this α,γ-rearrangement. Ingold and his students have, for some years, studied very extensively the effect of various groups in causing such rearrangements to take place, and they have found that the groups CH_2Cl– and CH_2Br– favor such rearrangements. This theory would suggest that ionization should occur preliminary to an α,γ-rearrangement. This would explain why the 1,2- and 1,4-dibromides rearrange into each other while the corresponding dichlorides do not, since it is well known that the C–Br bond is much easier to break than the C–Cl bond.

The chlorination of phenylbutadiene could be formulated as follows, employing the electronic formula for phenylbutadiene developed by Muskat and Becker[1]



$$C_6H_5{-}\underset{+}{\overset{1}{CH}}{=}\underset{-}{\overset{2}{CH}}{-}\underset{+}{\overset{3}{CH}}{=}\underset{-}{\overset{4}{CH_2}} + Cl_2 \longrightarrow C_6H_5{-}\overset{1}{CH}{=}\overset{2}{CH}{-}\underset{+}{\overset{3}{CH}}{-}\underset{Cl}{\overset{4}{CH_2}} \;(\text{I})$$

$$\longrightarrow C_6H_5{-}\underset{+}{CH}{-}CH{=}CH{-}\underset{Cl}{CH_2} \;(\text{II})$$

We would not expect to find addition taking place, in the first phase, to the 2 carbon atom, since it is well known that phenyl groups attached to a

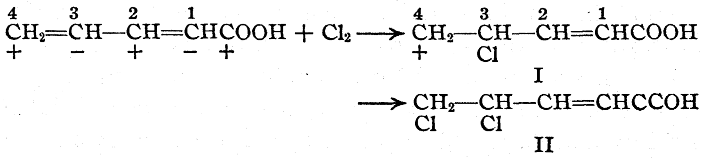
---

[19] Terry and Eichelberger, THIS JOURNAL, 47, 1067 (1925).

[20] Francis, *ibid.*, 47, 2344 (1925).

double bond hinder addition to that double bond. Now, however, the effect of the phenyl group in retarding such a rearrangement I ⟶ II is far greater than the effect of the CH_2Cl group in promoting this rearrangement, and, consequently, we should expect chlorination to occur mostly in the 3,4-position. This is in agreement with the results of Muskat and Huggins,[1] who found that phenylbutadiene absorbs chlorine in the 3,4-position.

The chlorination of vinylacrylic acid presents a somewhat different condition. Again, employing the electronic formula for vinylacrylic acid developed by Muskat and Becker,[1] we see that the carbon atoms 1 and 3 are the only ones that could react in the first phase with the positive chlorine atom. Since a,@-unsaturatedacids are known to add halogen with considerably more difficultythan do the corresponding @ y- or γ,δ-unsaturated acids



$$\overset{4}{\underset{+}{CH_2}}=\overset{3}{\underset{-}{CH}}-\overset{2}{\underset{+}{CH}}=\overset{1}{\underset{-}{CH}}\underset{+}{COOH}+Cl_2\longrightarrow\underset{\text{I}}{\overset{4}{\underset{+}{CH_2}}-\overset{3}{\underset{Cl}{CH}}-\overset{2}{CH}=\overset{1}{CH}COOH}$$

$$\longrightarrow\underset{\text{II}}{\underset{Cl}{CH_2}-\underset{Cl}{CH}-CH=CHCCOH}$$

we should expect carbon atom 3 to be attacked by chlorine in preference to carbon atom 1. This is borne out by the fact that we were not able to prepare a tetrachloride of vinylacrylic acid from the 3,4-dichloride. The first step of the chlorination of vinylacrylic acid would be represented as above. Now, however, the interme ate I cannot undergo an α,γ-rearrangement and the negative chlorine atom must add to the terminal carbon atom to give a 3,4-dichloride exclusively. This is in perfect agreement with the results of Muskat, Becker and Lowenstein[1] on the chlorination and bromination of vinylacrylic acid in which they obtained only 3,4-addition products.

This same theory would apply equally well to the addition of HX and HOX to conjugatedsystems. An extension of this theory to reduction and oxidation of conjugated systems will be presented in a later paper.

Experimental Part

The Preparation of **Butadiene.**—The preparation of butadiene as finally developed consisted of three major operations: (1) converting butyl alcohol into butyl chloride, (2) chlorinating butyl chloride to dichlorobutane and (3) converting dichlorobutane into butadiene by passing it over heated soda lime.

(1) n-Butyl alcohol was converted into n-butyl chloride according to the method of Norris[6] by heating the alcohol with concentrated hydrochloric acid and anhydrous zinc chloride.

(2) The pure butyl chloride was then chlorinated to the dichloride by allowing the vapors of butyl chloride to react with chlorine gas under the influence of light. Perkin[6] describes an apparatus, which he used for this purpose, but we have remodeled and improved this apparatus so that it gives a much better yield of the chlorinated product and requires very little attention. In Fig. 1 is shown the chlorinating apparatus that was

used. **A** is a three-liter round-bottomed flask which contains two liters of butyl chloride heated on an electric plate. A thermometer B is immersed in the liquid in flask **A;** this gives the distillation temperature of the liquid. As the chlorination proceeds the distillation temperature of the liquid rises, and it is thus possible to follow the extent of the reaction. C is a heat insulated Vigreux column (about 40 cm. long), and D is the reaction tube where the chlorine gas and the vapors of the butyl chloride are mixed. The mixed vapors are carried on up the tube and are exposed to the light coming from a 1000-watt lamp placed at X. Under the influence of the light reaction occurs with the formation of the higher-boiling dichlorobutane. F is a bulb reflux condenser so designed that the openings of the bulbs are large at the bottom, where most of the condensation occurs, and become gradually smaller as they approach the top, where the condensate is slight. This type of condenser is very efficient for any purpose in which a great deal of condensate is formed. The hydrogen chloride vapors pass through the reflux condenser F and are absorbed over water. The butyl chloride in A is heated to boiling; when the butyl chloride vapors have filled tube D, the chlorine is allowed to pass in through **E** and the 1000-watt lamp is turned on. The chlorine is passed in through a flowmeter and a sulfuric acid washbottle at a rate, calculated for standard conditions, of 1120 cc. of chlorine per minute. The course of the reaction is followed by the thermometer B. At the beginning of the chlorination the temperature is 77°, the boiling point of butyl chloride. As the distillation proceeds the distillation temperature of the liquid in A rises. The chlorination is allowed to proceed until the temperature reaches 115°. This requires about six hours. If the temperature is allowed to go much higher than 115° some higher chlorinated products are formed. The time could be reduced even more if the reflux condenser F was made larger than the one we actually used. After the reaction was over the chlorinated mixture was roughly fractionated through a column one meter long filled with glass beads. The results of four such runs are recorded in Table I. In each run 2000 cc. (about 1775 g.) of butyl chloride was used. and the chlorination was continued at a constant rate for about six hours, allowing the distillation temperature to rise to 115".

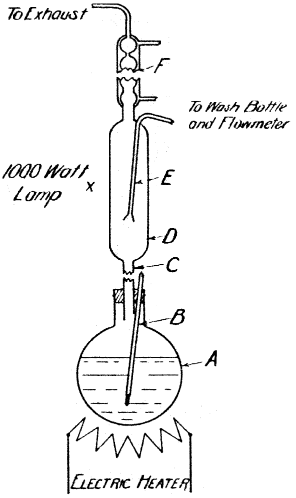


Fig. 1.

TABLE I

CHLORINATION EXPERIMENTS ON BUTYL CHLORIDE

Run no.	1 77–110°, g.	2 110–120°, g.	3 120–130°, g.	4 130–140°, g.	5 140–150°, g.	6 150–165°, g.	Residue, g.
1	242	330	503	546	166	132	100
2	382	300	472	552	191	127	114
3	392	252	418	516	169	138	100
4	292	345	500	540	207	122	107

Fraction 1 (77–110°) contains mostly unreacted butyl chloride and some of the lower dichlorides. Fraction 2 (110–120°) may very likely contain α,α-dichlorobutane, b. p. 114'. Fraction 3 (120–130") contains most of the α,β-dichlorobutane, b. p. 125°. Fraction 4 (130–140°) contains most of the α,γ-dichlorobutane, b. p. 134–137°. Fraction 6 (150–165°) contains most of the α,δ-dichlorobutane, b. p. 161–163°. Fraction 5 (140–150°) is probably a mixture of fractions 4 and 6.

It is interesting to note that in the chlorination of butyl chloride α,γ- and α,β-dichlorobutanes are the main products. There is some α,δ- and probably some α,α-dichlorobutane formed.

(3) The different fractions of dichlorobutane were now distilled over heated soda lime, which removed two moles of hydrogen chloride to give butadiene. The apparatus that was used for this purpose is illustrated in Fig. 2. The dichlorobutane was placed in the separatory funnel A and it was allowed to flow through a tube one meter long (in order to give sufficient pressure to force the vapors through the apparatus) into the round-bottomed flask (500-cc.) B, which was heated on an electric plate. The rate of flow of the dichlorobutane and the temperature of the flask B were so controlled that the process was essentially a flash distillation. The dichlorobutane then passed into the steel tube D, which contained coarse soda lime (about 450 g.). The tube was heated to about 700–730° by means of the electric oven E. At this temperature the soda lime removed two moles of hydrogen chloride from the dichlorobutane to give butadiene.

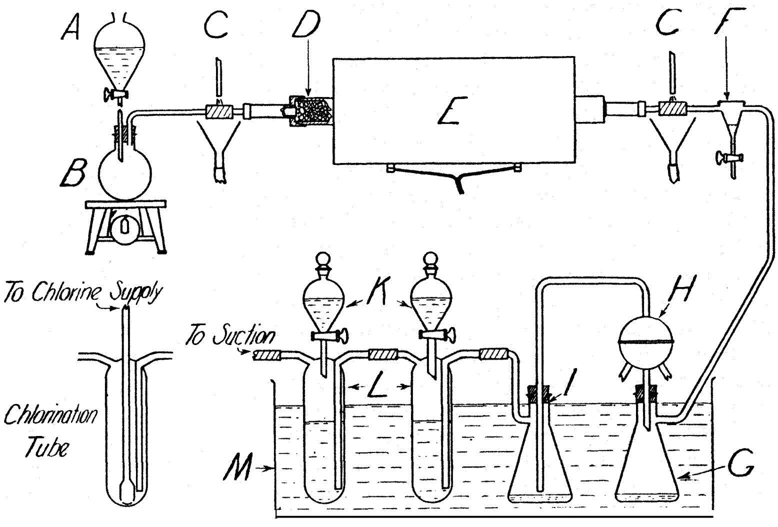

Fig. 2.

The vapors were then passed in succession through the flasks G, ball condenser H and flask I. These flasks were immersed in an ice–salt bath M and served to free the butadiene gas from water, unreacted dichlorobutane and resinous decomposition products. At C water was allowed to run over the rubber connections joining the hot steel tube D to the rest of the apparatus. F is a trap which served to collect a great deal of the water and resinous decomposition products. The butadiene coming from flask I was sufficiently pure to use in our work.

In order to determine which fraction of the dichlorobutane gave the best yield of butadiene, a number of runs were made with each of the fractions of the dichlorides. The butadiene formed was collected as the tetrabromide. For this purpose the butadiene coming from I was passed into the bromination flasks L, which were immersed in the ice–salt bath M. These flasks were about half-filled with chloroform and the bromine was added from the separatory funnels K so that an excess of bromine was always present. Usually the absorption was complete in the first flask but the second flask was used in order to prevent any possible loss of butadiene. In order to overcome the pressure in the system, a slight suction was applied at the end of the second bromination flask. At the completion of the run the brominated mixture was removed from the flasks and warmed under diminished pressure to remove any excess bromine and chloroform. At this stage some solid butadiene tetrabromide would crystallize out of solution. This was removed and the filtrate was subjected to fractional distillation under 50 mm. pressure. From the lower-boiling fractions of the chlorinated butyl chloride considerable dibromobutane distilled over at 75–82° under 50 mm. pressure. This is no doubt due to some unchanged butyl chloride still present in the chlorinated mixture, which is converted into 1-butene by the hot soda lime and which in turn is brominated to 1,2-dibromobutane. After all of the dibromobutane had distilled over, the temperature rose quickly to about 145°, at which temperature the lower-boiling stereoisomeric tetrabromide of butadiene distilled over. The temperature then rose to 175°, at which temperature the pure solid tetrabromide, m. p. 117°, distilled. The fraction from 145–175° consisted of a mixture of the two tetrabromides. From the higher-boiling fractions of the chlorinated butyl chloride the two stereoisomeric tetrabromides alone were obtained. From the combined filtered and distilled butadiene tetrabromides the yield of butadiene was calculated. In Table II are recorded the yields of butadiene obtained from 200 g. of each of the chlorinated fractions. About one hour was required for each run. Two runs were made on each fraction.

TABLE II

PERCENTAGE OF BUTADIENE OBTAINED FROM EACH OF THE CHLORINATED FRACTIONS

	1 75–110° g.	2 110–120°, g.	3 120–130°, g.	4 130–140°, g.	5 140–150°. g.	6 150–165°, g.
Butadiene tetrabromide obtained, g..........	40	118	148	174	139	146
	41	104	144	174	...	157
Yield of butadiene, %..	6.9	18.8	24.8	29.6	23.6	25.6

It is thus seen that the α,γ-dichlorobutane gave the best yield of butadiene, 29.6% of the theoretical.

The Chlorination of Butadiene.—The butadiene coming from I was passed into the chlorination tube shown in the diagram. Usually two such chlorination tubes were used and these were immersed in the ice–salt bath M. The tubes were about half filled with carbon disulfide and a slow stream of chlorine gas was passed in. At the completion of the run (about one hour for 200 g. of dichlorobutane) the chlorinated mixture was removed and freed from carbon disulfide by means of suction. The residual oil was subjected to fractional distillation. After several redistillations four fractions were collected under 40 mm. pressure: (a) 45–45.5°, (b) 75–76°, (c) 110–111°, (d) 130–134°. Each fraction was analyzed for chlorine; the first two fractions proved to be dichloro addition compounds of butadiene, while the last two fractions proved to be tetrachloro addition compounds of butadiene.

It was possible to control the chlorination of butadiene so that the dichlorides were formed almost exclusively. This was accomplished by allowing the butadiene to pass into the chlorination tubes at a more rapid rate than the chlorine. This was usually accompanied by a loss of some of the butadiene. If the chlorine was allowed to pass in at a fairly rapid rate, or if the reaction was allowed to warm up, the tetrachlorides of butadiene were formed exclusively. In one experiment the pure butadiene was chlorinated directly, without any solvent, at about –75° and the same products were formed.

1,2-Dichlorobutadiene.—The lower-boiling dichloride is a colorless oil. It distils at 45–45.5° under 40 mm. pressure and at 115° under atmospheric pressure, without decomposition. Its refractive index was determined with an Abbé refractometer; at 30.5° its refractive index is 1.4550.

Anal. Calcd. for $C_4H_6Cl_2$: Cl, 56.75. Found: Cl, 56.73, 56.80.

The structure of the lower-boiling dichloride (a) was determined by ozonization. Considerable difficulty was experienced in isolating the oxidized fragments. Its identification was finally effected by ozonizing the pure dichloride, without any solvent, and keeping the temperature of the oxidation reaction at about 0°. After the ozonization was complete, water was added to the viscous ozonide, and it was warmed on the water-bath to decompose it. The aldehydes were taken up in ether and washed several times with dilute alkali to remove any acids. If the ozonization was not allowed to continue too long, only negligible quantities of acids were formed. The ethereal solution was dried over sodium sulfate, the ether removed by suction, and the residual oil was distilled under diminished pressure. Most of it distilled over at 73° under 50 mm. pressure, the boiling point of α,β-dichloropropionic aldehyde. This was further identified by treating with sodium acetate according to the method of Piloty and Stock,[21] which converted the dichloride into a-chloro-acrolein. This distilled over at 40° under 30 mm. pressure, the recorded boiling point of a-chloro-acrolein. The water solution remaining from the ethereal extract gave the usual color tests for formaldehyde. This proved that the lower-boiling dichloride (a) has the 1,2-structure, $CH_2ClCHClCH{=}CH_2$.

This structure was further confirmed by oxidizing the lower dichloride with potassium permanganate in dilute alcoholic solution. An acidic oil was obtained which crystallized on standing to a solid melting at 50°, the recorded melting point of α,β-dichloropropionic acid.

1,4-Dichlorobutadiene.—The higher-boiling dichloride (b), when first distilled, is a yellow oil with a pungent odor, but after several distillations it is obtained as a colorless oil with a very faint odor. It distils at 75–76° under 40 mm. pressure and at about 145° under atmospheric pressure without decomposition. Its refractive index was determined with an Abbé refractometer; its refractive index is 1.4745 at 30.5°.

Anal. Calcd. for $C_4H_6Cl_2$: Cl, 56.75. Found: Cl, 56.84, 56.97.

The structure of the higher-boiling dichloride (b) was determined in a manner entirely analogous to the method used for the lower-boiling dichloride. However, in this case, no difficulty was encountered in working up the products of oxidation. A number of oxidation experiments were carried out both with ozone and potassium permanganate and in every case a good yield of chloro-acetic acid was isolated. This was identified by its melting point, 62°, and the melting point of a mixture with a sample of known origin. This proves that the higher-boiling dichloride has the 1,4-structure, $CH_2Cl-CH{=}CHCH_2Cl$.

Tetrachlorobutanes.—Fractions (c) and (d) are the two stereoisomeric tetrachlorobutanes. Fraction (c) is a colorless oil with a faint odor. It distils at 110–111° under 40 mm. pressure.

Anal. Calcd. for $C_4H_6Cl_4$: Cl, 72.41. Found: Cl, 72.49, 72.57.

Fraction (d) crystallized to a solid which melted at 72°.

Anal. Calcd. for $C_4H_6Cl_4$: Cl, 72.41. Found: Cl, 72.64. 72.55.

Reduction of the Di- and Tetrachlorides of Butadiene.—Samples of each of the dichlorides and of the tetrachlorides were reduced with powdered zinc and alcohol according to the method of Thiele.[8] In each case butadiene was formed, which was identified as the tetrabromide, m. p. 114°. This proves that these chlorides are true addition products of butadiene.

1-Chlorobutadiene.—If either of the dichlorides, the 1,2- or 1,4-isomer, is heated to about 90° with twice its weight of powdered potassium hydroxide, a vigorous reaction occurs, and a lower-boiling chloride is formed and distils over through a condenser which is attached to the reaction flask. After several fractionations a colorless liquid is ob-

---

[21] Piloty and Stock, Ber., 31, 1385 (1898).

tained which boils at 85° under atmospheric pressure. It polymerized on standing to a dark resinous mass. It was analyzed for chlorine and proved to be the monochloride, $CHCl{=}CHCH{=}CH_2$.

Anal. Calcd. for C_4H_5Cl: Cl, 40.07. Found: Cl, 39.99, 40.08.

Attempted Rearrangements of the Two Dichlorides.—Samples of each of the dichlorides, the 1,2- and 1,4-isomers, were allowed to stand for several weeks at room temperature (about 25–30°) but no change in their refractive indices occurred. They were then redistilled several times at atmospheric pressure, and their refractive indices were again measured, but no change could be detected. Finally, samples of each were sealed in bomb tubes and heated for four hours at 90°. There was no change in the index of refraction of either of the two dichlorides and we must therefore conclude that even at 90° and under pressure the dichlorides are stable and do not rearrange into one another.

Summary

1. An improved method for the preparation of butadiene starting from *n*-butyl alcohol is given, including a detailed description of the apparatus used.

2. On chlorinating butadiene a mixture of two dichlorides and two tetrachlorides is obtained. The structures of the two dichlorides were proved by oxidation experiments: the lower-boiling dichloride, b. p. 45–45.5' under 40 mm. pressure, is a 1,2-dichloride—$CH_2ClCHClCH{=}CH_2$; the higher-boiling dichloride, b. p. 75–7G°, is a 1,4-dichloride—$CHClCH{=}CHCH_2Cl$. The two stereoisomeric tetrachlorides distilled at 110–111° and 130–134°, respectively. The latter crystallized to a solid, m. p. 72°.

3. It was definitely established that the two dichlorides did not rearrange into each other even at 90° and under pressure.

4. On heating either of the dichlorides with solid potassium hydroxide a monochloride, b. p. 85° under atmospheric pressure, is formed. Its structure is $CHCl{=}CHCH{=}CH_2$.

5. A theory to interpret the addition reactions of conjugated systems without recourse to any special hypothesis of conjugation is presented.

STUDIES RELATING TO ALKYL TIN COMPOUNDS. IV. PROPERTIES OF THE COMPLEX HYDROXY BROMIDE, $[(CH_3)_3SnOH]_2 \cdot (CH_3)_3SnBr$

BY CHARLES A. KRAUS AND RALPH H. BULLARD

RECEIVED JULY 9, 1930 PUBLISHED OCTOBER 6, 1930

As mentioned in a preceding article of this series, Kraus and Harada[1] have prepared compounds of the type $[(CH_3)_3SnOH]_2 \cdot (CH_3)_3SnX$ where X is a halogen. These compounds are readily obtained in the form of well-defined crystals and preliminary investigation indicated that they have measurable stability in solution. It appeared of interest to study these compounds in order to gain some knowledge as to the nature of the complex formed. Dissolved in alcohol or acetone, the compounds conduct the electric current with considerable facility much better than corresponding solutions of trimethyl tin halide or trimethyl tin hydroxide. This indicates that a complex cation of some kind is formed which is moderately electropositive. On treating the compound with silver hydroxide in aqueous solution, an hydroxy derivative of the complex cation was obtained which has approximately the same strength as trimethyl tin hydroxide. However, as indicated by conductance measurements, this complex hydroxide, which is isomeric with trimethyl tin hydroxide, gradually breaks down to form the latter compound.

While the precise nature of the complex cation has not, as yet, been determined, it seems fairly clear that it contains three trimethyl tin groups along with two hydroxy groups. The nature of the linkage is uncertain. That trimethyl tin hydroxide is involved, perhaps after the manner of an oxonium compound, seems fairly certain. This is further borne out by the fact that trimethyl tin hydroxide reacts with methyl iodide to yield a compound whose ionization is considerably higher than that of either of its constituents.

Preparation and Properties of $[(CH_3)_3SnOH]_2 \cdot (CH_3)_3SnBr$.—The compound may be prepared by a variety of methods. According to Callis[2] it is formed by the action of oxygen on trimethyl tin iodide in the sunlight. As will be shown below, it may also be formed by the oxidation of trimethyl tin in the presence of trimethyl tin bromide and water in benzene solution. It is most conveniently prepared by adding two equivalents of trimethyl tin hydroxide to one of the corresponding bromide (or another halide) in various solvents. We have found chloroform the most convenient solvent for this purpose.

One mole of trimethyl tin bromide is treated with two moles of trimethyl tin hydroxide in chloroform at room temperatures. Reaction takes place immediately with

[2] Callis, Dissertation, Clark University, 1922.

the formation of a supersaturated solution of the compound, which crystallizes out slowly on standing, large, well-formed crystals being produced. On vigorously shaking the solution, the greater proportion of the compound is immediately precipitated in the form of fine crystals, while the remainder of the material crystallizes out as the chloroform evaporates. The crystals so prepared are quite pure and melt sharply at 116° with slow decomposition. They appear to be identical with the compound prepared by Kraus and Harada.[1] Crystals of the compound, prepared and purified by various methods, were analyzed for bromine and tin. The results of the analyses were the same for the various preparations.

Anal. Subs., 0.4503, 0.5277, 0.4819: AgBr, 0.1398, 0.1641, 0.1496. Calcd. for $[(CH_3)_3SnOH]_2(CH_3)SnBr$: Br, 13.17. Found: Br, 13.21, 13.23, 13.21; mean, 13.22. Subs., 0.4229, 0.4120, 0.5124: SnO_2, 0.3159, 0.3076, 0.3736. Calcd.: Sn, 58.83. Found. Sn, 58.84, 58.81, 58.97; mean 58.87.

The results of the analyses indicate that the composition of the compound corresponds to the formula $[(CH_3)_3SnOH]_2\cdot(CH_3)_3SnBr$.

The formula of the compound may be written $[(CH_3)_3Sn]_3OBr\cdot H_2O$. This would correspond to an oxonium type of compound containing one molecule of water. The attempt was made to prepare an anhydrous compound corresponding to this formula For this purpose, equivalent amounts of trimethyl tin and trimethyl tin bromide were dissolved in dry benzene under an atmosphere of oxygen. A control experiment was carried out in which moist benzene was employed as solvent. The apparatus was attached to a manometer so that the rate of absorption of oxygen could be measured. Absorption of oxygen took place in both experiments, the rate in moist benzene being about twice that in the dry solvent. In the dry benzene, a white amorphous powder was precipitated, which appeared to be trimethyl tin oxide. In moist benzene, crystals were formed which closely resembled the dihydroxy bromide.[3] Unfortunately, this sample was lost and an analysis of the crystals could not be made. The experiments indicate, however, that, while the dihydroxy bromide is formed in the presence of moisture, it is not formed in the dry solvent.

Some Reactions of $[(CH_3)_3SnOH]_2\cdot(CH_3)_3SnBr$

Reduction with Metallic Sodium in Liquid Ammonia.—If the dihydroxy bromide contains one molecule of water as such, we should expect that, on reduction with metallic sodium in liquid ammonia, hydrogen would be evolved and sodium hydroxide precipitated. On the other hand, if hydroxyl groups are present in combination with tin, sodium hydroxide should be formed without evolution of hydrogen, while the trimethyl tin group should be reduced to the corresponding stannide, $NaSn(CH_3)_3$.

A quantity of the dihydroxy bromide (1.526 g.) was dissolved in liquid ammonia, a clear colorless solution being formed. On adding sodium, reaction took place immediately with the precipitation of a white solid which was doubtless trimethyl tin. On further addition of sodium, this solid dissolved, yielding a solution having a faint yellow color. This color is characteristic of sodium trimethyl stannide,[4] which is formed by the action of sodium on trimethyl tin, As the reaction proceeded, a gelatinous precipitate was formed which was doubtless sodium hydroxide. Sufficient sodium was added to impart a permanent blue color to the solution.

In the course of the reaction a small quantity of gas was evolved which was collected

---

[3] Since accepted rules for the nomenclature of compounds of this type have not been elaborated, the complex compounds of the type $[(CH_3)_3SnOH]_2\cdot(CH_3)_3SnX$ will for convenience be termed "dihydroxy halides."

[4] Kraus and Sessions, THIS JOURNAL, 47, 2361 (1925).

over water. Assuming the compound to contain one molecule of water, 28 cc. of hydrogen should have been produced. In the experiment 9 cc. of hydrogen was collected This was given off slowly throughout the course of the reaction. Since the volume of hydrogen found was much below that required for one molecule of water per mole of compound, we must conclude that hydroxyl groups are present in the compound, which, for the most part, are split off on addition of sodium with the formation of sodium hydroxide.

Reaction with Ammonia.—It was suspected that, in a solution of the dihydroxy bromide, there exists an equilibrium between free trimethyl tin hydroxide and trimethyl tin bromide. If such is the case, then on treating the compound with ammonia in a suitable solvent, ammino trimethyl tin bromide, $(CH_3)_3SnBr\cdot NH_3$, should be formed and, if insoluble, precipitated.[6]

A quantity of the dihydroxy bromide was dissolved in chloroform and ammonia gas was passed through the solution. A precipitate was immediately formed. This was thrown on a filter and the excess chloroform evaporated. The resulting solid sublimed on heating and answered to tests for ammino trimethyl tin bromide.

Although ammino trimethyl tin bromide is precipitated under the conditions of the experiment just described, when the dihydroxy bromide is dissolved in liquid ammonia, little change occurs. A quantity of the compound was dissolved in liquid ammonia, the solvent was allowed to evaporate and the melting point of the residue determined. The substance melted at 107°, while the original pure dihydroxy bromide melted at 115°. Apparently, on solution in liquid ammonia, only an inconsiderable amount of the material was transformed. Other properties of the residue, such as the products of thermal decomposition, remained unchanged on treating with liquid ammonia. It seems that in liquid ammonia solution the compound is not extensively dissociated into its constituents.

Thermal Decomposition.—When the compound is heated under atmospheric pressure, it melts at 115° to form a clear liquid which boils slowly, giving a distillate containing trimethyl tin bromide. This was shown by collecting the distillate, dissolving it in ether, and precipitating the bromide as ammino trimethyl tin bromide by means of ammonia.

A weighed quantity of the compound was introduced into one leg of an inverted U-tube, which was then evacuated. The limb containing the compound was heated, while the other limb was cooled in liquid ammonia. In this experiment. 3.226 g. of compound was subjected to sublimation. Most of the material sublimed to the cooler parts of the tube above the oil-bath. A small quantity of solid residue was left behind, while some liquid was collected in the second limb of the U-tube. Of the total material, 3.0731 g. was found in the sublimate and 0.0428 g. in the residue. By difference, the weight of the distillate was 0.110 g.

The solid residue was analyzed for tin by the modified Krause method.'

Using 23.3 mg. of the residue, 29.9 mg. of SnO_2 was obtained, corresponding to 70.68% of tin, as compared with 72.04% required for dimethyl tin oxide. The sublimate for the most part melted at 115°, the same temperature as the original compound. In the distillate, the presence of both water and tetramethyl tin was established.

It is evident that, on heating the original compound, dissociation takes place according to the equation

$$[(CH_3)_3SnOH]_2\cdot(CH_3)_3SnBr = 2(CH_3)_3SnOH + (CH_3)_3SnBr \qquad (I)$$

When the vapors reach the colder portions of the tube, condensation occurs and the reaction is reversed.

---

[5] Kraus and Greer, THIS JOURNAL, 45, 3078 (1923).

[6] Kraus and Bullard, *ibid.*, 51, 3606 (1929).

As was shown in a preceding article: when trimethyl tin hydroxide is heated to a temperature from 80 to 100°, it breaks down according to the equation

$$2(CH_3)_3SnOH = (CH_3)_2SnO + (CH_3)_4Sn + H_2O \qquad (II)$$

In the above experiment, during the process of sublimation, some of the hydroxide decomposed according to this reaction equation, which accounts for the residue of dimethyl tin oxide The dimethyl tin oxide left behind, weighing 0.0428 g., corresponds to 0.108 g. combined weight of tetramethyl tin and water, according to Equation II. The weight of distillate, as determined by difference, was found to be 0.110 g. The water formed on sublimation of the original compound, therefore, resulted from the decomposition of the trimethyl tin hydroxide and not from the loss of water of hydration.

Molecular Weight.—The preceding experiments indicate that the hydroxyl group retains its linkage to tin in the compounds formed between trimethyl tin hydroxide and the trimethyl tin halides. It was surmised that in solution an equilibrium exists between the compound and its constituents. A determination of the molecular weight of the compound in solution should give clear evidence of dissociation, if such exists.

The compound is not sufficiently soluble in benzene to permit of molecular weight determination in that solvent. Accordingly, its molecular weight was determined in naphthalene by the cryoscopic method. The results are given in Table I.

TABLE I

MOLECULAR WEIGHT OF $[(CH_3)_3SnOH]_2\cdot(CH_3)_3SnBr$ IN NAPHTHALENE

Naphthalene, g.	Compd., g.	At	Mol. wt.
23.38	0.3515	0.408	262
26.16	.2358	.254	252

The formula weight of the dihydroxy bromide is 605.3, while that of the corresponding mixture of trimethyl tin hydroxide and trimethyl tin bromide is 201.6. The value obtained for the mean molecular weight in naphthalene shows that the compound is largely dissociated into its constituents in that solvent.

Conductance of Mixtures of $(CH_3)_3SnBr$ and $(CH_3)_3SnOH$ in Solution.—It was thought that a study of the conductance of the dihydroxy bromide and of various mixtures with trimethyl tin bromide in non-aqueous solvents might yield some information as to the existence of a complex compound and its properties. Accordingly, the conductance of such mixtures was studied in absolute alcohol and in acetone. The conductance was measured in suitable cells by the usual Kohlrausch method and with the usual precautions. No claims are made for exceptional precision, since the object of these experiments was to get the general order of magnitude and the course of the conductance curve as a function of the composition of the solution.

Absolute Alcohol.—The conductance of a solution of the dihydroxy bromide was compared with that of an equivalent mixture of its constituents in absolute alcohol. The specific conductance of the alcohol was 0.5 × 10^{-6}. All measurements were carried out at 25°. The results are given in Table II, concentrations being expressed in moles per liter and the specific conductance L in reciprocal ohms.

TABLE II

CONDUCTANCE OF $[(CH_3)_3SnOH]_2 \cdot (CH_3)_3SnBr$ AND OF MIXTURES OF $(CH_3)_3SnOH$ AND $(CH_3)_3SnBr$ IN ABSOLUTE ALCOHOL AT 25°

$(CH_3)_3SnOH$	$(CH_3)_3SnBr$	$[(CH_3)_3SnOH]_2$ $(CH_3)_3SnBr$	L × 10^4
0.03314	0.0	0.0	0.03
.02601	.01657	.0	.87
.03314	.01657	.0	.96
.0	.01657	.0	.54
.0	.0	.01657	.95

As may be seen from the table, a solution of the compound at a concentration of 0.0166 mole per liter has a specific conductance of 0.95 × 10^{-4}, which is substantially identical with that of an equivalent mixture of its constituents. It follows that, when solutions of trimethyl tin hydroxide and bromide are mixed, reaction takes place immediately with the formation of a complex compound. It will be noted that the conductance of the pure hydroxide, at a concentration equivalent to that of hydroxide in a solution of the compound, was only 0.03 × 10^{-4}, while that of a corresponding solution of trimethyl tin bromide was 0.54 × 10^{-4}. In other words, in ethyl alcohol solution, the conductance of the compound is nearly twice as great as the sum of that of its constituents taken separately in the same solvent. The molecular conductance of the compound at a concentration of 0.0166 molar is approximately 5.8.

Acetone.—As Kraus and Callis[7] have shown, the alcohols, or other hydroxy compounds, react with trimethyl tin bromide to form a complex cation which is fairly electropositive and the solutions of which are therefore markedly ionized. It was to be expected, therefore, that, in other types of solvents, the relative conductance of the dihydroxy bromide and of trimethyl tin bromide would differ greatly from that found in alcohol.

The conductance of the dihydroxy bromide was compared with that of various mixtures of the hydroxide and the bromide in acetone at 25°. The specific conductance of the acetone used was 1.2 × 10^{-6}. A solution containing 0.01657 mole of dihydroxy bromide per liter had a specific conductance of 101 × 10^{-6}, while a solution of trimethyl tin bromide at the same concentration had a conductance of only 2.06 × 10^{-6}. The conductance of a solution of the hydroxide of equivalent concentration (0.033 N) was not determined but a 0.1 N solution of the hydroxide was found to have a specific conductance of 5.02 × 10^{-6}. It is evident that

---

[7] Kraus and Callis, THIS JOURNAL, 45, 2624 (1923).

the dihydroxy bromide is a much better conductor than either of the constituents at corresponding concentrations. It is noteworthy that, in acetone, trimethyl tin hydroxide is a slightly better conductor than is the corresponding bromide.

A 0.1 *N* solution of trimethyl tin bromide in acetone was made up and varying amounts of hydroxide were added. The specific conductance of these solutions was measured in the usual way. The values are tabulated below.

TABLE III

CONDUCTANCE OF 0.1 *N* $(CH_3)_3SnBr$ IN ACETONE IN THE PRESENCE OF $(CH_3)_3SnOH$

Concn. $(CH_3)_3SnOH$	0.00	0.01	0.02	0.03	0.04	0.05	0.06
Ratio of hydroxide to bromide	0.0	0.1	0.2	0.3	0.4	0.5	0.6
Sp. cond. $\times 10^4$	0.0345	1.13	2.06	2.93	3.73	4.45	5.19
Concn. $(CH_3)_3SnOH$	0.07	0.08	0.09	0.10	0.15	0.20	
Ratio of hydroxide to bromide	0.7	0.8	0.9	1.0	1.5	2.0	
Sp. cond. $\times 10^4$	5.85	6.37	6.88	7.37	9.36	10.73	

As may be seen from the table, on adding trimethyl tin hydroxide to a solution of trimethyl tin bromide in acetone, the conductance is greatly increased. For an addition of one-tenth mole of the hydroxide per mole of bromide, the conductance is increased approximately 30 times, while for an addition of 2 moles it is increased 300 times. It may be pointed out that the final solution, containing 2 moles of hydroxide per mole of bromide, had a molecular conductance of 10.7. This value approaches that of some salts.

A second series of measurements was carried out with solutions containing 0.0166 mole of trimethyl tin bromide and varying amounts of trimethyl tin hydroxide from 0.0 to 0.0833 N. In other words, the ratio of hydroxide to bromide varied from 0.0 to 5.0. The specific conductance of the solutions was corrected for the conductance of the solvent and was approximately corrected for the conductance of excess trimethyl tin bromide, it being assumed that two molecules of hydroxide combine with one molecule of bromide. The results, including the corrections, are given in Table IV.

TABLE IV

CONDUCTANCE OF 0.0166 N $(CH_3)_3SnBr$ IN ACETONE AT 25° IN THE PRESENCE OF $(CH_3)_3SnOH$

Corr. sp. cond. $\times 10^6$	0.0	9.5	18.5	25.8	33.9	39.6	46.2	50.1
Ratio of hydroxide to bromide	0.8	0.9	1.0	1.5	2.0	3.0	5.0	
Corr. applied $L \times 10^6$	1.72	1.67	1.63	1.41	1.2	1.2	1.2	
Corr. sp. cond. $\times 10^6$	56.8	60.6	66.8	88.1	105	131.0	174.0	

The original solution of trimethyl tin bromide had a conductance of 2.07×10^{-6}. On adding only 0.1 mole of hydroxide per mole of bromide, the conductance was raised to 11.8×10^{-6}. The correction due to the conductance of the solvent and to excess bromide was 2.03×10^{-6}, leaving a conductance of 9.5×10^{-6} due to the compound formed between the hydroxide and the bromide. On further addition of the hydroxide, the specific conductance increased, although the rate of increase fell off with increase of total hydroxide added. It may be noted, however, that, on increasing the trimethyl tin hydroxide from two to five moles per mole of bromide, the specific conductance increased from 105×10^{-6} to 174×10^{-6}, or approximately 70%. This indicates that, while a complex electrolyte is formed between the hydroxide and the bromide, it is considerably dissociated in solution. The extent of this dissociation, however, is probably much lower in acetone or in alcohol than it is in naphthalene, as is indicated by the molecular weight in the latter solvent.

The constitution of the complex cation of the dihydroxy bromide cannot be inferred with any degree of certainty from available data. Considering the behavior of trimethyl tin bromide in hydroxy and amino solvents, one might be inclined to ascribe a formula of the oxonium type to the complex cation. Since two molecules of hydroxide are present in the compound, it would then be necessary to consider, either that two oxygen atoms are linked together or that a much more complex structure is involved. For the present, the precise structure of this complex cation must be left open.

The Ditrimethyl Tin Hydroxy Hydroxide, $[(CH_3)_3SnOH]_2 \cdot (CH_3)_3SnOH$.—The experiments described above indicate the existence of a complex cation corresponding to the formula $\{[(CH_3)_3SnOH]_2 \cdot (CH_3)_3Sn)^+$. If such a complex cation exists, we should expect that, on treating the corresponding bromide with silver oxide in aqueous solution, the hydroxide of this ion would be formed. This hydroxide would be isomeric with trimethyl tin hydroxide. In order to determine whether a complex hydroxide is formed under these conditions, the conductance of equivalent solutions of the two hydroxides was compared.

A 0.1 N solution of the complex hydroxide was prepared by treating the corresponding bromide with freshly precipitated silver oxide until the solution gave no test for bromine. The solution was kept in the neighborhood of 0° throughout its preparation. After allowing the precipitated silver bromide to settle, the supernatant solution was siphoned into a cell in which its conductance was measured. If trimethyl tin hydroxide is formed in the above preparation, it would have a concentration of 0.3 N. The specific conductance of a 0.3 N solution of trimethyl tin hydroxide in water at 0 and 25° was found to be 0.890×10^{-4} and 2.03×10^{-4}, respectively, The specific conductance $L \times 10^4$, of the solution of the complex hydroxide, as measured at different times and temperatures, is given in Table V.

TABLE V

CONDUCTANCE OF 0.1 N $(CH_3)_3SnOH_2(CH_3)_3SnOH$ IN WATER

Temp., °C.....	**0**	**0**	**25**	**25**	**29**	**26**	**25**	**25**	**25.05**
Time, hours...	**0**	**12**	**0**	**12**	**24**	**48**	**60**	**72**	**120**
$L \times 10^4$.......	**0.256**	**0.453**	**0.565**	**0.923**	**1.710**	**2.048**	**1.978**	**1.984**	**2.040**

As may be seen from the table, the conductance of the freshly prepared solution of the complex hydroxide is approximately one-fourth that of trimethyl tin hydroxide at the same temperature. Thus, the specific conductance of the freshly prepared solution at 25° was 0.56×10^{-4}, while that of the trimethyl tin hydroxide was 2.03×10^{-4}. The complex hydroxide is not stable. It gradually goes over to trimethyl tin hydroxide, the reaction rate being greatly influenced by the temperature; but even at 0°, the specific conductance increased from 0.26×10^{-4} to 0.45×10^{-4} in a period of twelve hours. Nevertheless, even at 25°, the conversion of the complex hydroxide is not complete until at the end of nearly one hundred hours. At the end of 120 hours, the specific conductance was found to be 2.04×10^{-4} at 25°, while that of a 0.3 N solution of trimethyl tin hydroxide was found to be 2.03×10^{-4}.

The above results show that two moles of trimethyl tin hydroxide combine with one mole of trimethyl tin bromide to form a complex electrolyte in which the bromine is largely ionized. The bromide ion may be replaced by hydroxyl, by treating with silver oxide. The resulting base is a comparatively weak electrolyte, its ionization being about the same as that of trimethyl tin hydroxide at the same molal concentration. It is gradually converted to the normal hydroxide on standing.

Reaction between Trimethyl Tin Hydroxide and Methyl Iodide.—Harada has found evidence that a compound is formed when trimethyl tin hydroxide is treated with methyl iodide in acetone solution.[8]

In order to test this point further, a solution was made up containing 0.1 mole of trimethyl tin hydroxide per liter, and to this was added 0.05 mole of methyl iodide. The conductance of this solution was measured at 25°. The specific conductance of the pure acetone was 1.2×10^{-6} while that of a 0.1 *N* solution of methyl iodide was 1.4×10^{-6} and of the hydroxide, at the same concentration, 5.2×10^{-6}.

Immediately on adding methyl iodide to the solution of trimethyl tin hydroxide, the conductance began to increase and this continued over a considerable period of time. The results are given in Table VI.

The initial values of the conductance rose very rapidly with time. The addition of a large excess of methyl iodide at the end of sixteen hours

[8] Harada, Thesis, Clark University, 1923.

TABLE VI

CONDUCTANCE OF MIXTURES OF $(CH_3)_3SnOH$ AND CH_3I IN ACETONE

Time, hours	0	0.43	1.0	4.5	13.0	16.0	16.6
$L \times 10^4$	0.184	0.402	0.513	0.987	1.77	2.05	1.86
Time, hours	18.0	20.0	25.8	42.7	49.0	67.0	85.7
$L \times 10^4$	2.51	3.43	4.59	5.42	5.76	6.10	63.1

[a] At this point a large excess of CH_3I was added.

resulted in a marked increase in the rate of reaction, as may be seen from the table. The sum of the conductance due to the components was approximately 0.078×10^{-4}, as against 0.184×10^{-4} for the mixture as initially measured. As time went on, however, the conductance rose. At the end of sixteen hours the specific conductance of the solution had a value approximately twenty-six times that calculated for a mixture of the constituents. At that point, a large excess of methyl iodide was added in order to accelerate the reaction. At the end of eighty-six hours, the solution had reached practically a constant value of 6.31×10^{-4}. Assuming a compound to be formed of the type $[(CH_3)_3SnOH]_2 \cdot CH_3I$, the equivalent conductance of the final solution had a value of 12.6. This value is greater than that of many salts, for example, lithium chloride,[9] lithium nitrate or silver nitrate.[10]

Summary

A convenient method is described for the preparation of the complex dihydroxy bromide, $[(CH_3)_3SnOH]_2 \cdot (CH_3)_3SnBr$. The molecular weight of this compound in naphthalene indicates that it is largely dissociated into its constituents in that solvent.

When the dihydroxy bromide is reduced with sodium in liquid ammonia, some hydrogen is evolved but not enough to correspond to one mole of water in the compound.

Ammino trimethyl tin bromide is precipitated from solutions of the compound in organic solvents. However, the compound is not greatly altered on solution in liquid ammonia.

At higher temperatures the compound is dissociated into its constituents which sublime and recombine. A small proportion of trimethyl tin hydroxide breaks down to dimethyl tin oxide, tetramethyl tin and water under these conditions.

The electrical conductance of the compound in alcohol is approximately twice that of its constituents in the same solvent taken separately.

The conductance of the compound in acetone is much greater than that of its constituents in the same solvent. The conductance of trimethyl tin bromide, on addition of 0.1 mole of hydroxide per mole of

[9] Sêrkov, J. *Russ. Phys.-Chem. Soc.*, *41*, 9 (1909).

[10] Roshdestwensky and Lewis, J. *Chem. Soc.*, *80*, 2140 (1911).

bromide, is increased thirty times and on addition of two moles, 300 times. On further addition of hydroxide the conductance is further increased, indicating appreciable dissociation of the complex compound in acetone.

On treating the dihydroxy bromide with silver oxide in an aqueous solution, the corresponding hydroxy derivative is obtained. The conductance of the solution clearly indicates that this complex hydroxide has considerable stability. It goes over gradually to trimethyl tin hydroxide, with which it is isomeric.

Trimethyl tin hydroxide forms a complex compound with methyl iodide in acetone. This compound is formed gradually and its solutions are relatively highly ionized. At a concentration of 0.1 N, the equivalent conductance has a value of the order of that of such salts as lithium nitrate and silver nitrate.

THE MECHANISM OF CARBOHYDRATE OXIDATION. XIII. THE ACTION OF POTASSIUM HYDROXIDE ON CALCIUM HEXOSEDIPHOSPHATE. A COMPARISON WITH THAT OF GLUCOSE AND FRUCTOSE[1]

BY WILLIAM LLOYD EVANS AND ROBERT CASAD HOCKETT[2]

RECEIVED JULY 12, 1930 PUBLISHED OCTOBER 6, 1930

The rates of fermentation of glucose, mannose and fructose are almost the same and the products of these reactions are identical.[3] These facts suggested a fermentation mechanism involving the formation of common intermediates—a condition which seemed easily satisfied on the assumption that these substances were the enediols of the hexoses, especially since no other hexose can yield the same enediols as these, and no other is fermented at a comparable rate. This point of view seemed strengthened through Young's discovery that the same hexosediphosphoric acid[4] ($C_6H_{10}O_4(PO_2(OH)_2)_2$) is formed from each of these three sugars as an intermediate in fermentation as evidenced by the identity, regardless of its source, of all its properties, including optical rotation. Furthermore, this acid has little reducing power except on hydrolysis, and it does not form an osazone without hydrolysis of a phosphate group.

Schlubach and Rauchenberger[5] have recently methylated this common hexosediphosphoric acid and found that only seven methyl groups were

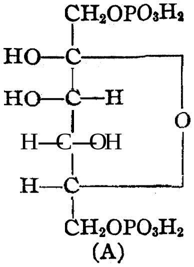
introduced into the molecule. If this acid were the derivative of an enediol, eight methyl groups should have been present in the resulting compound. The recently proposed structure (A) for this acid[6] easily satisfies the experimental data with reference to the formation of the tetramethyl ester of trimethylhexose-diphosphoric acid.



(A)

By reason of the results obtained in this Laboratory with reference to the action of glucose,[7a] fructose[7b] and mannose[7c] in aqueous solutions of potassium hydroxide, it became of much interest to know the behavior of calcium hexosediphosphate, commercially known as "candiolin," when it was subjected to the same experimental conditions as the three well-known hexose sugars. Especially were we anxious to obtain the experimental data with reference to lactic acid formation. These brief statements summarize our principal objectives in this work.

Experimental Part

Reagents.—The potassium hydroxide, zinc carbonate, phosphoric acid and ether used were of the same degree of purity as the reagents employed with glyceric aldehydes and dihydroxy-acetone.9 The glucose and fructose were Pfanstiehl's c. p. special anhydrous brand with specific rotations recorded, respectively, as +52.5° and −91.66". The calcium hexosediphosphate was presented by the H. A. Metz Laboratories, and was purified before use by the method of Neuberg and Sabatay.[10]

Anal. Subs., 0.900: $Ca_3(PO_4)_2$ by ignition, 0.0411. Calcd. $Ca_3(PO_4)_2$: 45.73. Found: 45.66.

Procedure.—The experimental details were practically the same as in the case of glyceric aldehyde. Glucose and fructose samples of 2.25 g. were used and candiolin samples of 2.827 g. corresponding to 1.125 g. of hexose. The object was to conserve the difficultly prepared material. The three substances were treated as nearly alike as possible.

Products of the Reaction.—The reactions were all carried out at an alkali normality of five and at a temperature of 50°, with time as the variable. Qualitative examination was made for hydroxy acids, acetol, pyruvic acid, formic acid, acetic acid and lactic acid. Quantitative determinations were carried out for the last three named which were the only substances detected.

Data.—The quantitative data are shown in Fig. 1.

Theoretical Discussion and Summary

1. It was found that the yield of lactic acid from glucose in 5 N potassium hydroxide solutions at 50° rises rapidly to a maximum in about

twenty-four hours and then remains constant up to at least five hundred and twenty-eight hours. The yields of formic and acetic acids are very low and remain constant over the same range of alkalinity. With fructose the yield of all three acids is greater in amount and constant, at least up to **374** hours. The maximum is reached more rapidly, however, so that in two hours a high yield of lactic acid was obtained. This behavior of fructose seems to be in harmony with the observation that this ketohexose is much more sensitive to some chemical reagents than either glucose or mannose.

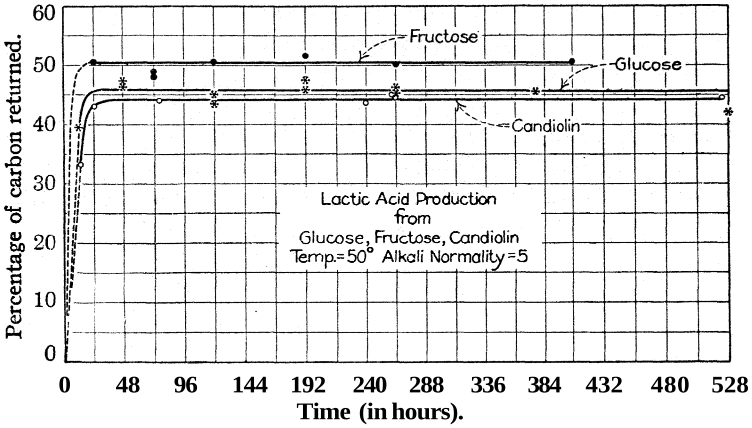

Fig. 1.

2. Candiolin shows a striking similarity in behavior to fructose and glucose. The maximum yield of lactic acid is a little more slowly attained and remains lower than with either of the other compounds, while acetic acid is obtained in larger quantity. It is clear that the rate of hydrolysis of the calcium salt in alkaline solution becomes an important factor in determining the concentration of the resulting hexose. It has been recently pointed out by Shaffer and Friedmann[11] that the yields of products obtained by the action of alkalies on the hexoses are dependent in part on the concentration of the sugar undergoing decomposition. The average yields after attaining a constant production are as follows

	Glucose, %	Fructose. %	Candiolin, %
Lactic	45.55	50.27	44.11
Acetic	0.85	1.52	2.31
Formic	0.47	0 63	0.20
Total	46.87	52.42	46.62

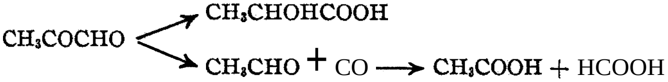
3. From these data and those compared in the diagram, it is clear that the mechanism involved in the formation of lactic, acetic and formic acids in alkaline systems of candiolin is best understood on the basis that

---

[11] Shaffer and Friedmann, J. *Biol.* Cham., 86, 361 (1930).

the calcium salt undergoes hydrolysis, thus liberating the keto-hexose, fructose. This sugar is then acted upon by the potassium hydroxide present, thus giving rise both to the sugars formed in the de Bruyn and van Ekenstein[12] interconversion and also to the enediols postulated by Nef.[13] It has been repeatedly pointed out in these studies that lactic acid arises from the hexose-3,4-enediols.

4. It has previously been considered[7"] that acetic and lactic acids, and also a portion of the formic acid obtained in the alkaline decomposition of the sugars are derived from pyruvic aldehyde by a series of reactions which are represented by the equations



$$CH_3COCHO \rightarrow CH_3CHOHCOOH$$
$$CH_3COCHO \rightarrow CH_3CHO + CO \longrightarrow CH_3COOH + HCOOH$$

Formic acid may also be derived from hydroxymethylene formed from the cleavage of hexose-1,2-enediol. From the figures given in paragraph 2, it is seen that the ratios of the yields of acetic and formic acids from glucose and fructose tend to approximate the stoichiometrical relations indicated in the above chemical equations. In the case of candiolin, however, the figures show that the acetic acid is proportionally too great for this equation. Furthermore, it should be pointed out that pyruvic aldehyde osazone has never been obtained in any notable quantity from either glucose, fructose or mannose in 5 N potassium hydroxide solution~.~'At this alkalinity the pyruvic aldehyde intermediate is completely converted into lactic acid. From these facts it follows that an independent source of acetic acid must be postulated. The junior author[14] proposes the following mechanism which is strictly analogous to that suggested by Evans and Benoy[7a] for the formation of lactic acid from glyceric aldehyde.

[14] (a) R. C. Hockett, Master's Thesis, The Ohio State University, 1928. Note the analogy between the rearrangement of acetylene oxide into ketene and the well-known rearrangement of ethylene oxide into acetaldehyde. (b) Mr. P. G. Hoff, Doctor's Dissertation, The Ohio State University, 1926, made a similar proposal for the presence of acetic acid in the alkaline decomposition of galactose in which he assumed that glycol aldehyde, through the loss of water, would give rise to ketene, $CH_2=C=O$ as an intermediate, a compound which is known to add water with the formation of acetic acid. This proposal is included as a possibility in the above equations.

The presence of glycol aldehyde is due to the cleavage of the hexose-2,3-enediol or that of a triose-1,2-enediol. It is also conceivable that the formic acid in these reactions may arise from the cleavage of the ethene diol molecule into two molecules of hydroxymethylene.

THE DISSOCIATION PRESSURES OF CERTAIN METAL PYRIDINE THIOCYANATES

BY TENNEY L. DAVIS AND HOWARD R. BATCHELDER

RECEIVED JULY 15, 1930 PUBLISHED OCTOBER 6, 1930

The determination of the dissociation pressures of the compounds of pyridine with metal thiocyanates is part of an investigation of the affinities by which pyridine and similar nitrogen bases are linked in their complex compounds. Of two compounds, such as nickelous tetrapyridine thiocyanate and cobaltous tetrapyridine thiocyanate, for example, which have the same molecular constitution and differ only in the metal which they contain, the one which has the lower dissociation pressure of pyridine is evidently the one in which the pyridine is attached more firmly to the metal. Since the pyridine is supposed to be attached to the coordination valence of the metal, it is to be expected that the order of the metals with reference to their affinity for pyridine will be the same in the series of the salts of one acid as in the series of the salts of another. By comparison, also, of the dissociation pressures of the corresponding pyridine derivatives of different salts of the same metal, it is possible to estimate the effect of the acid radical—for one acid will occupy more or less of the affinity of the metal than another acid and will leave less or more of the affinity available for combination through the coordination valences.

We have worked with cobaltous, cupric, nickelous and zinc pyridine thiocyanates. The compounds were prepared and purified by the methods which had been used earlier for the chloroform-soluble metal pyridine cyanates.[1] Dissociation pressures were measured by starting with a mixture of pyridine with the most highly pyridinated compound of the metal thiocyanate, evacuating the space above it and allowing to come to equilibrium, noting the pressure, then pumping off a small amount of pyridine, again allowing to come to equilibrium and again noting the pressure, and so on, until the pyridine was completely removed from the substance. Thus we were able to be certain that none of the intermediate pyridine complexes escaped us, and that the dissociation pressures of all of the compounds, from that which existed in the presence of an excess

---

[1] Davis and Logan, THIS JOURNAL, 50, 2493 (1928).

of pyridine to that which existed in the presence of the non-pyridinated metal thiocyanate, were actually observed.

Cobaltous thiocyanate forms compounds only with two and with four molecules of pyridine, while cobaltous cyanate forms compounds with two, with four and with six molecules—a fact which suggests that the affinity of pyridine for the metal in the thiocyanate series is probably less than in the cyanate series. Studies on the dissociation pressures of the metal pyridine cyanates which are now going on in this Laboratory will throw further light upon the matter.

Description of the Compounds

Cobaltous tetrapyridine thiocyanate[2] separates from chloroform in pink crystals which are moderately soluble in chloroform and more readily soluble in a mixture of chloroform and pyridine. Its solutions in organic solvents undergo the same color changes under the same conditions as solutions of cobaltous hexapyridine cyanate. After a week of exposure to the open air, it is converted entirely into deep blue cobaltous dipyridine thiocyanate.

Cupric dipyridine thiocyanate[3] is a green powder, less soluble in chloroform than the cobalt compound and more readily soluble in chloroform if an excess of pyridine is present. It loses pyridine to form the monopyridine compound, not previously reported, somewhat paler green in color and somewhat less soluble in chloroform than the dipyridine compound. When warmed in a vacuum, it yields black cupric thiocyanate.

Nickelous tetrapyridine thiocyanate[4] crystallizes from chloroform containing an excess of pyridine in blue crystals which resemble crystals of hydrated copper sulfate. When the chloroform solution is distilled or when the crystals are exposed to the air, the substance is converted into a pale blue powder of nickelous dipyridine thiocyanate,[5] sparingly soluble in chloroform. When the tetrapyridine compound is moistened with pyridine, or exposed for a long time to an atmosphere saturated with pyridine, it yields blue-violet crystals of a substance, not heretofore reported, which contains seven molecules of pyridine, possibly nickelous tetrapyridine thiocyanate with three molecules of pyridine of crystallization. The dissociation pressure curve of this substance is parallel to and only slightly lower than the vapor pressure curve of pure pyridine, and is of markedly different slope from those of the other nickelous thiocyanate pyridine complexes.

Zinc tetrapyridine thiocyanate[6] crystallizes in fine white needles from chloroform and pyridine mixture, in which it is moderately soluble. When moistened with pyridine and allowed to stand, it forms a cake of crystals from which the pyridine is removed with difficulty.

TABLE I

ANALYSES

Substance	Metal, %	
	Calcd	Found
Cobaltous monopyridine thiocyanate	23.30	. . .
Cobaltous dipyridine thiocyanate	17.70	17.32, 17.71
Cobaltous tripyridine thiocyanate	14.31	. . .
Cobaltous tetrapyridine thiocyanate	12.00	11.97, 11.92
Cobaltous pentapyridine thiocyanate	10.34	. . .
Cupric monopyridine thiocyanate	24.58	24.92, 25.02
Cupric dipyridine thiocyanate	18.83	18.80
Cupric tripyridine thiocyanate	15.26	. . .
Nickelous monopyridine thiocyanate	23.10	. . .
Nickelous dipyridine thiocyanate	17.62	17.51, 17.35
Nickelous tripyridine thiocyanate	14.24	. . .
Nickelous tetrapyridine thiocyanate	11.95	12.14, 12.04
Nickelous pentapyridine thiocyanate	10.29	. . .
Nickelous hexapyridine thiocyanate	9.04	. . .
Nickelous heptapyridine thiocyanate	8.06	8.46, 8.27
Nickelous octapyridine thiocyanate	7.27	
Zinc tripyridine thiocyanate	15.60	. . .
Zinc tetrapyridine thiocyanate	13.13	13.61, 13.63
Zinc pentapyridine thiocyanate	11.33	

The substances were analyzed for metal—cobalt, nickel and zinc being determined as sulfate, copper as oxide. Results are shown in Table I, where the calculated values for the substances containing one more and one less molecule of pyridine than the found substances are included for comparison.

Measurement of Dissociation Pressures

The apparatus consisted of an ordinary closed-arm manometer mounted on a transparent millimeter scale and sealed to a side-arm, parallel to the arm of the U of the manometer, to the lower extremity of which a 50-cc. Erlenmeyer flask containing a few grams of the substance to be studied had been sealed. As near as practicable beyond this side-arm a tube carrying a glass stopcock was sealed on and inclined upward in such a manner that the Erlenmeyer flask and manometer and side-arm could be immersed completely in the bath while the stopcock remained above the cover of the bath. The apparatus was set up in a 4-liter beaker filled with distilled water, fitted with a tin cover and an electric stirrer, and having an electric light mounted behind it to illuminate the scale. The cover served to prevent excessive evaporation and provided a support from which to suspend the apparatus and the thermometer. Heat was supplied by a micro-burner and, with adequate protection from drafts, it was easy to maintain the temperature constant for several hours within a tenth of a degree. In preliminary ex-

---

[6] Grossmann and Hünseler, *Z. anorg. Chem.*, 46, 361 (1905).

periments in which the manometer was outside of the bath, it was found that pyridine distilled into the manometer and that the observed pressure was the vapor pressure of pyridine. The above-described simple apparatus was found to avoid the difficulty. A tube containing phosphorus pentoxide for the absorption of pyridine was inserted between the stopcock and the pump, for it was found that the pyridine, by dissolving in the oil of the pump, otherwise reduced the pump's efficiency.

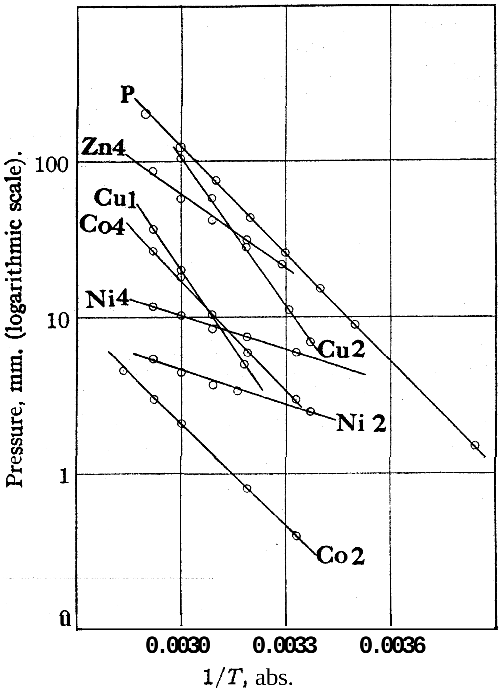

Fig. 1.—Dissociation pressures of metal pyridine thiocyanates. P, pyridine (vapor pressure); Co 4, cobaltous tetrapyridine thiocyanate; Co 2, dipyridine; Cu 2, cupric dipyridine; Cu 1, monopyridine; Ni 4, nickelous tetrapyridine; Ni 2, dipyridine; Zn 4, zinc tetrapyridine.

After the apparatus was assembled, the flask containing the substance having been sealed on, a cubic centimeter or more of pyridine was introduced through the stopcock by means of a capillary dropper, for the purpose of providing enough pyridine to displace all of the air in the system and to insure the presence of the most highly pyridinated compound. The bath was then brought to the desired temperature, the apparatus evacuated, the stopcock closed and readings were taken at intervals until it was apparent that equilibrium had been attained. In each series of experiments, the complete removal of air was confirmed and the accuracy of the apparatus was checked by comparison of the equilibrium pressure when some pyridine was in the flask with the reported vapor pressure of pyridine at that temperature. The pump was then again operated for a short time and a second equilibrium attained checking the first. After this the pump was operated for a longer time, removing pyridine, until it was evident either from a color change or from a sudden decrease in pressure that a change in the substance was taking place. The stopcock was then closed, readings taken as before, and the system again pumped out enough to displace the equilibrium, and so on, until the equilibrium pressure after two successive pumpings was the same. The system was then brought to equilibrium at a different temperature or it was evacuated until the compound of next lower pyridine content began to decompose, and the process was repeated. Observed pressures were corrected to 20° to take account of the expansion of the mercury and glass of the manometer.

The results are conveniently summarized by the chart, Fig. 1, in which the logarithm of the pressure is plotted against the reciprocal of the absolute temperature.

The curves for the dissociation pressures of cobaltous tetra- and dipyridine thiocyanates are practically parallel to each other and to the curve for the vapor pressure of pyridine, which indicates that the affinities of cobaltous dipyridine thiocyanate and of cobaltous thiocyanate for pyridine are practically constant over the temperature range of our observations.

The curves of the cupric compounds approach the pyridine curve at the higher temperatures—and the affinities of cupric thiocyanate and of cupric monopyridine thiocyanate for pyridine decrease with increasing temperature. The curve of cupric dipyridine thiocyanate intersects the pyridine curve at about 70°, at which point the dissociation pressure of the complex and the vapor pressure of pyridine are both equal to 170 mm. Above this temperature the dipyridine compound decomposes spontaneously into cupric monopyridine thiocyanate and pyridine.

The nickelous compounds, on the other hand, show increased affinities for pyridine at the higher temperatures. The curve of nickelous tetrapyridine thiocyanate intersects the pyridine curve at about −3°, and the substance spontaneously decomposes below that temperature. We find that the higher pyridinated compound, when cooled in a freezing mixture, does in fact decompose to produce the lower pyridinated one, but have not been able to measure the vapor pressure at the low temperature.

The affinity of zinc thiocyanate for pyridine decreases with decreasing temperature and disappears at about 20°. A sample of zinc tetrapyridine thiocyanate cooled to −13° showed a pressure of 1.5 mm., which corresponds very closely to the vapor pressure of pyridine at that temperature.

We are not acquainted with any other complex salts which show the remarkable property, exhibited by the nickelous and zinc pyridine thiocyanates, of decomposing when they are cooled.

Reading from the chart, Fig. 1, we get the values for the dissociation pressures at the even temperatures which are shown in Table II.

Table II

Dissociation Pressures (My. of Mercury at 20°)

Temp., °C..........	20	30	40	50	60	70	80
$Co(NCS)_2 \cdot 4Py$	1.9	3.4	6.0	10.6	18.0	27.0	44.0
$Co(NCS)_2 \cdot 2Py$	...	0.5	0.8	1.3	2.1	3.0	4.7
$Cu(NCS)_2 \cdot 2Py$	5.1	12.0	27.0	58.0	106.0	..	..
$Cu(NCS)_2 \cdot Py$	...	3.4	5.0	10.1	20.0	36.0	..
$Ni(NCS)_2 \cdot 4Py$	5.0	6.1	7.5	9.8	10.5	12.0	..
$Ni(NCS)_2 \cdot 2Py$	2.3	2.7	3.3	3.9	4.6	5.2	..
$Zn(NCS)_2 \cdot 4Py$	...	21.5	31.0	42.0	57.0	100.0	..

Summary

The dissociation pressures of cobaltous tetra-and dipyridine thiocyanates, of cupric di- and monopyridine thiocyanates, of nickelous tetra- and dipyridine thiocyanates, and of zinc tetrapyridine thiocyanate have been measured at temperatures between 20 and 80°.

The affinity which holds the pyridine in the cobaltous compounds is practically constant over the temperature range 20 to 80°. In the cupric compounds it decreases at the higher temperatures, while in the nickelous and zinc compounds it decreases at the lower temperatures.

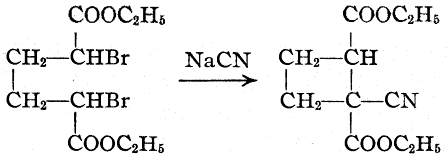
RING CLOSURES IN THE CYCLOBUTANE SERIES. II. CYCLIZATION OF α,α'-DIBROMO-ADIPIC ESTERS

BY REYNOLD C. FUSON, OSCAR R. KREIMEIER AND GILBERT L. NIMMO

RECEIVED JULY 17, 1930 PUBLISHED OCTOBER 6, 1930

A new method of effecting the closure of the cyclobutane ring has been reported by Fuson and Kao,[1] who obtained diethyl 1-cyanocyclobutane-1,2-dicarboxylate (I) from diethyl α,α'-dibromo-adipate by treatment with sodium cyanide in absolute alcohol.



I

The method has now been tried with other esters of α,α'-dibromo-adipic acid and of β-methyl-α,α'-dibromo-adipic acid The present article is a report of these experiments.

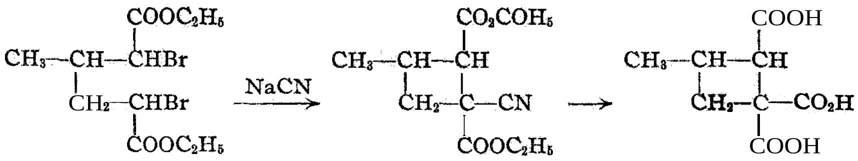
Since the weight of substituents is known to influence the ease of ring closure, attempts have been made to extend the closure method to α,α'-dibromo-adipic esters in which the alkyl groups were large. For this purpose diphenyl α,α'-dibromo-adipate and di-β-naphthyl α,α'-dibromo-adipate were prepared. The diphenyl ester was prepared from α,α'-dibromo-adipyl chloride by treatment with sodium phenoxide. A somewhat better yield was obtained by heating the acid chloride with phenol. The dinaphthyl ester was prepared by heating α,α'-dibromo-adipyl chloride with β-naphthol.

As was to be expected, these esters could not be studied in ethyl alcohol solutions because of rapid ester interchange. Attempts to replace the absolute alcohol by acetone, ethers, acetonitrile and other solvents led to negative results. Attempts to use other metal cyanides in these solvents were likewise fruitless.

The influence of substituents in the adipic acid chain was then examined. Diethyl α,α'-dibromo-β-methyl adipate (II) was heated for twenty-four hours with powdered sodium cyanide in absolute alcohol.

---

[1] Fuson and Kao, THIS JOURNAL, 51, 1536 (1929).



II III IV

The expected cyano ester (III) was obtained in a yield of 62% of the theoretical. The yield is not quite as high as those obtained with diethyl α,α'-dibromo-adipate (70 to 80%). The position of the cyano group in III has not been determined. The compound is a colorless oil which does not decolorize bromine water or dilute alkaline permanganate solution.

Treatment with a solution of barium hydroxide converted the cyano ester into the methylcyclobutane tricarboxylic acid, IV, which was isolated in the form of the barium salt. Here, of course, the structure was indefinite with respect to one of the carboxyl groups.

Experimental Part

Diphenyl **α,α'-Dibromo-adipate** (from Phenol).—One hundred and forty-six g. (1 mole) of adipic acid was placed in a I-liter flask equipped with a return condenser and 288 g. (2.4 moles) of thionyl chloride was poured in at once. The mixture was warmed gently (50 to 60°) on a water-bath until solution was complete and the evolution of hydrogen chloride had practically ceased. The excess thionyl chloride was then removed by distillation under diminished pressure. The crude adipyl chloride was brominated by adding 367.5 g. (2.3 moles) of dry bromine and 10 g. of phosphorus tribromide and heating at 50 to 60° for thirty-six to forty-eight hours under a strong light.

To the crude α,α'-dibromo-adipyl chloride was added 188 g. (2 moles) of phenol. The mixture was maintained at a temperature of 50 to 60° for twenty-four hours. To the reaction mixture was then added 500 cc. of benzene; the solution obtained by heating this mixture was cooled and the ester separated in crystalline form. Treatment with charcoal removed the dark color from the benzene solution and the ester was obtained after one additional recrystallization from benzene as colorless crystals melting at 146–148". The yield was 83 g. or 18.4% of the theoretical.

Anal. Calcd. for $C_{18}H_{16}O_4Br_2$: Br, 35.1. Found: Br, 34.7.

Diphenyl **α,α'-Dibromo-adipate** (from Sodium Phenoxide).—The ester was made also by treating one mole of the crude α,α'-dibromo-adipyl chloride with 232 g. (2 moles) of sodium phenoxide. The chloride was placed in an ice-bath and the sodium phenoxide was added gradually in small portions. Small amounts of benzene (200 cc. in all) were added from time to time and the reactants were thoroughly mixed by shaking. The ester was removed by extracting the solid mass with 800 cc. of boiling benzene. By concentration of the benzene extracts, 31.5 g. of the ester was obtained in nearly pure form. This corresponds to a yield of 7% of the theoretical.

Di-β-naphthyl α,α'-Dibromo-adipate.—To the dibromo-adipyl chloride obtained from one-half mole of adipic acid was added in portions one mole of β-naphthol. The mixture was stirred vigorously during the addition and after being dissolved in 200 to 300 cc. of benzene was allowed to stand. The crude ester which separated after several hours was recrystallized from acetone. It melted at 165–166.8°. The yield was 28.5 g. or 10% of the theoretical.

Anal. Calcd. for $C_{26}H_{20}O_4Br_2$: Br, 28.7. Found: 28.4.

Diethyl 3-Methyl-1-(or 2)-cyano-1,2-cyclobutane Dicarboxylate.—Eight g. of powdered sodium cyanide was placed in a 200-cc. round-bottomed flask containing a solution of 20 g. of diethyl α,α'-dibromo-β-methyl adipate in 15 cc. of absolute alcohol. The mixture was heated under reflux on the steam-bath for twenty-four hours. It was then cooled and filtered by means of suction to remove solid inorganic substances (sodium bromide and excess sodium cyanide). The solid material was washed with ether and the washings were added to the filtrate, which after the removal of the ether and alcohol boiled at 140 to 143° at 3 mm. The yield of diethyl 3-methyl-1-(or 2)-cyano-1.2-cyclobutane dicarboxylate was 8 g. or 63% of the theoretical; d_4^{20} 1.08854; n_D^{21} 1.44735.

Anal. Calcd. for $C_{12}H_{17}O_4N$: C, 60.2; H, 7.2. Found: C, 59.7; H, 7.2.

Hydrolysis of the Cyano Ester.—The cyano ester was hydrolyzed by treatment with hot barium hydroxide (20%) according to the method of Perkin.[2] From 8 g. of the ester was obtained 8.5 g. of the barium salt of the tricarboxylic acid; this corresponds to a yield of 67% of the theoretical.

Anal. Calcd. for $C_{16}H_{14}O_{12}Ba_3$: Ba, 50.8. Found: Ba, 50.9.

Summary

Diethyl α,α'-dibromo-β-methyl adipate has been converted by treatment with sodium cyanide in absolute alcohol into diethyl 3-methyl-1-(or 2)-cyano-1,2-cyclobutane dicarboxylate. The latter has been hydrolyzed to the corresponding cyclobutanetricarboxylic acid, which has been isolated in the form of its neutral barium salt.

The diphenyl and di-β-naphthyl esters of α,α'-dibromo-adipic acid have been prepared. Attempts at ring closure were unsuccessful with these esters.

THE SYNTHESIS OF SOME NEW COMPOUNDS RELATED TO APOCYNIN AND APOCYNOL[1]

BY HENRY P. HOWELLS, B. H. LITTLE AND H. P. ANDERSEN

RECEIVED JULY 19, 1930 PUBLISHED OCTOBER 6, 1930

The syntheses described herein were undertaken originally with the aim of securing intermediates for a study of the effect of length of side chain upon the physiological properties of certain unstudied phenolic bodies related to guaiacol. In choosing the method of preparation for such intermediates as the acyl substituted guaiacols, the findings of Finnemore[2] on methods of obtaining acetovanillone appeared to answer our immediate problem. His work[3] suggested also new lines of thought that made the

[2] Perkin, J. *Chem. Soc.*, *65*, 580 (1894).

---

[1] This communication is an abstract of portions of theses submitted by B. H. Little and H. P. Andersen in partial fulfilment of the requirements for the degree of Master of Science at the Oklahoma Agricultural and Mechanical College.

[2] Finnemore, J. *Chem. Soc.*, 93, 1520 (1908).

[3] Finnemore[2] pointed out that apocynol or α-(4-hydroxy-3-methoxyphenyl)-methyl carbinol and its demethylated product possessed certain structural similarities to epinephrine, and stated that these products were still under investigation since the

synthesis of our products seem even more interesting in a study of the relation of structure to physiological action.

Apocynin, a constituent of the extract from Canadian Hemp (*Apocynum cannabinum*) used in medicine mainly as a cardiac stimulant and a diuretic, was shown by Finnemore[4] to be identical with acetovanilloneor (4-hydroxy-3-methoxyphenyl) methyl ketone. In order to obtain the latter substance in sufficient amounts for further study, a new synthesis[2] was devised in which apocynol, resulting from the hydrolysis of the product obtained by the action of vanillin benzoate with the Grignard reagent, was oxidized with a chromic acid mixture. The carbinol could not be obtained directly by reacting vanillin with methylmagnesium iodide. In the present work this reaction also failed to go when other alkylmagnesium halides were used with vanillin.

It was hoped that the above method for obtaining the benzoate of apocynol could be adapted here in the preparation of its ethyl, n-propyl, *n*-butyl and n-amyl homologs, which might serve as starting materials. These compounds would yield the desired homologs of apocynol and apocynin when subjected to suitable oxidation and hydrolytic changes. Such changes have been carried out with greatest success in the case of the n-butyl derivatives by modifying the work of Finnemore for similar transformations. The various modifications will be described in detail later, but two of the more important changes should be pointed out here. First, it was found essential to use molecular quantities in reacting vanillin benzoate with the Grignard reagent to form the a-(4-benzoxy-3-methoxyphenyl)-*n*-alkyl carbinols. This was accomplished through the use of the titration method of Gilman[5] and co-workers for determining R-Mg-X in the reagent. Second, alcoholic potassium hydroxide was used to hydrolyze the benzoate esters in place of aqueous potassium hydroxide as used by Finnemore in forming apocynol. The factor which necessitated this change was no doubt due to the decreased solubility in water of the higher molecular weight esters. Absolute alcohol possessed a marked advantage over water as a solvent in diminishing greatly the time required for the reaction and the degree of decomposition of the hydrolyzed product in the hot alkaline solution. Since the n-butyl members of the above groups of compounds were much more easily prepared than the n-propyl and n-amyl members of each series, and since the five carbon side chain appeared to be of sufficient length for representative pharmacological testing, only the work with the n-butyl compounds has been described in detail in this paper.

physiological properties promised to be of interest. Through private communication it was learned that he did not extend this work.

[4] Finnemore, J. *Chem. Soc.*, 93, 1513 (1908).

[5] Gilman, Zoellner and Dickey, THIS JOURNAL, 51,1576 (1929).

The faint vanillin-like odor of apocynin noted by Finnemore[2] suggested to us at the start that the present study might lead to some interesting observations of the relation between chemical constitution and odor. It was observed also that Nomura and co-workers had made in recent years a series of studies with homologs of zingerone and related compounds with the view of unraveling the relation between their chemical constitution and pungency. In one of the earlier papers[6] it was found that 4-hydroxy-3-methoxyphenylbutane, possessed a pungent taste similar to zingerone. Thus it appeared that the presence of the carbonyl group in the side chain of zingerone is not essential, although it did seem to produce some effect on the taste. In view of the latter fact, the isomeric ketones which are prepared in the progress of this work may be of additional value in a study of the effect on taste or odor produced by the shifting of the carbonyl group in the side chain. The work has not been sufficiently advanced to draw conclusions but the odor and taste of certain products described herein at least indicate that some interesting correlations along this line may be possible.

Experimental

Benzoate of Vanillin.—The method used by Popovici[7] for the preparation of this compound was modified as follows. To a solution of 50 g. of vanillin in 125 cc. of 10% sodium hydroxide there was added rapidly and with vigorous shaking 46 cc. of benzoyl chloride, cooling intermittently so as to allow the benzoate ester to crystallize out in small white globules. Excess benzoyl chloride was decomposed by addition of 50 cc. of 10% sodium hydroxide and shaking well. The precipitate was collected, washed with 2 *N* ammonium hydroxide followed by slightly warmed water, dried and crystallized from 75% alcohol, when it appeared as colorless, monoclinic needles, m. p. 77" (corr.); yield, about 78%. Popovici reported the m. p. as 78° and Worner[8] gave 75°.

α-(4-Benzoxy-3-methoxyphenyl)-*n*-butyl carbinol, $C_6H_3(OCOC_6H_5)(OCH_3)$-**$(CHOHC_4H_9)$.—This** compound was prepared by a method somewhat similar to that used by **Finnemore**[2] for obtaining the simpler methyl carbinol by the action of the Grignard reagent upon the benzoate of vanillin. The present Grignard reagent was prepared essentially by the method recommended recently by Gilman[6] and co-workers, using 37 g. of *n*-butyl iodide, 4.8 g. of magnesium, a small crystal of iodine and 10 cc. of anhydrous ether in a closed system. The titration method of Gilman and co-workers for estimating n-butylmagnesium iodide showed the yield of reagent to be about 70% in most of the runs. The diluted Grignard reagent was cooled with an ice-bath and to it was added dropwise with constant stirring 35 g. of vanillin benzoate dissolved in slightly warmed anhydrous ether. The mixture was stirred for three hours and then boiled gently for half an hour, after which it was cooled and decomposed with cracked ice and 2 *N* sulfuric acid. The ether layer was washed with a saturated sodium bisulfite solution. 1.0% sodium hydroxide, and water in the order named The ether solution was saturated with carbon dioxide. dried over anhydrous sodium sulfate, filtered and evaporated under diminished pressure on a water-bath. A colorless oil remained which solidified largely upon cooling. The oily solid was washed with ligroin (b. p 90–120°)

and crystallized from 75% alcohol, when it appeared as colorless monoclinic needles, m. p. 109.3° (corr.); yield, about 48%.

Ad. Calcd. for $C_{19}H_{22}O_4$: C, 72.61; H, 7.06. Found: C, 73.05; H, 7.20.

The compound was soluble in alcohol, acetone, ether and glacial acetic acid, but insoluble in water. The crystals dissolved in cancentrated sulfuric acid to give a red color, but dilute alcoholic ferric chloride gave no change.

α-(4-Hydroxy-3-methoxyphenyl)-*n*-butyl carbinol, $C_6H_3(OH)(OCH_3)(CHOHC_4H_9)$, was obtained by the hydrolysis of the above benzoate ester through a modification of the method used by Finnemore[2] for preparing the simpler homolog, apocynol. A solution of 3 g. of the benzoate in 50 cc. of 10% alcoholic potassium hydroxide was refluxed for thirty minutes. The alcohol was evaporated off under suction and the residue was dissolved in water. The solution was saturated with carbon dioxide and the precipitate which settled out was taken up in ether. The ether solution was dried over anhydrous sodium sulfate and then evaporated to a brown solid residue mixed with some oily impurity. The oil was insoluble in boiling ligroin (b. p. 90–120°) but the solid material dissolved and separated out upon cooling as colorless monoclinic crystals, m. p. 81.5° (corr.); yield, about 10%.

Anal. Calcd. for $C_{12}H_{18}O_3$: C, 68.57; H, 8.57. Found: C, 68.10; H, 8.82.

The crystals dissolved in concentrated sulfuric acid to give a red color, and in dilute alcoholic ferric chloride to form a blue color. The product was soluble in alcohol, acetone, chloroform, ethyl acetate and dilute sodium hydroxide. The product possessed a very faint clove-like odor.

(4-Benzoxy-3-methoxyphenyl)-*n*-butyl ketone, $C_6H_3(OCOC_6H_5)(OCH_3)(COC_4H_9)$.—The corresponding carbinol was oxidized to the ketone derivative in essentially the same manner as described by Bogert and Howells[9] for the oxidation of acyl hydroquinones to the corresponding quinones. A solution of 10 g. of the carbinol in 50 cc. of warm glacial acetic acid was added slowly (ten minutes) to a mixture of 10 g. of potassium dichromate, 10 cc. of concentrated sulfuric acid and 100 cc. of water, while the solution was stirred vigorously. This stirring was continued for about ten minutes after all of the carbinol had been added, during which time the temperature was brought to about 85°, and then cooled. The mixture was diluted with an equal volume of water and, after a short period of standing, the precipitate was filtered off, washed well with water and dried. Recrystallized from alcohol, it gave colorless, shiny triclinic crystals, m. p. 88.1° (corr.) yield, about 92%.

Anal. Calcd. for $C_{19}H_{20}O_4$: C, 73.08; H, 6.39. Found: C, 72.87; H, 6.42.

The product was soluble in ether, acetone and chloroform, but insoluble in dilute sodium hydroxide. The crystals dissolved in concentrated sulfuric acid to give a yellow color. The product possessed no particular odor.

The phenylhydrazone when crystallized from alcohol gave colorless triclinic crystals, m. p. 163' (corr.); yield, about 46.5%. The crystals dissolved in concentrated sulfuric acid to give a yellow color. Nitrogen was determined by Milbauer's[10] modification of the Kieldahl method.

Anal. Calcd. for $C_{25}H_{26}O_3N_2$: N, 6.96. Found: N, 6.94.

(4-Hydroxy-3-methoxyphenyl)-*n*-butyl ketone, $C_6H_3(OH)(OCH_3)(COC_4H_9)$, was obtained by the hydrolysis of the above benzoate ester, using the same method already described for the corresponding carbinol derivative. The solid residue which remained after evaporating off the ether was recrystallized from 25% alcohol. A mixture of color-

---

[9] Bogert and Howells, THIS JOURNAL, 52, 837 (1930).

[10] Milbauer, *Z. anal.* Chem., 42, 725 (1903).

less monoclinic and triclinic crystals seemed to separate out, m. p. 62.9° (corr.); yield, about 90%.

Anal. Calcd. for $C_{12}H_{16}O_3$: C, 69.23; H, 7.69. Found: C, 68.95; H, 7.68.

The ketone did not possess the faint vanillin odor characteristic of the lower homolog, acetovanillone (apocynin), but it did carry a very faint pleasant odor. The product was soluble in alcohol, acetone, chloroform, ethyl acetate, hot benzene and toluene, and slightly soluble in hot water. The crystals dissolved in concentrated sulfuric acid to give a yellow color, and in dilute alcoholic ferric chloride to form a greenish-yellow color. The ketone was apparently decomposed by boiling 50% sulfuric acid with the evolution of products having a faint guaiacol odor mixed with a penetrating odor characteristic of some of the lower fatty aldehydes. The remaining solution turned a greenish-yellow color unlike the red color noted by Finnemore[2] in the case of apocynin.

Attempts were made to prepare the phenylhydrazone, β-naphthylhydrazone and *p*-nitrophenylhydrazone, but the products were all oils which were too difficult to purify. The semicarbazone seemed to form, but physical examination and color reaction pointed to it as being the starting material.

The diphenyl urethan was formed from diphenylcarbamine chloride in the usual manner. The product gave fluffy needles from alcohol, m. p. 121.5–123° (corr.); yield, about 52%.

Anal. Calcd. for $C_{25}H_{25}O_4N$: N, 3.47. Found: N, 3.30.

Comparative Yields of Carbinols from Vanillin Benzoate with Some Grignard Reagents.—In view of the findings of Gilman[6] and co-workers, that the even-numbered halides give yields of Grignard reagents higher than the preceding halides that have an odd number of carbon atoms and furthermore a gradual drop in yield results in a given series with the ascent of that series to halides of higher molecular weight, it might be expected that n-butylmagnesium bromide would give a better yield of the carbinol than that from n-propyl- or n-amylmagnesium bromide in the usual mode of synthesis. However, the relative yields obtained in this work cannot be accounted for in this way, since the titration method of Gilman and co-workers was used in correcting for molecular proportions of reagents. It was also found that n-butyl iodide gave better results than n-butyl bromide when used in the synthesis of the carbinol, although we had predicted greater success with the bromide, since the above workers found that with a given alkyl group the lower yields are with iodide and the higher with the bromide. Perhaps n-butylmagnesium bromide is too active and not only attacks the aldehyde part of vanillin benzoate but also reacts with the phenyl ester group giving rise to oily by-products. Recent work[11] on the relative reactivities of some Grignard reagents indicates butylmagnesium bromide to be much more reactive than the iodide. Further work is being done in this connection to determine the relative merits of R-Mg-I and R-Mg-Br in reactions of the above type.

α-(4-Benzoxy-3-methoxyphenyl)-*n*-propyl carbinol, $C_6H_3(OCOC_6H_5)(OCH_3)(CHOHC_3H_7)$, was obtained by essentially the same method that was described for the

---

n-butyl homolog. Colorless monoclinic crystals formed upon recrystallization from alcohol, m. p. 111.3° (corr.); yield, about 31.5%.

Anal. Calcd. for $C_{18}H_{20}O_4$: C, 72.00; H, 6.67. Found: C, 71.61; H, 6.90.

The crystals were soluble in ether, chloroform and glacial acetic acid, but insoluble in water. The product dissolved in concentrated sulfuric acid to give a red color. The compound possessed a faint pleasant odor.

(4-Benzoxy-3-methoxyphenyl)-*n*-propyl ketone, $C_6H_3(OCOC_6H_5)(OCH_3)(COC_3H_7)$.—The above carbinol was oxidized readily by the method already described for the n-butyl homolog. Colorless triclinic crystals were obtained from alcohol, m. p. 79° (corr.); yield, about 51.5%.

Anal. Calcd. for $C_{18}H_{18}O_4$: C, 72.48; H, 6.04. Found: C, 71.82; H, 6.00.

The crystals were soluble in ether, acetone and chloroform, but insoluble in dilute alkali. The product dissolved in concentrated sulfuric acid to give a yellow color.

The phenylhydrazone when crystallized from alcohol gave colorless triclinic crystals, m. p. 175.5° (corr.). The crystals dissolved in concentrated sulfuric acid to give a yellow color.

Anal. Calcd. for $C_{24}H_{24}O_3N_2$: N, 7.22. Found: N, 7.12.

α-(4-Benzoxy-3-methoxyphenyl)-*n*-amyl carbinol, $C_6H_3(OCOC_6H_5)(OCH_3)(CHOHC_5H_{11})$, was also obtained by essentially the same method as described for its n-butyl homolog. The crude product was an oil mixed with about an equal amount of solid material, which was finally purified after considerable difficulty. Most of the oil was eliminated by pressing the crude product on a porous plate and allowing it to stand for several hours in a refrigerator. The mixture had a pleasant pungent odor along with a marked odor resembling that of valeric acid. The product was finally washed with ligroin and recrystallized from alcohol as colorless monoclinic crystals, m. p. 95.6° (corr). The yield varied widely and usually resulted a bit below 10%, although one run seemed to give close to a 48% yield of a product which melted only a few degrees from the correct melting point.

Anal. Calcd. for $C_{20}H_{24}O_4$: C, 73.17; H, 7.32. Found: C, 72.91; H, 7.95.

The crystals were soluble in ether, chloroform, acetic acid and ethyl acetate, but insoluble in water. The product dissolved in concentrated sulfuric acid to give a red color.

The carbinol was oxidized with a chromic acid mixture for producing the ketone derivatives but the small amount of liquid product could not be sufficiently purified for complete identification. The small quantity of oil was apparently changed readily to the phenylhydrazone in the usual manner. The product after one crystallization from 75% alcohol gave colorless crystals, m. p. 134.6" (corr.). The crystals dissolved in concentrated sulfuric acid to give a yellow color.

Anal. Calcd. for $C_{26}H_{28}O_3N_2$: N, 6.73. Found: N, 6.65.

Summary

1. Some new derivatives of the n-propyl, n-butyl and *n*-amyl homologs of apocynol and apocynin have been prepared and described. The n-butyl derivatives are apparently the most readily obtained of the series and thus have been studied in detail to give the n-butyl homologs of apocynol and apocynin, which appear to be of interest in a study of the relation between structure and physiological action.

2. Tests on the comparative yields of the carbinols from vanillin benzoate and the Grignard reagent seem to indicate that R-Mg-I reagents are

superior to the R-Mg-Br type. Further work is being planned to determine the relative merits of the iodides and bromides in reactions of the above type.

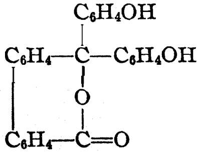
STUDIES IN THE DIPHENIC ACID AND PHTHALIC ACID SERIES. IV

BY H. W. UNDERWOOD, JR., AND G. E. BARKER[1]

RECEIVED JULY 19, 1930 PUBLISHED OCTOBER 6, 1930

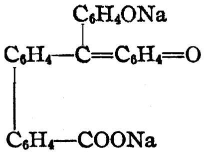
I. The Structure of Phenoldiphenein

Phenoldiphenein dissolves in sodium hydroxide solution with the development of a light yellow color.[2] The apparently anomalous behavior of this compound makes it desirable to obtain evidence regarding its structure. The arrangement of the groups in phenolphthalein has been established by the isolation of *p,p'*-dihydroxybenzophenone and benzoic acid from the melt obtained by the fusion of the phthalein with potassium hydroxide. The analysis of the potassium salt of phenolphthalein and the preparation of a dimethyl ether show the presence of two acidic hydrogen atoms and two hydroxyl groups. An account of the application of these procedures to phenoldiphenein is given in this paper. The results of our experiments show that phenoldiphenein and its sodium salt are represented by the formulas



$$\begin{array}{lcl} & C_6H_4OH & \\ & | & \\ C_6H_4- & C & -C_6H_4OH \\ | & | & \\ | & O & \\ | & | & \\ C_6H_4- & C & =O \end{array}$$

and



$$\begin{array}{lcl} & C_6H_4ONa & \\ & | & \\ C_6H_4- & C & =C_6H_4=O \\ | & & \\ | & & \\ C_6H_4- & COONa & \end{array}$$

Apparently the groups in diphenic anhydride give a light yellow instead of a red color to the sodium salt of the phenol condensation product.

Discussion of Experiments

All of the temperatures given are uncorrected.

Fusions of Phenolphthalein, Phenoldiphenein and the Fluorenone-phenol Condensation Product with Potassium Hydroxide.—A procedure which gave satisfactory results with phenolphthalein was first developed, and this was applied to phenoldiphenein and the fluorenone–phenol condensation product.

---

[1] Some of the experimental results described in this paper are taken from a thesis submitted to the Faculty of the Massachusetts Institute of Technology by G. E. Barker in partial fulfilment of the requirements for the degree of Bachelor of Science.

[2] Underwood and Kochmann, THIS JOURNAL, 45, 3071 (1923); 46, 2069 (1924).

An intimate mixture of 5 g. of powdered phenolphthalein (0.016 mole) and 20 g. of powdered potassium hydroxide (0.357 mole) was placed in a 60-cc. nickel crucible, and heated over a free flame until the solid melted. The crucible was allowed to cool while its contents were thoroughly stirred. The product was transferred to a mortar, ground to a fine powder and then placed in the crucible. After the mixture had been heated to its melting point, it was cooled, transferred to a mortar and reduced to a powder. The product was fused a third time, Since a solution of a sample of the mixture in water was not red, it was concluded that all of the phenolphthalein had been decomposed. The melt was extracted with four 50-cc. portions of boiling water and the solution was acidified with hydrochloric acid. The precipitate was collected on a filter, dried in the air and ground in a mortar with two 25-cc. portions of chloroform. Evaporation of the filtered chloroform extracts to dryness gave a colorless solid; this was crystallized from 15 cc. of boiling water. The product, which weighed 0.84 g. (43.8% yield) and melted at 119–120°, was identified as benzoic acid. The material which did not dissolve in chloroform was crystallized twice from 15 cc. of boiling water. About 1 1 g. (32.7% yield) of *p,p'*-dihydroxybenzophenone, m. p. 206–207°, was obtained.

The procedure described above was employed in the fusion of 3 g. of phenoldiphenein (0.0076 mole) with 9.6 g. of potassium hydroxide (0.1711 mole). During the fusion a white vapor which had an odor like that of biphenyl was evolved, and the mixture was black after a third fusion. Acidification of the filtered solution of the melt caused the evolution of considerable carbon dioxide and the formation of a dark colored gelatinous precipitate. The solid was collected on a filter, dried and extracted with four 10-cc. portions of boiling benzene. Evaporation of the benzene solutions to dryness gave a light gray solid which weighed 0.5 g. (33% yield) and melted at 110–111° after crystallization from a small amount of an alcohol–water mixture. The material dissolved in concd. sulfuric acid with the development of a wine-red color. The properties of this substance indicated that it was o-phenylbenzoic acid. Addition of an excess of bromine water to the filtrate from the gelatinous precipitate gave a colorless solid; this was filtered and dried in the air. The material, which weighed 1.22 g. and melted at 95°, was identified as *sym.*-tribromophenol; the product is equivalent to 0.347 g. of phenol (24.3% yield). Apparently phenoldiphenein is transformed into salts of phenol, o-phenylbenzoic acid and carbon dioxide by fusion with potassium hydroxide.

Similarly we secured 0.79 g. of *sym.*-tribromophenol (13.95% yield) and about 0.1 g. of o-phenylbenzoic acid (6% yield) from the melt obtained by fusing 3 g. of the fluorenone-phenol condensation product (0.0086 mole) with 7 g. of potassium hydroxide (0.1247 mole).

Analysis of the Potassium Salts of Phenolphthalein and Phenoldiphenein.—Procedures which gave satisfactory results with phenolphthalein were first developed, and these were applied to phenoldiphenein.

A solution of 0.5 g. of potassium hydroxide in 18 cc. of distilled water was thoroughly shaken with 1.49 g. of powdered phenolphthalein (calcd. amt. X 1.05) for twenty minutes and filtered. The filtrate was evaporated to dryness in a large dish; the dark red potassium salt was dried at 160° for four hours and cooled in a desiccator over concd. sulfuric acid.

Two-tenths gram of the dry potassium salt of phenolphthalein was placed in a weighed platinum crucible, and the latter was inclined on its side on a nichrome wire triangle. After three drops of pure, concd. sulfuric acid had been added to the salt, a platinum cover was placed on the crucible and the latter was carefully heated for about two and one-half hours at a temperature just below visible redness. At the end of this period the ash was practically colorless. A lump of pure ammonium carbonate about the size of a pea was introduced, and the mixture was heated to dull redness for half an hour.

The crucible was now allowed to cool to room temperature in a desiccator containing anhydrous calcium chloride, weighed, heated again and reweighed. This procedure was repeated until the weight of the crucible was constant. From the quantity of colorless potassium sulfate in the crucible the percentage of potassium in the salt was calculated.

Anal. Calcd. for $C_{20}H_{12}O_4K_2$: K, 19.83. Found: K, 19.88, 19.81.

The procedures described above were used for the preparation and analysis of the potassium salt of phenoldiphenein. This salt is an amorphous greenish-yellow powder; its color is between shade 1 of yellow and the normal tone of greenish-yellow in Mulliken's color charts.[8] A very dilute solution of the sodium salt of phenoldiphenein becomes practically colorless upon the addition of a large excess of concd. sodium hydroxide solution.

Anal. Calcd. for $C_{26}H_{16}O_4K_2$: K, 16.62. Found: K, 16.67. 16.61.

Lactone Dimethyl Ethers of Phenolphthalein and Phenoldiphenein.—Procedures which gave satisfactory results with phenolphthalein were first developed, and these were applied to phenoldiphenein.

A solution of 6 g. of phenolphthalein, 18 g. of methyl iodide (calcd. amt. X 3.36) and 0.6 g. of powdered potassium hydroxide in 40 cc. of methyl alcohol was maintained at 40–45° for twenty-four hours, and then 0.6 g. of powdered potassium hydroxide was added. At intervals of twenty-four hours another 0.6-g. and a 0.4-g. portion of powdered potassium hydroxide were introduced, and the mixture was kept at 40–45° during this period and for twenty hours after the last addition of alkali. The product was transferred to a beaker which was left in a vacuum desiccator over anhydrous calcium chloride until the solvent evaporated. The dry residue was placed in a beaker, stirred with 50 cc. of water, collected on a filter, washed with two 20-cc. portions of 5% potassium hydroxide solution and with 20 cc. of water and dried. The yield of phenolphthalein lactone dimethyl ether, m. p. 100–101°, was 5.68 g. (87%).

By use of the procedure described above, we secured 1.6 g. of crystalline lactone dimethyl ether of phenoldiphenein (50% yield) from 3 g. of phenoldiphenein, 7.26 g. of methyl iodide (calcd. amt. × 3.36) and 0.9 g of powdered potassium hydroxide (calcd. amt. × 1.05), added in three portions of 0.25 g. and one of 0.15 g. Thirty-five cc. of methyl alcohol was used as a solvent. Phenoldiphenein lactone dimethyl ether was obtained in the form of colorless stout needles, m. p. 150–151°, by crystallization from a small amount of methyl alcohol. The compound is insoluble in 10% sodium hydroxide solution.

Anal. Calcd. for $C_{28}H_{22}O_4$: C, 79.59; H, 5.25. Found: C, 79.36, 79.56; H, 5.61, 5.58.

Forty grams of active, anhydrous aluminum chloride was added, with stirring, to 40 g. of dry phthalic anhydride and 50 g. of dry anisole (calcd. amt. X 0.855). After a reflux water condenser fitted with a drying tube containing anhydrous calcium chloride had been attached to the flask, the mixture was allowed to stand overnight at room temperature and then heated for three hours on a water-bath. The contents of the flask were diluted with 200 cc. of water and heated for an hour on a water-bath. The product was transferred to a beaker, and 50% sodium carbonate solution was added until the mixture was neutral. The solid was collected on a filter, ground in a mortar with two 50-cc. portions of 50% sodium carbonate solution and then with 50 cc. of 6 *N* potassium hydroxide solution. The material was collected on a filter again, washed with 50 cc. of water, dried and extracted with two 200-cc. portions of boiling methyl

alcohol. The filtered methyl alcohol solution was concentrated and cooled in ice to facilitate the crystallization of the phenolphthalein lactone dimethyl ether. The product weighed 28 g. (35% yield) and melted at 100–101°.

By use of the procedure described above, we obtained 0.76 g. (11.1% yield) of crystalline lactone dimethyl ether of phenoldiphenein, m. p., 150–151°, from 5 g. of dry diphenic anhydride, 3.5 g. of dry anisole (calcd. amt. × 0.725) and 3.1 g. of active, anhydrous aluminum chloride. Fifty cc. of water was used to dilute the reaction mixture. The solid reaction product was washed successively with 15 cc. each of 50% sodium carbonate solution, 6 *N* potassium hydroxide solution and water. The dry material was extracted with two 50-cc. portions of boiling methyl alcohol.

II. Reactions of Derivatives of Diphenic Acid and Phthalic Acid with Acetic Anhydride

When the monomethyl, mono-ethyl, dimethyl and diethyl esters of diphenic acid were heated with acetic anhydride, each compound remained unchanged. Under similar conditions diphenamic acid was dehydrated in two different ways, giving diphenimide and 1-cyanobiphenyl-10-carboxylic acid; the diamide of diphenic acid was transformed into 2,2′-dicyanobiphenyl. These reactions are dehydrations and involve union of the side chains attached to the rings.[4] Since our investigations involve a comparison of the behavior of derivatives of diphenic acid and those of phthalic acid, we have studied the action of acetic anhydride upon the methyl and ethyl esters, the mono-amide and the diamide of phthalic acid.

Discussion of Experiments

Monomethyl Phthalate.—After a mixture of 25 g. of phthalic anhydride and 125 g. of absolute methyl alcohol (calcd. amt. × 23.1) had been refluxed on a water-bath for five hours, the excess methanol was distilled and the reaction product transferred to a beaker which was left in a desiccator over anhydrous calcium chloride for several hours. The yield of monomethyl phthalate, m. p. 82–82.5°, was 24.4 g. (80.2%).

Ten grams of the ester was heated with 20 g. of glacial acetic acid and 30 g. of acetic anhydride for sixteen hours at 145°. The mixture was cooled in ice and the solid which formed was collected on a filter and dried. The filtrate was concentrated by distillation at 145° and the residue was transferred to a beaker, cooled and dried. The solid reaction product, which weighed 8.1 g. (98.5% yield), was identified as phthalic anhydride. Two cc. of impure methyl acetate was obtained by several fractionations of the distillate. Three and nine-tenths grams of phthalic anhydride was secured by heating 10 g. of monomethyl phthalate for sixteen hours at 145°. Two 10-cc. portions of pure anhydrous ether were used to separate the unchanged ester from the phthalic anhydride.

Mono-ethyl Phthalate.—Twenty-five grams of phthalic anhydride was dissolved in 200 cc. of absolute ethyl alcohol (calcd. amt. × 20.4) by refluxing the mixture for two hours on a water-bath. Removal of the alcohol by distillation produced a sirupy liquid. In order to separate the mono-ethyl ester from diethyl phthalate, the product was dissolved in 100 cc. of water. The solution was maintained at its boiling point for an hour, and 25 g. of powdered barium carbonate was added during this period. The neutral mixture was cooled to room temperature and filtered; the filtrate was acidified with concd. hydrochloric acid and extracted with 100 cc. of ether. After the ether solution had been shaken with 10 cc. of water, it was dried overnight with 5 g. of an-

---

[4] Underwood and Clough, THIS JOURNAL, 51, 583 (1929).

hydrous sodium sulfate and then filtered. The ether was removed by distillation on a water-bath. After drying in a vacuum desiccator over anhydrous calcium chloride, the product weighed 8 g. (24.4% yield).

By use of the procedure described above, we obtained 7.5 g. of phthalic anhydride (98.4% yield) by heating 10 g. of mono-ethyl phthalate with 20 g. of glacial acetic acid and 30 g. of acetic anhydride at 145° for sixteen hours. Two cc. of impure ethyl acetate was secured by several fractionations of the distillate. Ten grams of mono-ethyl phthalate yielded 4.7 g. of phthalic anhydride when heated at 145° for sixteen hours.

The results of our experiments show that the hydroxyl and alkoxyl groups in mono-methyl and mono-ethyl phthalates are loosely held.

Dimethyl and Diethyl Phthalates.—Ten g. of each of these compounds was heated with 20 g. of glacial acetic acid and 30 g. of acetic anhydride for sixteen hours at 145°, and the mixture was then fractionated. In each case, practically all of the ester was recovered unchanged.

Phthalamic Acid.—Acidification of a solution of 50 g. of phthalimide in 150 g. of 25% potassium hydroxide solution (calcd. amt. × 1.97) with concd. hydrochloric acid, gave a light brown precipitate. This was collected on a filter, ground with three 25-cc. portions of water in a mortar and dried. The yield of phthalamic acid, m. p. 147–148°, was 43.2 g. (77%).

After a mixture of 10 g. of phthalamic acid (the mono-amide of phthalic acid), 20 g. of glacial acetic acid and 30 g. of acetic anhydride had been refluxed for sixteen hours at 145°, practically all of the liquid was removed by distillation and the residue was stirred with 100 cc. of alcohol. The insoluble material was collected on a filter, washed and dried; this substance, which weighed 4.2 g., was identified as phthalimide. Evaporation of the filtrate to dryness gave 4.73 g. of phthalic anhydride. Ten grams of phthalamic acid was converted into 6.0 g. of phthalimide and 2.9 g. of phthalic anhydride by heating at 145° for sixteen hours. The products were separated by treatment with alcohol.

In "Beilstein" it is stated that phthalamic acid decomposes smoothly at 155° into phthalimide and water, and that treatment with glacial acetic acid transforms phthalamic acid into phthalic anhydride.

Phthalamide.—A mixture of 25 g. of phthalimide and 100 cc. of concd. ammonium hydroxide (*d* 0 9; calcd. amt. × 9.03) was maintained at its boiling point for twenty minutes, and then allowed to cool to room temperature. The precipitated phthalamide was collected on a filter, washed with 20 cc. of 5% ammonia solution and dried for half an hour at 100°. The product weighed 25.8 g. (92.5% yield) and melted at 219–220° with evolution of ammonia.

The solution obtained upon heating 10 g. of phthalamide, 20 g. of glacial acetic acid and 30 g. of acetic anhydride at 145° for an hour was cooled in ice. The precipitate which formed was collected on a filter and dried; it weighed 4.5 g. and melted at 170–172°. The properties of this substance indicated that it was o-cyanobenzamide. Practically all of the liquid in the filtrate was removed by distillation at 145'. When the residue was cooled in ice, it deposited a colorless solid which weighed 3.7 g. after drying. This product was identified as phthalimide. Ten g. of phthalimide was unchanged by heating for an hour at 145".

In Beilstein it is stated that treatment with acetic anhydride (free from acetic acid) converts phthalamide into o-cyanobenzamide, phthalonitrile, phthalimide and acetylphthaliide.

Summary

Fusion with potassium hydroxide converts phenoldiphenein into the potassium salts of phenol and o-pbenylbenzoic acid. The lactone di-

methyl ether of phenoldiphenein is formed by treatment of the latter with methyl iodide and potassium hydroxide and by the reaction of diphenic anhydride with anisole in the presence of anhydrous aluminum chloride. The presence of two acidic hydrogen atoms in phenoldiphenein is shown by analysis of the potassium salt. These transformations indicate that the structure of phenoldiphenein is similar to that of phenolphthalein and that the sodium salt of phenoldiphenein contains a quinoid ring. The groups in this salt give it a light yellow instead of a red color.

When dimethyl phthalate and diethyl phthalate are heated with acetic anhydride, each ester remains unchanged. Under similar conditions the monomethyl and mono-ethyl esters of phthalic acid yield phthalic anhydride. Phthalamic acid is converted into phthalimide and phthalic anhydride by treatment with acetic anhydride, and phthalamide gives *o*-cyanobenzamide and phthalimide.

PREPARATION OF SOLID DERIVATIVES FOR THE IDENTIFICATION OF ETHERS

BY H. W. UNDERWOOD, JR., O. L. BARIL AND G. C. TOONE[1]

RECEIVED JULY 19, 1930 PUBLISHED OCTOBER 6, 1930

Ethers are usually described as inert compounds; the carbon–oxygen bond is firmly held, and drastic treatments, such as heating with hydriodic acid or anhydrous aluminum chloride, are generally employed to split ethers. These methods are not suitable for the preparation of solid derivatives for the identification of small amounts of ethers. Recently it was shown that ethyl 3,5-dinitrobenzoate is formed by the treatment of the dinitrobenzoyl chloride with pure, dry ethyl ether in the presence of anhydrous zinc chloride.[2] This paper describes the preparation of crystalline 3,5-dinitrobenzoates from small amounts of representative, simple aliphatic ethers. Procedures for the conversion of typical aromatic ethers into crystalline bromo derivatives are also discussed.

Discussion of Experiments

All the temperatures given are uncorrected.

Purification of Ethers.—The aliphatic ethers were purified by the method described in a previous paper.[3] Experiments with samples of

---

[1] Some of the experimental results described in this and a previous paper are taken from a thesis submitted to the Faculty of the Massachusetts Institute of Technology by G. C. Toone in partial fulfilment of the requirements for the degree of Master of Science. The bromo derivatives of the aromatic ethers were prepared by O. L. Baril.

[2] Underwood and Wakeman, THIS JOURNAL, 52,387 (1930).

[3] Underwood and Toone, *ibid.*, 52, 391 (1930).

all the aliphatic ethers, except isobutyl and n-hexyl, obtained from the Eastman Kodak Company gave results similar to those obtained with the purified compounds.

Reactions of Simple Aliphatic Ethers with 3,5-Dinitrobenzoyl Chloride

General Procedure.—One cubic centimeter of each ether was added to a mixture of 0.1–0.15 g. of finely powdered, anhydrous zinc chloride and 0.5 g. of 3,5-dinitrobenzoyl chloride in a dry 7.6-cm. test-tube. A small reflux water condenser, constructed from two pieces of glass tubing, was attached immediately, and the mixture was refluxed gently by heating in an oil-bath for about one hour. The product was then poured into a small beaker. The test-tube was rinsed with 10 cc. of 1.5 N sodium carbonate solution and this was added to the reaction mixture. The contents of the beaker were stirred and heated in a water-bath, maintained at 90–100°, for about one minute. The mixture was allowed to stand at room temperature for five minutes, and then filtered by suction. The precipitate was washed on the filter with 5 cc. of 1.5 N sodium carbonate solution and with two 5-cc. portions of water, and then drained thoroughly. The solid was transferred to a 15-cm. test-tube and extracted with 10 cc. of carbon tetrachloride, kept at its boiling point by heating over a free flame, for about three minutes. The hot mixture was filtered immediately and the filtrate was evaporated to dryness by a current of air. The residue was crystallized from 2–3 cc. of carbon tetrachloride. Crystallization was facilitated by cooling the solution in ice. The crystals were dried in the air. The yield of alkyl 3,5-dinitrobenzoate was 0.1–0.15 g.

The ethers investigated and the melting points of the 3,5-dinitrobenzoates obtained are as follows: ethyl, 92–93°; n-propyl, 73.5–74°; isopropyl, 120–121°; n-butyl, 62–63°; isobutyl, 84.5–85.5°; n-amyl, 42–43°; iso-amyl, 60–61°; n-hexyl, 54.5–55.5°. In some experiments it was necessary to evaporate the carbon tetrachloride solutions of the products from n-amyl, iso-amyl and n-hexyl ethers almost to dryness in order to isolate the esters, and subsequently to recrystallize the latter from about 2 cc. of ethyl alcohol. Carbon tetrachloride was used instead of alcohol in our experiments in order to avoid reactions of unchanged dinitrobenzoyl chloride with the alcohol.

Several investigators have given different melting points for alkyl dinitrobenzoates.[4] Each melting point, except that of the n-amyl ester which is listed as 44.4–44.6° by Tseng,[4] obtained by us agrees with one previously reported. We found that we could raise the melting point of n-amyl

Acta*, 9, 802 (1926); Majima, Nagaoka and Yamada, Ber., 55, 215 (1922); Mulliken, "Identification of Pure Organic Compounds," John Wiley and Sons, Inc., New York City, 1904, Vol. I, pp. 168–172; Research on derivatives of alcohols carried out at the Massachusetts Institute of Technology by Tseng under the direction of Professor Mulliken.

3,5-dinitrobenzoate by preparing a relatively large amount of the ester and recrystallizing it several times from ethyl alcohol. The melting points given above are those usually obtained under the conditions we used. We checked the identity of our products by mixed melting points with samples of alkyl dinitrobenzoates prepared from pure alcohols.

Reactions of Aromatic Ethers

Anisole, Phenetole and *p*-Nitrobenzoyl Chloride.—It has been noted that diphenyl ether and anisole behave like aromatic hydrocarbons when heated with acetyl and benzoyl chlorides in the presence of anhydrous zinc chloride; ketones are formed by the introduction of an acetyl or benzoyl group into the aromatic nucleus.[2] The reactions of these (and other aromatic) ethers with 3,5-dinitrobenzoyl chloride gave products which had undesirable properties.

4'-Nitro-4-methoxybenzophenone and 4'-nitro-4-ethoxybenzophenone were readily prepared from anisole and phenetole. A mixture of 1 cc. of each ether, 0.8 g. of pure *p*-nitrobenzoyl chloride, 1 cc. of dry carbon disulfide and 0.1 g. of granular, anhydrous aluminum chloride was placed in a dry 7.6-cm. test-tube, and warmed gently over a free flame to start the reaction. After the evolution of hydrogen chloride had subsided, a small water condenser, constructed from two pieces of glass tubing, was attached to the tube and the mixture was refluxed gently for half an hour by heating in an oil-bath. The contents of the tube were rinsed into a small beaker with 15 cc. of water and allowed to cool. The mixture was next extracted, in a separatory funnel, with a 15-cc. and a 5-cc. portion of ether. The combined ether layers were shaken with 15 cc. of 10% sodium hydroxide solution, and then dried with 1 g. of anhydrous sodium sulfate for half an hour. The dry ether solution was decanted and the solvent was allowed to evaporate under a hood. The solid residue was crystallized two or three times from 5 cc. of alcohol. Our 4'-nitro-4-methoxybenzophenone melted at 120.5–121°, and the 4'-nitro4-ethoxybenzophenone melted at 110.5–111°. These compounds are listed in Beilstein; the melting point of the ethoxy derivative is given as 112". We found no references to the preparation of these substances from small amounts of the ethers. It is believed that our products are the most satisfactory solid derivatives now available for anisole and phenetole.

Attempts to prepare *p*-nitrobenzoyl derivatives of naphthyl, benzyl and other aromatic ethers gave oils which would not crystallize. Consequently, it was decided to investigate another reaction for ethers containing aromatic groups.

Bromination of Aromatic Ethers.—Procedures for the preparation of crystalline bromo derivatives from representative aromatic ethers were devised; details are given in Table I.

The bromo derivatives of *o*-cresylmethyl, benzyl, α-naphthylmethyl and β-naphthylmethyl ethers are new compounds. The other products are listed in Beilstein, but we found no references to the preparation of these compounds from small amounts of the ethers. In most cases it was necessary to modify considerably the preparative methods given in the literature; the rate of addition of bromine and temperature control are particularly important.

Brominations of anisole and phenetole gave oils which would not solidify.

16	1-Bromo	15 cc. pet. ether	Plates	.48	66.1

[a] The mixture of guaiacol and bromine was heated for twenty minutes on a water-bath. After the alcohol had been removed by distillation, 1 cc. of glacial acetic acid was added; crystallization occurred at once. [b] The reaction mixture obtained from veratrole was diluted with 40 cc. of water, stirred, allowed to stand for two hours and filtered. [c] Before crystallization, dibromoresorcinol dimethyl ether was washed with 1 cc. of alcohol. [d] The dibromo derivative of hydroquinone dimethyl ether was washed with 3 cc. of 80% acetic acid before crystallization. [e] The ether solution of anethole was cooled in ice during the addition of bromine; the crystals formed when the solvent evaporated were ground with 1 cc. of cold alcohol in a mortar before crystallization. [f] The mixture of safrole and bromine was heated for fifteen minutes on a water-bath. [g] Before crystallization, the impure monobromo-isosafrole dibromide was ground in a mortar with 3 cc. of cold alcohol. [h] During the addition of bromine the ether solutions of eugenol methyl ether and of isoeugenol methyl ether were cooled in ice. Subsequently the reaction mixtures were allowed to stand for half an hour at room temperature, and then cooled in a bath of ice and concd. hydrochloric acid. Crystallization was induced by scratching the wall of the container with a sharp glass rod. Monobromo-eugenol methyl ether dibromide was washed with 3 cc. of cold alcohol before crystallization. [i] The chloroform solution of α-naphthyl methyl ether was cooled in ice during the addition of bromine and for fifteen minutes longer; subsequently it was allowed to stand overnight at room temperature. [j] In some experiments with α-naphthyl ethyl ether the bromo derivative crystallized only when allowed to stand for a long time. [k] The reaction mixture obtained from β-naphthyl ethyl ether was cooled for ten minutes after the addition of bromine.

Oxidation of Cresyl Ethers.—Brominations of p-cresyl methyl, *p*-cresyl ethyl and o-cresyl ethyl ethers gave oils which would not solidify. Details of a procedure for the oxidation of these compounds to anisic, *p*-ethoxybenzoic and o-ethoxybenzoic acids are given below. A mixture of 0.5 g. of the ether, 2.5 g. of concd. sulfuric acid, 37 cc. of water and 1.75 g. of powdered potassium dichromate was heated at its boiling point in a flask connected with a reflux water condenser. The periods of heating were four, three and two hours, respectively. The mixture was cooled to room temperature, diluted with 50 cc. of water, transferred to a separatory funnel and extracted with 30. 10 and 10-cc. portions of ether. The combined ether layers were shaken with 25 cc. of 10% sodium carbonate solution. The sodium carbonate extract was acidified with 20 cc. of 6 *N* hydrochloric acid. The precipitated anisic and *p*-ethoxybenzoic acids were collected on a filter, washed with 5 cc. of water and crystallized from 50 cc. of hot water and from 10 cc. of alcohol, respectively. o-Ethoxybenzoic acid was precipitated as an oil; this was extracted with two 25-cc. portions of ether. The ether solution was dried with 2 g. of anhydrous sodium sulfate for an hour, decanted and allowed to stand until the solvent evaporated. About 0.1 g. of an oil which melted at 19–19.5' was thus obtained. The yields of anisic and *p*-ethoxybenzoic acids were 0.2 and 0.3 g.; the products melted at 183.9 and 195.2–195.5°, respectively.

Summary

Small amounts of ethyl, n-propyl, isopropyl, n-butyl, isobutyl, *n*-amyl, iso-amyl and n-hexyl ethers are converted into the corresponding 3,5-dinitrobenzoates by treatment with 3,5-dinitrobenzoyl chloride in the presence of anhydrous zinc chloride. The reactions of *p*-nitrobenzoyl chloride with small quantities of anisole and phenetole give 4'-nitro-4-methoxybenzophenone and 4'-nitro-4-ethoxybenzophenone. Crystalline bromo derivatives can be readily prepared from small amounts of o-cresyl methyl, resorcinol dimethyl, hydroquinone dimethyl, eugenol methyl, isoeugenol methyl, diphenyl, benzyl, a-naphthyl methyl, *β*-naphthyl methyl, *α*-naphthyl ethyl and *β*-naphthyl ethyl ethers, guaiacol, veratrole, anethole, safrole and isosafrole. The oxidation of *p*-cresyl methyl, P-cresyl ethyl and o-cresyl ethyl ethers on a small scale gives anisic, *p*-ethoxybenzoic and o-ethoxybenzoic acids.

THE ACTION OF ULTRAVIOLET LIGHT ON TERPENES. I. THE ACTION ON CITRONELLAL

BY MARSTON TAYLOR BOGERT AND TORSTEN HASSELSTRÖM[1]

RECEIVED JULY 21, 1930 PUBLISHED OCTOBER 6, 1930

As is well known,[2] citronellal can be changed into isopulegol or its derivatives by the action of acids or acid anhydrides. In fact, isopulegol is most conveniently prepared in the laboratory by the action of acetic anhydride upon citronellal, and the mechanism of this reaction has been elucidated by Semmler,[2f] who found that the aldehyde was changed first into its enol acetate, which then added a second molecule of acetic acid with formation of a diacetate, this diacetate in turn splitting out a mole of acetic acid again in such manner that ring closure was effected and isopulegol acetate produced.

When such acids as formic or phosphoric are used as condensing agents, hydrates of isopulegol are obtained, as shown by Prins.[2h]

Labbe[3] observed that citronellal on standing gradually changed almost wholly to the isomeric isopulegol. A sample which nearly completely filled its container, after standing for two months, no longer exhaled any citronellal odor or gave any appreciable reaction with bisulfite, but when oxidized with dichromate and sulfuric acid yielded isopulegone.

Sernagiotto[4] likewise noted that when citronellal was exposed to direct sunlight, in the presence of air and moisture, isopulegol was formed, as well as dihydroxycitronellic acid. The conditions under which this experiment and that of Labbe[3] were carried out, however, were such as to make it desirable to ascertain the effect of ultraviolet light alone upon the aldehyde.

For this purpose, citronellal was placed in a closed quartz vessel and exposed to ultraviolet light, the effect of this exposure being followed by noting the gradual rise in the refractive index. Examination of the product showed that a considerable amount of the citronellal had been changed into isopulegol. This conversion must have been due therefore chiefly to the action of the light rays and not to an hydration–dehydration reaction, since all moisture had been excluded.

To prove that under these conditions also the enol form of citronellal

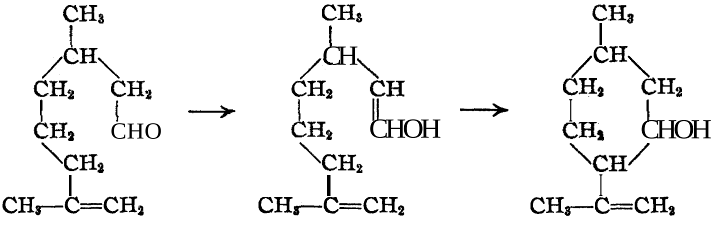
was probably the intermediate product, some of this enol acetate was prepared by the method of Semmler[2f] and exposed to the ultraviolet rays. Isopulegol acetate was formed.

It is believed therefore that the effect of the ultraviolet rays upon citronellal (I) is to rearrange it first to the enol formation (II), and then to close the latter to the cyclic isopulegol (III)



I II III

This hypothesis is supported further by the facts that reagents effective in accomplishing this ring closure have been shown to function as enolizing agents, and because the enol being the unstable form of the aldehyde it has been observed by Stoermer[5] that light can change the stable forms of certain compounds into unstable tautomers.

Several investigators[6] have observed that the action of light upon aldehydes often results in the production also of di- and trimolecular polymers. It is worth noting, therefore, that in our own experiments a trimolecular polymer of citronellal was isolated among the products formed by the action of the ultraviolet light. Prins[2h] reported a dimolecular polymer as one of the products when formic acid acted upon citronellal.

That "citronellal," as ordinarily obtained, is probably an equilibrium mixture of two structural isomers, one, the so-called "alpha" or "limonene" **form,** corresponding to Formula (I) above, and the other, the "beta," "terpinolene" or "rhodinal" form, $(CH_3)_2C{=}CH(CH_2)_2CH(CH_3)CH_2$-CHO, seems indicated by the reports of various workers.[2h,7]

The nature of the citronellal used in our experiments is described beyond. Although both forms yield isopulegol when treated with strong

\end{tikzcd}$$

If, then, light alone is capable of changing citronellal into isopulegol and higher polymers, it is of considerable significance for phytochemistry and botany as a plausible, or at least possible, explanation of the origin of certain cyclic terpenes found in the vegetable kingdom.

Experimental Part

Apparatus.—The source of the ultraviolet light was a mercury vapor lamp manufactured by the Hanovia Chemical and Manufacturing Company, of Newark, N. J., and known as the "Advanced Research Lamp," with an average life of about **4000** hours. The container for the material to be exposed to the rays was a quartz box, 10 X 5 X 1 cm., furnished with quartz inlet and outlet tubes, which were kept closed with rubber tubing during the experiments. This box was placed four inches from the burner and its temperature was maintained at **45–50'** by a stream of air. In Runs A and B, Table I, the box was filled completely by the citronellal. In Run C, the quantity of aldehyde available was not enough for this, so the space remaining was filled with dry carbon dioxide, to prevent oxidation, and this was done also in Run B after the removal of the sample for analysis following fifty hours' exposure.

Citronellal.—A high-class commercial article, supplied through the courtesy of Fritzsche Brothers, of New York, was used as initial material; b. p. **200–202°**, d^{m} **0.8578**, n_{D}^{22} **1.44991**, α_{D}^{30} +4°22′ (2 = 0.5 dm.).

To determine the amount of non-volatile impurities present, 5 g. of the aldehyde was distilled with steam. What remained in the distilling flask was extracted repeatedly with ether, the ether extracts dried and the ether driven off. There remained **0.02** g. of a yellow oil, equivalent to 0.4% of the original aldehyde.

The determination of the non-aldehydic content of the volatile material was based upon the experiments of Tiemann and Schmidt[7c] which proved that citronellal condenses quantitatively with semicarbazide under proper conditions. Three grams of the steam-distilled aldehyde, which had been dried with anhydrous sodium sulfate, was poured into an aqueous solution of 3 g. of semicarbazide hydrochloride and 3 g. of anhydrous sodium acetate. Alcohol was added to this solution until it became slightly opalescent. The mixture was kept at room temperature overnight, then heated for six hours at 60–70°, after which it was transferred to a larger flask and distilled with steam. The oil driven over by the steam was collected with ether, the ether extracts dried with anhydrous sodium sulfate and the ether removed. There remained **0.25** g. of oil, or 8.3% of the original aldehyde.

In conducting the runs recorded in Table I, the change in refractive index of the citronellal was determined with a Pulfrich refractometer at the intervals indicated. It will be noted that indices recorded in Runs B and C are mostly lower than in Run A, for the same total exposure, and this we believe can be ascribed, in part at least, to the decreasing activity of the lamp with use.

After exposure, as shown in Table I, samples were removed and analyzed for non-volatile and for volatile non-aldehydic content by the methods given above. The refractive index for the volatile non-aldehydic material obtained was also recorded. These data are given in Table II.

Examination of the volatile non-aldehydic material separated (from Run A after

177.5 hours' exposure, which amounted to **27.9%.—It** was distilled under reduced pressure. Practically all came over at **90–91°** at **9 mm.** pressure and showed the properties of isopulegol, including d^{20} **0.9125** and n_D^{22} **1.47078,** as compared with $d^{17.5}$ **0.9154** and n_D^{20} **1.47292** as recorded for isopulegol in the literature.''

This product (**3.2** g.) was oxidized to isopulegone by potassium dichromate and sulfuric acid, as described by Tiemann and Schmidt,[7c,8] except that sodium bicarbonate was added to the oxidized mixture before it was distilled with steam. The ketone recovered (**2** g.) was converted into its semicarbazone which, after two recrystallizations from dilute alcohol, formed colorless needles, m. p. 183° (uncorr.), in agreement **with** the figure **given** in the literature[9] for the inactive isopulegone semicarbazone.

Anal. Calcd. for $C_{11}H_{19}ON_3$: N, **20.10.** Found: N, **19.95.**

Tiemann and Schmidt obtained the active semicarbazone by their process.

Examination of that Portion of **the** Exposed Aldehyde which was not Volatile **with** Steam.—This portion was recovered, by the method already described, by ether extraction of the mixture remaining in the distilling flask after subjecting to steam distillation that sample of exposed citronellal (Run **A)** used above **for** the determination of volatile non-aldehydic constituents. The viscous yellow oil **(62.1%)** left after the evaporation of the dried ether could not be distilled without decomposition. After being kept in an evacuated desiccator for several weeks, to remove all traces of ether or moisture, it was analyzed and its molecular weight determined.

Anal. Calcd. for $(C_{10}H_{18}O)_x$: C, **77.92;** H, **11.69.** Found: *C,* **78.23;** H, **11.50.** Mol. wt. found. **466.7** and **460.8; calcd.** for $C_{30}H_{54}O_3$, **462.4.**

These results lead to the conclusion that the product was a **trimolecular** polymer of citronellal.

Examination of the curve plotted from Run A discloses some irregularity and flattening in the middle region, and it was to learn more about this that Run B was carried out and the content of volatile non-aldehydic and of non-volatile material determined after 50 and after 118 hours' exposure (see Table II). These results indicate a condition approaching

TABLE II

RESULTS OF EXPERIMENTS

Run	Total hours of exposure	Nan-volatile, %	Volatile non-aldehydic %	Volatile non-aldehydic n_D^{22}
	0	0.4	8.3	1.46387
C	20	12	18.7	1.46852
C	40	20	28.1	1.47051
B	50	34.4	32.1	1.46783
B	118	34.4	34.4	1.46931 (n_D^{26})
A	177.5	62.1	27.9	1.47078

The refractive index of the volatile non-aldehydic portion was determined on the distilled oil in Run A, but on the undistilled material from Runs B and C.

equilibrium in this region. The variation in the refractive index during this period of temporary equilibrium may be due to a change in the character of this non-volatile material, rather than in its total amount, after which change the curve resumes its normal course. Similarly, the fall in volatile non-aldehydic ingredients after 118 hours' exposure is believed to be due to polymerization of the isopulegol.

The Action of Ultraviolet Light upon the Enol Acetate of Citronellal.—This was prepared by the method of Semmler[2f] and showed the following constants: b. p. (10 mm.) 110–115°, d^{20} 0.9068, n_D^{28} 1.44801.

Fifteen grams of this acetate was placed in the quartz box, the remaining space in the box being filled with dry carbon dioxide, and was exposed to the ultraviolet light, the changes produced in the enol acetate being followed by determining the changes in its density. The results are presented in Table III.

TABLE III

EXPERIMENTAL DATA

Total hours exposed	d^{20}
0	0.9068
7	.9078
16	.9102
26	.9122
38	.9236
46	.9238

Citronellal enol acetate,[2f] d^{20} 0.902, n_D 1.45762. Isopulegol acetate,'' d^{20} 0.925, n_D 1.459

Upon the conclusion of this exposure, 14 g. of the exposed enol acetate was repeatedly distilled under diminished pressure. On the sixth distillation, the following fractions were collected.

Fraction	B. p. at 10 mm., °C.	Amt., g.	d^{20}	n_D^{26}
1	90–105	1.5	0.9168	1.45541
2	105–107	7	.9278	1.45691
3	107–125	3	.9054	1.45341

There remained in the distilling flask only a small quantity of viscous oil.

Fraction 1 was not examined, but its high density would indicate that it was composed chiefly of isopulegol acetate.

Fraction 2 was analyzed with the following results.

Anal. Calcd. for $C_{12}H_{20}O_2$: C, 73.47; H, 10.20. Found: C, 73.0; H, 10.14.

These analytical figures, taken together with the density and refractive index of this fraction, supported the conclusion that it was mainly isopulegol acetate. It (4 g.) was therefore saponified by an alcoholic potassium hydroxide solution and the mixture distilled with steam. The volatile oil was extracted from the distillate with ether, the ether evaporated and the residual isopulegol oxidized by dichromate and sulfuric acid to the isopulegone, whose semicarbazone was prepared and melted at 183° (uncorr.). This product, when mixed with the inactive isopulegone semicarbazone obtained from citronellal itself, as already reported, showed no change in melting point.

Fraction 3 contained unchanged enol acetate.

Summary

1. Citronellal can be changed to isopulegol by the action of ultraviolet light, a fact which is of considerable significance to phytochemistry as well as to botany.

2. The mechanism of the reaction is believed to consist first in the rearrangement of the aldehyde into its enol formation, which then closes to the cyclic isopulegol, since it is shown that citronellal enol acetate also can be converted into isopulegol acetate by ultraviolet light.

STEREOCHEMISTRY OF DIPHENYLBENZENES. PREPARATION OF STEREOISOMERIC 3,6-DI-(2,4-DIMETHYLPHENYL)-2,5-DIBROMOHYDROQUINONES AND THEIR DERIVATIVES. IX[1]

BY E. BROWNING[2] AND ROGER ADAMS

RECEIVED JULY 25, 1930 PUBLISHED OCTOBER 6, 1930

In a recent article[3] on the isomerism of diphenyl compounds it was pointed out that interesting possibilities for stereoisomerism existed in diphenylbenzene derivatives if the same conditions were found in these latter molecules that produced isomerism in diphenyl derivatives. Thus. for example, in a molecule of type (I) in which each of the two end benzene rings are asymmetric in themselves and similar to each other, meso and racemic modifications should exist. The meso form is of peculiar interest

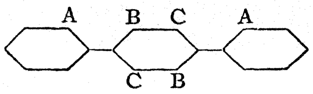
---

[1] For article No. VIII in this series see Stanley and Adams, THIS JOURNAL, 52, November, 1930.

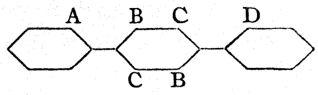
[2] This communication is the abstract of a thesis submitted by E. Browning in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry at the University of Illinois.

[3] Stanley and Adams. *Rec. trav. chim.*, 48,1035 (1929).

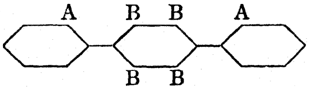
in that it contains a point of symmetry in distinction to a plane of symmetry found usually. If, on the other hand, the two end rings are dissimilar to each other (II), but still asymmetric in themselves, two racemic modifications should be possible. A third even more interesting type is that found in a formula of type (III) in which optical isomerism is not possible of existence but *cis–trans* isomers should occur whether the two end rings are similar or dissimilar, provided each is asymmetric in itself.



I



II



III

Investigations on these compounds are now under way in this Laboratory and the preliminary results are being presented in this communication on the study of compounds of type (I). In a recent article, Kogl and Erxleben,[4] who, apparently, had not read the communication from this Laboratory which contained a discussion of diphenylbenzene isomerism and a statement of the intention to undertake here a study of this problem experimentally, announced that they are planning to work on the resolution of terphenyl derivatives. The authors of this article, as they have established priority, desire to reserve this field for the next few years or until such a time, at least, as the predictions set forth by them in the article mentioned may be verified or disproved.

The specific compound which has been selected for study in this initial investigation is a derivative of 3,6-di-(2,4-dimethylphenyl)-hydroquinone (IV). This latter substance can, fortunately, be obtained with readiness following the general procedure of Pummerer.[5] A 50% yield of product was obtained by condensation of *m*-xylene with *p*-benzoquinone. This substance in itself has only two ortho substituents in each set of four positions existing adjacent to the linkages between the benzene rings. Past experience has shown that at least three groups are necessary in the adjacent positions before free rotation between the benzene rings is prevented. The compound, however, lends itself well to the satisfying of such conditions by the formation of a derivative which has these properties. Upon bromination with two moles of bromine in chloroform as a solvent, there is obtained a reaction mixture which, after reduction to remove traces of quinones which have been formed simultaneously, is found to contain two dibromo derivatives. That these two substances actually represent

---

[4] Kogl and Erxleben, Ann., 479, 17, footnote (1930).

[5] Pummerer and Huppmann, Ber., 60, 1445 (1927).

the meso (V) and the racemic (VI) modifications of 3,6-di-(2,4-dimethylphenyl)-2,5-dibromohydroquinone has been quite definitely established.

The two substances thus obtained differ from each other quite widely in melting point, 190–191 and 236–237°. Mixed melting points where less than 10% of the high-melting form is present, show values lower than the lower melting. The two compounds have a different solubility in various solvents.

Each of the two dibromohydroquinones can be acetylated to give its own perfectly stable characteristic diacetate (VII and VIII), and each of the diacetates can, in turn, be nitrated to the corresponding individual tetranitro compound (IX and X).

That the substances are actually stereoisomers and not simple isomers due to different positions of the two bromine atoms in each of the molecules, was proved in more than one way. Each of the two dibromohydroquinones could be oxidized to give the same dibromoquinone (XI). It would thus appear either that diphenyl isomerism cannot exist in the molecule when the quinone ring is present, or that, if it does exist, one form is so much more stable than the other that only one isomer of the corresponding quinones is actually isolated.

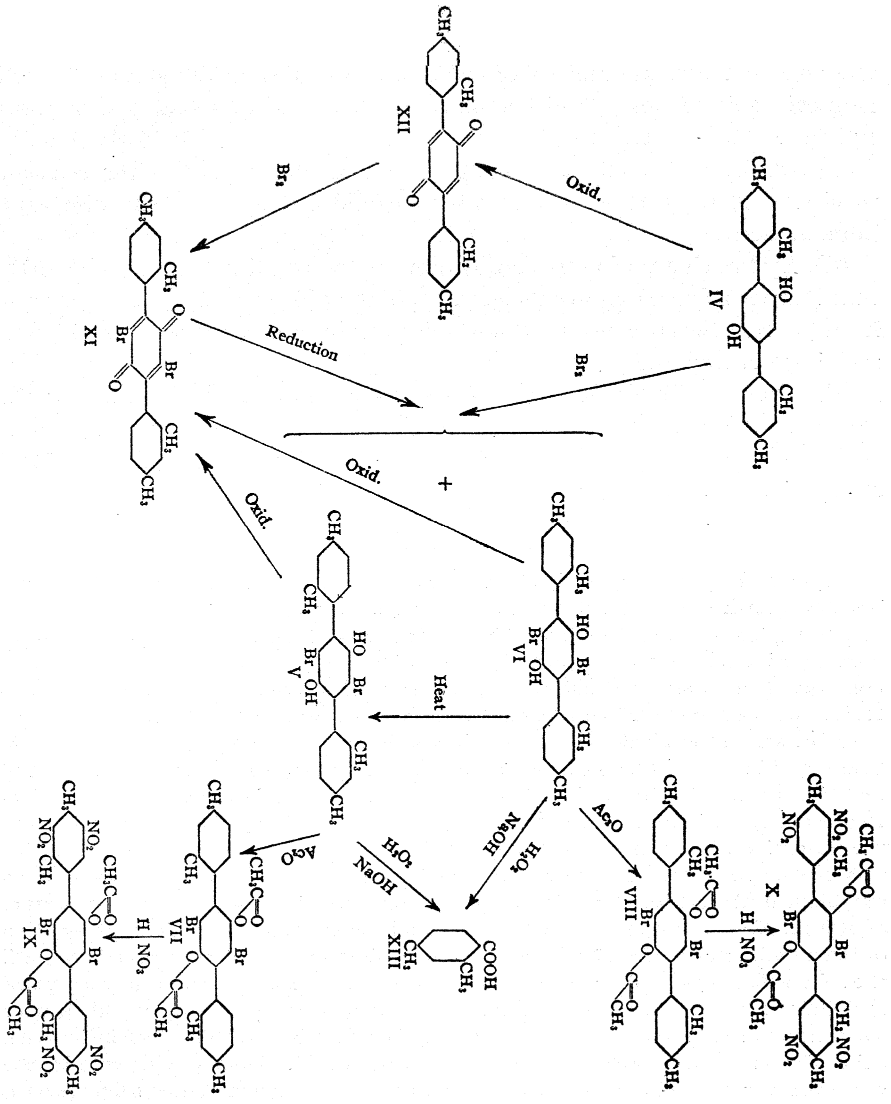
It is of interest to apply calculations based on x-ray data to this quinone in order to determine whether interference might be expected. If the assumptions are made that the internuclear distance between the linked carbon atoms of the benzene ring and the quinone ring is essentially the same as the distance between the linked carbon atoms of the two rings in diphenyl, and that the angles in the quinone ring are the same as in benzene, then the sum of the x-ray values for the $—C{=}O$ and the $C—CH_3$ should indicate the possibility or impossibility of resolution.[6] If the $C—CH_3$ is 1.73 Å. and the $C{=}O$ value is 1.15 Å. (merely the volume of the oxygen atom is taken here), and from their sum, 2.88 Å., the value 2.90 Å. (the distance between the linked carbon atoms in diphenyl) is subtracted, there is obtained a value of —0.02 Å. Thus the quinone oxygen and the methyl group of the benzene ring may be assumed not to collide and free rotation of the rings should be possible. Regardless of the proper explanation, the fact that identically the same compound is obtained by the oxidation of these two quite different hydroquinones, demonstrates quite positively the stereoisomeric nature of the two products.

Further evidence that these two dibromo compounds are of the type presented, and that both bromines are ortho to the hydroxyls in each molecule, was obtained. (1) The dibromoquinone (XI) from oxidation of either of the two pure hydroquinones gives upon reduction always a mixture of the high- and low-melting hydroquinones (V and VI). (2) The 3,6-di-(2,4-dimethylphenyl)-quinone (XII) from the oxidation of 3,6-di-(2,4-

---

[6] Stanley and Adams, THIS JOURNAL, 52, 1200 (1930).

dimethylphenyl)hydroquinone (IV) can be brominated in chloroform to give the same dibromoquinone (XI) that is obtained by oxidation of the dibromohydroquinones.



(3) Each of the two dibromohydroquinones (V and VI) is oxidized by means of strong sodium hydroxide solution and hydrogen peroxide, presumably with the primary formation of the corresponding quinone which is then oxidized further to a benzene derivative. The final compound obtained in each case is 2,4-dimethylbenzoic acid (XIII). Unfortunately the

yields are lower than might be desired (about one mole per mole of original hydroquinone, whereas, theoretically, two moles are possible). However, in an oxidation of this sort it is not to be unexpected that a quantitative yield of product is not obtained. It is pertinent, however, that the dimethylbenzoic acid which is produced is essentially pure as it comes from the reaction mixture and this is true in the oxidation of each of the two isomeric substances. If either of the two compounds had one or more bromine atoms in either of the two end rings, it is extremely likely that the corresponding bromodimethylbenzoic acid would appear in the reaction product, at least to an extent which would contaminate the dimethylbenzoic acid.

(4) By heating the lower-melting dibromohydroquinone (m. p. 190–191°) to a temperature 30° above its melting point and holding it there for several hours, a reaction product results which contains a proportion of the higher-melting compound.

Whether the higher-melting dibromohydroquinone is the meso or the racemic modification has not as yet been determined. It should be possible to introduce a salt-forming group into the molecule and then through a study of the resolution characterize each substance.

Experimental Part

3,6-Di-(2,4-dimethylphenyl)-hydroquinone.—In a 1-liter, three-necked, round-bottomed flask equipped with a thermometer and very efficient stirrer was placed 375 cc. of m-xylene of b. p. 138–139°. The m-xylene was cooled to 5° and 140 g. of aluminum chloride added with stirring, after which 70 g. of pure, dry, powdered benzoquinone (purified by steam distilling crude product and then drying over phosphorus pentoxide) was added in portions of about 0.5 g. The reaction mixture immediately turned dark brown and gradually became so viscous that stirring was difficult. In order to insure rapid mixing of the solid quinone it was added at such a rate that most of it had been incorporated before the mixture became thick (about forty-five minutes). Efficient cooling to keep the temperature below 20° is necessary since above this point the formation of tar seems to be considerably increased. After the addition the stirring was continued for two hours and the dark brown reaction mixture allowed to stand overnight in the refrigerator. It was then poured with vigorous stirring into a mixture of 100 cc. of concentrated hydrochloric acid and 400 cc. of water. The decomposition of the aluminum chloride complex was somewhat slow and the mixture was stirred until the solid which separated was dark gray in color and the excess of m-xylene had separated in a definite layer. The solid was filtered by suction and dried in a vacuum desiccator over phosphorus pentoxide. The dark gray powdery product was dissolved in benzene. boiled for one hour with decolorizing charcoal and filtered. Upon cooling with ice the product separated as an amorphous powder which, upon recrystallization from benzene, came down in white microscopic needles. The yield was 30 g. (43.7% of the theoretical) of a product melting at 188–189°.

Anal. Calcd. for $C_{22}H_{22}O_2$: C, 82.97; H, 6.97. Found: C, 82.70; H, 6.76.

Stereoisomeric **3,6-Di-(2,4-dimethylphenyl)-2,5-dibromohydroquinones.**—In a 200-cc., three-necked, round-bottomed flask fitted with a dropping funnel, mercury-sealed stirrer **and** condenser with a trap for hydrogen bromide fumes were placed 13 g. (0.04

mole) of 3,6-di-(2,4-dimethylphenyl)-hydroquinone and 150 cc. of chloroform. The flask was warmed until the solid was completely dissolved, and the solution was then cooled to 40–50°. To this solution was added slowly with stirring 13 g. (0.08 mole) of bromine dissolved in 30 g. of chloroform (30% solution). The rate of addition was controlled so that the bromine was absorbed almost as rapidly as it entered the reaction mixture. After about three-fourths of the bromine had been added the temperature was raised to 70° to increase the rate of reaction. At this temperature fumes of hydrogen bromide were evolved for the first time; in experiments in which the entire bromination was carried out at 70°, however, the evolution of hydrogen bromide was continuous throughout the entire procedure.

The chloroform and slight amount of unreacted bromine were removed at once by distilling from a steam-bath under reduced pressure, adding more chloroform as required until the distillate was no longer colored with bromine. The chloroform was then distilled completely and to the dry, slightly yellow reaction product (amounting to 16-18 g.) was added 100 cc. of ethyl alcohol. If the bromination was properly controlled, the color was only slightly yellow (due to the presence of 3,6-di-(2,4-dimethylphenyl)-2,5-dibromoquinone from oxidation of the hydroquinone). To the alcohol containing the partially dissolved product was added a few drops of hydrochloric acid and the minimum amount of stannous chloride required to decolorize the product. It is highly desirable to control the rate of addition of the bromine as indicated previously in the procedure so as to avoid oxidation and the use of stannous chloride as far as possible, since the latter seems to make the subsequent separation and purification of the two compounds in the product more difficult. The total yield of bromination product before crystallization was 16 g. (82% of the theoretical).

High-Melting Modification. a-Form.—The ethyl alcohol containing the partially dissolved bromination product and stannous chloride was boiled until completely decolorized, cooled somewhat and filtered by suction. The residue was recrystallized from acetone until it reached a constant melting point at 236–237°. The yield was 6 g. of white hexagonal prisms.

Anal. (Parr Bomb) Calcd. for $C_{22}H_{20}O_2Br_2$: Br. 33.61. Found: Br, 33.5.

Low-Melting Modification. β-Form.—The filtrate from the ethyl alcohol treatment of the bromination product of 3,6-di-(2,4-dimethylphenyl)-hydroquinone was cooled in an ice-bath for about two hours, during which time a small quantity of white crystals separated. This was filtered and 1.5 g. of a product was obtained melting without recrystallization at 130-131° which proved to be the high-melting modification contaminated with a small amount of the low-melting compound. The filtrate was evaporated to dryness at room temperature under reduced pressure. The slightly yellow product was recrystallized from acetone. Repeated crystallization from both acetone and methyl alcohol gave a product having a constant melting point of 190-191°. The yield was 4 g. of white tetragonal prisms.

Anal. Calcd. for $C_{22}H_{20}O_2Br_2$: Br, 33.61. Found: Br, 33.5.

The melting of a mixture of 5% 236-237' compound with 95% 190–191° compound showed softening at 181° and melting at 184–189°.

The solubility of the low- and high-melting compounds is markedly different. The compound melting at 236-237' is only slightly soluble in hot ethyl alcohol while the compound melting at 190-191' can be induced to crystallize from its solution in ethyl alcohol only by evaporation and cooling. A difference, though not so great, is found in methyl alcohol and acetone.

The successful isolation of the high- and low-melting compounds in the pure state depends upon the initial separation by the use of ethyl alcohol as described in the above procedure. If too much alcohol is used, the low-melting compound is contaminated with the high-melting product and is purified by subsequent recrystallization only with great difficulty and loss of material in the filtrates. If too little alcohol is used the high-melting compound will be contaminated with the other form, but this product is more easily purified, at least to a point a few degrees below the correct melting point.

One attempt was made to carry out a fractional crystallization of the crude bromination product using methyl alcohol as the solvent and omitting the preliminary separation with ethyl alcohol. The different fractions obtained after several crystallizations seemed from their melting points to be mixtures of various proportions of the more and less soluble modifications.

3,6-Di-(2,4-dimethylphenyl)-2,5-dibromohydroquinone Diacetate. **α-Form.** A. (Derivative of Hydroquinone Melting at 236–237°.)—Six grams of 3,6-di-(2,4-dimethylphenyl)-2,5-dibromohydroquinone was dissolved in 10 cc. of hot pyridine and 12 cc. of acetic anhydride added with stirring. The solution was heated almost to boiling for fifteen minutes, after which time the acetyl derivative began to separate from the hot solution. The reaction mixture was cooled with ice and allowed to stand for several hours, after which the product was filtered, recrystallized from acetic anhydride and left in a vacuum desiccator until the odor of acetic anhydride could no longer be detected. The yield was 6 g. of hard, white, orthorhombic crystals melting at 235–236°. Only a small amount of additional material was obtained by pouring the original pyridine–acetic anhydride filtrate into water. This acetyl derivative is only slightly soluble in hot acetone.

Anal. Calcd. for $C_{26}H_{24}O_4Br_2$: Br, 28.57. Found: Br, 28.29.

3,6-Di-(2,4-dimethyl-3,5-dinitrophenyl)-2,5-dibromohydroquinone Diacetate. α-Form.—To 40 cc. of fuming nitric acid (sp. gr. 1.48) coaled below −5° was addedslowly with very rapid stirring 6 g. of the powdered diacetyl derivative just previously described and melting at 235–236°. A red coloration appeared momentarily as the solid came in contact with the acid but disappeared as the compound went into solution. After standing in the freezing mixture for 15 minutes a solid began to separate, and after one hour the nitration mixture was poured into ice water. The nitro derivative was filtered, washed free of acid with a 5% sodium carbonate solution, followed by water and dried. The product was washed with acetone until pure white and melted at 304–305° after drying. Crystallization from acetic anhydride yielded 4.8 g. of white needles melting sharply at 305–306° (decomposed after melting, with evolution of gas bubbles).

Anal. (Parr Bomb) Calcd. for $C_{26}H_{20}O_{12}N_4Br_2$: Br, 21.62. Found: Br, 21.78.

3,6-Di-(2,4-dimethylphenyl)-2,5-dibromohydroquinone Diacetate. **β-Form.** B. (Derivative of Hydroquinone Melting at 190–191°.)—The acetylation was carried out in the same way as for the acetylation of the high-melting hydroquinone using 4 g. of the substituted hydroquinone, 5 cc. of pyridine and 8 cc. of acetic anhydride. The acetyl derivative did not separate from the hot solution as in the previous case, but came out on cooling in an ice–salt mixture. It was allowed to stand overnight and the white powdery product filtered by suction. The amount thus obtained was 3.5 g. and 1 g. additional by pouring the filtrate into water. The product was readily soluble in acetone as contrasted with the preceding diacetyl derivative, and upon recrystallization from this solvent yielded 3 g. of white microscopic needles melting at 193–194° (with previous softening). A mixed melting point with the starting material showed a depression and melted over a range of 160–165°.

Anal. Calcd. for $C_{26}H_{24}O_4Br_2$: Br, 28.57. Found: Br. 28.42.

3,6-Di-(2,4-dimethyl-3,5-dinitrophenyl)-2,5-dibromohydroquinone Diacetate. *B*-Form.—The nitration of the diacetate just described was carried out as in the case of the higher-melting diacetate using 2 g. of the diacetyl derivative and 20 cc. of fuming nitric acid. The product in this case did not precipitate from the cold nitration mixture even after long standing, and it was found more satisfactory to pour the solution immediately into ice water in order to avoid excessive formation of a lemon-yellow by-product, presumably formed by hydrolysis of the acetyl groups, followed by oxidation. Recrystallization from acetone yielded 0.4 g. of microscopic white needles melting at 282–283° with slight decomposition and evolution of gas.

Anal. Calcd. for $C_{26}H_{20}O_{12}N_4Br_2$: Br, 21.62. Found: Br, 21.43.

3,6-Di-(2,4-dimethylphenyl)-2,5-dibromoquinone.—Oxidation of the substituted hydroquinones to the corresponding quinones was carried out most readily by the method of Pummerer,[5] using benzoquinone as the oxidizing agent.

One gram of 3,6-di-(2,4-dimethylphenyl)-2,5-dibromohydroquinone was dissolved in the minimum amount of hot methyl alcohol and 0.1 g. of benzoquinone added. The solution turned orange almost at once, and was boiled for ten minutes, during which time the less soluble substituted quinone began to precipitate. Another 0.1-g. portion of benzoquinone was added, the reaction mixture boiled for ten minutes and then cooled with ice. The product was filtered, recrystallized from methyl alcohol and dried in a vacuum desiccator; yield, 0.7 g. of microscopic orange needles melting at 197–198°.

Anal. Calcd. for $C_{22}H_{18}O_2Br_2$: Br, 33.75. Found: Br, 33.60.

One gram of 3,6-di-(2,4-dimethylphenyl)-2,5-dibromohydroquinone (m. p. 236–237°) was oxidized as in the preceding experiment, and yielded 0.8 g. of orange needles melting at 198° after one recrystallization from methyl alcohol. Repeated crystallization failed to raise the melting point.

A mixed melting point of the quinones obtained from the 190–191° and 236–237° compounds showed no depression.

3,6-Di-(2,4-dimethylphenyl)-quinone and **3,6-Di-(2,4-dimethylphenyl)-2,5-dibromoquine.**—3,6-Di-(2,4-dimethylphenyl)-quinone was prepared from the corresponding hydroquinone by the oxidation procedure given in the preceding experiment. The product, after crystallization from methyl alcohol, from 2 g. of hydroquinone was 1.8 g. of reddish-brown crystals melting at 180°.

The 1.8 g. of 3,6-di-(2,4-dimethylphenyl)-quinone was dissolved in 50 cc. of chloroform and a 30% solution of 2 g. of bromine in chloroform was added slowly with stirring at room temperature. The bromine was absorbed instantly but no hydrogen bromide was evolved until the solution was warmed. The chloroform was distilled, leaving 4 g. of an orange, crystalline product. Upon dissolving the material in methyl alcohol it was observed that some white crystalline substance was present, possibly some substituted hydroquinone formed by the addition of hydrogen bromide to the quinone. The solution was, therefore, treated with benzoquinone and boiled, after which an orange product separated which resembled in appearance the dibromoquinones previously prepared. After repeated crystallization from methyl alcohol, there was obtained 2 g. of an orange product melting sharply at 198°. A mixed melting point with 3,6-di-(2,4-dimethylphenyl)-2,5-dibromoquinone prepared by the other method described showed no depression.

Reduction of **3,6-Di-(2,4-dimethylphenyl)-2,5-dibromoquinone.**—A solution of 3.8 g. of 3,6-di-(2,4-dimethylphenyl)-2,5-dibromoquinone in acetone was reduced by means of 1.5 g. of stannous chloride and 2 cc. of concentrated hydrochloric acid. Decolorization of the orange solution was almost immediate after slight warming. The solution was poured into four times its amount of water and the precipitated reduction product filtered, washed several times with water and dried. To the product was added 40 cc. of ethyl alcohol; the mixture was heated for five minutes and filtered while warm. The insoluble part amounting to 1.2 g. was recrystallized from acetone to constant melting point and yielded 1.1 g. of a compound melting at 236–237°. The filtrate was cooled and permitted to stand for one hour, after which the crystals that had separated were filtered. Four-tenths of a gram of high-melting compound contaminated with some of the low-melting modification was thus obtained. It melted at 230–232° (softens at 225°). The acetone filtrate was evaporated to dryness at ordinary temperature and under reduced pressure and yielded 1.3 g. of substance melting at 190–192° (softens at 187°). This, after recrystallization from acetone, yielded 0.8 g. of a compound melting constantly at 190–191°. The compounds have also been purified in other experiments by crystallization from methyl alcohol.

Stability to Heat of 3,6-Di-(2,4-dimethylphenyl)-2,5-dibromohydroquinone, m. p. 190–191°.—In a small bomb tube was placed one gram of 3,6-di-(2,4-dimethylphenyl)-2,5-dibromohydroquinone (m. p. 190–191°) and the tube evacuated to 10 mm. The tube was then filled with nitrogen, again evacuated and the process repeated several times to insure complete removal of oxygen. The bomb tube was then sealed off while filled with nitrogen and immersed in an oil-bath at 220°, whereupon the substance melted to a clear liquid. After one hour (longer heating is not possible because of decomposition) the tube was allowed to cool to room temperature, after which it was opened and the white solidified product heated with 15 cc. of ethyl alcohol. The residue insoluble in alcohol was filtered and crystallized from acetone. There was thus obtained 0.05 g. of white crystals melting at 235–236°. A mixed melting point with the high-melting modification showed no depression.

Oxidation of 3,6-Di-(2,4-dimethylphenyl)-2,5-dibromoquinone to 2,4-Dimethylbenzoic Acid.—One gram of 3,6-di-(2,4-dimethylphenyl)-2,5-dibromoquinone was suspended in 50 cc. of 20% sodium hydroxide solution and 25 cc. of 30% hydrogen peroxide added with stirring. The quinone gradually dissolved and the original deep red color of the solution changed to pink in the course of six hours. The addition of 25 cc. more of hydrogen peroxide and longer stirring failed to effect further change. The solution, in which the odor characteristic of aromatic aldehydes was noticeable, was acidified and the yellow solid which precipitated was filtered and dried. It was redissolved in very dilute sodium hydroxide and the pink color reappeared. Upon addition of 10 cc. of hydrogen peroxide to this faintly alkaline solution, a vigorous reaction occurred and the solution became decolorized in a few minutes. Acidification with hydrochloric acid caused the precipitation of a fairly white product. This was extracted with ether, the ether solution shaken out with a saturated sodium bicarbonate solution, and this alkaline solution acidified with hydrochloric acid. The product precipitated and was filtered and recrystallized from dilute ethyl alcohol. The yield was 0.2 g. of a compound melting sharply at 125–126°. A mixed melting point with 2,4-dimethylbenzoic acid showed no depression.

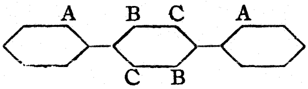
Neut. Equiv. Subs., 0.0788 g.: 0.1015 *N* NaOH, 5.07 cc. Calcd. for C_8H_9COOH: mol. wt., 150. Found: mol. wt. 153.

Oxidation of 3,6-Di-(2,4-dimethylphenyl)-2,5-dibromohydroquinone (m. p. 190–191°) to 2,4-Dimethylbenzoic Acid.—The oxidation was carried out in the same way as in the preceding experiment using 0.25 g. of the substituted hydroquinone, 30 cc. of 20% sodium hydroxide and 25 cc. of 30% hydrogen peroxide. The yield after the various extractions and purification was 0.06 g. (*i. e.*, 0.7 mole of acid from 1 mole of the compound) of 2,4-dimethylbenzoic acid melting at 125–126°.

Oxidation of 3,6-Di-(2,4-dimethylphenyl)-2,5-dibromohydroquinone (m. p. 236–237°) to 2,4-Dimethylbenzoic Acid.—The oxidation was accomplished as before, using 0.47 g. of substance, 50 cc. of 20% sodium hydroxide solution, and 50 cc. of 30% hydrogen peroxide. The 2,4-dimethylbenzoic acid was isolated and purified as before, and amounted to 0.13 g. (0.8 mole of acid from 1 mole of substance). The melting point was 125–126°.

Summary

1. Two stereoisomeric 3,6-di-(2,4-dimethylphenyl)-2,5-dibromodihydroquinones and some derivatives have been prepared.
2. These substances are the racemic and the meso modifications of a molecule of the following type



3. It may be concluded that the same conditions which cause optical isomerism in the diphenyl series also exist in the terphenyl series.

MIXED BENZOINS. II

BY JOHANNES S. BUCK AND WALTER S. IDE

RECEIVED JULY 26, 1930 PUBLISHED OCTOBER 6, 1930

In continuation of the work described in Part I,[1] six new benzoins, together with their benzils and desoxy compounds have been prepared. The work described cannot be said to support, or detract from, the theoretical conclusions advanced in Part I, as data on the reactivity of the aldehydes are lacking. The benzoins described in the present paper were all prepared in the usual manner, by mixing the reactants and refluxing, as it was found that the technique earlier described gave little, if any, better yields in the present cases. The results described in Part I and Part II represent the best that can be obtained by fractionation methods, and it is evident that further knowledge can only be attained by complete analysis of the reaction mixtures. It is hoped to carry this out in some cases.

Attention was given to the possibility of the occurrence of isomeric mixed benzoins, but no examples were found. Their occurrence, however, is not excluded, as in general only about one-half of the reactants was accounted for. The mixed benzoins described are very probably individuals and not mixtures or addition compounds, as in each case only one desoxy compound was obtained on reduction.

The mixed benzoins described are not specifically named, as it is not possible to assign either of the two alternative structures with any degree of probability,

Experimental

Benzoin from *p*-Dimethylaminobenzaldehyde and Anisaldehyde, (A).—Seven and one-half grams of *p*-dimethylaminobenzaldehyde, and 7.0 g. of anisaldehyde, dis-

---

[1] Buck and Ide, THIS JOURNAL, 52,220 (1930).

solved in 50 cc. of 50% alcohol, were refluxed for two and one-half hours with 4.0 g. of potassium cyanide. The product, recrystallized from alcohol, forms white flakes, moderately soluble in alcohol and very soluble in ether, benzene and ligroin; yield 52%. The product melts at 144° (uncorr.).

Anal. Calcd. for $C_{17}H_{19}O_3N$: N, 4.91. Found: N, 4.67.

Benzoin from *p*-Chlorobenzaldehyde and Piperonal, (B).—This benzoin was prepared by refluxing a solution of 3.5 g of p-chlorobenzaldehyde, 3.8 g. of piperonal and 5.0 g. of potassium cyanide in 50 cc. of 50% alcohol for two hours. The yield was 40%. On recrystallization from alcohol the compound forms yellow needles melting at 110° (uncorr.). It is moderately soluble in alcohol, very soluble in ether and chloroform and slightly soluble in benzene and ligroin.

Anal. Calcd. for $C_{15}H_{11}O_4Cl$: C, 61.95; H, 3.79. Found: C, 61.81; H, 3.68.

Benzoin from o-Chlorobenzaldehyde and Anisaldehyde, (C).—Seven grams of o-chlorobenzaldehyde, 6.8 g. of anisaldehyde and 4.0 g. of potassium cyanide, dissolved in 75 cc. of 50% alcohol, were refluxed for two hours. On standing crystals separated. After recrystallization from alcohol, the compound forms colorless, hexagonal crystals, melting at 84° (uncorr.). It is moderately soluble in alcohol and ligroin and very soluble in benzene, ether and chloroform; yield 60%.

Anal. Calcd. for $C_{15}H_{13}O_3Cl$: Cl, 12.83. Found: Cl, 12.72.

Benzoin from o-Chlorobenzaldehyde and Veratric Aldehyde, (D).—A solution of 8.3 g. of veratric aldehyde, 7.0 g. of o-chlorobenzaldehyde and 4.0 g. of potassium cyanide in 75 cc. of 50% alcohol was refluxed for two and one-half hours. On cooling the product crystallized out. After recrystallization from alcohol the compound forms fine white needles, melting at 140° (uncorr.). It is moderately soluble in alcohol, ligroin and benzene and very soluble in ether and chloroform; yield 70%.

Anal. Calcd. for $C_{16}H_{15}O_4Cl$: Cl, 11.57. Found: Cl, 11.31).

Benzoin from m-Chlorobenzaldehyde and p-Dimethylaminobenzaldehyde, (E).—The compound was prepared by refluxing, for two hours, a solution of 7.0 g. of *m*-chlorobenzaldehyde, 7.5 g. of *p*-dimethylaminobenzaldehyde and 4.0 g. of potassium cyanide in 75 cc. of 50% alcohol. After recrystallization from alcohol, the benzoin forms either large dark brown rhombs, or small yellow rhombs, both forms melting at 140° (uncorr.) and showing no depression when mixed. On reduction both gave the same desoxy compound. The compound is moderately soluble in benzene, alcohol and ether, slightly soluble in ligroin and very soluble in chloroform: yield 45%.

Anal. Calcd. for $C_{16}H_{16}O_2NCl$: Cl, 12.24. Found: Cl, 11.98.

Benzoin from m-Bromobenzaldehyde and Anisaldehyde, (F).—Seven grams of anisaldehyde, 9.3 g. of *m*-bromobenzaldehyde and 4.0 g. of potassium cyanide. dissolved in 50 cc. of 50% alcohol, were refluxed for two and one-half hours. The oil which separated was crystallized from alcohol. After recrystallization the compound forms yellow cubes, melting at 88° (uncorr.). It is moderately soluble in alcohol, benzene, ether and ligroin and very soluble in chloroform: yield 20%.

Anal. Calcd. for $C_{15}H_{13}O_3Br$: C. 56.04; H, 4.08. Found: C, 55.79; H, 3.91.

It should be pointed out that in the preparation of some mixed benzoins considerable patience is necessary to induce crystallization of the crude products, prolonged exposure of the solutions to temperatures around 0° sometimes being required. The authors have obtained clear indications of the formation of a number of other mixed benzoins but as yet have not succeeded in isolating sufficient crystalline material to justify descriptions of the experiments.

Benzil Derivatives.—The mixed benzoin (usually 2.0 g. was taken) dissolved in alcohol was oxidized with a slight excess of Fehling's solution and recrystallized from alcohol until pure. There is, of course, no ambiguity in the structure. The benzils are tabulated in Table I.

TABLE I

BENZIL DERIVATIVES

Formula	Benzoin	M. p., °C.	Yield, %	Appearance	Analysis, %	Calcd.	Found

Desoxy Compounds.—These were prepared in general by refluxing 2.0 g. of mixed benzoin, 3 cc. of concentrated hydrochloric acid, 10 cc. of alcohol and 2.0 g. of tin with a trace of copper sulfate for five to six hours. The product was then crystallized from alcohol. The structure naturally depends on that of the parent benzoin and at present it is not possible to decide between the two alternative structures. Only one desoxy compound was obtained from each benzoin, indicating that the latter was a definite compound, not a mixture of two isomers (see Table II).

Summary

In continuation of previous work, six new mixed benzoins have been isolated and their benzils and desoxy compounds prepared.

TUCKAHOE, NEW YORK

[CONTRIBUTION NO. 40 FROM THE EXPERIMENTAL STATION OF E. I. DU PONT DE NEMOURS AND COMPANY]

STUDIES ON POLYMERIZATION AND RING FORMATION. VI. ADIPIC ANHYDRIDE

BY JULIAN W. HILL

RECEIVED JULY 26, 1930 PUBLISHED OCTOBER 6, 1930

The anhydrides of succinic and glutaric acids are known and are monomeric rings of five and six atoms, respectively. The monomeric anhydride of the next member of the series, adipic acid, is a seven-atom ring, and therefore the direct preparation of this anhydride by the removal of water from the acid should give a polymolecular product, in accordance with the generalizations formulated in the previous papers in this series.[1] This has been found to be the case. We have. also been successful in preparing monomeric adipic anhydride for the first time.

Adipic anhydride has been prepared by Voerman[2] and by Farmer and Kracovski,[3] both of whom describe it as a solid. Voerman prepared the compound by treating adipic acid with acetyl chloride, removing volatile compounds in *vacuo*, and finally crystallizing from benzene. He gives a melting point of 98°. On the basis of a molecular weight determination in phenol, with which, however, we have found it to react, he seemed to regard the compound as a monomeric ring. The abnormally high molecular weight obtained in boiling acetone, the lack of definite crystallinity, and the relatively low solubility of the compound, however, led him to consider that it might be polymeric. He does not make his viewpoint altogether clear, but apparently he regarded the anomalous properties of the compound as due to some sort of association of simple rings and did not consider the probability of the existence of a long chain or large ring.

Farmer and Kracovski state that adipic anhydride is definitely unimolecular and ascribe to it a melting point of 97°. This is certainly not correct since we have found the monomer to melt at a very much lower temperature.

We have prepared adipic anhydride by both of these methods and have found that the product before subjection to distillation is polymeric, as we had anticipated and Voerman suspected. Polymeric adipic anhydride separates from hot benzene as a microcrystalline powder. Samples prepared in various experiments showed melting points ranging from 70 to 85°. This variation and the difference between the melting points of our products and those of previous investigators may be due to differences in molecu-

lar size. A molecular weight determination in boiling benzene gave a value about six times the normal value. This value is probably low as the substance is very sensitive to moisture, and only the ordinary precautions were taken to exclude it. The compound hydrolyzes in boiling water to yield the acid and reacts rapidly with aniline and phenol. It is hygroscopic and on standing unprotected gradually reverts to the acid. It is not distillable as such, but when heated in *vacuo* to somewhat above 200°, it breaks down and yields the true monomeric adipic anhydride, which distils out.

Monomeric adipic anhydride is a liquid freezing at about 20° and boiling at about 100° at 0.1 mm. It reacts with cold water quickly with the evolution of much heat to yield the acid. It reacts almost instantly with aniline to give a very high yield of pure monoanilide. On being heated at 100° for a few hours, it changes to a polymer melting at 80–85°. On standing at room temperature for ten days or more, it gradually solidifies. It is probable that traces of water bring about the polymerization. When a sample of liquid anhydride is transferred to a vessel which has not been very carefully dried, an amorphous skin soon coats the glass.

The reactions of the monomeric and polymeric adipic anhydrides with aniline establish the structures of these compounds, the former as a seven-membered ring and the latter as a long chain, which may be a large ring or an open chain with terminal carboxyl groups. Monomeric anhydride (I), which has a symmetrical structure, can react with aniline to give but one product, adipic acid monoanilide (II). This has been verified experimentally. Polymeric adipic anhydride, to which we may assign formula III, on the other hand, is no longer symmetrical as soon as one anhydride group reacts with aniline. The product formed, therefore, depends on which side of the oxygen atom the next anhydride group along the chain breaks. It will be seen from the scheme above that the reaction of polymeric adipic anhydride with aniline may lead to three products: adipic acid, adipic acid monoanilide and adipic acid dianilide. All of these compounds have been isolated from the reaction of the polymer with aniline.

$$\mathrm{C_6H_5NH}$$

III

On the assumption that a random reaction takes place and that the carboxyl groups which are probably at the ends of the chain may be neglected, these products should be formed in the proportion of one mole of acid to one mole of dianilide to two moles of monoanilide. In a quantitative experiment a 25% yield of dianilide was obtained. The adipic acid and monoanilide formed were not estimated quantitatively. Similarly the solid anhydride yields diphenyl adipate on warming with phenol.

The experiments with aniline show definitely that the solid adipic anhydride is a true condensation polymer in which the structural units are held together by primary valence forces. It is presumed that the polymers are open chains with carboxyl groups at the ends as has been demonstrated in the case of some of the polymeric ethylene succinates.[4] This view is further supported by the presence of adipic acid in the distillate when the polymeric anhydride is cracked to form the monomer.

The writer wishes to thank Dr. W. H. Carothers for his interest and advice, and Mr. S. B. Kuykendall for determinations of carbon and hydrogen.

Experimental Part

Preparation of Polymeric Adipic Anhydride.--One hundred grams of recrystallized adipic acid and 300 cc. of redistilled acetic anhydride were refluxed together for four to six hours, and the volatile constituents were removed in a vacuum at 100°. The residue melted at about 70°. It was repeatedly recrystallized from dry benzene, from which it separated as a micro-crystalline powder. Various samples prepared in this same way melted at temperatures varying from 70 to 85°. At temperatures above the melting point, all these samples were viscous liquids, which solidified on cooling to waxy masses. In all experiments moisture was carefully excluded. In the most careful preparation carried out, moisture was excluded by phosphorus pentoxide tubes, the residue was heated overnight in an exhausted system which contained caustic potash in an adjacent vessel and then recrystallized four times with one filtration in a closed system. After each recrystallization the mother liquor was removed by careful decantation. The product melted at 73-75°. The polymeric anhydride melted under boiling water and gradually went into solution. On cooling adipic acid crystallized out.

Anal. Calcd. for $(C_6H_8O_3)_n$: saponification equiv., 64.0. Found: saponification equiv., 63.2, 63.4.

Reaction of Polymeric Adipic Anhydride with Aniline.—A sample of polymer prepared directly from adipic acid and acetic anhydride (m. p. 75°) was added to a slight excess of aniline and triturated in a mortar. Reaction took place spontaneously with the evolution of heat. The mixture was treated with dilute hydrochloric acid and the solid precipitate was filtered off. The filtrate was evaporated to dryness and the residue was then taken up in a volume of water not quite sufficient for complete solution, filtered and washed. The residue after crystallization from water was identified as adipic acid by a mixed melting point determination. The residue from the hydrochloric acid treatment was boiled with water and filtered. The filtrate deposited needles on cooling, which, after recrystallization from water, were identified as adipic acid monoanilide by a mixed

[4] Carothers and Dorough, This Journal, 52, 711 (1930).

melting point with an authentic sample, The residue insoluble in boiling water, consisting of adipic acid dianilide, was recrystallized from alcohol; needles, m. p. 240–241°.[5] This experiment was carried out with various samples of polymeric anhydride: crude polymer prepared directly from adipic acid and acetic anhydride, recrystallized polymer, polymer formed by heating the monomer, and still-residue from distillation of the monomer. In every case dianilide was isolated and identified. The experiment with the heat polymer was carried out quantitatively and gave a 25% yield of dianilide.

Anal. Calcd. for $C_{18}H_{20}O_2N_2$: C, 72.96; H, 6.81. Found: C, 73.31, 73.24; H, 6.95, 7.12.

Reaction of Polymeric Adipic Anhydride with Phenol.—Polymeric adipic anhydride was warmed with phenol to fusion and poured into cold water. On agitation a white solid separated out. This, after two recrystallizations from a mixture of alcohol and water (1:1), separated as lustrous plates of m. p. 105.5–106°. The method of preparation and the ultimate analysis showed this compound to be diphenyl adipate.

Anal. Calcd. for $C_{18}H_{18}O_4$: C, 72.45; H, 6.08. Found: C, 72.63, 72.19; H, 6.07, 6.29.

Preparation of Monomeric Adipic Anhydride.—One hundred grams of adipic acid and 300 cc. of acetic anhydride were refluxed together for four hours. The acetic acid formed in the reaction and the excess acetic anhydride were removed by distillation in a vacuum. The residue was transferred to a Claisen flask and heated under vacuum. After the removal of the residual acetic anhydride at 0.1 mm. no further distillation took place up to 210° bath temperature. At this temperature the pressure rose, and in different experiments from 50 to 60 g. distilled between 105 and 125" under pressure from 3 to 8 mm., the bath temperature ranging from 210 to 235°. The residue was viscous when hot and solidified to a dark colored mass on cooling. The distillate consisted of a light pink liquid containing a small amount of crystalline material. The liquid and solid phases were separated by centrifuging. The crystalline material was washed with benzene, recrystallized from ethyl acetate, and identified as adipic acid by a mixed melting point determination. The liquid was redistilled in an all-glass apparatus. The boiling point was 98 to 100° at 0.1 mm. at a bath temperature of 117 to 120°. Only about half of the material could be recovered by distillation since the residue gradually polymerized. Samples of the colorless distillate were sealed in small, carefully dried glass tubes for freezing point determinations. The compound froze at 19° to large translucent plates and remelted at 22°.

Anal. Calcd. for $C_6H_8O_3$: C, 56.25; H, 6.30; mol. wt., 128; saponification equiv., 64.0. Found: C, 55.89, 55.98; H, 6.51, 6.52; mol. wt. (in boiling benzene), 134, 131; saponification equiv., 63.7, 63.6.

Polymerization of Monomeric Adipic Anhydride.—When monomeric adipic anhydride was transferred to a vessel which had not been carefully dried, a translucent coating appeared on the surface of the glass. The coating was amorphous and in places skin-like. It melted at 60–65°. When the liquid was heated in a sealed tube at 100°, it polymerized completely and a maximum melting point of 80–84° was reached in about seven hours. On being heated at 138°, a maximum melting point of 81–85" was reached in about two hours. In neither experiment did further heating affect the melting point.

Anal. Calcd. for $(C_6H_8O_3)_n$: saponification equiv., 64.0. Found: saponification equiv., 63.5, 63.3; mol. wt. (in boiling benzene), 860, 710.

---

[5] Bodtker [*Ber.*, 39, 2765, 4003 (1906)] gives 240°; Balbiano [*Gazz. chim. ital.*, 32, *I*, 446 (1902)] gives 240–241°; Bouveault and Titry [*Bull. soc. chim.*, [3] *25*, 444 (1901)] gives 235°.

Reaction of Monomeric Adipic Anhydride with Aniline.—One cubic centimeter of anhydride was added to about eight cubic centimeters of aniline with stimng. Reaction was immediate and much heat was evolved. The excess aniline was dissolved in dilute hydrochloric acid. The solution was diluted to 200 cc. and filtered. The crude product was dried and weighed; m. p. 152–153°; yield 80%. The monoanilide of adipic acid has previously been prepared by heating $C_6H_5NHCOCH(COOH)(CH_2)_3COOH$.[6] Recrystallization from water did not raise the melting point. The crude compound was completely soluble in hot water (absence of dianilide). A similar experiment was carried out and worked up in smaller volume; m. p. (crude), 151–153°; yield, 87%.

Anal. Calcd. for $C_{12}H_{15}O_3N$: C, 65.12; H, 6.80; neutralization equiv., 221. Found: C, 64.76, 64.86; H, 6.81, 7.01; neutralization equiv., 222,223.

Summary

The monomeric and polymeric forms of adipic anhydride have been prepared, the former for the first time, and they have been shown to be mutually interconvertible. The reactions of the compounds with aniline have shown the monomer to be a seven-atom ring and the polymer a long chain or large ring. Diphenyl adipate is described.

BRAZIL NUT OIL

BY H. A. SCHUETTE, RALPH W. THOMAS AND MABEL DUTHEY

RECEIVED JULY 28, 1930 PUBLISHED OCTOBER 6, 1930

Data pertinent to the composition of the oil in the seeds of the Brazil nut tree, *Bertholletea excelsa,* are few. A statement by Andes[1] that this oil consists of stearin, palmitin and olein, and several reports by others[2] on a few of its more common chemical and physical constants appear to represent the published information on its chemical composition.

This oil finds a limited use in the arts in this zone but in the country of its origin it serves the inhabitants much the same as olive oil does elsewhere, that is, for alimentary purposes, for soapmaking and, to some extent, as a fuel for lamps. The nut meats contain approximately 70% of oil, more than one-half of which may be removed merely by expression in a hand press.

In view of the situation which obtains as above noted, and the ambiguity surrounding the methods of recovery of the oil used by others, it seemed worthwhile to re-investigate the chemical and physical characteristics of

---

[6] Dieckmann, *Ann.*, **317**, 62 (1901). *The* melting point given is 152–153°.

[2] De Negri and Fabris, *Z. anal. Chem.*, 33, 563 (1894); De Negri, *Chem.-Ztg.*, 22, 961 (1898); Merrill, *Maine* Agr. *Expt. Sta. Bull.*, 65, 111 (1900); Grimme, *Analyst*, 36, 21 (1911); Niederstadt, *Ber. deut. pharm. Ges.*, 35, 145 (1902).

both the expressed product and that recoverable from the residues by solvent extraction, and to make an analysis of the latter. The presentation of these data is the object of this communication.

I. Preparation of Materials

The oil in the meats[3] from twelve kg. of fresh Brazil nuts was expressed in a small, manual press rather than one of the hydraulic type because it had been demonstrated by experimental trials that a cleaner product and one better adapted for chemical analysis without a preliminary refining process is obtainable by using this method of recovery. The residual meat pulp was then extracted in percolators with low-boiling petroleum ether, the final portions of which were in turn removed from the oil in the presence of carbon dioxide. A dark brown oil was recovered from which, in distinction to that obtained by expression, no glycerides separated when stored in the refrigerator (5–10°). The expressed oil possessed, after filtration, a pale yellow color and a taste suggestive of the nut itself.

II. Analysis of Oils

(a) Chemical and Physical Characteristics.—The more important chemical and physical characteristics (Table I) of both the expressed oil and that recovered from the residual meat pulp were determined by recog-

TABLE I

CHEMICAL AND PHYSICAL CHARACTERISTICS OF BRAZIL NUT OIL

	Expressed oil	Residual oil
Specific gravity 25°/25°	0.9150	0.9143
Index of refraction 20°	1.4678	1.4683
Titer test	...	33.3[a]
Iodine number (Wijs)	99.92	95.21
Saponification number	194.0	198.00
Ester number	193.9	193.8
Reichert–Meissl number	0.0	0.31
Polenske number	0.0	0.32
Free fatty acids (per cent, oleic)	0.006	0.02
Acetyl number	12.3	12.3
Soluble acids (per cent. as butyric)	0.87[a]	0.56
Insoluble acids (per cent.)	94.16[a]	93.88
Unsaturated acids (per cent.) corrected	73.00	70.10
Saturated acids (per cent.) corrected	20.29	21.36
Iodine number of unsaturated acids	129.18	127.92
Saponification no. of unsaturated acids	199.6	201.2
Unsaponifiable matter	0.64	0.68

[a] Grateful acknowledgment is made to C. A. Tarnutzer and W. W. F. Enz who determined the titer test of the residual oil and the soluble and the insoluble acids of the expressed oils, respectively.

---

[3] The average of five determinations of the (ethyl) ether extract of these meats was 68.67%.

nized procedures.[4] Separation of the saturated from the unsaturated acids was effected by the lead salt–ether method[5] after which corrections were made[6] for the small amount of unsaturated acids contaminating them when this procedure is used, and for the unsaponifiable matter accompanying the insoluble acids.

Glycerides of fatty acids of low molecular weight are absent, or at least present in very small amount, a situation pertinent also to sterols and hydroxylated compounds. The low acidity suggests the probable absence of any very active fat splitting enzymes in the nut. Its iodine number assigns this oil to the semi-drying group.

(b) Unsaturated Acids.—Bromination[7] of the unsaturated acids led to the formation of no hexabromide, the derivative of linolenic acid. Appreciable quantities of the tetrabromide (m. p. 114.5°; Br, 53.58%) of linoleic acid were obtained. The bromine content (39.73%) of the dibromide fraction showed that the latter was contaminated with a small amount of the linoleic derivative. Using the former value and the theoretical iodine numbers of oleic and linoleic acids, the percentage composition of the whole was then calculated[8] with the following results.

TABLE II

COMPOSITION OF THE UNSATURATED ACID FRACTION OF THE RESIDUAL OIL

Acid	In oil, %	Glycerides in oil, %	Total,[a] %
Oleic	51.26	53.57	55.64
Linoleic	18.84	19.69	21.65

[a] This column includes the unsaturated acids present with the saturated.

The same acids were qualitatively identified, both by bromine content and melting point, in the unsaturated fraction of the expressed oil.

TABLE III

RESULTS OF ANALYSIS OF METHYL ESTERS OF THE SATURATED FATTY ACIDS

Fraction	Boiling range, 3 mm.	Wt., g.	Iodine no.	Sapon. no.	Mean mol. wt.	Unsatd. acids, g.	Myristic acid, g.	Palmitic acid, g.	Stearic acid, g.

[8] Baughman and Jamieson, THIS JOURNAL, 42, 157 (1920).

(c) Saturated Acids.—Separation of the methyl esters[8] of the saturated acids into five fractions whose boiling range was 145 to 175° (3 mm.) (Table III) was followed by the calculation of the mean molecular weight of each from saponification and iodine numbers, the latter serving as a measure of the degree of contamination by unsaturated acids. These values lay between 259.3 and 289.6, indicating the presence of esters in the C_{12} to C_{18} group. Myristic, palmitic and stearic acids were subsequently identified by their melting points.

These data lead to the following statement of the percentage composition of the saturated acid fraction.

TABLE IV

COMPOSITION OF THE SATURATED FRACTION OF THE RESIDUAL OIL

Acid	%	Percentage in oil	Glycerides in oil
Myristic	7.94	1.70	1.79
Palmitic	60.48	12.92	13.55
Stearic	11.57	2.47	2.58

The same fatty acids were qualitatively identified by means of their melting points in the corresponding fraction of the expressed oil.

Summary

The chemical and physical characteristics of the expressed and the residual portions of a specimen of Brazil nut oil have been determined. The statement[1] that this oil contains stearin, palmitin and olein has been confirmed. To this list have been added myristin and linolein.

The percentage composition of the residual oil was found to be as follows: myristin, 1.79; palmitin, 13.55; stearin, 2.58; olein, 55.64; linolein, 21.65; unsaponifiable matter, 0.68; residues and undetermined, **4.11.**

THE ACIDITY OPTIMUM OF YEAST HEXOSEDIPHOSPHATASE[1]

BY Z. I. KERTESZ

RECEIVED JULY 28, 1930 PUBLISHED OCTOBER 6, 1930

The hexosediphosphoric acid ester and the enzyme which splits it into fructose and phosphoric acid were discovered by Harden and Young. It has been shown that the enzyme is present in practically all kinds of yeast and also in the *Coli* bacteria. It is present in different organs of the animal body, as well as in many higher plants. Although a great many papers have dealt with yeast hexosediphosphatases, we have but very little information concerning its optimum PH.

---

[1] The writer's sincere thanks are due to Professor H. v. Euler and to the Stockhoms Hogskola for the opportunity to make this study.

The *PH* optima of the zymase group of enzymes have been determined by various authors. In spite of the fact that it might be expected that the PH optima of these would be in the same acidity range as that of the yeast fermentation as a whole the experiments have not supported this supposition. Thus the optimum of the hexosedehydrogenase was found to be ***PH*** 8.0–8.5.[2]

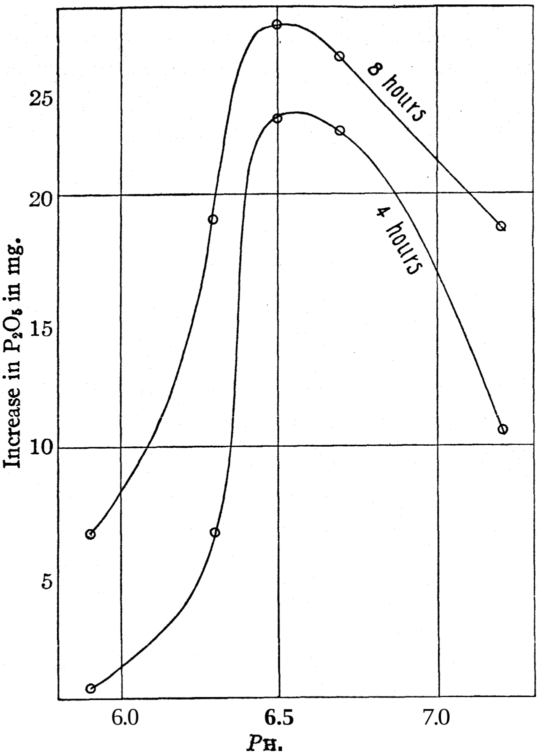

Fig. 1.—The *PH* optimum of hexosediphosphatase.

Euler and Nordlund[3] showed that the optimum of the synthetic enzyme of yeast producing hexosediphosphoric acid ester is at PH 6.4. Because of the obvious importance of knowing this point for all enzymes, it has been determined for yeast hexosediphosphatase.

Experimental

The sodium salt of hexosediphosphate was made from Candiolin by the method of Meyerhof.[4] The yeast applied was a dry preparation of bottom-yeast "H" of the St. Erick Brewery of Stockholm. The zymase of the yeast was very active. The composition of the reaction mixtures was as follows

1.6 g. dry yeast
2.5 cc. 4% hexosediphosphate
2.5 cc. distilled water
5.0 cc. buffer (citric acid, after S. P. L. Sorensen)

The ***PH*** was determined potentiometrically by the use of hydrogen electrodes. The reaction mixtures were kept in a thermostat at 30°. At the beginning and after certain intervals the increase in amount of inorganic phosphoric acid in the reaction mixture was determined by the micro method of Embden.[5]

---

[2] **H. v. Euler, K. Myrbäck and R. Nilsson, *Ergeb. der Physiol.*, *26*, *547* (1928).**

[3] **H. v. Euler and F. Nordlund, Z. *physiol. Chem.*, 116, 229 (1921).**

[4] **Meyerhof, *ibid.*, 102, 1 (1918).**

[5] **Embden, *ibid.*, 113, 108 (1921).**

PH OPTIMUM OF YEAST HEXOSEPHOSPHATASE

PH	4 Hours		8 Hours	
	P_2O_5, mg.	Relative action	P_2O_5, mg.	Relative action
5.9	0.4	1.7	6.6	25
6.3	6.6	29	19.0	71
6.5	23.0	100	26.8	100
6.7	22.6	98	25.4	95
7.2	10.6	46	18.8	70

The results are given in the table. In each set the maximum amount of phosphorus pentoxide formed was taken as 100, and the others were calculated as percentages of it. It will be seen that the optimum PH is very close to 6.5. At this *PH* in eight hours about 38% of the substrate was hydrolyzed.

Summary

The *PH* optimum of the yeast hexosediphosphatase has been determined to be *PH* 6.5.

SYNTHESIS OF LODAL AND EPININE

BY JOHANNES S. BUCK

RECEIVED AUGUST 4, 1930 PUBLISHED OCTOBER 6, 1930

Lodal, 4,5-dimethoxy-2-β-methylamino-ethylbenzaldehyde, was obtained by Pyman[1] by the oxidation of laudanosine. It is also related to papaverine, since N-benzoyltetrahydropapaverine can be degraded to 6.7-dimethoxy-3,4-dihydroisoquinoline,[2] whose methochloride (6,7-dimethoxy-2-methyl-3,4-dihydroisoquinolinium chloride) is identical with the compound obtained from lodal by means of hydrochloric acid.

Epinine, 3,4-dihydroxyphenylethylmethylamine, was obtained by Pyman[1,2] by heating 1-keto-6,7-dimethoxy-2-methyltetrahydroisoquinoline, obtained from laudanosine or papaverine, with hydrochloric acid.

Lodal is a post-partum constrictor for uterine vessels, and a styptic in uterine hemorrhage,[3] while epinine shows hemostatic and pressor properties similar to those of adrenaline,[4] with the advantage of greater stability in solution. Up to the present time no complete syntheses of these compounds have been reported. The author has carried out complete syntheses of lodal and epinine, starting from homoveratrylamine (prepared from vanillin). This amine is monomethylated, via the Schiff base, and

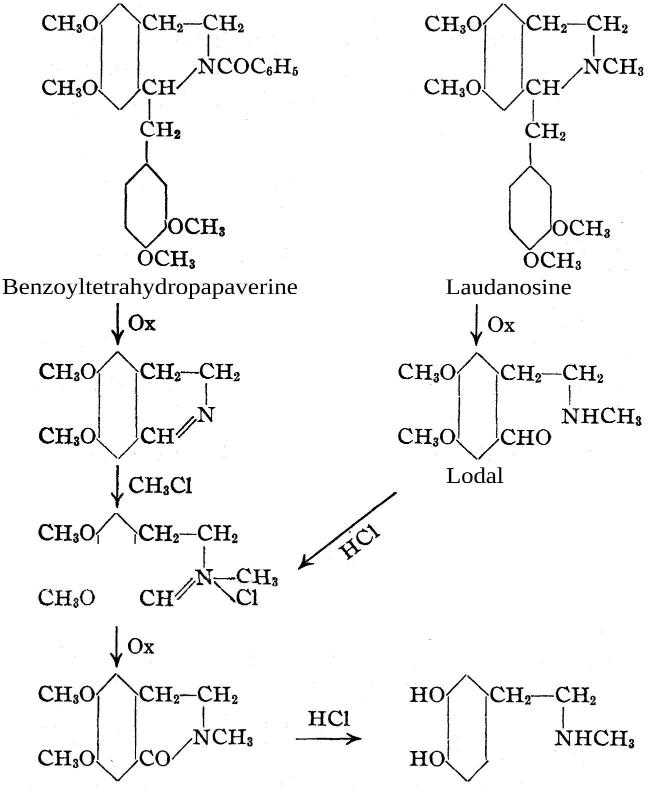
then demethylated to produce epinine hydrochloride. Alternatively, methylhomoveratrylamine is converted into the formyl derivative and this then cyclized by the peculiar reaction of Decker.[5] In both cases the synthetic products were compared with authentic compounds prepared by Pyman's method and found to be identical with these.

The relationships mentioned may be shown thus



Experimental

Homoveratrylamine.[6]—This amine was prepared from dimethoxyphenylpropionamide. Veratric aldehyde was condensed with ethyl acetate and the resulting dimethoxycinnamic ester hydrolyzed and reduced to dimethoxyphenylpropionic acid as described by Perkin and Robinson.[7] By heating the ammonium salt of the acid,[5] dimethoxyphenylpropionamide was obtained. This was then converted into homoveratrylamine by the regular Hofmann method.[5,6]

Methylhomoveratrylamine.—The methylation was carried out by first forming the benzal derivative and then treating this with methyl iodide. The benzal group was then split off, giving methylhomoveratrylamine hydriodide.[5] Molecular amounts of homo-

veratrylamine and benzaldehyde were mixed. Heat was evolved and the mixture became turbid through the separation of water, which was then removed by heating under reduced pressure. An equivalent amount of methyl iodide was added and the mixture heated, with the careful exclusion of air and moisture for twenty hours at 37". The resulting solid, yellow, crystalline mass was boiled with 90% alcohol. On cooling and adding ether, the hydriodide of methylhomoveratrylamine separated. The yield was 79% of the theoretical.

The hydriodide after crystallization forms a dull white mass of jagged irregular prisms melting at 131° (uncorr.). It is very soluble in water, readily soluble in alcohol and sparingly soluble in ether.

Anal. Calcd. for $C_{11}H_{18}O_2NI$: C, 40.86; H, 5.57. Found: C, 41.09; H, 5.59.

The base was prepared by adding an excess of strong sodium hydroxide solution to an aqueous solution of the hydriodide and extracting with benzene It forms an almost colorless and odorless oily liquid, b. p. 159° (11 mm.), n_{15} 1.5362; d^{20}_{20} 1.0597. It is very soluble in water, giving an alkaline solution, and is miscible with the usual organic solvents. Unlike homoveratrylamine, it appears not to form a carbonate in air.

Anal. Calcd. for $C_{11}H_{17}O_2N$: C, 67.69; H, 8.72; N, 7.18. Found: C. 68.09; H, 8.65; N, 6.93.

The **picrate,** prepared in aqueous solution, forms a yellow crystalline powder, melting at 162–163" (uncorr.).

Anal. Calcd. for $C_{17}H_{20}O_9N_4$: C, 48.11; H, 4.72. Found: C, 47.95; H, 4.75.

The quaternary iodide, formed when the amine is warmed in alcoholic solution with methyl iodide, consists of beautiful pearly masses of plates. It is soluble in water and alcohol and melts at 226° (uncorr.).

Anal. Calcd. for $C_{13}H_{22}O_2NI$: C. 44.44; H, 6.26. Found: C, 44.37; H, 6.39.

The platinichloride forms a pale orange granular precipitate, melting at 190° (uncorr.) with frothing and blackening.

Anal. Calcd. for $(C_{11}H_{17}O_2N)_2 \cdot H_2PtCl_6$: C, 33.0; H, 4.5; Pt, 24.4. Found: C, 34.0; H, 4.5; Pt, 24.6.

The aurichloride forms a bulky orange powder, melting with frothing and blackening at 148° (uncorr.).

Anal. Calcd. for $C_{11}H_{17}O_2N \cdot HAuCl_4$: C, 24.7; H, 3.4; Au, 36.9. Found: C, 25.0; H, 3.5; Au, 37.4.

Epinine.—Methylhomoveratrylamine hydriodide was heated with five times its weight of hydriodic acid (sp. gr. 1.70) for thirty minutes at 120–130°. Surplus acid was then distilled off under reduced pressure. The residual golden oil was dissolved in water and converted into the hydrochloride by means of silver chloride. The yield of hydrochloride was over 65% of the theoretical. The hydrochloride and the base prepared from it were identical in every respect with authentic specimens prepared by Pyman's method. Mixed melting point determinations showed no depression.

Anal. Calcd. for $C_9H_{14}O_2NCl$: N, 6.88; Cl, 17.42. Found: N, 6.90; Cl, 17.54.

Lodal.—Four and nine-tenths grams of methylhomoveratrylamine and 2.3 g. (2 mols) of absolute formic acid were mixed and the whole heated for one hour in an oil-bath at 210". A clear almost colorless sirup of the formyl compound resulted. This was dissolved in 50 cc. of toluene and boiled with 20 g. of phosphorus pentoxide for thirty minutes. After cooling, the toluene was decanted and the pentoxide added to crushed ice. The solution was then filtered, neutralized with sodium bicarbonate, extracted with benzene, and the aqueous liquor made strongly alkaline with 20% sodium hydroxide solution. On standing, a portion of the product crystallized out and the rest was extracted with benzene; yield, 61% of crude material. The compound was identified by comparison with an authentic specimen and by mixed melting point determinations on the base, the picrate and the very characteristic cyano derivative.

Summary

Complete syntheses of lodal (4,5-dimethoxy-2-β-methylamino-ethylbenzaldehyde) and epinine (3,4-dihydroxyphenylethylmethylamine), from vanillin, via homoveratrylamine, have been carried out. The products were identical with those prepared by Pyman's[1,2] method from papaverine or laudanosine.

THE ARSONATION OF AROMATIC ALDEHYDES

By Albert B. Scott[1] and Cliff S. Hamilton

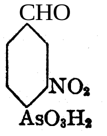
Received August 4, 1930 Published October 6, 1930

Certain organic arsenical compounds exert a specific curative action in syphilis and the trypanosomiases. Although arsonated aromatic compounds containing the amino group substituted in the nucleus have been widely investigated for many years, little attention has been devoted to arsonated aromatic molecules containing a non-cyclic carbonyl group. The present investigation deals with the preparation and properties of arsonated aromatic aldehydes, molecules which contain a nuclear arsono group (AsO_3H_2) and a non-cyclic carbonyl group. The only reference to this type of substance was found in certain patents. Pfleger and Albert[2] claim derivatives of p-arsonobenzaldehyde. Margulies claims 3-nitro-4-arsonobenzaldehyde and *p*-arsonobenzaldehyde.[3]

Kalberlah[4] claims unique effectiveness for a new aromatic arsenical compound containing a non-cyclic carbonyl group.

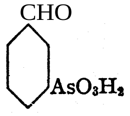
In the present investigation derivatives of three arsonated aromatic aldehydes have been prepared. The structures of the parent compounds are as follows

I



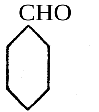
3-Nitro-4-arsono-benzaldehyde

II



m-Arsono-benzaldehyde

III



p-Arsono-benzaldehyde

---

3-Nitro-4-arsonobenzaldehyde (I) was prepared from 3-nitro-4-aminobenzaldehyde by Bart's reaction.[5] The diazotization proved difficult and was accomplished by the use of a large volume of acetic acid and a great excess of nitrous acid. Arsonation was carried out by adding dilute sodium hydroxide solution to the strongly acid mixture of diazonium compound and arsenious acid. This procedure permits coupling to form the arsonic acid over a wide range of hydrogen-ion concentrations and is consequently advantageous in the preparation of a new arsonic acid where the optimum conditions for coupling are unknown.

Purification of 3-nitro-4-arsonobenzaldehyde was unsatisfactory. The *p*-nitrophenylhydrazone, the β-naphthylhydrazone and the semicarbazone of this arsonated aromatic aldehyde were obtained in pure condition. The method of purification found most suitable for these derivatives was solution in dilute sodium carbonate solution followed by re-precipitation with dilute hydrochloric acid. From the semicarbazone of 3-nitro-4-arsonobenzaldehyde the semicarbazone of 3-amino-4-arsonobenzaldehyde was prepared by reduction with ferrous hydroxide in alkaline medium as suggested by Jacobs, Heidelberger and Rolf[6] and modified by Palmer and Adams.[7] While the alkaline medium was quite satisfactory for the reduction of the semicarbazone it might have been incompatible with the parent aldehyde.

m-Arsonobenzaldehyde was prepared from m-aminobenzaldehyde by Bart's reaction and isolated as the *p*-nitrophenylhydrazone. A solution of m-aminobenzaldehyde was prepared by reduction of *m*-nitrobenzaldehyde as the sodium bisulfite addition compound with ferrous sulfate and calcium carbonate.[8] Excess iron was precipitated from the very dilute solution and the filtrate containing *m*-aminobenzaldehyde was arsonated. m-Aminobenzaldehyde formed tars with remarkable readiness except in neutral or nearly neutral dilute solutions. After arsonation *m*-arsonobenzaldehyde was obtained from the solution as the p-nitrophenylhydrazone.

To avoid the extreme difficulty of working with certain aminoaldehydes, a new and independent method of synthesis of arsonated aromatic aldehydes was developed. *p*-Methylphenylarsonic acid was oxidized to *p*-arsonobenzaldehyde by means of solid chromic oxide (CrO_3) in the presence of acetic anhydride, glacial acetic acid and concentrated sulfuric acid. Formation of the aldehyde diacetate prevents further oxidation of the aldehyde group. The arsonated aromatic aldehyde, *p*-arsonobenzaldehyde, prepared by this method was isolated as the p-nitrophenylhydra-

zone. The yield of *p*-arsonobenzaldehyde was low but the method is being improved and will be extended to other alkyl arsonic acids in the near future. The great advantage of this method of preparing certain arsonated aromatic aldehydes lies in the ease of preparation of the alkyl arsonic acids which serve as intermediates to be oxidized to the corresponding aldehydes.

In this investigation the question of qualitatively proving the presence of the arsono group (AsO_3H_2) arose repeatedly and lack of a suitable qualitative test for arsonation was a marked handicap. Ordinary qualitative tests for arsenic fail completely to differentiate between arsenic in inorganic combination and arsenic in organic combination. The reduction of aromatic arsonic acids to the less soluble arseno compounds by means of hypophosphorous acid was found to be adaptable for use as a rapid qualitative test for the arsonation of aromatic compounds. With all of the arsonic acids examined a characteristic precipitate of the corresponding arseno compound was obtained within twenty minutes under the conditions described in the experimental portion of this work. Experience with this reduction indicates that a mixture of the arsine oxide and arseno compound corresponding to the arsonic acid may form in some cases but this does not affect the validity of the test. However, much more extensive study will be necessary to prove that this qualitative test is general.

Experimental

I. 3-Nitro-4-Arsonobenzaldehyde

3-Nitro-4-aminobenzaldehyde.—Following the method of Hodgson and Beard[9] 3-nitro-4-aminobenzaldehyde was prepared in approximately 10% yield, the greatest loss occurring in the conversion of *p*-nitrotoluene to *p*-acetaminobenzaldehyde. The product after recrystallization from 80% acetic acid melted at 188–189° (Hodgson and Beard give m. p. 191" for the crude product).

Arsonation of 3-Nitro-4-aminobenzaldehyde.—A solution of 16 g. of recrystallized 3-nitro-4-aminobenzaldehyde was obtained by stirring for thirty minutes at 95° with 200 cc. of 80% acetic acid. The hot solution was filtered and then, by cooling to 20°, a thick paste of fine crystals was formed. Diazotization was carried out at 20° with stirring by the simultaneous dropwise addition of 20% sodium nitrite solution and concentrated hydrochloric acid. The dropwise addition was carried out at such a rate that all of the hydrochloric acid (90 cc.) had been added in sixty minutes and all of the sodium nitrite solution (220 cc.) in ninety minutes. After the addition of the sodium nitrite solution was complete, stirring was continued for thirty minutes making a total of one hundred and twenty minutes for the diazotization. The bright red acid diazonium solution was then filtered, treated cautiously with urea, and poured into a 4-liter crock containing 75 cc. of a 20% sodium meta-arsenite solution and 125 cc. of water. Then with constant stirring and below 15° 4 N sodium hydroxide solution was added dropwise until there was 25 cc. excess over the amount necessary to make the solution just alkaline to litmus paper. After standing overnight at room temperature, the dark

---

[9] Hodgson and Beard, J. Chem. *Soc.*, 20 (1927).

brown solution was stirred for sixty minutes at 60–70°. At the end of this time a test with alkaline R-salt solution showed that all of the diazo compound had reacted. The solution was then made just acid to litmus paper with hydrochloric acid, heated to boiling with decolorizing charcoal, filtered, made acid to Congo red paper with hydrochloric acid and concentrated to 300 cc. on the steam-bath. The golden yellow solution was then made just neutral to litmus paper with 6 *N* sodium hydroxide solution added slowly with stirring and cooling. The solution of the monosodium salt of 3-nitro-4-arsonobenzaldehyde was then filtered from undissolved material and the free arsonic acid precipitated from the filtrate as a yellow paste by adding 6 N hydrochloric acid drop by drop with stirring and cooling until the solution was acid to Congo red paper. The pasty yellow product was combined with a further quantity recovered from the filtrate and washings and dried in vacuum over calcium chloride to form a heavy yellow amorphous powder which softened and darkened at about 155° and decomposed slowly above this temperature; wt., 12.5 g.; yield, 47%. In one run the arsonic acid was isolated as the semicarbazone and a weight of semicarbazone corresponding to 54% yield of 3-nitro-4-arsonobenzaldehyde was obtained.

The crude arsonic acid gave an arsine odor when burned; gave a precipitate with hypophosphorous acid when warmed in either aqueous or alcoholic solution; dissolved in concentrated ammonium hydroxide, dilute sodium carbonate solution and dilute sodium hydroxide solution; formed a *p*-nitrophenylhydrazone, a β-naphthylhydrazone and a semicarbazone; and was slightly soluble in water while practically insoluble in ethyl alcohol, methyl alcohol, ethyl acetate, ether, chloroform, ligroin and benzene.

Anal. (1) After recrystallization from water. Subs., 0.1448: 21.60 cc. of potassium bromate (1 cc. = 0.001874 g. As). Calcd. for $C_7H_6O_6NAs$: As, 27.25. Found: As, 27.95. (2) After solution in dilute sodium carbonate solution and re-precipitation with dilute hydrochloric acid. Subs., 0.1602: 23.17 cc. of potassium bromate (1 cc. = 0.001874 g. As). Found: As, 27.10.

Analytical values on this substance were not consistent. It was possible, however. to prepare pure derivatives.

***p*-Nitrophenylhydrazone of 3-Nitro-4-arsonobenzaldehyde.—A** clear amber solution of 3.5 g. of crude 3-nitro-4-arsonobenzaldehyde in 400 cc. of water was obtained by boiling, cooling and filtering. To the cooled solution was added 4 g. of solid sodium acetate. The solution was then heated nearly to boiling and a solution of 2 g. of #-nitrophenylhydrazine in 100 cc. of water and 10 cc. of 6 N hydrochloric acid was then poured in with vigorous stirring. A brilliant orange-red flocculent precipitate formed at once. After digestion for ninety minutes this product was filtered, washed with water and ether, and dried in vacuum over phosphorus pentoxide to form an amorphous orange powder which began to decompose at about 260–270°.

The product was purified by dissolving in 10% sodium carbonate solution, filtering and re-precipitating by making just acid to Congo red paper with 6 *N* hydrochloric acid added dropwise with stirring and cooling.[10] After washing and drying as before, an orange amorphous powder was obtained.

Anal. Subs., 0.2484, 0.2759: 23.90, 26.30 cc. of potassium bromate (1 cc. = 0.001874 g. As). Calcd. for $C_{13}H_{11}O_7N_4As$: As, 18.29. Found: As, 18.03, 17.86.

β-Naphthylhydrazone of 3-Nitro-4-arsonobenzaldehyde.—A solution of β-naphthylhydrazine was obtained by dissolving 0.7 g. of β-naphthylhydrazine hydrochloride

---

[10] When the sodium carbonate solution of the hydrazone came through the filter with a marked cloudy or silky appearance, it was warmed with a small amount of decolorizing charcoal and filtered again. This treatment gave a solution which was free from suspended fine particles.

in **100 cc.** of boiling water, adding **0.3** g. of solid sodium acetate, cooling to about 50° and filtering. This solution was then poured, with vigorous stirring, into a hot solution of **1** g. of crude 3-nitro-4-arsonobenzaldehyde in **200** cc. of water, and the heavy brick-red precipitate digested, washed and dried. The dry dark red powder darkened at about **210"** and decomposed at about 235–245°; wt., **0.75 g.** For purification **3** g. of the crude hydrazone was treated with **5** cc. of 10% sodium carbonate solution and **200** cc. of water and filtered. The insoluble residue was treated with 5 cc. of 10% sodium carbonate solution and 50 cc. of water and filtered. The combined filtrates were muddy and a clear solution was obtained by warming with decolorizing charcoal and again filtering. From the final clear red solution the hydrazone was precipitated by the addition of **6** N hydrochloric acid added dropwise with stirring and cooling until the solution was acid to Congo red paper.

Anal. Subs., **0.2322, 0.2334: 22.20, 22.40** cc. of potassium bromate (**1** cc. = **0.001874** g. As). Calcd. for $C_{17}H_{14}O_6N_3As$: As, **18.07.** Found: As, **17.92, 17.99.**

The Semicarbazone of **3-Nitro-4-arsonobenzaldehyde.**—A solution of **1** g. of semicarbazide hydrochloride in **50 cc.** of water was added to a clear solution of **2** g. of crude 3-nitro-4-arsonobenzaldehyde in **400** cc. of water containing **0.73** g. of solid sodium acetate. The solution became cloudy and immediately deposited heavy yellow crystals. When dried the semicarbazone was a pale yellow powder which began to darken at about 220° and decomposed at about 250°; wt., **1.62g.**

For purification the semicarbazone was recrystallized twice from methyl alcohol and then **2** g. of the recrystallized material was treated with 10% sodium carbonate until nearly all of it dissolved. The golden yellow solution obtained by filtering was then made just acid to Congo red paper by adding **6** N hydrochloric acid dropwise with stirring and cooling. The light yellow product dried to form an almost white crystalline powder.

Anal. **(1)** Recrystallized twice from methyl alcohol. Subs.. 0.1906, **0.2385:** 22.50, 28.20 cc. of potassium bromate (1 cc. = **0.001874** g. As). Calcd. for $C_8H_9O_6N_4As$: As, **22.59.** Found: As, **22.12, 22.16. (2)** Recrystallized material after solution in dilute sodium carbonate solution and re-precipitation with dilute hydrochloric acid. Subs., **0.2374: 28.40** cc. of potassium bromate (**1** cc. = **0.001874** g. As). Found: As, **22.42.**

The semicarbazone of 3-nitro-4-arsonobenzaldehyde was found to be readily hydrolyzed by heating on the steam-bath with dilute hydrochloric acid.

Semicarbazone of **3-Amino-4-arsonobenzaldehyde.—A** solution of **20** g. of the semicarbazone of 3-nitro-4-arsonobenzaldehyde in **200 cc.** of water and **10** cc. of **6** *N* sodium hydroxide solution was added to a mixture of **127** cc. of **3.3** molar ferrous chloride and **170** cc. of **6** *N* sodium hydroxide solution in a bottle with a wide mouth and the bottle tightly stoppered. The mixture turned reddish-brown at once but was subjected to occasional shaking during sixty minutes and was then filtered through a large Biichner funnel. The filtrate was made just acid to Congo red paper with 3 N hydrochloric acid. The brown pasty precipitate dried to a light brown powder; wt., **11.0** g. The material did not fuse but a gas was evolved over a considerable range of temperature.

The material was found to be moderately soluble in dilute hydrochloric acid and to give a brilliant red product when diazotized and coupled with alkaline R-salt solution.

Anal. Subs., **0.1980, 0.1962: 26.55, 26.40** cc. of potassium bromate (1 cc. = **0.001874** g. As). Calcd. for $C_8H_{11}O_4N_4As$: As, **24.83.** Found: As, 25.13, 25.22.

II. *m*-Arsonobenzaldehyde

Preparation and Arsonation of ***m*-Aminobenzaldehyde.**—To **2000** cc. of water was added **680** g. of ferrous sulfate and **250** g. of calcium carbonate, the latter as a paste with water. This mixture was heated to 85° and during twenty minutes with stirring 500 cc. of an aqueous solution containing 60 g. of m-nitrobenzaldehyde and 40 g. of solid C. P. sodium bisulfite were added. The mixture turned brown and carbon dioxide was evolved After cooling the solution was acidified to Congo red paper and boiled to expel sulfur dioxide. At this point diazotization was unsuccessful because of excess ferrous salts so the solution was diluted to 4 liters, made faintly alkaline to litmus paper with sodium hydroxide solution and filtered. The m-nminobenzaldehyde in the filtrate as a solution was arsonated. The filtrate was made acid to Congo red paper with hydrochloric acid and then 60 cc. excess of concentrated hydrochloric acid was added. At a temperature below 10°, 207 cc of 20% sodium nitrite solution was added dropwise with stirring. The diazonium solution was then poured into 195 cc. of 20% sodium meta-arsenite solution and 6 N sodium hydroxide was added until the solution was just alkaline to litmus paper. Vigorous nitrogen evolution occurred. The solution, after stirring for one hour at 50°, was made just acid to litmus paper, heated to boiling with decolorizing charcoal, filtered and concentrated to 1000 cc.

Isolation of **m-Arsonobenzaldehyde** as the **p-Nitrophenylhydrazone.**—To 300 cc. of the solution of m-arsonobenzaldehyde at 100° was added a solution containing 4 g. of p-nitrophenylhydrazine, 500 cc. of water, 20 cc. of 6 N hydrochloric acid and 8.3 g. of solid sodium acetate. The brilliant orange flocculent precipitate was washed with water and ether and dried in vacuum over phosphorus pentoxide to form an amorphous orange powder which melted with decomposition between 200 and 210°; wt., 5.4 g. The product was purified by three successive re-precipitations with sodium carbonate solution and hydrochloric acid as previously described.

Anal. Subs., 0.1968, 0.1599: 21.60, 17.75 cc. of potassium bromate (1 cc. = 0.001874 g. As). Calcd. for $C_{13}H_{12}O_5N_3As$: As, 20.55. Found: As, 20.57, 20.80.

III. p-Arsonobenzaldehyde

Chromic Acid Oxidation of **p-Methylphenylarsonic** Acid.—The quantities used in this procedure correspond to those recommended by Thiele and Winter[11] for the oxidation of p-nitrotoluene to p-nitrobenzaldehyde. A solution of 15.8 g. of p-methylphenylarsonic acid in 80 g. of acetic anhydride. 80 g. of glacial acetic acid, and 30 g. of concentrated sulfuric acid was treated with 20 g. of solid chromic oxide (CrO_3) added during thirty minutes. The temperature was maintained at 0–lo°. The mixture was stirred for thirty minutes at 10° following the addition of all of the chromic oxide and was then extracted with two 175-cc. portions of ether. The ethereal extract was taken almost to dryness under diminished pressure, diluted with about 50 cc. of water and 6 g. of a gray solid filtered off.

Isolation of p-Arsonobenzaldehyde as the **p-Nitrophenylhydrazone.**—In order to hydrolyze p-arsonobenzal diacetate, 2 g. of this gray solid was heated for thirty minutes on the steam-bath with 10 cc. of 6 N hydrochloric acid. Then 150 cc. of water was added, the solution filtered and treated with p-nitrophenylhydrazine. The flocculent golden-yellow precipitate was digested for sixty minutes on the steam-bath, filtered, washed and dried to a fine yellow powder; wt., 0.44 g.

Anal. Subs., 0.2006, 0.2047: 22.55, 23.00 cc of potassium bromate (1 cc. = 0.001874 g. As). Calcd. for $C_{13}H_{12}O_5N_3As$: As, 20.55. Found: As, 21.07, 21.06.

IV. Rapid Qualitative Proof of Arsonation of Aromatic Compounds

Enough of the compound was placed in a test-tube to cover the bottom, about 3 cc. of water added, the mixture heated to boiling, cooled and filtered. To the perfectly clear aqueous solution was then added 5 cc. of concentrated hypophosphorous acid.

---

[11] Thiele and Winter, Ann., 311,353 (1900).

The tube was placed in a water-bath at 100° and observations made every two or three minutes. With every arsonic acid examined a characteristic precipitate of the corresponding arseno compound (with perhaps some arsine oxide) was obtained within twenty minutes. When a solution of arsenic trioxide in dilute hydrochloric acid was treated with hypophosphorous acid under these conditions, no precipitate was obtained. Table I summarizes the results obtained in testing a series of arsonic acids. In two cases it was found more satisfactory to dissolve the arsonic acid in hypophosphorous acid and omit the water.

TABLE I

ACTION OR HYPOPHOSPHOROUS ACID

	Arsonic acid	Solvent	Minutes for reduction	Color of precipitate
1	p-Hydroxyphenylarsonic acid	H_2O	4	Red
2	Phenylarsonic acid	H_2O	1	White
3	Mono-sodium salt of *p*-arsonophenoxyethanol	H_2O	1	Pale yellow
4	p-Arsanilic acid	(a) H_2O	19	Red
		(b) H_3PO_2	13	Solid red mass
5	Tryparsamide		2	Red
6	3-Nitro-4-aminophenylarsonic acid	H_2O	2	Golden-yellow

Summary

1. A rapid qualitative test of arsonation for aromatic compounds has been suggested.

2. A new type of arsonic acid, the arsonated aromatic aldehyde, has been developed.

3. The preparation of three arsonated aromatic aldehydes, 3-nitro-4-arsonobenzaldehyde, m-arsonobenzaldehyde and *p*-arsonobenzaldehyde has been described *p*-Arsonobenzaldehyde was prepared by a new and independent synthetic method.

THE REACTION BETWEEN HIGHLY PHENYLATED COMPOUNDS AND ORGANIC MAGNESIUM COMPOUNDS

BY E. P. KOHLER AND E. M. NYGAARD

RECEIVED AUGUST 7, 1930 PUBLISHED OCTOBER 6, 1930

A study of the reaction between α,β-unsaturated ketones and organic magnesium compounds, made many years ago, included every member except the last of a series beginning with acrolein and ending with its most highly phenylated substitution product, tetraphenyl propenone. In view of the increasing interest in highly phenylated compounds and especially of our own results with highly phenylated unsaturated nitro compounds, it was desirable to complete the study of this series.

We have, therefore, investigated the behavior of the completely phenylated unsaturated ketone I both toward methyl magnesium iodide and toward phenyl magnesium bromide. And since the results were rather surprising, we also included in the investigation the behavior of the corresponding saturated ketone, α,β,β-triphenylpropiophenone, II.

$$\underset{\text{I}}{(C_6H_5)_2C{=}C(C_6H_5)COC_6H_5} \qquad \underset{\text{II}}{(C_6H_5)_2CHCH(C_6H_5)COC_6H_5}$$

We found that the saturated ketone reacts much more readily than we had anticipated, both with methyl magnesium iodide and with phenyl magnesium bromide. Indeed the reaction with methyl magnesium iodide proceeds rapidly in ethereal solution at the ordinary temperature, and the yield of the tertiary alcohol to be expected is practically quantitative. The structure of the product was established by treating it with a dehydrating agent and ozonizing the resultant hydrocarbon. The oxidation product was the original ketone

$$\underset{\text{II}}{(C_6H_5)_2CHCH(C_6H_5)COC_6H_5} \longrightarrow \underset{\text{III}}{(C_6H_5)_2CHCH(C_6H_5)C(CH_3)(C_6H_5)OH} \longrightarrow$$

$$(C_6H_5)_2CHCH(C_6H_5)C(C_6H_5){=}CH_2 \longrightarrow \underset{\text{IV}}{(C_6H_5)_2CHCH(C_6H_5)COC_6H_5}$$

With phenyl magnesium bromide the saturated ketone reacts less readily, but this reaction can likewise be completed in ether, at the ordinary temperature. In this case also the principal product is the tertiary alcohol but the yield is not nearly so good, doubtless because of the ease with which the highly phenylated carbinols undergo cleavage to a mixture of simpler products. The proof of the structure of the Grignard product was obtained by oxidation. The carbinol was readily oxidized by chromic acid in glacial acetic acid, and yielded two moles of benzophenone to one of benzoic acid.

$$\text{II} \longrightarrow \underset{\text{V}}{(C_6H_5)_2CHCH(C_6H_5)C(C_6H_5)_2OH} \longrightarrow 2(C_6H_5)_2CO + C_6H_5CO_2H$$

In sharp contrast with the saturated ketone, the corresponding unsaturated compound does not react at all with either of the Grignard reagents at the ordinary temperature, and it was recovered even after prolonged boiling. In order to secure any reaction it was necessary to replace most of the ether with benzene and operate at a higher temperature.

The reaction between the unsaturated ketone and methyl magnesium iodide gave two solid products and a small quantity of oil. The composition of the principal product indicates that it is formed as a result of the addition of one molecule of methyl magnesium iodide to the unsaturated ketone. The second product, always formed only in relatively small quantities, is a hydrocarbon which is doubtless formed from the primary product by loss of water.

A quantitative examination of the behavior of the primary product toward methyl magnesium iodide showed that it reacts with only one mole of the reagent and liberates one mole of gas; it therefore probably is a hydroxyl compound. It reacts with ozone and is in part converted into a peroxide, and in part oxidized to benzophenone and other products. These transformations indicate that the substance is a tertiary alcohol formed by addition to the carbonyl group. The results are, however, not quite conclusive because it was impossible to prove the presence of methyl benzoin in the ozonization products.

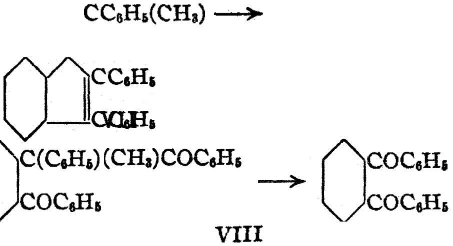
$$\underset{\text{I}}{(C_6H_5)_2C{=}C(C_6H_5)COC_6H_5} \longrightarrow \underset{\text{VI}}{(C_6H_5)_2C{=}C(C_6H_5)C(C_6H_5)(CH_3)OH} \longrightarrow$$

$$(C_6H_5)_2CO + C_6H_5COC(C_6H_5)(CH_3)OH$$

More definite proof of the structure of the substance was obtained by studying the hydrocarbon that is formed in the same reaction. This hydrocarbon can be obtained at will by heating the primary product with acetic anhydride and sodium acetate. When it is gently oxidized with chromic acid, it first combines with two atoms of oxygen and forms a diketone and when this diketone is oxidized more intensively it passes into ortho dibenzoyl benzene. The hydrocarbon is, therefore, methyl triphenyl indene and the primary product must be the carbinol, VI.

$$(C_6H_5)_2C{=}C(C_6H_5)C(CH_3)(C_6H_5)OH \longrightarrow$$

VI



VIII

It proved to be far more difficult to establish the course of the reaction with phenyl magnesium bromide because, although the conditions under which the experiments were conducted were varied in every conceivable manner, the almost invariable result was a mixture of heavy oils from which but little solid product could be extracted. It was not until we adopted the device of decomposing the magnesium compound with acid at the lowest possible temperature and subjecting the product to the action of air or oxygen that we began to get solids in sufficient quantity for examination.

It is known from earlier experiments,[1] that when the enolic modifications which are obtained by 1,4-addition to such unsaturated ketones as contain a hydrocarbon residue in the a-position are exposed to oxygen they form peroxides. This procedure in our case likewise resulted in the addition of a molecule of oxygen but surprisingly enough the product had a deep yellow color. We were therefore confronted with the fact that we had started with a colorless unsaturated compound, added first the equivalent of a

---

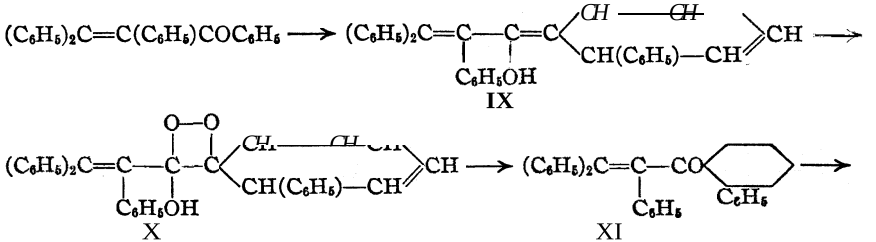
[1] Kohler, *Am. Chem. J.*, 36, 181 (1908).

molecule of benzene and then a molecule of oxygen, and had ended with a deep yellow product which to all appearances was more highly unsaturated than our original substance. The conclusion appeared inevitable that a benzene ring had become involved in the reaction. The transformations of the product confirmed this conclusion.

When the yellow peroxide was treated with cold sodium methylate, which usually cleaves these enolic peroxides, it lost oxygen and water and passed into a new yellow compound which had the composition $C_{33}H_{24}O$. This new yellow compound was subjected to the action of ozone, which, as usual, added two atoms of oxygen and gave two products—benzophenone and a third yellow substance with the composition $C_{20}H_{14}O_2$.

Inasmuch as a yellow compound that is formed by ozonization is most likely to be an a-diketone, we treated this yellow ozonization product with ortho phenylene diamine and found that it readily formed a glyoxaline derivative. Ortho diketones are most cleanly oxidized with alkaline hydrogen peroxide, which cleaves them between the two carbonyl groups. With this reagent our third yellow product gave, quantitatively, benzoic and ortho phenyl benzoic acids.

The organic degradation products of our peroxide are, therefore, benzophenone, benzoic acid and ortho phenyl benzoic acid. The ortho phenyl benzoic acid proves that one of the phenyl groups participates in the reaction, and when all the degradation products are reassembled in their proper order they show quite conclusively which of the phenyl groups is involved, the long series of transformations being represented as follows



IX

X

XI

$$(C_6H_5)_2CO + C_6H_5COCOC_6H_4C_6H_5\ (o) \longrightarrow C_6H_5CO_2H + C_6H_5C_6H_4CO_2H\ (o)$$

XII

In addition to the 1,4-addition product IX, there is formed a relatively small quantity of an unstable colorless compound. This substance liberates gas from methyl magnesium iodide and is capable of forming an acetate. Since it is colorless it cannot be the enol IX, but it might be either a rearrangement product of the enol (XIV) or the 1,2-addition product (XV)

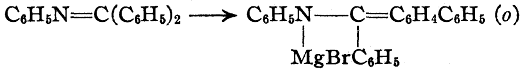
$$(C_6H_5)_2C{=}C(C_6H_5)CHOHC_6H_4C_6H_5\ (o) \qquad (C_6H_5)_2C{=}C(C_6H_5)C(C_6H_5)_2OH$$

XIV XV

In order to distinguish between these two possible formulas we oxidized the acetate and found that one mole of the substance gives one mole of benzoic acid and two moles of benzophenone, proving that the substance must be the 1,2-addition product. Our total yield of definite products is unsatisfactory; at best, we account for only 70% of the unsaturated ketone. But whether this low yield is due to the formation of other substances or the difficulty of isolating these unstable compounds we have been unable to ascertain.

Taken in their entirety, our results show that the most highly phenylated α,β-unsaturated ketone, like most other members of the series, is capable of forming both 1,2- and 1,4-addition products with organic magnesium compounds. Here, however, the resemblance ceases. In all other cases in which both types of addition occur, the relative quantity of the 1,4-addition product is always larger with alkyl than with aryl magnesium compounds. In our case these relations are completely reversed. Methyl magnesium bromide gives no 1,4-addition product, phenyl magnesium bromide but little of the 1,2-product.

A much more interesting difference, however, is represented by the fact that it is not, as in the case of all other members of this series, the ethylenic system but a phenyl group that is involved in 1,4-addition. The first—and only other—case of an addition of this type was reported last year. The two cases are not dissimilar. Gilman and his co-workers[2] found that benzophenone anil reacts with phenyl magnesium bromide only at a relatively high temperature, and that the reaction then consists in 1,4-addition and involves one of the phenyl groups



$$C_6H_5N{=}C(C_6H_5)_2 \longrightarrow C_6H_5\underset{\textstyle MgBr}{N}{-\!-}\underset{\textstyle C_6H_5}{C}{=}C_6H_4C_6H_5\ (o)$$

These two cases serve to diminish to some extent the difference between aromatic and ethylenic systems. It is clear that a phenyl group will participate in a reaction involving 1,4-addition when the hindrance to every other reaction is sufficiently great. It is far from clear, however, why there should be so much more hindrance to 1,2-addition in the unsaturated than in the saturated ketone.

Experimental Part

I. Preparation of Materials

No better methods were found for preparing either the saturated or the unsaturated ketones, but the yields have been improved greatly by modifying the procedure at nearly every stage. The steps involved in the preparation of the saturated ketone are shown in the following series of formulas

$$C_6H_5CHOHCOC_6H_5 \longrightarrow C_6H_5CH_2COC_6H_5 \longrightarrow C_6H_5CHClCH(C_6H_5)COC_6H_5 \longrightarrow$$
$$C_6H_5CH{=}C(C_6H_5)COC_6H_5 \longrightarrow (C_6H_5)_2CHCH(C_6H_5)COC_6H_5$$

---

[2] Gilman, Kirby and Kinney, THIS JOURNAL, 51, 2252 (1929).

For the reduction of benzoin to desoxybenzoin we used zinc and glacial acetic acid as recommended by Sudborough,[3] but by introducing an effective mechanical stirrer and by raising the temperature from that of the steam-bath to that of the boiling point of the liquid we not only greatly decreased the time of heating but improved the yield as well. The success of this method depends almost entirely on the quality of the zinc dust. With the finely powdered zinc which is frequently sold as zinc dust the yield is small. Instead of separating a part of the product by crystallization we found it advantageous to subject the entire product to distillation under diminished pressure.

Desoxybenzoin.—Two lots. each of 346 g. of benzoin, 600 g. of glacial acetic acid and 105 g. of zinc dust contained in a flask provided with a mechanical stirrer and an air condenser, were heated in an oil-bath at the boiling point of the liquid until a sample no longer gave a flocculent precipitate when it was dropped into water (four to five hours). The benzoin was first dissolved in the acid heated to about 115°, then the zinc dust was added as rapidly as possible without causing frothing, and finally the temperature was raised to the boiling point.

The solution was poured into hot water, the mixture boiled until the oil collected on the bottom, then cooled and filtered. The solid was washed with water and dissolved in alcohol. After removal of the zinc, the alcoholic solution was distilled under ordinary pressure until free from alcohol, then fractionated under diminished pressure. The yield was 534 g. of desoxybenzoin, equal to 82%.

β-Chloro Benzyl Desoxybenzoin.—The desoxybenzoin obtained in the preceding experiment was dissolved in 350 g. of benzaldehyde, the solution cooled in a freezing mixture, and saturated with hydrogen chloride which was passed into it for seven to eight hours. After standing overnight the resulting solid cake was broken up under alcohol, washed—first with alcohol, then with ether—and dried. The yield was 622 g. of chloro compound from 534 g. of desoxybenzoin, equal to 71%.

Benzal Desoxybenzoin.—A suspension of 250 g. of *p*-chloro benzyl desoxybenzoin, 200 g. of fused potassium acetate and 65 g. of dry sodium carbonate in one liter of methyl alcohol was boiled with constant vigorous mechanical stirring for three hours, then cooled and filtered. The solid was washed with sufficient water to remove inorganic salts completely. Its melting point was 100°, only 1° below that of the pure substance, which was obtained by one crystallization from ether. The yield is 180 g.—equivalent to 81%.

The Saturated Ketone (II).—To a solution of phenyl magnesium bromide prepared from 10 g. of magnesium, 50 g. of finely ground benzal desoxybenzoin was added as fast as it dissolved. The mixture was heated for a short time, then cooled and decomposed with ammonium chloride and ammonia in the usual manner. It yielded 61 g. of pure ketone equivalent to 95.8%.

The saturated ketone cannot be brominated. The route to the unsaturated ketone. therefore, follows the course

$$C_6H_5CH{=}C(C_6H_5)COC_6H_5 \longrightarrow (C_6H_5)_2CHC(C_6H_5){=}C(OMgBr)C_6H_5 \longrightarrow$$
$$(C_6H_5)_2CHC(C_6H_5)BrCOC_6H_5 \longrightarrow (C_6H_5)_2C{=}C(C_6H_5)COC_6H_5$$

For the purpose of preparing the α-bromo compound, 100 g. of finely ground benzal desoxybenzoin was added to a solution of phenyl magnesium bromide made from 20 g. of magnesium. The mixture was heated for a short time, then cooled in a freezing mix-

---

[3] Sudborough, *J. Cham. Soc.*, **71, 219 (1897).**

ture. To it was added, with constant stirring and very slowly, to avoid local rise in temperature, **120** g. of bromine which had been dried over phosphorus pentoxide. The mixture was poured into ice and hydrochloric acid and shaken until solid began to separate. The ethereal layer was then diluted with petroleum ether. The resulting solid was washed with water, a mixture of ether and petroleum ether and finally petroleum ether alone. The yield of a-bromo compound was **133** g., equivalent to **87%.**

The Unsaturated Ketone.—A suspension of **130** g. of the **α-bromo** compound and an **equal** weight of potassium acetate in **650 g.** of dry ethyl alcohol was boiled for two hours with sufficiently rapid stirring to prevent bumping. Most of the unsaturated ketone separates on cooling, mixed with potassium chloride. After washing and drying it is sufficiently pure for most purposes. The remainder of the product is obtained by distilling off most of the alcohol, diluting the residue with water and extracting with ether. This is less pure and needs to be recrystallized from chloroform and alcohol. The yield was **94.5** g., equal to **89%.**

II. Experiments with the Saturated Ketone

2,3,4,4,-Tetraphenyl Butanol-2 **(III).—Fifteen** grams of the finely ground saturated ketone was added to a solution of phenyl magnesium bromide made from 4 g. of magnesium. There was no perceptible warming and no change in color but the solid gradually dissolved. After remaining for two hours at the ordinary temperature, the clear solution was decomposed with iced ammonium chloride in the usual manner. The washed and dried ethereal layer, on evaporation, left a solid. This was recrystallized from methyl alcohol. The yield was **12.5** g. of pure product and **2** g. of material, largely composed of the same substance as the principal product.

Anal. **Calcd.** for $C_{28}H_{26}O$: **C, 88.8; H, 6.9.** Found: **88.4;** H, 7.0.

The **carbinol** is readily soluble in all common organic solvents except petroleum ether. It **crystallizes** in long, flat needles and melts at **140°.** It appears to be stable in the air but its melting point gradually drops when it is kept over sulfuric acid in a vacuum desiccator.

2,3,4,4-Tetraphenyl Butene **(IV).—A** solution of one gram of the hydroxyl compound in the requisite quantity of glacial acetic acid containing two drops of sulfuric acid was set aside for twelve hours. It deposited **0.71** g. of a colorless solid and when the acid was pumped off it left **0.2** g. more of the same substance. The substance is quite readily soluble in **all** common organic solvents including petroleum ether. It was recrystallized from methyl alcohol, from which it separated in needles melting at **104–106".**

Anal. **Calcd. for $C_{28}H_{24}$: C, 93.3; H, 6.7.** Found: **C, 93.2; H, 6.9.**

Ozonization.—A current of ozonized oxygen containing about **6%** of ozone was passed through a solution of **2** g. of the hydrocarbon in ethyl bromide for two hours. A considerable quantity of a crystalline solid separated from the solution during the passage of the ozone and more of the same substance was obtained when the ozonized solution was manipulated in the usual manner. The solid had the melting point of the saturated **ketone—tetraphenyl** propanone—and it caused no depression of the melting point when it was mixed with this ketone. The saturated ketone was **likewise** obtained when the hydrocarbon was oxidized with permanganate.

1,1,2,3,3-Pentaphenyl Propanol-1 (V).—A solution of 5 g. of the saturated ketone in dry benzene was added to a solution of phenyl magnesium bromide which had been made from 1.4 g. of magnesium and cooled in a freezing mixture. After the addition, the solution was stirred at the ordinary temperature for an hour. A test made at this time still showed much unchanged ketone. The mixture was therefore set aside for seven hours, then decomposed with iced acid in the usual manner. In addition to much oil, it gave **3.0** g. of a solid melting at **158–159°—a** yield of about **33%.**

All attempts to reduce the quantity of oil and increase the yield of the solid carbinol were unsuccessful. Lowering *the* temperature and stopping the reaction sooner resulted in mixtures of products and unchanged substance which were difficult to handle, and decomposing with ice and ammonium chloride in place of hydrochloric acid had no effect on the yield.

The solid product was purified by crystallizing it from methyl alcohol, from which it separates in the form of small white prisms melting at 159°.

Anal. Calcd. for $C_{33}H_{28}O$: C, 90.0, H, 6.4. Found: C, 89.5; H, 6.8.

A test by the Zeisel method showed that the substance has no alkoxyl group, and a quantitative examination of its reaction with a solution of methyl magnesium iodide in iso-amyl ether showed that it reacts with one mole of the reagent and liberates one mole of gas.

Oxidation.—All attempts to eliminate water from the hydroxyl compound led to unmanageable oils. The compound was therefore oxidized with excess of chromic acid in hot glacial acetic acid. To this end one gram of the substance in glacial acetic acid was treated with excess of chromic acid and heated on a steam-bath for two hours. It yielded 0.73 g of benzophenone and 0.16 g. of benzoic acid, instead of 0.83 g. of the former, 0 2 g. of the latter assuming that one mole of substance gives two moles of the ketone and one mole of the acid.

III. Experiments with the Unsaturated Ketone

A. Reaction with Methyl Magnesium Iodide

The reaction between methyl magnesium iodide and the unsaturated ketone was carried out a great many times. In the early experiments we became convinced that the reaction would not run in ether alone, no matter how prolonged the boiling. We then turned to benzene and found that the minimum temperature at which the reaction would run at an appreciable rate was about 50".

In subsequent experiments, therefore, we used four equivalents of the reagent. replaced the ether with benzene, heated for periods ranging between forty minutes and ten hours and decomposed sometimes with ice and acid, sometimes with ice and ammonium chloride. The yields of carbinol varied from 53.6 to 63.4%. In addition to the carbinol the product usually contained small quantities of its dehydration product—methyl triphenyl indene. No evidence was found for any 1.4-addition product. The lack of color showed conclusively that no phenyl group was involved in the reaction, and the inability to obtain a peroxide was good even if inconclusive evidence that no other type of 1,4-addition had occurred.

2,3,4,4-Tetraphenyl Butenol-2 (VI).—A solution of 10 g. of the unsaturated ketone in 60 cc. of dry benzene was added rapidly to a solution of methyl magnesium iodide which had been prepared in an atmosphere of dry nitrogen from 2.72 g. of magnesium. The mixture was heated to 60° for ten hours while a current of dry nitrogen was passed through the apparatus. After decomposing the magnesium compounds with ice and ammonium chloride in the usual manner, the benzene-ether layer was washed, dried and evaporated in a current of dry air. It deposited a solid which after washing with petroleum ether melted at 96.5°, therefore was pure carbinol. The petroleum ether washings yielded 0.8 g. of methyl triphenyl indene. The rest was oil.

The carbinol dissolves freely in all common organic solvents except petroleum ether. It crystallizes well From ether and petroleum ether and it can also be recrystallized from methyl alcohol and water. It separated in white plates and melts at 96.5'.

Anal. Calcd. for $C_{28}H_{24}O$: C, 89.4; H, 6.4. Found: C, 89.5; H, 6.7.

Proof of Hydroxyl Group.—One mole of the substance reacted with one mole of methyl magnesium iodide and liberated one mole of methane.

Proof of Double Linkage.—The carbinol was ozonized in ethyl bromide with ozonized oxygen containing 6% ozone. The product, decomposed with ice in the usual manner, and then set aside, slowly deposited a small quantity of solid. After recrystallization from alcohol the solid melted with decomposition at about 148°. Its composition corresponds to that of a peroxide of the carbinol and it flashed when it was heated rapidly.

Anal. Calcd. for $C_{28}H_{24}O{\cdot}O_2$: C, 82.4; H, 5.9. Found: C, 82.3; H, 6.0.

The oil that was left after the removal of the peroxide was distilled with steam. The oil in the distillate formed an oxime which melted at 141° and a phenylhydrazone melting at 138°, therefore was benzophenone.

Conversion into Methyl Triphenyl Indene.—A solution of one gram of the carbinol and the same quantity of sodium acetate in acetic anhydride was boiled for five hours, then poured into water and made alkaline with excess of sodium carbonate. The alkaline solution was extracted with ether, the ethereal layer washed, dried and evaporated. It left a solid which after washing with a little ether proved to be pure methyl triphenyl indene. The yield was 0.67 g.

Methyl Triphenyl Indene (VII).—The indene derivative, as has been shown, can be obtained in an excellent yield by heating the carbinol with a suitable condensing agent. It was generally obtained in small quantities as a by-product of the Grignard reaction. In one experiment, 50 g. of the ketone gave 12 g. of the pure indene derivative. Whether this uncommonly large yield was formed during the reaction or during the decomposition of the magnesium derivatives with hydrochloric acid could not be ascertained because we were unable to duplicate the result. The indene crystallizes from absolute ethyl alcohol in the form of prisms melting at 118°.

Anal. Calcd. for $C_{28}H_{22}$: C, 93.9; H, 6 2; mol. wt., 358. Found: C, 93.8; H, 6.2; mol. wt., 320.

Oxidation: α,α,α-Benzoyl-methyl-phenyl-ortho-tolyl Phenyl Ketone (VIII).—A solution of 1.5 g. of the hydrocarbon and 1.2 g. of chromic acid in glacial acetic acid was warmed until oxidation began at 50–60°. The temperature was held at this point for fifteen minutes. The solution was then diluted with water and extracted with ether. The washed and dried ethereal solution was concentrated and diluted with petroleum ether, whereupon it deposited a solid. The solid was recrystallized from anhydrous ether, from which it separated in white prisms melting at 182°.

Anal. Calcd. for $C_{28}H_{22}O_2$: C, 86.2; H, 5.6. Found: C, 86.4; H, 5.2.

Ortho Dibenzoyl Benzene.—The oily mother liquors from the diketone were oxidized with a larger quantity of chromic acid. The principal product was o-dibenzoyl benzene, which was identified by comparison with a sample on hand. Ortho dibenzoyl benzene was also one of the products formed when the oily by-products of the Grignard reaction were oxidized with excess of chromic acid.

B. Reaction with Phenyl Magnesium Bromide

A series of preliminary experiments showed that the unsaturated ketone does not react with phenyl magnesium bromide in boiling ether and that when the reaction was carried out in boiling benzene no solid products could be isolated. We used, therefore, a large excess of the reagent—usually four equivalents—and operated at temperatures between 45–60°. The procedure most favorable for securing the peroxide was the least favorable for isolating the unstable 1,2-addition product. Moreover, the acetate of the 1,2-addition product was most easily obtained directly from the magnesium derivative

$$(C_6H_5)_2C{=}C(C_6H_5)COC_6H_5 \longrightarrow (C_6H_5)_2C{=}C(C_6H_5)C(C_6H_5)_2OMgBr \longrightarrow$$
$$(C_6H_5)_2C{=}C(C_6H_5)C(C_6H_5)_2OCOCH_3$$

The Peroxide (X).—A solution of 15 g. of the ketone in 90 cc. of benzene was added drop by drop to an ethereal solution of phenyl magnesium bromide that was made from 4.08 g. of magnesium. Each drop of the solution produced a momentary red color, which turned to yellow, but by the time all of the ketone had been added, the color of the solution was dark red to brown. Ether was boiled off until the boiling point of the solution reached 50–52°.

After the solution had been boiled at 50–52° for an hour, it was cooled and poured into iced hydrochloric acid contained in a separating funnel. The mixture was shaken vigorously, the acid layer drawn off and the ethereal layer rapidly washed with ice water. The washed ethereal solution was then transferred to a suction flask which was cooled with ice while a rapid current of air was drawn through it. A yellow precipitate soon began to separate. This was collected on a filter when the solution became too thick; a second crop was obtained by diluting the oily residue with ether and repeating the operation, and a third by treating the oil with ether and petroleum ether. The total yield was 7.3 g., equivalent to 37.3%.

The peroxide was recrystallized from ether, from methyl alcohol, and from chloroform, but it is doubtful that this increased its purity. Its melting point varied with the mode of heating, the highest being 186.5".

Anal. Calcd. for $C_{33}H_{26}O_3$: C, 84.3; H, 5.5. Found: C, 84.0; H, 6.0.

In the machine one mole of the compound consumed three moles of methyl magnesium iodide and liberated one mole of gas. The peroxide crystallizes in long yellow prisms.

Ozonization.—The peroxide was oxidized with ozone in the usual manner but the results were not very instructive. It gave a considerable quantity of benzophenone, showing that the ethylene linkage was intact but, as was to be expected, the remainder of the molecule was converted into highly colored oils from which only benzoic acid could be isolated.

Reaction with Sodium Methylate. The Unsaturated Ketone (XI).—When the peroxide is added to a concentrated solution of sodium methylate in methyl alcohol it dissolves in part and forms a brilliant red solution, but the ketone begins to separate before solution is complete. The reaction appears to be complete in an hour, but the mixture was usually set aside overnight. Thus 2.5 g. of the finely ground peroxide was added to 20 cc. of 10% sodium methylate. The mixture was set aside for fifteen hours, then diluted with water and extracted with ether. The washed and dried yellow ethereal solution, on evaporation, deposited 2.45 g. of crude product. This was washed with methyl alcohol and further purified by recrystallization from the same medium. The yield of pure ketone was 1.6 g., equivalent to 69%.

Anal. Calcd. for $C_{33}H_{24}O$: C, 90.8; H, 5.5; mol. wt., 436. Found: C, 90.9; H, 5.6; mol. wt., 412.

The color of the ketone is a lighter yellow than that of the peroxide. It crystallizes in long plates and melts at 138°.

Ozonization: Ortho Phenyl Benzil (XII).—A current of ozonized oxygen containing about 6% of ozone was passed through a solution of one gram of the ketone in ethyl bromide for one and one-half hours The ozonide was decomposed in the usual manner and the solvent removed. The residue was an oil which partially solidified when it was rubbed with alcohol. The resulting solid was recrystallized from alcohol, from which it separated in pale yellow plates melting at 80".

Anal. Calcd. for $C_{20}H_{14}O_2$: C, 83.9; H, 4.9. Found: C, 83.5; H, 5.3.

The filtrate from the diketone was distilled with steam and the distillate extracted with ether. The ethereal solution contained benzophenone, which was identified by converting it into phenylhydrazone and comparing this with a sample on hand.

The Glyoxaline Derivative, .—An alcoholic solution of 0.1 g. of the diketone, 0.09 g. of ortho phenylene diamine hydrochloride and an equivalent quantity of sodium acetate was boiled for a short time, then diluted with water and extracted with ether. The ethereal extract was freed from excess of the diamine by shaking with dilute acid, then washed, dried and evaporated. It deposited a colorless solid. The solid was recrystallized from alcohol, which deposited it in large square plates which melted at 163°.

Anal. Calcd. for $C_{26}H_{18}N_2$: C, 87.1; H, 5.0. Found: C, 86.6; H, 5.1.

Oxidation of the Diketone: Ortho Phenyl Benzoic Acid.—A solution of 0.2 g. of the diketone in methyl alcohol was treated first with excess of 15% hydrogen peroxide, then with excess of 10% sodium hydroxide. It soon became colorless. It was then heated to remove the methyl alcohol, and acidified. From the acid solution ether extracted 0.23 g. of a mixture of acids which could not be separated by steam distillation. but which was readily separated by sublimation. The sublimate was benzoic acid. The residue (0.15 g.) melted at 113°. It was identified as ortho phenyl benzoic acid by comparison with a sample of this acid which was obtained by fusing fluorenone with potassium hydroxide.

Triphenylvinyl Diphenyl Carbinol (XV).—A solution of 10 g. of the ketone was added in the usual manner to a solution of phenyl magnesium bromide made from 2 7 g. of magnesium. The mixture was heated to 60° for two hours, then decomposed with iced hydrochloric acid. The ethereal layer was washed, dried and then evaporated in *a* draught. It first deposited the yellow peroxide, and later a colorless solid which was purified by recrystallization from ether–petroleum ether; yield, 12%.

Anal. Calcd. for $C_{33}H_{26}O$: C, 90.4; H, 5.9. Found: C, 90.1; H. 6.0.

The carbinol is sparingly soluble in alcohol, moderately soluble in ether. It crystallizes in thin white plates. It melts with decomposition, and the melting point varies with the rate of heating. The highest melting point observed was 169°. Even the purest samples slowly change at the ordinary temperature, turning ultimately into brown viscous oils, but it can be kept apparently without change at 0°.

The Acetate (XVI).—The acetate was first obtained by boiling a solution of the carbinol for seventeen hours with acetyl chloride and then distilling off the excess of the chloride. It is made much more easily directly from the magnesium derivative of the carbinol. Thus a solution of 25 g. of the ketone in benzene was added to an ethereal solution of phenyl magnesium bromide which contained 6.8 g. of magnesium. The mixture was kept for one hour at 50°, then cooled in a freezing mixture. Into the cooled solution was dropped a mixture of 33 g. of acetyl chloride and twice its volume of absolute ether. The brilliant red solution was allowed to reach the temperature of the room, then decomposed with ice and acid in the usual manner.

The ethereal layer was thoroughly washed with water, dried and concentrated. It yielded 10 6 g. of the same acetate that had been obtained from the carbinol. It was purified by recrystallization from chloroform and ether.

Anal. Calcd. for $C_{35}H_{28}O_2$: C, 87.5; H, 5.8. Found: C, 87.5; H, 6.2.

The acetate is readily soluble in benzene and in chloroform, very sparingly soluble in ether and in alcohol. It crystallizes in colorless plates and melts at 218°.

Oxidation.—A solution of one gram of the acetate and an equal weight of chromic acid in glacial acetic acid was heated on a steam-bath for about an hour, then cooled and

diluted with ice and ether. The ethereal layer was shaken with sodium carbonate, which extracted benzoic acid, then dried and evaporated. The residue when distilled with steam yielded 0.61 g. of pure benzophenone.

Summary

When tetraphenyl propenone reacts with phenyl magnesium bromide, the principal product is a diphenyl derivative which is formed by 1,4-addition to the system $-CO-C_6H_5$.

CAMBRIDGE, MASSACHUSETTS

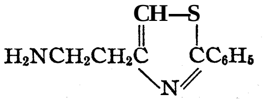
[CONTRIBUTION PROM THE DEPARTMENT OF CHEMISTRY, YALE UNIVERSITY]

THE SYNTHESIS OF THIAZOLE AMINES POSSESSING PHARMACOLOGICAL INTEREST. V

BY W. S. HINEGARDNER[1] AND T. B. JOHNSON

RECEIVED AUGUST 8, 1930 PUBLISHED OCTOBER 6, 1930

In Paper IV of this series, Hinegardner and Johnson[2] have described the synthesis of 2-phenylthiazole-4-ethylamine, expressed structurally by formula I. This is a representative of a new type of aliphatic amines in which the thiazole nucleus has been substituted for a methylene *radical* in y-phenylpropylamine. It is a bridged thiazole compound of pharmacological interest and is only one of a series of compounds of its type which may be prepared by our method of synthesis. In this paper we describe a series of intermediate compounds which have been prepared in the development of a practical synthesis of 2-*p*-hydroxyphenylthiazole-4-ethylamine, XIV. This latter amine bears the same relationship to tyramine III as the thiazole amine I does to phenylethylamine II. It is a very potent substance biologically and its pharmacological activity is being investigated.



I

$C_6H_5CH_2CH_2NH_2$

II

$HOC_6H_4CH_2CH_2NH_2$

III

The starting points for our research were *sym.*-dichloro-acetone and the thioamide of anisic acid. These interact smoothly when warmed together in alcoholic solution, giving an excellent yield of the primary halide IV. Utilizing then the same technique as was described in our previous paper[B] for the preparation of the amine I, the various transformations recorded in Table I have been carried through successfully, leading up to the desired amine, XIV. The experimental data establishing the constitution and chemical identity of these various thiazoles are recorded in Table II.

[a] This acid crystallizes with two molecules of water.

Experimental Part

Thioanisamide was prepared according to the following series of reactions: anisic aldehyde ⟶ anisaldoxime ⟶ anisic nitrile (81%) ⟶ thioanisamide (88.8%). The reaction of this thioamide with dichloro-acetone is easily brought about by warming in alcohol solution, and the product of reaction IV can be purified by crystallization or distillation.

Preparation of the Malonate, V.—In the preparation of this ester we were not troubled with the formation of a disubstitution derivative of the malonic ester when the chloride IV was used as was observed in the first synthesis applied by Hinegardner and Johnson.[2] For this reason the yield of our primary malonic ester V was better than that in our previous work. Saponification of the ester and decarboxylation of the resulting malonic acid VI to form the propionic acid VII are easily accomplished by the usual organic technique and the yield in each operation is excellent. Formation of the hydrazide IX is brought about by refluxing the ester VIII in alcohol with 50% hydrazine hydrate solution. Complete transformation requires about twelve hours of digestion on a steam-bath.

Formation of the Amine XIII from Its Phthalimide.—The phthalimide XII is formed by heating the urea XI with phthalic anhydride at 220–225° as long as carbon dioxide is evolved. The imide is then decomposed by digestion in alcohol with 40% hydrazine hydrate solution and the amine XIII obtained in the form of its hydrochloric acid salt. Conversion of this methoxy compound into the free phenolic amine XIV was brought about by refluxing the base XIII for three hours with 48% hydrobromic acid solution. The amine XIV was obtained as an oil which showed no signs of solidifying on standing and was preserved in the form of its hydrochloric acid salt. Attempts to convert the urea XI directly into the amine XIV by digestion with 48% hydrobromic acid were unsuccessful.

Summary

1. *Sym.*-dichloro-acetone and thioanisamide interact in alcohol solution to form the compound 2-*p*-methoxyphenylthiazole-4-chloromethyl.
2. This halide has been incorporated into malonic ester and the resulting product converted by a standard series of reactions into a bridged thiazole derivative of tyramine, namely, 2-p-hydroxyphenylthiazole-4-ethylamine.
3. Eleven new thiazole compounds have been described.

THE SYNTHESIS OF THIAZOLE AMINES POSSESSING PHARMACOLOGICAL INTEREST. VI

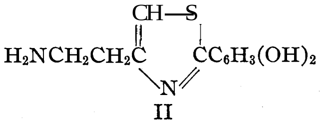
BY W. S. HINEGARDNER[1] AND T. B. JOHNSON

RECEIVED AUGUST 8, 1930 PUBLISHED OCTOBER 6, 1930

In the development of a practical method for synthesizing a bridged thiazole amine of the adrenaline type we undertook first the preparation of the thiazole amine expressed structurally by formula II. It was important, during the progress of our work, to compare the pharmacological activity of this base with that of 3,4-dihydroxyphenylethylamine I already described by Mannich and Jacobsohn.[2]

$(HO)_2C_6H_3CH_2CH_2NH_2$

I



II

The method of synthesis utilized by us for obtaining this interesting amine is an extension of the technique previously applied for the preparation of the corresponding bridged thiazole derivatives of phenylethylamine

and tyramine. The starting points were vanillin and dichloro-acetone. The vanillin was first methylated according to the procedure of Barger and Silberschmidt,[3] and converted into the oxime of methylvanillin. Veratrol nitrile was then prepared and converted by the action of hydrogen sulfide into 3,4-dimethoxythiobenzamide. When this thioamide and dichloro-acetone were warmed together in alcohol solution, an immediate reaction took place with formation of the primary halide, 2-(3,4-dimethoxyphenylthiazole)-4-chloromethyl, III, in excellent yield.

---

[3] Barger and Silberschmidt, *J. Chem. Soc.*, 133, 2924 (1928).

The different steps of the synthetic process leading up to the amine construction XIII are shown in Table I. The yields in each step are very favorable, and the intermediate compounds can be easily obtained in a high degree of purity.

The conversion of the dimethyl ether represented by formula XII into the amine XIII has not, thus far, been accomplished successfully. Demethylation of this thiazole by the action of hydriodic and hydrobromic acids leads to the formation of the base XIII, but this has not been obtained thus far in a state of purity. For this reason no constants for this compound are reported. The study of this interesting compound and several of its derivatives is being continued. The experimental data characterizing the different thiazoles prepared are recorded in Table II.

Experimental Part

3,4-Dimethoxythiobenzamide $(CH_3O)_2C_6H_3CSNH_2$.—This was prepared by heating veratrol nitrile with an alcohol solution of hydrogen sulfide in an iron bomb at 100° and was easily obtained in a yield of 90% of the theoretical. The amide crystallizes from alcohol in the form of prisms or needles melting at 183°. It is difficultly soluble in alcohol, acetone and benzene and practically insoluble in water. Alcohol is the best solvent for crystallization.

Anal. Calcd. for $C_9H_{11}O_2NS$: N, 7.10. Found: N, 7.08, 7.02.

Preparation of the Hydrazide, VIII.—This is easily obtained by heating the propionate VII in alcohol solution with the required amount of 40% hydrazine hydrate solution for twelve to fifteen hours. Conversion to the corresponding azide is accomplished by diazotization in acetic acid solution. This compound is a very unstable compound when heated above its melting point. By warming the azide in dilute acetic acid solution, almost the theoretical yield of the urea X is obtained. The following steps of the synthesis leading up to the amine XII from this urea do not present any experimental difficulties.

Demethylation of the Amine, XII.—Thus far, conversion of this compound into the hydroxyl compound XIII has not been accomplished successfully. Refluxing with hydriodic and hydrobromic acids leads to complete demethylation, but the base formed is very susceptible to oxidation and the solutions take on a very dark color during the digestion process. Neutralization of the hydrobromic acid solution by potassium hydroxide causes separation of the amine as an oil, which dissolves immediately when the solution is made alkaline. The base was extracted with ether and dried over sodium sulfate. On evaporating the solvent, a brown resinous substance was obtained which could not be distilled without decomposition and also showed no signs of crystallization. Further attempts are being made to purify this base and separate it if possible in the form of its hydrochloride.

Summary

1. 3,4-Dimethoxythiobenzamide has been prepared. This interacts smoothly with dichloro-acetone to form 2-(3,4-dimethoxyphenylthiazole)-4-chloromethyl.

2. This chlorothiazole compound has been transformed by a series of standardized reactions into the new bridged thiazole amine 2-(3,4-di-

methoxyphenylthiazole)-4-ethylamine. The further study of this base is being continued with the object of developing a practical synthesis of the bridged thiazole derivative of 3,4-dihydroxyphenylethylamine represented by formula II in this paper.

3. Ten new thiazole derivatives have been described.

STUDIES ON THE POLYMETHYLBENZENES. IV. THE PREPARATION AND PHYSICAL PROPERTIES OF PURE PSEUDOCUMENE[1]

BY LEE IRVIN SMITH AND AXEL P. LUND

RECEIVED AUGUST 11, 1930 PUBLISHED OCTOBER 6, 1930

The work reported in this paper is a continuation of a research which has for one of its immediate purposes the separation of the isomeric liquid hydrocarbons which result from the methylation of xylene by the method of Friedel and Crafts.[2] In the previous papers reports were made on the pure tetramethylbenzenes, and on penta- and hexamethylbenzenes. This paper deals with pseudocumene (1,2,4-trimethylbenzene), and reports the preparation and purification, together with the freezing point, refractive index and vapor pressure curve of a very pure sample.

Pseudocumene has been obtained from petroleum,[3] but the commercial source is coal tar.[4] However, pseudocumene obtained in this way is always contaminated with mesitylene, and it is very doubtful whether a specimen of the pure hydrocarbon has ever been obtained from any of these sources.

Synthetic pseudocumene has been made in several ways, but the yields were always low and, in addition, most of the methods are open to the objection that isomeric by-products might result. Thus Jacobsen[5] reports that if phorone is heated with phosphorus pentoxide or zinc chloride, some pseudocumene results, but if concd. sulfuric acid be used, only mesitylene results. The decomposition of camphor by zinc chloride is reported to give pseudocumene[6] but these syntheses do not give pure products, nor good enough yields for purposes of preparation.

[6] R. Fittig, Köbrich and Jilke, *Ann.*, 145, 140 (1868); Reuter, *Ber.*, 16, 626 (1883).

Paul Jannasch, and others[7] have prepared pseudocumene by treating bromoxylenes with methyl iodide and sodium, or by treating dibromotoluenes with the same reagents, but in every case there is question as to the purity of the aromatic bromo compounds, and the yields of pseudocumene were very low.

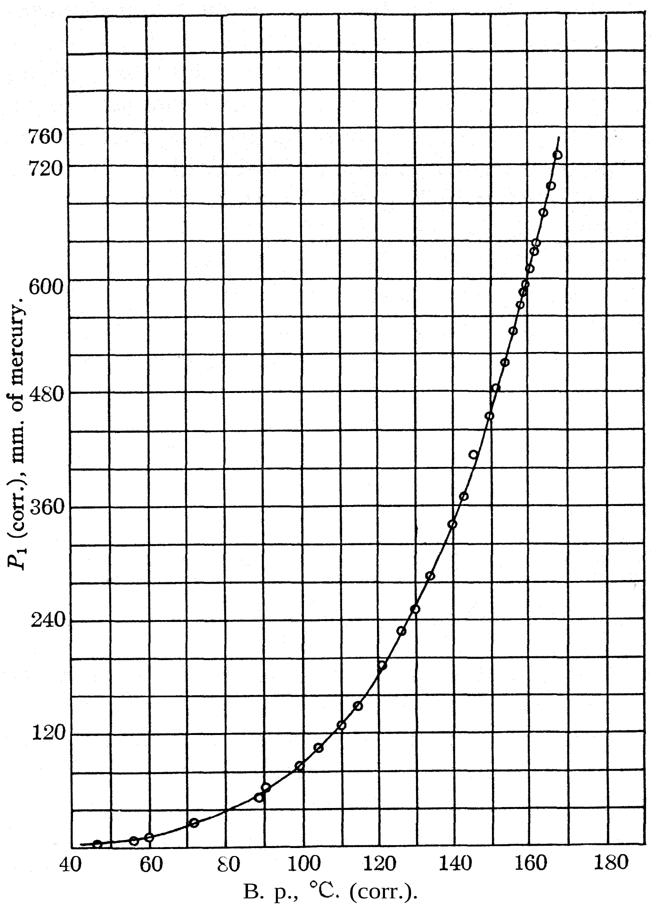

Fig. 1.—Vapor pressure curve for pseudocumene.

While the direct methylation of the xylenes using aluminum chloride and methyl chloride has been used to prepare pseudocumene, such a method always gives a mixture and none of the specimens prepared in this way were pure. This is because the methylation in the presence of aluminum chloride is reversible, and methyl groups are eliminated as well as intro-

---

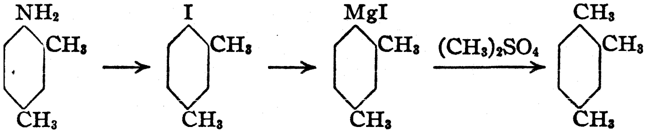
[7] Jannasch, *Ann.*, **176**, 283 (1875); E. and R. Fittig, *ibid.*, 139, 187 (1866); R. Fittig and Laubinger, *ibid.*, **151**, 258 (1869); R. Fittig and Jannasch, *ibid.*, 151, 291 (1869); Jannasch, *ibid.*, 176, 283 (1875).

duced, so that the final result will depend upon many factors; but in every case the product is a mixture of substances, and very little is known about the way in which various factors influence the result. About the only generalization that can be safely made is that ortho methylation apparently occurs in very small amounts: that is, of the trimethylbenzenes formed, very little will be the 1,2,3-isomer, and of the tetramethylbenzenes, the 1,2,3,4-isomer will result in least amount.[8]

The one synthesis in the literature which might be made to give pure pseudocumene in fair yields is that of Haller,[9] who started with pseudocumidine, a solid, which could be obtained in a pure state. This was diazotized, and then reduced to the hydrazine, after which the hydrazine group was eliminated by boiling with a solution of copper sulfate. Haller gives the boiling point of his product as 169–170° (corr.), but does not mention the over-all yield nor the amount of material he prepared. His synthesis was used to prepare pseudocumene in 1919 by Auwers,[10] who gave the boiling point as 169° and n_{D}^{20} as 1.5046.

All the other samples of pseudocumene which have been used for the determination of physical constants were commercial products, and nothing is known as to their method of preparation.[11]

Preparation of Pseudocumene.—The preparation of pseudocumene for this work involves the following series of reactions



Starting with pure xylidine, the series gives intermediates which. are easily purified. No rearrangements are involved, and the only trimethylbenzene which can result from these reactions is pseudocumene. Some xylene is formed, due to the reducing action of the Grignard reagent, but this is easily separated by fractional distillation.[12]

[12] While this paper was being written, the paper of Maxwell and Adams [THIS JOURNAL. 52, 2962 (1930)] appeared, in which these authors prepared pseudocumene from m-xylene by bromination, followed by conversion of the bromo-*m*-xylene to pseudocumene through the Grignard reagent. Their yield of pseudocumene, based upon the m-xylene, was about 40%, as compared with our over-all yield of about 30%.

Experimental Part

4-Amino-1,3-dimethylbenzene.—This was obtained from the Eastman Kodak Co., and was distilled immediately before using; b. p. 111° at 18 mm. Practically all of the sample showed a constant boiling point.

4-Iodo-1,3-dimethylbenzene.[13]—In a 3-liter round-bottom flask are placed 200 g. of concd. sulfuric acid, 1500 cc. of water and 121 g. (1 mole) of xylidine. The mixture is warmed on the steam-bath until all of the xylidine sulfate dissolves, and is then cooled to 0°, with stirring to produce small crystals. To the cold solution is added a solution of 69 g. of sodium nitrite in 200 cc. of water with stirring and cooling. (The temperature should not be allowed to rise above +5°.) An excess of nitrous acid should be used, and after about 80% of the sodium nitrite is added, the starch–potassium iodide test should be applied. It should be positive for fifteen minutes after an excess of sodium nitrite has been added. When enough sodium nitrite has been supplied, a solution of 250 g. of potassium iodide (30% excess) in 300 cc. of water is gradually run in, with stirring and cooling. The temperature of the mixture is kept at 5–10° for twenty-four hours and then allowed to come to room temperature. The iodo compound settles to the bottom as a black, oily layer. The mixture is allowed to stand for a day at room temperature, and is finally warmed on the steam-bath until effervescence ceases. The mixture is then made strongly alkaline, stirred and the aqueous layer siphoned off. The dark oil is again treated with alkali, after which it is steam distilled. The orange colored oil is separated from the water, dried over calcium chloride and distilled *in vacuo;* b. p. 105–106° at 5 mm.; 108–110° at 10–12 mm.; 124–126° at 28–30 mm. Runs were made in 0.5, 1.0, 1.5 and 2.0 molar quantities, the yields running from 69.0 to 82.7%, with an average yield of about 75% for 1.0 molar quantities. Two important factors which influence the yields very much are the amount of potassium iodide used and the time of the reaction. An excess of about 30% of potassium iodide and very slow raising of the temperature after the potassium iodide has been added give the best yields.[14]

Pseudocumene.—The iodoxylene was converted to pseudocumene using the method already described for the preparation of isodurene.[15] The product is worked up in the same way: the excess diiethyl sulfate is destroyed with alcoholic alkali and, after washing out the alcohol and alkali, the oil is dried over calcium chloride and then warmed with sodium shavings to remove the last traces of halogen compounds. The oil is then filtered from the sodium and distilled in *vacuo* using a long packed column with a double jacket. Grignard reactions were carried out using 0.5 to 3.0 molar quantities, but the yields do not differ very much from the smaller to larger runs. The material from six different runs, totaling $11^3/_8$ moles of iodo compound, was combined and fractionated three times, with the results shown in Table I.

TABLE I

FRACTIONATION OF CRUDE REACTION PRODUCT

Fraction	B. p., °C.	Pressure, mm.	Wt., g.	Yield, %

---

[13] See also Hammerich, *Ber.*, 23, 1634 (1890); Willgerodt, *ibid.*, 33, 842 (1900).

[14] It is very interesting in this connection that we were unable to make the corresponding bromo compound from xylidine using the Sandmeyer reaction. The product is chiefly xylenol and the yield of bromo compound is very small.

[15] Smith and MacDougall, THIS JOURNAL, 51, 3003 (1929); Smith, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1931, Vol. XI.

About a third of the material is lost in the synthesis, probably as m-xylene which is very difficult to hold in a receiver under vacuum. That Fraction I is m-xylene was shown by converting a sample of it to the dinitro compound, m. p. 92–93°, and the trinitro compound melting at 181.5–182°.

In order to get a very pure sample for the determination of physical constants, Fraction III was refractionated, cutting off the first and final fourths and taking only the middle half. Then the process was repeated, using as starting material the middle half from the previous fractionation, and again cutting off the first and final fourths. This gave 125 g. of pseudocumene having a constant boiling point of 68.0° at 22 mm., but all the fractions of the pseudocumene boiled over a range of about 0.5°.

A further attempt to purify the hydrocarbon by making the picrate and recrystallizing this was a failure because the picrate of the substance is too soluble and has too low a melting point to be of any use for purification purposes.

The Vapor Pressure Curve of Pseudocumene.—There is, apparently, only one study on the vapor pressure of pseudocumene in the literature, that of Woringer,[16] and all the data on the vapor pressure of this substance in the literature are copied from Woringer's paper.[17]

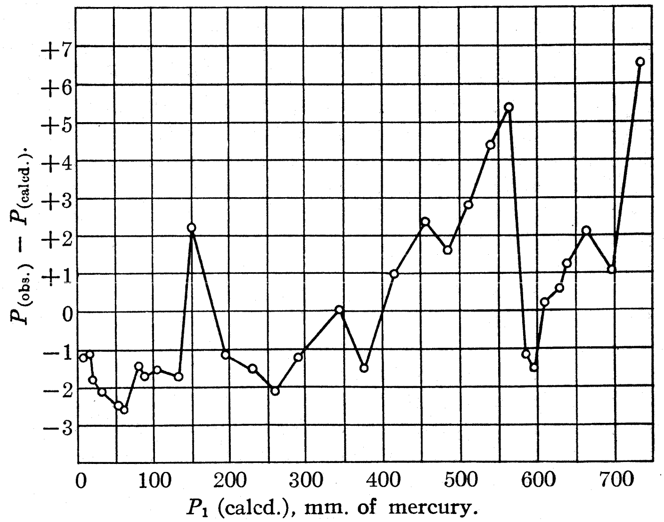

Fig. 2.—Vapor pressure–deviation plot for pseudocumene. $\text{Log}_{10}p = 7.0144 - 1.5014\mu - 0.1447\mu^2$. ($\mu = 1000/T_{\text{abs.}}$)

The method used for determining the vapor pressure curve is a dynamic one, and the apparatus and procedure have already been described.[18] The results are given in the form of tables and curves. The equation

$$\log_{10} p = 7.0144 - 1.5014\mu - 0.1447p^2 \text{ (where } \mu = 1000/T)$$

---

[16] Woringer, Z. *physik.* Chem., 34, 263 (1900).

[17] "International Critical Tables," McGraw-Hill Book Co., Inc., New York, 1928, Vol. III, p. 225; Spielmann, "The Constituents of Coal Tar," Longmans, Green & Co., New York, 1924, p. 62.

[18] MacDougall and Smith, This Journal, 52, 1998 (1930).

fits these results fairly well. For comparison, the calculated and observed vapor pressures are given in the table, and the deviations are shown in the form of a graph. In every case Woringer's boiling points are lower than ours, and in the region from 5 to 100 mm. pressure Woringer's boiling points are too low by as much as 50" in extreme cases. In the region of higher pressures, Woringer's boiling points agree fairly well with ours, but are always too low, approaching ours more closely the higher the pressure.

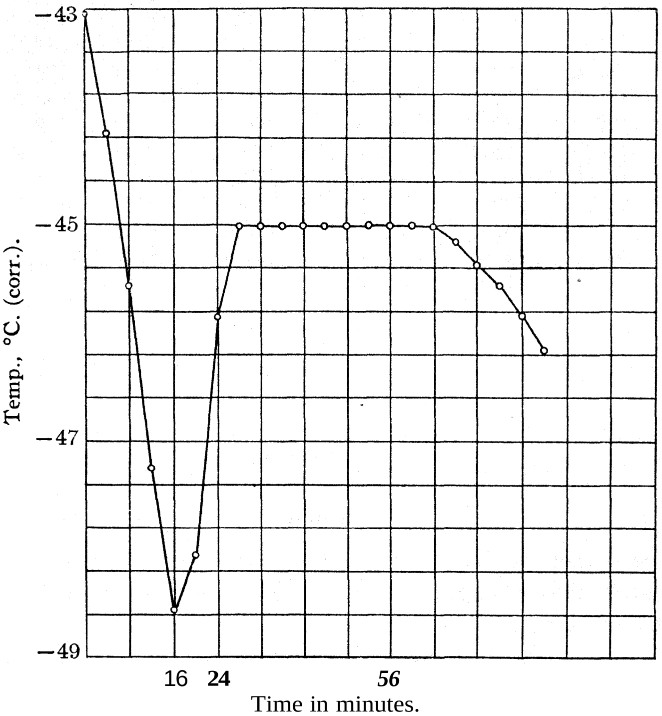

Fig. 3.—Cooling curve, freezing point of pseudocumene.

The boiling point of pseudocumene under 760 mm. pressure is 169.34°, calculated from the vapor pressure equation, and 169.1" by extrapolation of the vapor pressure curve.

The Freezing Point of **Pseudocumene.**—This was determined essentially as described in connection with previous work.[19] The cooling bath was composed of chlorobenzene (freezing point −45°) to which was added carbon dioxide snow and ether until the bath was at −60°. Once this temperature was reached, it was easy to maintain it by adding small amounts of ether and solid carbon dioxide from time to time. Readings were taken every minute and the results are shown graphically in Fig. 3. The freezing point of pseudocumene is —45.00 ± 0.05" corr.

140.1	341.6	341.5	+0.1				

Refractive Index.—Previous determinations, recorded in the literature, for the refractive index of pseudocumene are Auwers,[10] n_D^{20} 1.5046; Auwers and Müller,[11a] $n_D^{13.9}$ 1.50780; Landoldt and John,[11b] $n_D^{14.7}$ 1.5072; and Brühl,[11c] $n_D^{21.6}$ 1.50441. All our fractions of pseudocumene, after the second distillation, gave the value n_D^{24} 1.5032 (Abbé refractometer).

Summary

1. A new method has been devised for preparing pseudocumene in quantity and fairly cheaply. The method gives a product free from any isomeric by-products.

2. The vapor pressure curve, freezing point and refractive index of a very pure specimen of pseudocumene have been determined.

THE ACTION OF HEAT ON ETHYLAMINE AND BENZYLAMINE

BY CHARLES D. HURD AND FLOYD L. CARNAHAN[1]

RECEIVED AUGUST 11, 1930 PUBLISHED OCTOBER 6, 1930

The only primary aliphatic amines whose pyrolysis has been studied are ethylamine and propylamine. The former has been investigated at 500, 700 and 1000° over kaolin by Upson and Sands.[2] At the lower temperatures the major primary reaction is the formation of acetonitrile and hydrogen, along with the not inappreciable production of ethylene and ammonia. The products at 1000° are stated to be hydrogen, nitrogen and butane. Müller[3] found that at 1240° the products are hydrogen cyanide and methane. From n-propylamine at 700°, Upson and Sands obtained propionitrile, hydrogen cyanide, ammonia, ethylene, propylene, hydrogen and nitrogen.

In the present investigation, an experiment with ethylamine at 600° was carried out but our major interest was at higher temperatures. Several runs were made at 890–900° (furnace temperature of 980°), and in these the contact time was varied from one second to 300 seconds.

Acetonitrile was found at 600° but not at 900°. Hydrogen cyanide was always present at the higher temperature, but only a small amount of ammonium cyanide was noticed when the contact time was in excess of one minute. No cyanogen was formed whatsoever. The effect of contact time on the yield of ethylene at 900° is marked. With a contact time of one second the ethylene content of the gases was 10.3%; with 15.5 seconds, 5.0%; with eighty seconds, 0.5%; and with longer durations, no ethylene at all. This agrees with Bone and Coward's[4] statement that ethylene is nine-tenths decomposed in one minute at 950°, chiefly into methane and hydrogen.

In experiments with a kaolin-packed tube (as in Upson and Sands' experiments), the formation of appreciable volumes of carbon monoxide was observed. This is not a new type of observation for Bone and Cowards noticed carbon monoxide formation in the high-temperature pyrolysis of methane in a porcelain tube. These authors mention that it is impossible to avoid reduction of the porcelain by carbon at temperatures above a red glow.

In the theoretical treatment of Upson and Sands' paper it is stated that the primary dissociation of ethylamine yields the ethylidene radical and ammonia: $CH_3CH_2NH_2 \longrightarrow CH_3CH= + NH_3$. The ethylidene was regarded as the precursor of ethylene (by rearrangement), of ethane (by

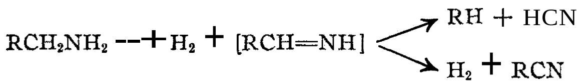
hydrogenation) and of butane. Regarding the latter it is stated: "Butane was the chief hydrocarbon formed at 1000°. This must have been formed by the union of 2 ethylidene radicals and 2 atoms of hydrogen as in the Wurtz reaction: $2CH_3CH{=} + 2H \longrightarrow C_4H_{10}$."

The data of Upson and Sands appear to show that at 1000° 32.9 g. (26.9 g. C and 6.0 g. H) of butane was formed per 100 g. of ethylamine decomposed. To be sure, the stated ratio of 26.9 g. C to 6.0 g. H, or 4.48 to 1, corresponds fairly well to the value for butane which is 4.8 to 1. However, it agrees even more closely to the C–H ratio in propane, which is 4.5 to 1. Because of subsequent work wherein it has been demonstrated that both n- and *i*-butane are rapidly decomposed[6] at temperatures far below 1000°, namely, at 650–700°, it seemed to us that this recorded synthesis of butane from ethylamine at 1000° was of sufficient theoretical importance to merit further study.

In our work butane was searched for under a wide variety of conditions at 900–1000° but none was ever found. Attempts to condense it at −78° from the gaseous products were fruitless, though butane had been shown to condense in this manner even if highly diluted. Furthermore, in our analyses of the paraffin gases of the reaction, methane rather than butane was indicated. The value of n in the hydrocarbon formula, C_nH_{2n+2}, was only slightly greater than unity (1.02–1.15).

Benzylamine.—Benzylamine was subjected to different temperatures for various lengths of time. Its stability is evidenced by the fact that heating at 275–300° for several hours produced no change. It was also found to be stable at 545° with a contact time of about one minute With the use of a temperature of 630° and a contact time of 160 seconds, pyrolysis into benzene, toluene, benzonitrile, hydrogen cyanide and ammonia was effected. Much unchanged benzylamine was apparent when a contact time of forty-nine seconds at 700° was chosen. The other products were benzene, toluene, gas and only a trace of benzonitrile.

Mechanism of the Pyrolysis.—In certain respects the behavior of ethylamine and benzylamine at high temperatures is strictly comparable. The formation of acetonitrile and hydrogen from the former is analogous to the production of benzonitrile and hydrogen from the latter. So also, the formation of methane, hydrogen cyanide and hydrogen from ethylamine has its parallel (in benzylamine) in the production of benzene, hydrogen, cyanide and hydrogen. Both of these processes may be considered to proceed through an intermediate aldimide, $RCH{=}NH$, wherein R represents methyl or phenyl.



$$\mathrm{RCH_2NH_2} \longrightarrow \mathrm{H_2} + [\mathrm{RCH{=}NH}] \begin{cases} \nearrow \mathrm{RH} + \mathrm{HCN} \\ \searrow \mathrm{H_2} + \mathrm{RCN} \end{cases}$$

---

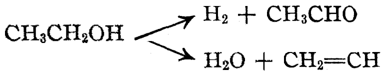
[6] Pease, This Journal, *50*, 1779 (1928); Hurd and Spence, *ibid.*, 51, 3353 (1929).

Hydrogen escapes in part but presumably only in part. Reaction with unused amine would give rise to ammonia and either ethane or toluene

$$\mathrm{RCH_2NH_2} + 2\mathrm{H} \longrightarrow \mathrm{RCH_3} + \mathrm{NH_3}$$

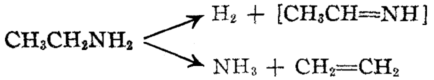
both of which were observed. Further reduction[7] of the $\mathrm{RCH_3}$ into RH (methane or benzene) and $\mathrm{CH_4}$ would also follow in part.

Ethylamine is "ammono-ethyl alcohol." The analogies in the water and the ammonia system of compounds may be extended to the field of pyrolysis. Alcohol, on pyrolysis, undergoes reactions[8] of dehydration and of dehydrogenation



$$\mathrm{CH_3CH_2OH} \begin{array}{l} \nearrow \mathrm{H_2 + CH_3CHO} \\ \searrow \mathrm{H_2O + CH_2{=}CH_2} \end{array}$$

Ammono-ethyl alcohol may be expected to undergo similar reactions of deammonation and of dehydrogenation



$$\mathrm{CH_3CH_2NH_2} \begin{array}{l} \nearrow \mathrm{H_2 + [CH_3CH{=}NH]} \\ \searrow \mathrm{NH_3 + CH_2{=}CH_2} \end{array}$$

The dehydrogenation reaction, leading to the aldimide and eventually to cyanides, has already been discussed. Equally representative of fact is the deammonation reaction, of which ethylene is an important reaction product.

Benzyl alcohol and benzylamine are analogous compounds in the two systems. The former cannot lose water unimolecularly without changing into the phenylmethylene radical. This it evidently does not do since stilbene is not formed. Bimolecular dehydration into dibenzyl ether or its pyrolytic products (toluene and benzaldehyde) is the reaction which has been recorded.[9] Similarly, no test for stilbene could be obtained in the pyrolysis of benzylamine. With no evidence for the phenylmethylene radical from this source, it seems equally unnecessary to postulate the ethylidene radical from the ethylamine pyrolysis. For a bimolecular deammonation of benzylamine, dibenzylamine or its decomposition products (toluene and iminobenzaldehyde) would be anticipated. Traces of a secondary amine were realized but the high temperature of the reaction practically excluded the possibility of the synthesis of dibenzylamine. The decomposition of the aldimide, which may thus be formed from dibenzylamine or directly from benzylamine, into benzene and hydrogen cyanide is evidently more rapid than the alternative decomposition into benzonitrile and hydrogen, since only traces of benzonitrile were among the decomposition products from a run at 700° with a contact time of forty-nine seconds. At 630° and

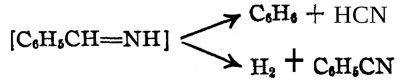
[a] An iron thermocouple sheath was used in this run. It seemed to cause considerable carbonization, and was accordingly omitted in later runs. [b] Indicates outside temperature. [c] Calculated as methane. [d] A negative search was made for cyanogen in this run. The off-gas was passed through concentrated hydrochloric acid. No precipitate was formed as is the case with even traces of cyanogen. [e] Mostly ammonium cyanide. [f] A small amount of tar was formed in the reaction tube. [g] Not freed from the nitrogen used before the run. [h] In this and in the following runs considerable carbonization was noted. [i] This consisted of 2.0 g. CH_3CN and 4.25 g. NH_4CN. [j] This is all NH_4CN. [k] The filliig here consisted of porcelain chips coated with kaolin. [l] This condensate boiled above room temperature and thus was not butane.

160 seconds, however, benzonitrile was an important product. With ethylamine, a similar phenomenon was noticed, for the proportionate yield of methane was far greater in a run of 900° and one second than at 900° and fifteen seconds.

Thus, the primary equations for the pyrolysis of benzylamine may be summarized as follows

$$C_6H_5CH_2NH_2 \longrightarrow H_2 + [C_6H_5CH{=}NH]$$
$$2C_6H_5CH_2NH_2 \longrightarrow NH_3 + C_6H_5CH_3 + [C_6H_5CH{=}NH]$$

These reactions are followed by reduction and by decomposition of the aldimide



$$[C_6H_5CH{=}NH] \begin{array}{l} \nearrow C_6H_6 + HCN \\ \searrow H_2 + C_6H_5CN \end{array}$$

Experimental Part

Ethylamine.—The data obtained from pyrolysis of ethylamine are shown in Table I. One experiment at an "outside temperature" of 500" is not listed, since no pyrolysis occurred. A brief summary of experimental details will serve to make clear the means of arriving at these results.

Apparatus.—An empty pyrex tube was used for the decomposition of ethylamine at 500 and at 600°. For the 890–900° temperatures a quartz tube of 2 cm. diameter was employed. In Run 11 a quartz tube with a diameter of 0.55 cm. was used in order to obtain a short time of contact. The temperatures were obtained by the use of a potentiometer and a calibrated chromelalumel thermocouple. In one instance an iron thermocouple sheath was present, but it was omitted in later runs on account of its tendency to increase carbonization. In four runs a filling of porcelain chips coated with kaolin was present; in three runs small cubes of kaolin were used. An ordinary gas combustion furnace was suitable for the lower temperatures but a Hoskins electric furnace with an effective heating length of 25 cm. was used in the vicinity of 900°.

Liquid ethylamine was pushed into the reaction tube from a 25-cc. graduated capsule in an ice-salt bath by displacement with mercury. In this manner the rate of feed could be easily controlled. The off gas first passed through a U-tube cooled in an ice–salt bath to about −10°. This served to collect ammonium cyanide, acetonitrile and the greater part of any unchanged amine. Next in the train was a gas washing bottle containing 200 cc. of hydrochloric acid of such concentration as to be equivalent to more than the total base used. The gases were then dried by passing them through a 15-cm. calcium chloride drying tower and a U-tube containing dehydrite. To condense any butane in the previously dried gases, a spiral condenser held at −78° by a mixture of acetone and solid carbon dioxide in a Dewar flask was used. This condenser was so constructed that any condensate could be volatilized and analyzed as a gas. It is of the type described by H. S. Davis.[10] Under the conditions used, butane could be readily condensed from 2-liter samples containing 10% by volume and detected as a liquid when only 5% was present. Finally, the residual gas was collected over water in 2.5-liter bottles. The connections used were of rubber tubing with extra heavy walls.

Procedure.—The ethylamine was Eastman's anhydrous product. The filling used in Runs 4 to 7, inclusive, was prepared by wetting porcelain chips and rolling them in kaolin. The filling for Runs 8 to 10, inclusive, was made by grinding kaolin into a stiff paste with water, spreading it on a plate and cutting it as it dried into cubes about 5 mm.

---

[10] Davis, *Ind.* Eng. Chem., Anal. Ed., 1, 61 (1929).

on an edge. In order to insure that the filling did not contain moisture, the tube was heated to 500° along the filled length while a stream of dry nitrogen was passed through. The volume of the filling was determined after the run by pouring it into a graduated cylinder partly full of water and noting the volume increase. Before each experiment: the whole train was swept out with dry nitrogen.

The furnace used was thrown directly on the line and carried a practically constant current during the run. The temperatures were taken inside the tube at the end of the operation and, as can be seen from the table, varied from 890 to 900°. These correspond to a temperature outside the tube of 980".

Cyanide was tested for in the usual way by boiling an alkaline solution of the sample with ferrous sulfate and ferric chloride solutions, and then acidifying to obtain Prussian blue.

In Run No. 2, the only one made at 600°, 2 g. of acetonitrile, b. p. 79–80', was definitely identified.

In Run No. 4 cyanogen was tested for by passing the off gas through concentrated hydrochloric acid. No oxamide was obtained, as is the case when even traces of cyanogen are present."

Benzylamine.—Benzylamine from Eastman Kodak Company was used. In sealed tube experiments this material was recovered practically unchanged after five hours of heating at 275° and eight hours at 300°. In the latter experiment, however, a positive test for secondary amine was obtained by Liebermann's nitroso reaction. Using the flow method through a pyrex tube, benzylamine was also recovered unchanged at 535° with a contact time of fifty-four seconds.

Pyrolysis at 630°.—Fifteen grams of benzylamine was allowed to run very slowly during 8.25 hours from a dropping funnel into a 50-cc. distilling flask heated at 270° in a fused salt bath. The arm of the distilling flask was connected to an unfilled pyrex tube (1.1 X 60 cm.) heated to 630° in a gas combustion furnace. The thermocouple was encased by a small pyrex tube within the main reaction tube. The products were condensed in a 25-cc. distilling flask surrounded by an ice–salt bath. A U-tube, at the same temperature and in series with the first receiver, collected nothing. The system was swept out with nitrogen before the run.

A contact time of 160 seconds was used. From a 15-g. sample were obtained 13.1 g. of liquid product and about 1500 cc. of gas insoluble in water. Hydrogen cyanide and ammonia were also evolved. Distillation of the liquid product gave 20 g. of benzene boiling up to 90°; 2.28 g. at 90–103° (mostly at 102°) identified as toluene; 1.38 g. of a mixture of products at 103–185°. Continuation at 50 mm. gave 2.85 g. at 102°, identified as benzonitrile through evolution of ammonia and formation of benzoic acid on boiling with potassium hydroxide solution; at 102–190°, 0.90 g., one-third of which was identified as benzylamine. A dark mobile residue remained in the flask. Qualitative tests failed to show the presence of lophine or stilbene, which are listed as pyrolytic products[12] of di- and tribenzylamine.

The gas contained 81.5% hydrogen, 2.0% carbon monoxide, 6 0% saturated hydrocarbons (n in C_nH_{2n+2} = 1.22) and 10.5% nitrogen.

Pyrolysis at 700°.—A 30-g. sample of benzylamine was displaced by mercury from a graduated capsule into a vertical pyrex tube heated in a multiple unit electric furnace held at 700" by a Leeds and Northrup recording controller. The time was fifty-eight minutes, the tube 2.1 X 90 cm., giving thus a contact time of 49.4 sec. The bottom of the reaction tube was sealed to a piece of smaller bore. The latter extended into a 100-cc.

distilling flask immersed in an ice–salt bath. A U-tube in series with the first receiver and at the same temperature collected nothing. The residual gas was collected over water.

The weight of liquid product was 26.2 g. Distillation gave 4.3 g. of material boiling up to 110" at ordinary pressure. This distillate was evidently a mixture of benzene and toluene as previously encountered. Distillation of the residue at 23 mm. gave a product at 80–85° which weighed 18.1 g. While it possessed the characteristic odor of benzonitrile, it gave practically no benzoic acid on hydrolysis with potassium hydroxide. Treatment of 1.8 g. with 35 cc. of 2 N potassium hydroxide and 5.0 g. of *p*-toluenesulfonyl chloride gave 3.7 g. of *p*-toluenesulfonebenzylamide, corresponding to the yield from a pure sample. The derivative melted at 117° on recrystallization from methyl alcohol, and a mixed melting point with an authentic sample confirmed its identity.

Three liters of gas was collected which, by volume, was 68.8% hydrogen, 10.1% saturated hydrocarbons ($n = 1.09$). 11.3% nitrogen, 2.3% carbon monoxide, 4.4% oxygen and 0.1% carbon dioxide.

Preparation of *p*-Toluenesulfonebenzylamide.—A mixture of 5.4 g. of benzylamine, 18 g. of p-toluenesulfonyl chloride and 100 cc. of 2 N potassium hydroxide was allowed to stand overnight. After acidification of the mixture with 3 N hydrochloric acid, the solid material was filtered off. It was then boiled for five minutes with 75 cc. of 2 N potassium hydroxide, cooled and filtered. (A precipitate often forms here even when the hot alkali has given a clear solution; accordingly the separation must be applied with caution in the case of benzylamine mixtures. The treatment of alkali-insoluble material with sodium ethoxide should never be omitted. The solution was made by dissolving 0.4 g. of sodium in 10 cc. of 95% alcohol for each gram of base used. Under the conditions the primary amine derivative is soluble.) The filtrate was acidified with hydrochloric acid and the product filtered off.

The crude weight was 9 g., 69% of the calculated amount. Purification was effected by one or two crystallizations from methyl alcohol, using bone black. The pure product melted at 117.8' (119°, corr.).

Anal. Subs., 0.4478, 0.4101: 0.1311 N HCl, 13.06, 11.88. Calcd. for $C_{14}H_{15}O_2NS$: N, 5.36. Found: N, 5.34, 5.33.

Preparation of *p*-Toluenesulfonedibenzylamide.—*p*-Toluenesulfonedibenzylamide was also prepared for purposes of comparison. A mixture of 2 g. of benzylamine and 3 g. of benzyl bromide was allowed to stand for three hours. A crystalline hydrobromide separated. Without any preliminary separation, 40 cc. of 2 N potassium hydroxide solution and 6 g. of p-toluenesulfonylchloride were added. The mixture was allowed to stand overnight and was worked up in the usual way. The alkali-insoluble material was treated with sodium ethoxide. The residue from this operation was crystallized from methyl alcohol accompanied by treatment with charocoal. It formed small white needles, melting at 80.8° (81.3°, corr.).

Anal. Subs., 0.5526: 0.1311 *N* HCl, 12.06 cc. Calcd. for $C_{21}H_{21}O_2NS$: N, 3.99. Found: N, 4.01.

Summary

The subjection of ethylamine to a temperature of 600° has been found to produce largely acetonitrile and hydrogen. Some ethylene, ammonia, hydrogen cyanide and methane were also produced.

A number of pyrolyses of ethylamine at 890–900°, inside temperature, or 980° outside temperature, have been carried out with various tube

fillings and contact times. No butane was found in any instance although especial search was made for it because its presence has been inferred by other investigators. With a contact time of one second, the gas produced carried 10.3% ethylene; 15.5 seconds, 5.0%; eighty seconds, 0.5 per cent; with longer contact time, none at all. Hydrogen cyanide was always present at 890–900°, but only traces of ammonium cyanide or acetonitrile were noted except in a run made with a contact time of one second. In this particular run the saturated hydrocarbon content was also unusually high. Cyanogen is not a product of the pyrolysis.

Benzylamine was unchanged on being heated for several hours at 275–300° in a sealed tube. It was, furthermore, almost unchanged at 535° with a contact time of fifty-four seconds.

Benzylamine decomposed in 160 seconds at 630° to give benzonitrile, benzene, toluene, saturated hydrocarbons, hydrogen, hydrogen cyanide and traces of secondary amine. A mechanism for the reaction has been proposed.

p-Toluenesulfonebenzylamide and *p*-toluenesulfonedibenzylamide have been synthesized and characterized.

RESEARCHES ON CHLORIMINES. II. SOME NEGATIVELY SUBSTITUTED AROMATIC ALD-CHLORIMINES

BY C. R. HAUSER, M. L. HAUSER AND A. GILLASPIE[1]

RECEIVED AUGUST 11, 1930 PUBLISHED OCTOBER 6, 1930

A recent communication[2] from this Laboratory has described the preparation and properties of o-chlorobenzalchlorimine and anisalchlorimine. It has been shown that the latter compound undergoes spontaneous decomposition more rapidly than does the former, according to the general equation $RCH{=}NCl = RCN + HCl$. This difference in rate of decomposition of these compounds suggests that the nature of a substituent group in an aromatic ald-chlorimine may be an important factor in its stability.

In the present investigation a number of aromatic ald-chlorimines have been prepared with the purpose of studying the effect of the presence of substituent groups on the stability of these compounds as well as extending the list of readily available ald-chlorimines to be used in subse-

[2] Hauser and Hauser, THIS JOURNAL, 52, 2050 (1930). It should be mentioned that Raschig seems to have condensed anisaldehyde with monochloramine but no details are given; Raschig, "Schwefel und Stickstoff-Studien," 1924, p. 80.

quent work. Excellent yields of certain chlorimines have been obtained within a few minutes by reaction of aldehydes in ethereal solution with monochloramine in cold aqueous solution. A comparison of the temperatures at which the purified chlorimines decomposed when heated gradually, and of the rates of decomposition at 30°, showed that certain ones were more stable than others, but since the decompositions are apparently catalyzed by impurities and reproducible results were not obtained in several cases, only a general classification of these compounds seems warranted at this time. In general, anisal-, o-methoxybenzal-, piperonal- and o-nitrobenzal-chlorimines comprise a relatively unstable class as compared with o-chloro-, *p*-chloro-, *p*-bromo- and 2-chloro-5-nitro-benzal-chlorimines.

Experimental

Preparation of Ald-chlorimines from Solid Aldehydes.—Although several ald-chlorimines have been prepared by using alcohol as solvent, they were generally best prepared when solid aldehydes were used by vigorously shaking an ether solution of the aldehyde with a cold aqueous solution of monochloramine. By this method all of the aldehydes studied, with the exception of one, were rapidly converted into the corresponding chlorimines in 80–90% yields. The exception was *p*-dimethylaminobenzaldehyde which, when allowed to react with monochloramine by the method described below, was recovered in great part unchanged. However, when alcohol was used as solvent a small amount of dark colored material, which appeared to consist of some unstable chlorimine, was obtained. This was not further studied in this investigation.

The following method was adopted for the preparation of the chlorimines from solid aldehydes. An ether solution[3] of the aldehyde was vigorously shaken with three times the calculated amount of freshly prepared cold alkaline monochloramine[4] solution (1 *N*) containing crushed ice. A milky mixture or emulsion was formed almost immediately, and usually within a minute or two a precipitate was produced. After shaking for several minutes or until the solid material had coagulated sufficiently, the product was filtered and washed thoroughly with cold water. A yield of more than 85% of crude chlorimine was usually obtained.

Recrystallization and Analysis.—The chlorimines were best recrystallized from either 95% alcohol or acetone in the following manner. The sample was dissolved at room temperature (18–24°), the solution filtered and cold water added to the mixture until the precipitate which formed at first just redissolved on shaking. On standing in a cool place the product crystallized out. It was immediately filtered, dried on a porous plate and analyzed for active chlorine. The method of analysis previously described[a] has been modified as follows. A sample of chlorimine weighing 0.15–0.20 g. is dissolved in approximately 50 cc. of 95% alcohol, cooled and 10 cc. of 10% potassium iodide solution added. The cooled solution is then acidified with 0.5 cc. of concentrated hydrochloric acid and standard sodium thiosulfate solution immediately run in until the color of the solution has become light yellow. Starch indicator is next added, and then sufficient water to produce the characteristic blue color, after which the titration with thiosulfate is completed. In cases where the sample is sparingly soluble in 95% alcohol,

---

[3] The best results were obtained when 5–7 cc. of ether per 100 cc. of aqueous monochloramine solution was used.

[4] See Hauser, THIS JOURNAL, 52, 1108 (1930).

the analysis may be conveniently carried out in acetone solution or equally well in a mixture of the two solvents.

General Properties.—All of the chlorimines studied were obtained as crystalline compounds which underwent spontaneous decomposition yielding, as primary products, hydrogen chloride and the corresponding nitrile. When heated rapidly on a platinum foil or in a capillary tube they decomposed with a "puff" evolving a cloud of hydrogen chloride. The melting points and the decomposition temperatures of the chlorimines were determined, as soon as the compounds were dry, in the following manner. A capillary tube containing the sample was immersed in a bath which was 5–10° below the melting point of the substance, and the temperature raised at the rate of 1° in five to eight seconds. When the temperature of the bath was raised'above the melting point of the substance at about this rate, some of the compounds decomposed rather vigorously while in other cases the first evidence of decomposition was the appearance of a cloudiness and then a precipitate. Sometimes the melted compound frothed and rose in the tube before precipitating.

Attempts to isolate stereoisomers from products which had been melted and then solidified again, were unsuccessful. Fractional crystallization of crude chlorimines from alcohol or from hydrocarbon solvents yielded no isomers.

Piperonalchlorimine, obtained as white crystals from alcohol, melted at 68–69° and precipitated at **72–77'.** Sometimes the compound did not melt completely before precipitation began. On further heating more decomposition with discoloration resulted.

Anal. Calcd. for $CH_2O_2C_6H_3CH{=}NCl$: **Cl, 19.33;** N, **7.63.** Found: **Cl, 19.25, 19.20; N, 7.88.**

A sample **(0.3** g.) was immersed in a bath at **70–74'** until it melted and precipitated. It was then cooled and pressed on a plate, after which it melted at 58–65°. When mixed with some pure chlorimine the melting point was **63–67°. Recrystallization** of the material yielded pure chlorimine, m. p. **68–69'.** When **0.5** g. of chlorimine was immersed in a bath at 80°, it "puffed" vigorously, evolving hydrogen chloride, and **nitrile** was isolated from the residue. The **nitrile** was also isolated from a sample which had been allowed to decompose in a desiccator containing sodium hydroxide. **A** small amount of another substance, insoluble in ether, apparently the **imine** hydrochloride, was also obtained. **A** sample of chlorimine left on a plate for two hours at room temperature **(25–27°)** melted at **66–69°** and decomposed more readily than a **freshly** prepared product.

o-**Nitrobenzalchlorimine,** obtained as pale yellow crystals from alcohol, melted at **74–75"** and frothed at **84–85'. Since** the crude chlorimine soon darkens in color if allowed to remain in contact with the alkaline **monochloramine** solution, the product should be **filtered** as soon as it has coagulated.

Anal. Calcd. for $NO_2C_6H_4CH{=}NCl$: **Cl, 19.22.** Found: **Cl, 19.00.**

***m*-Nitrobenzalchlorimine** melted at **79–80'** and precipitated again at **81–83°.** Sometimes the compound did not melt completely, but merely softened and then began to solidify. **Its** crystals are white when pure, but usually they were slightly colored even after two crystallizations from alcohol.

Anal. Calcd. for $NO_2C_6H_4CH{=}NCl$: **Cl, 19.22.** Found: Cl, **19.15, 19.10.**

In one case the crude chlorimine after drying on a plate was dissolved in a small amount of benzene and filtered. When treated with about **4** volumes of **ligroin** a small **quantity** of light tan crystals was produced and filtered off. When the filtrate was cooled, white crystals were obtained. In a similar manner two crops of crystals were obtained from the crude chlorimine by using chloroform and ligroin. A **third** fraction was also obtained from the latter solvents by allowing them to evaporate spontaneously, until only a trace of the solvent remained. The crystals were then washed with a small amount of ligroin. The melting points of the various fractions ranged from 74 to 79°. By the mixed melting point method it was shown that all of the fractions were identical. A crude preparation of the chlorimine was also fractionally crystallized from alcohol and mixed melting points were taken with the crystals obtained from the other solvents mentioned above. All of the crystals were identical

When a sample of this chlorimine which had been allowed to decompose in a desiccator over sodium hydroxide was treated with ether, practically all of the material dissolved. The nitrile was isolated, but no appreciable amount of the imine hydrochloride was found.

This chlorimine was compared with its ortho isomer as follows. When samples of *m*- and o-chlorimines in capillary tubes were immersed together in a bath at 80°, and heated, they both melted. At 83–85" the meta compound solidified, and at 95" the ortho compound frothed and decomposed. When the two chlorimines were immersed at 117°, both melted, and after a few seconds the meta "puffed;" after a few more seconds the ortho compound did likewise.

_p_-Chlorobenzalchlorimine, obtained as small white needles from alcohol or acetone, melted at 79–80°, became slightly cloudy at 95" and boiled up and solidified at 115–120°. Several preparations of this chlorimine heated in the same manner gave the following average results: became slightly cloudy at 90–95°, frothed or boiled up and precipitated at 100–127°.

Anal. Calcd for $ClC_6H_4CH{=}NCl$: Cl, 20.39; N, 8.05. Found: Cl, 20.33, 20.10; N, 8 00, 8.19.

When the chlorimine was recrystallized from warm petroleum ether, needles were obtained which melted at 78–79", and precipitated at 95°. Some colorless rectangular needles 7–12 mm. long, obtained by the partial spontaneous evaporation of a chloroform–ligroin or benzene–ligroin solution at room temperature, melted at 79–80", became slightly cloudy at 90–95", and continued to decompose with increasing temperature until at 122" the compound boiled up and solidified.

Crude preparations of this chlorimine were fractionally crystallized from chloroform and ligroin and from alcohol and water. The first fractions comprised a small proportion of the material used. The last fraction from the alcohol was obtained by the addition of excess water as long as a precipitate was formed. By the mixed melting point method it was shown that all the fractions were identical.

_p_-Bromobenzalchlorimine, obtained as white crystals, melted at 87–88°, became slightly cloudy at 90–95° and precipitated at 95–103°. At 120° more decomposition occurred. The chlorimine melted when immersed in a bath at 100–105°, and then a precipitate formed which partly dissolved when agitated for several minutes. It was evident that the chlorimine slowly decomposed with the gradual evolution of hydrogen chloride.

Anal. Calcd. for $BrC_6H_4CH{=}NCl$: Cl, 16.24; N, 6.41. Found: Cl, 16.23; N, 6.67.

2-Chloro-5-nitrobenzalchlorimine melted at 85–86', frothed at 110°, and underwent more decomposition at 115°. Its crystals are white when pure.

Anal. Calcd. for $ClNO_2C_6H_3CH{=}NCl$: Cl, 16.20. Found: Cl, 16.25.

o-Methoxybenzalchlorimine, melted at 35–36° and frothed at 83–85". After standing for several hours on a porous plate at 18–20', it "puffed" mildly at 75°. This chlorimine precipitates with difficulty when the aldehyde is shaken with a solution of monochloramine according to the method[2] recently described for the preparation of anisalchlorimine. Two unsuccessful attempts were made before it was finally obtained as a white precipitate.

Anal. Calcd. for $CH_3OC_6H_4CH{=}NCl$: Cl, 20.92. Found: Cl, 20.70.

o-Chlorobenzalchlorimine has been obtained as a precipitate from Eastman's o-chlorobenzaldehyde (m. p. 8–9°) and monochloramine within three to five minutes when prepared according to the method[2] recently described, and within six to eight minutes when ether was used according to the method outlined in the present paper.

When this compound was heated gradually in a capillary tube, decomposition began at 110–118°. After this chlorimine had decomposed on standing in a desiccator over sodium hydroxide at 30°, the nitrile was isolated from the products. The material insoluble in ether or benzene consisted partly of ammonium chloride and of some unidentified substance.

Anisalchlorimine was prepared according to the method[3] recently described. When a sample was heated in a capillary tube it decomposed with a puff at 60–70°. One preparation of the crude chlorimine was fractionally crystallized from alcohol and water. Four fractions of about equal amounts were obtained. After drying it was shown by the mixed melting point method that all of the fractions were identical.

Stability of Chlorimines.—It has already been reported that anisalchlorimine is much less stable than o-chlorobenzalchlorimine. While working with the chlorimines described in this investigation, it soon became evident that certain ones were much more unstable than others. A qualitative classification of these compounds according to their stabilities was arrived at from a consideration of the temperatures at which the chlorimines decomposed when heated gradually in capillary tubes, and from a consideration of the length of time which they could be kept at room temperature without undergoing appreciable decomposition. Although anisalchlorimine appeared to be the least stable of any of the compounds described here, this compound along with o-methoxybenzal-, piperonal- and o-nitrobenzal-chlorimines, formed a class which was far more unstable than o-chloro-, *p*-chloro-, or *p*-bromo- and 2-chloro-5-nitrobenzalchlorimines. From a consideration of the temperature at which m-nitrobenzalchlorimine began to decompose, this compound should be classed with the unstable chlorimines. However, several preparations of the m-nitro compound were kept at room temperatures (18–24°) for several days without appreciable decomposition.

In an attempt to obtain a quantitative measure of the relative stabilities of these compounds, their velocity of decomposition was determined at 30°. After the chlorimines were purified by recrystallization from alcohol, and dried on a porous plate at room temperature (18–24°), weighed samples in small vials were placed in a desiccator which contained solid sodium hydroxide and kept in an air-bath at 30°. At suitable intervals the samples were analyzed for active chlorine. The data obtained are recorded graphically in Fig. 1.

It is evident from Fig. 1 that the qualitative classification of these compounds mentioned above is in general supported by these curves. While the rates of decomposition of the relatively unstable chlorimines checked fairly well, reproducible results were not obtained for some of the other compounds.

The product used in the determination of Curve 4 was prepared when the room temperature was about 20° and, after drying, an initial analysis of the compound was in close agreement with the theoretical. However, when the work was repeated the room temperature was about 30°, and although the compound was recrystallized several times from alcohol, analyses, after drying, gave low results, which indicated that some decomposition had occurred during the process of drying. This product decomposed at a much more rapid rate at 30° than that represented by Curve 4. After sixty-four hours the chlorimine was 20%, and after **110** hours, 47% decomposed. Similar results were obtained when crude m-nitrobenzalchlorimine was recrystallized from slightly warm chloroform and ligroin. These observations indicate that, in some cases at least, the rates of decomposition are catalyzed by the impurities present. A preliminary experiment showed that the rate of decomposition of m-nitrobenzalchlorimine was accelerated by *a* **nitrile** and retarded by **an** aldehyde.

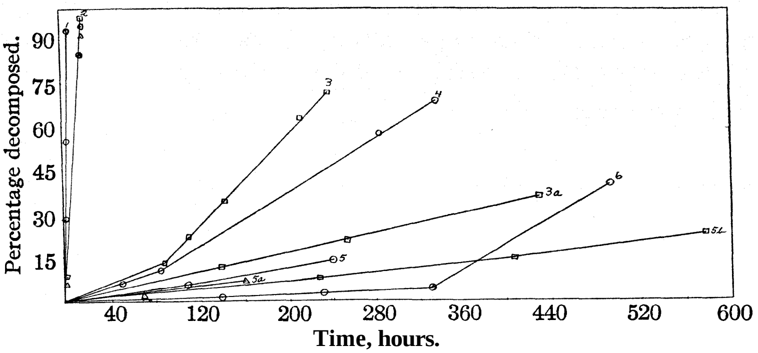

Fig. 1.—Rates of decomposition of ald-chlorimines at 30°. Curve 1, anisal- at 20–22°; o-methoxybenzal- gave approximately the same curve at 30°. Curve 2, points ○ and A, piperonal-; points □ and ⊗, *o*-nitrobenzal-. Curves 3 and 3a, o-chlorobenzal- (liq. at 30°). Curve 4, *m*-nitrobenzal-. Curves 5, 5a and 5b, *p*-chlorobenzal-. Curve 6, p-bromobenzal-.

Summary

A number of new aromatic ald-chlorimines have been prepared and their stabilities studied. In general, anisal-, o-methoxybenzal-, piperonal- and o-nitrobenzalchlorimines comprise a group which are distinctly less stable than o-chloro-, *p*-chloro-, p-bromo- and 2-chloro-5-nitrobenzalchlorimines.

DURHAM, NORTH CAROLINA

NOTES

The β-Chlorovinyl-arsines.[1]—The work of Miller and Witherspoon[2] has shown that the compound obtained by reacting β-chlorovinyl-dichloroarsine with diphenylamine is not 6-β-chlorovinyl-phenarsazine, as reported in the above entitled article, but 6-chloro-phenarsazine. The compound is extremely difficult to obtain pure by crystallizing from solvents. Five crystallizations from xylene gave a product melting at 189° (uncorr.). By vacuum sublimation, Miller reports a melting point of 193–194°.

Similar correction should hold for the product obtained when phenyl-α-naphthylamine is condensed with β-chlorovinyl-dichloro-arsine. Thus in both cases the amines apparently condense with arsenic chloride, present as a result of decomposition or equilibrium, giving a chloro-arsine and not a chlorovinyl-arsine.

Preparation of Benzene-azo Derivatives of 8-Hydroxyquinoline.—According to J. Mathëus,[1] the alkaline coupling of 8-hydroxyquinoline with diazobenzene-chloride gives 5-benzene-azo-8-hydroxyquinoline. In the present work, which was executed to obtain such a compound for use in the Skraup reaction with certain azo compounds, when diazobenzene-chloride and 8-hydroxyquinoline were coupled in equimolecular proportion in an alkaline medium with as small an amount of water as possible, the chief product obtained was found to be 5,7-benzene-disazo-8-hydroxyquinoline, which after three recrystallizations from alcohol gave deep violet crystals of excellent purity; m. p. 205–206°; yield, 16 g. from 14.5 g. of 8-hydroxyquinoline. Its alcoholic solution assumes a red color, and the solution in concd. sulfuric acid is indigo blue, but on addition of alcohol the color changes to violet red.

Anal. Subs., 6.320: CO_2, 16.558; H_2O, 2.488. Subs., 3.115, 1.897: N_2, 0.576 cc. (30°, 762 mm.) 0.344 cc. (31°, 756 mm.). Calcd. for $C_{21}H_{15}ON_5$: C, 71.39; H, 4.25; N, 19.83. Found: C, 71.45; H, 4.37; N, 20.08, 19.41.

On the other hand, when the coupling was conducted in a very dilute solution, the mono-azo compound was the chief product, which after four recrystallizations from alcohol gave brownish-yellow needles (m. p. 185–186°); its properties were identical with those of 5-benzene-azo-8-hydroxyquinoline given by Mathëus. The mono-azo compound, however, was

found to be readily obtained in a very pure state in almost the calculated quantity when the two components were coupled in an acetic acid medium, and after only one recrystallization from alcohol gave orange-yellow needles of m. p. 187°. Its yellow alcoholic solution, on the addition of ferric chloride, assumes a deep brown color and the solution in concd. sulfuric acid is red.

Anal. Subs., 4.372: CO_2, 11.558; H_2O, 1.875. Subs., 3.988: N_2, 0.578 cc. (21°, 760.4 mm.). Calcd. for $C_{15}H_{11}ON_3$: C, 7229; H, 4.42; N, 16.87. Found: C, 72.10; H, 4.77; N, 16.66.

The hydrochloride gave orange needles; m. p. 227° (decomp.). On pouring into water, it readily undergoes hydrolysis with the separation of the free base.

Anal. (Water of crystallization). Subs., 0.5407: H_2O, 0.0513. Calcd. for $C_{15}H_{12}ON_2Cl\cdot 1^1/_2H_2O$: H_2O, 9.05. Found: H_2O, 9.49. Subs., 0.2550: AgCl, 0.1321. Calcd. for $C_{15}H_{11}ON_2\cdot HCl$: HCl, 13.44. Found: HCl, 13.17.

Furthermore, the disazo compound could also be obtained by the alcoholic alkaline coupling of the mono-azo compound with diazobenzenechloride, but its quality was found to be far inferior after repeated recrystallizations from alcohol.

The Direct Nitration of Furfural.—In continuation of studies concerned with substitution reactions of sensitive furan types,[1] it was found possible to prepare 5-chloro-2-furfural by chlorination not only of furfural diacetate but also of furfural. This suggested that it might be possible to nitrate furfural directly, and so avoid the prior, independent preparation of furfural diacetate. Experiments have confirmed this expectation.

Using the same molar proportions and technique described previously, the yield of nitrofurfural *diacetate* obtained from 96 g. (1 mole) of freshly distilled furfural was 110 g., or 45%, melting at 85°. When crystallized from hot alcohol, the yield of pure nitrofurfural diacetate melting at 92° was 80 g., or 33%.

In the treatment with alkali subsequent to nitration of the furfural, sufficient sodium hydroxide is added to the iced mixture to give a faint but distinct alkaline reaction to litmus. The oil obtained in this manner is separated by decantation from the aqueous solution, and then warmed with sufficient pyridine (not less than 250 cc.) to effect complete solution. The

acetic acid removed in this manner from the intermediate compound, which may or may not be a product of ring scission, can also be removed by means of other bases like dimethylaniline. The nitrofurfural is readily obtained, if necessary, by hydrolysis[1] of the crude diacetate.

The authors are grateful to Mr. A. P. Hewlett for assistance.

A Note on the Preparation of Glycine.—The classical method of preparing glycine through the interaction of chloro-acetic acid and ammonia with the subsequent formation of the copper or lead salt has been abandoned by Clarke and Taylor[1] in favor of a method involving the hydrolysis of methylene-amino-acetonitrile. The starting material is fairly expensive and the yield of 31–37% is not high. Robertson,[2] after a study of the velocity and course of the reaction between chloro-acetic acid and ammonia, recommends the use of a large excess of ammonia. When the molecular ratio of ammonia to chloro-acetic acid is 60:1, the actual concentration of glycine in solution is increased to 86%. He eliminates the ammonium chloride by means of silver oxide and obtains a final yield of 50% of pure glycine.

It was thought that a correspondingly large yield of pure glycine could be obtained by making use of this high ratio of ammonia to chloro-acetic acid, and crystallizing the glycine directly from the concentrated reaction mixture in the presence of pyridine according to the method of Clarke and Taylor or in the presence of aniline as suggested by Benedict,[3] thus eliminating the time and expense involved in the use of silver oxide to remove the ammonium chloride. The attempt proved successful and the following method was worked out.

Two moles of chloro-acetic acid (189 g.) is dissolved in 8 liters of ammonium hydroxide (sp. gr. 0.90) in a 12-liter flask and allowed to stand at room temperature for forty-eight hours. The excess of ammonia is distilled off and recovered. The mixture is concentrated, in *vacuo* if preferred, until precipitation of ammonium chloride begins. The salt is dissolved by warming on the steam-bath with the addition of the smallest possible volume of water. If the solution is not clear, it is filtered by suction. The filtrate and washings should occupy a volume of about 500 cc. A

mixture of 800 cc. of methyl alcohol and 140 cc. of pyridine is stirred in. Crystallization of the glycine begins at once. After standing overnight, the glycine is filtered off, suspended in methyl alcohol, filtered and washed with methyl alcohol. A yield of 96 g. or 64% is obtained. A further yield of 2 to 3 g. may be secured from the combined mother liquor and washings on standing. If an attempt is made to crystallize the glycine from a warm solution of much greater concentration than the one suggested, the product will be contaminated with considerable ammonium chloride. This may be almost completely removed by washing with methyl alcohol. The glycine is recrystallized by dissolving in 300 cc. of water with warming. In order to remove the last traces of ammonia, 6 g. of permutit is added and after thorough stirring the mixture is filtered through a charcoal mat. The solution with washings should occupy about 400 cc. and should be crystal clear; 800 cc. of methyl alcohol is stirred in and the mixture is allowed to stand overnight until crystallization is complete. The glycine is filtered off and washed with methyl alcohol. The yield is 81 g. or 54%. The product is free from the chloride ion and from ammonia, as shown by testing with Nessler solution. It melts at from 225–230° (corr.), and shows the theoretical percentage of nitrogen and amino nitrogen. An equivalent amount of aniline may be substituted for the pyridine if desired in the first crystallization but the product carries a slight yellow color. This is completely removed on recrystallization.

***o*-Phenetylurea.**—On account of its industrial importance, dulcin has received considerable attention while the corresponding ortho derivative has been slighted. The writer finds but one literature reference in a paper by Pierron,[1] who prepared this compound from o-ethoxyphenylcyanamine as a means of identification of the latter. He quotes a melting point of 206°, which appears to be too high. It seemed worth while to make the compound principally in order to compare its properties with those of dulcin derivatives now in preparation.

A 5-g. portion of o-phenetidine is treated with 40 cc. of water and 2.5 cc. of concentrated hydrochloric acid. A solution of 2.25 g. of potassium cyanate in 20 cc. of water is added in small portions with a thorough shaking between additions. Precipitation is complete in about ten minutes. After filtration the solid is washed with dilute ammonium hydroxide and then with ether. It is at once recrystallized from hot dilute ethanol to

---

[1] Pierron, *Ann chim. phys.*, [7] **15**, 145 (1908).

which sufficient ammonium hydroxide is added to give a decided odor. The crystals are washed with ether. When dry the purification is completed by a recrystallization from hot benzene; yield, 2 g.; white microscopic needles. The compound shows a slight shrinkage at about 139° and melts at 142–143°. It is tasteless and odorless. Concentrated sulfuric acid gives a colorless solution which upon heating becomes a faint straw color.

Anal. Calcd. for $C_9H_{12}O_2N_2$: C, 60.0; H, 6.66; N, 15.56. Found: C, 60.10; H, 6.72; N, 15.64.

The compound is soluble in hot water, ethanol, amyl alcohol and hot benzene. It is very slightly soluble in ether.

COMMUNICATIATIOMS TO THE EDITOR

DR. C. S. HUDSON'S VIEWS ON THE RELATIONSHIP OF STRUCTURE TO THE OPTICAL ROTATIONS OF SUGARS

Sir:

Dr. C. S. Hudson has not utilized the means which were open to him to test the validity of his views by direct chemical experiments. The basis on which he develops his argument is the presumed existence, which his statistical methods enable him to detect, of a new form of mannose (calculated $[\alpha]_D$ +77°) in derivatives of 4-glucosido-mannose, obtainable from cellobiose through cellobial. If this foundation for his scheme fails, then the entire superstructure of rival formulas which he has raised upon it must collapse.

A survey of his two recent papers [THIS JOURNAL, 52, 1680, 1707 (1930)] has led me to select for this critical test an experimental method which he has tacitly approved: he has accepted and utilized the observation of Fischer and Armstrong that β-methylmaltoside gives rise by enzyme hydrolysis to β-methylglucoside without ring change. Implicit in Dr. Hudson's scheme, therefore, is the expectation that 4-glucosido-a-methylmannoside will yield by enzyme cleavage his hypothetical a-methylmannoside ($[\alpha]_D$ +125°), inasmuch as this is the glycoside of the unknown form of mannose to which he has assigned the 1,5-ring.

With my colleague Dr. E. L. Hirst and other co-workers (R. J. W. Reynolds, H. R. L. Streight, H. A. Thomas, J. I. Webb and Miss M. Plant) I have prepared and investigated the chemical behavior of both 4-glucosido-a-methylmannoside and 4-galactosido-a-methylmannoside to which the 1,4-ring cannot apply since the 4-position in the mannose residue is occupied by the biose link. Both these substances are hydrolyzed by *emulsin* and yield the ordinary known form of a-methylmannoside ($[\alpha]_D$ +79°) which is the pyranoside (1,5-ring).

The above biosides are prepared in the same way as the bioses, namely, from cellobial and lactal by the action of perbenzoic acid, but in the presence of methyl alcohol instead of water. The same 4-glucosido-α-methylmannoside has also been obtained from acetobromo-glucosido-mannose.

Had Dr. Hudson tried these experiments it is difficult to see how he could have committed himself to speculations that are at variance with this and with much more chemical evidence which is on record. Moreover, the rotations of these biosides and of the corresponding bioses are widely divergent from those required by his system of classification based on epimeric differences with cellobiosides and lactosides and the free sugars. The "principle of optical superposition" cannot be applied uniformly throughout the sugar group. The results now summarized are in complete agreement with the sugar formulas we have established by methylation studies, lactone formation and degradation, and by a comparison of the reaction velocities of glycosides under hydrolysis, and by other direct chemical methods.

POSSIBLE USE OF THE POULSEN ARC AS A MEANS OF DETECTING TRACES OF IMPURITIES IN METALS

Sir:

It has been shown by one of us in conjunction with E. Z. Stowell[1] that an atmosphere of hydrogen and usually cathode materials which are elements of even atomic number are necessary to produce radio frequency oscillations in the Poulsen Arc.

In the non-oscillating or ordinary direct current arc in hydrogen, the spectra of copper and sodium were revealed when these elements were used as cathodes. Upon connecting the oscillating circuit, the spectra of copper or sodium were either entirely suppressed, or appeared only faintly. Simultaneously the spectra of elements such as zinc, titanium and aluminum which will support oscillation, and which were present in small amount as impurities in the cathode metal, either appeared or if previously present were greatly accentuated.

The spectrum of H_B showed the presence of more atomic hydrogen in the oscillating than in the non-oscillating arc. Chemical analysis of the electrolytic copper showed titanium and aluminum present as 0.005 and 0.0045%, respectively.

---

[1] Stowell and Redeker, *Phys. Rev.*, **34**, 978 **(1929).**

When using an ammonia atmosphere and a tip of gold brazed onto a water-cooled copper cathode, the oscillating arc completely suppressed the spectra of these metals, and intensified the 3361–3372 Å. line of the titanium impurity in the copper. The above phenomena suggested the use of the Poulsen Arc as a means of detecting small traces of impurities of even atomic number in such metals as copper, gold and silver.

A quantitative analytical method involving these phenomena is now being worked out in this Laboratory.

COAGULATION OF PURE FERRIC HYDROXIDE SOLS

Sir:

In a recent article Judd and Sorum [THIS JOURNAL, 52, 2598 (1930)] have stated that with highly purified sols of ferric hydroxide, which are practically free from chloride ions, the amount of univalent coagulating ion decreases as the concentration of the sol increases.

In several publications [J. Phys. *Chem.*, 26, 701 (1922); 28, 313 (1924); 29,435,659 (1925); *Kolloid.-Z.*, 34,262 (1924); 36, 129 (1925)] from these Laboratories we have shown that ordinarily purified sols of ferric hydroxide require larger amounts of univalent electrolytes for coagulation when the concentration of the sol is increased. In a recent communication Dhar and Gore [J. *Indian Chem. Soc.*, 6, 31 (1929)] have shown that even highly purified sols of ferric hydroxide containing a very small amounts of chloride ion follow the general rule that the greater the concentration of the sol, the greater is the amount of electrolyte necessary for coagulation irrespective of the valency of the coagulating ion. It appears, therefore, that the results of Judd and Sorum are not in agreement with previous work and need confirmation.

A CONTINUOUS (OR BAND) FLUORESCENCE EMISSION SPECTRUM WHICH ACCOMPANIES A CHANGE OF COLOR

Sir:

An interesting phenomenon has been observed in a study of the Raman effect with a number of liquids listed later. A continuous (or band) emission spectrum (Fig. 1) has been found to appear on the plate in each case in which the colorless liquid becomes colored, and not to appear if there is no color change. The incident radiation of the mercury arc light appears to excite the molecules of the substance, and a part of the energy of excitation is released as a fluorescence radiation. A few of the details of this work are given below.

The Raman effect has been observed for a number of bromides: normal butyl bromide, secondary butyl bromide, isobutyl bromide, tertiary butyl bromide, normal propyl bromide, isopropyl bromide, normal amyl bromide and isoamyl bromide. The liquids were purified by distillation.

In addition to the lines of modified wave length, a continuous spectrum, which lies within the limits $\lambda = 4000$ Å. and $\lambda = 5500$ Å., was obtained with each liquid. The continuous spectrum was always accompanied by the appearance of a yellow color in the liquid. Usually an exposure of forty-eight hours sufficed for the production of the continuous spectrum; this, however, was not the case with n-propyl bromide, n-butyl bromide and secondary butyl bromide, since none of these showed either a continuous spectrum or a discoloration after being exposed to the mercury arc for forty-eight hours. If the time of exposure was extended to seventy-two hours or more, the continuous spectrum and the color change were observed for each of these liquids. In all cases where the exposure was long enough to give an intense continuous spectrum, the latter contained two regions of maximum intensity, one lying between the mercury lines at $\lambda = 4358$ Å. and $\lambda = 4916$ Å., and the other between the lines at $\lambda = 5460$ Å. and $\lambda = 5769$ Å.

Methyl and ethyl alcohols saturated with ammonia were studied for Raman spectra. The solutions were exposed to the mercury arc for ten to twelve hours. Methyl alcohol saturated with ammonia gave a continuous spectrum which was similar to that of the bromides in character and in position; the solution turned yellow during the exposure. Ethyl alcohol saturated with ammonia did not give a continuous spectrum or a color change. Neither of these two accompanying phenomena was observed in the case of the pure alcohols.

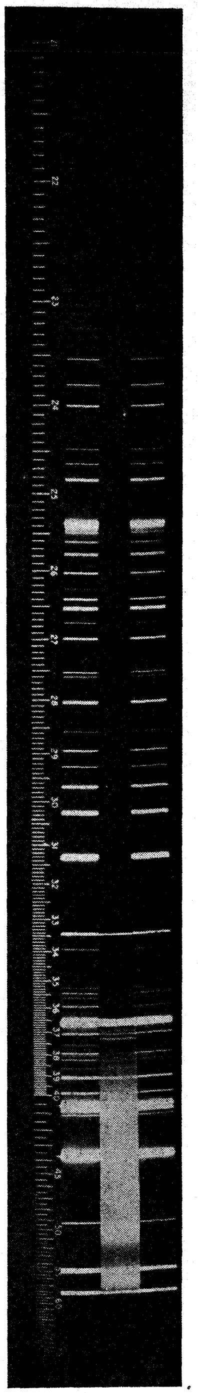

Fig. 1.—In the middle is the continuous fluorescence spectrum and the Raman spectrum of an alkyl bromide. The mercury comparison spectrum is shown above and below.

An attempt was made to ascertain whether the exclusion of oxygen would affect the color change and the continuous spectrum. A brisk stream of nitrogen was bubbled through isoamyl bromide for forty-five minutes prior to exposure and the Raman tube was closed by means of a stopcock; no diminution of the intensity of the continuous spectrum or of the color, was found.

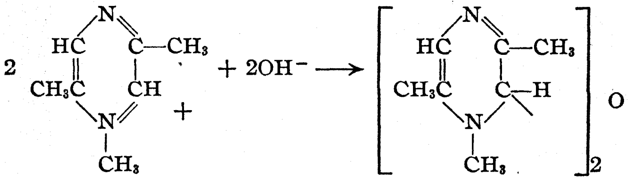
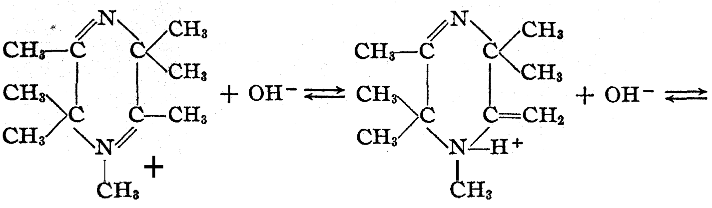
THE BASE FROM 2,5-DIMETHYLPYRAZINE-METHYL IODIDE

Sir:

Recently Princivalle[1] has reported unsuccessful attempts to isolate the base liberated from 2,5-dimethylpyrazine-methyl iodide. In connection with some work on pseudo bases, part of which has already been submitted for publication, the author has studied the action of alkali on this salt. Although the base isolated could not be obtained pure and gave analyses varying from C, 53.2; H, 6.94, to C, 49.5; H, 6.63, a kinetic study of the reaction using a conductimetric method has made it seem probable that the net reaction taking place is

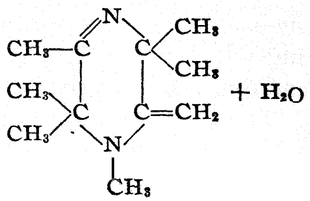


The salts 1,2,2,5,5-pentamethyl-2,5-dihydropyrazinium iodide and 1,2,2,3,5,5,6-heptamethyl-2,5-dihydropyrazinium iodide have also been prepared and their behavior with aqueous alkali studied. From these two salts the bases isolated were, respectively, 1,2,2,5,5-pentamethyl-6-hydroxy-1,2,5,6-tetrahydropyrazine (m. p. 110°) and 1,2,2,3,5,5-hexamethyl-6-methylene-1,2,5,6-tetrahydropyrazine (b. p. (6.5 mm.) 78°). Certain evidence has been obtained to show that the latter base was formed by an enolic change



---

[1] Princivalle, *Gazz. chim. ital.*, 60, 298–301 (1930); *C. A.*, 24, 3792 (1930).



It is believed that the reduced conjugation in the ring is the cause of this reaction, which does not occur in the case of 1,2,5-trimethylpyrazinium iodide. It is to be noted that the same reduced conjugation occurs in 1,2,5-trimethyl-6-keto-1,6-dihydropyrazine-methyl iodide, which by the action of alkali yields 1,2,4-trimethyl-5-methylene-6-keto-1,6,4,5-tetrahydropyrazine.[2]

It seems likely, in view of the above results, that the last compound is yielded by an enolic change similar to that already mentioned and that the reduced conjugation is the important factor in its production.

PRELIMINARY NOTE RELATING TO STUDIES ON KRYPTON AND XENON

Sir:

A research project having to do with the purification and properties of krypton and xenon has been in progress during the past four years. Some rather novel results have been obtained to which the authors desire to call attention at this time since the work has been interrupted on account of unavoidable delays attendant upon moving into a new building. A more complete report will follow at an early date.

Liquid air residues, mainly oxygen, were treated by cooled charcoal in a manner which concentrated the krypton and xenon considerably. The excess oxygen and other reactive gases were removed by suitable reagents and the remaining inert gases were separated by repeated fractional distillation. Finally about 70 cc. of krypton and 30 cc. of xenon were obtained in a condition of very high purity.

One of the first things investigated was the melting point. Krypton gave an exceedingly sharp melting point at $-156.6°$ with a corresponding vapor pressure of 558 mm. Note a difference of about 12° from the $-169°$ previously accepted as the melting point.

Xenon was harder to deal with in that it failed to give the sharp melting point that had been noted with krypton. Its behavior indicated the possibility of a transition point quite close to the melting point. The

---

[2] Gastaldi and Princivalle, *Gazz. chim ital.*, 59, 791 (1929); Princivalle, *ibid.*, 60,296,298 (1930).

melting point may be given, however, as −111.5 ± 0.5° with a corresponding vapor pressure of 600 * 20 mm. The accepted value for the xenon melting point is approximately −140°.

The processes of purification were checked by frequent density determinations and the densities of the best samples of krypton and xenon were rather carefully determined. The method employed was to collect a sample of the gas at a known temperature and pressure in a calibrated bulb, which was then weighed against a counterpoised bulb.

Density determinations made in connection with the fractionation work seem to indicate that the present accepted densities for krypton and xenon are too low. The value found for the heaviest krypton fraction was **3.733** g./l. and that for the heaviest xenon fraction 5.887 g./l. These figures would correspond, respectively, to atomic weights of 83.6 and 131.4 if Watson's [J. *Chem. Soc.*, 97, 833 (1910)] corrections are employed. No effort has yet been made to make final density determinations and these will be reported later.

Much of the work of extraction and purification followed the lines indicated by earlier investigators, but a number of new methods were used which will be reported in the more complete paper.

NEW BOOKS

Optical Activity and High Temperature Measurements. By F. M. JAEGER. McGraw-Hill Book Company, Inc., 370 Seventh Avenue, New York, 1930. 450 pp. 137 figs. 15.5 × 23.5 cm. Price, $4.00.

This volume contains the lectures delivered at Cornell University by Professor F. M. Jaeger during the second semester of 1928–1929 under the George Fisher Baker Non-Resident Lectureship in Chemistry. There are three series of the lectures. The first deals with the spatial arrangement of atomic systems and optical activity; the second with the methods, results and problems of precise measurements at high temperatures; the third with the constitution and structure of the ultramarines. Taken as a whole the lectures furnish a systematic presentation of investigations carried out by Professor Jaeger and his co-workers at the chemical laboratory of the University of Groningen.

The first lectures of the first series cover the principles of symmetry as applied to atomic systems, discussing the work of Pasteur, van't Hoff and Le Bel. The remaining lectures of this series are concerned chiefly with the optical activity of complex salts, many of them essentially inorganic. These latter lectures-are of particular interest as demonstrating the wide-spread occurrence of optical activity in the absence of any asymmetric carbon atom.

The lectures of the second series not only discuss and describe highly refined measurements of temperatures but also of specific heats and of the viscosities and surface tensions of liquids at elevated temperatures.

Systematic and connected accounts of this sort are always intrinsically useful, but this is particularly the case here, where the individual articles have already been published for the most part only in foreign journals.

We cannot but be grateful to Professor Jaeger and to the Baker Lectureship at Cornell for making it easy for us to become acquainted with these interesting and important researches.

ARTHUR B. LAMB

Physikalisch-chemische Übungen. (Manual of Physical Chemistry.) By W. A. ROTH, Professor in the Technical High School of Braunschweig. Fourth revised and enlarged edition. Leopold Voss, Leipzig, Germany, 1928. viii + 316 pp. 71 figs. 14 × 22.5 cm. Price, unbound, M. 13; bound, M. 15.

This fourth edition represents an extensive revision of this well-known manual, and is of interest as typifying the course in physical chemistry as given in the Technische Hochschule at Braunschweig. The manual is designed both for the beginners' course in which thirty obligatory exercises covering the general field are assigned, as well as for a more specialized course having an elastic program suitable as training for research candidates. The book is devoted largely to presenting the theory of the experiments and of the apparatus to be used along with concrete illustrative numerical examples.

Detailed directions for carrying out the experiments are exceedingly meager. Perhaps this is desirable. Instructive methods for evaluating graphically the errors in thermochemical experiments are set forth in considerable detail (pp. 72–75); likewise the introduction of nomographic methods deserves favorable comment, as well as the inclusion of experiments on the dielectric constant.

The treatment of electromotive force will be disappointing to most American readers. The reaction $Tl + KCNS \rightleftarrows TlCNS + KCl$ in aqueous solution with its uncertain and unavoidable liquid junction potential is certainly not a "htibsches Beispiel" today, particularly in discussing the Nernst Heat Theorem. The solubility of silver acetate in silver nitrate is discussed in detail in terms of the now obsolete degrees of dissociation of the salts followed by the statement (p. 159) "the small drift in solubility product becomes somewhat smaller on using activity coefficients," which makes one wonder if the "Moderne Anschauung" to which the student is referred has been grasped (*cf.* p. 157). The apparatus described for the conductivity experiments is hardly modern in character.

VICTOR K. LA MER

A Comprehensive Treatise on Inorganic and Theoretical Chemistry. Vol. X. Sulphur and Selenium. By J. W. Mellor, D.Sc. Longmans, Green and Company, 55 Fifth Avenue, New York, 1930. x + 958 pp. 217 figs. 25 X 16 cm. Price, 520.00.

The present volume (Vol. X) of the Treatise represents a significant milestone in this great undertaking, for with it all the non-metals have now been covered. There remain still to be done the metals of Groups VII and VIII of the periodic system. Of these, iron in particular will require extended treatment.

This volume, like its predecessors, will be for the general reader as well as for students of inorganic chemistry an exhaustive and yet practical reference handbook.

ARTHUR B. LAMB

Die Anwendung der **Interferometrie** in Wissenschaft **und** Technik. (Applications of Interferometry in Science and Industry.) By E. BERL AND L. RANIS, of the Chemicotechnical and Electrochemical Institute of the Technical High School of Darmstadt. Gebrüder Borntraeger, W 35 Schoneberger Ufer 12 a, Berlin, Germany, 1928. v + 52 pp. 28 figs. 16.5 X 25 cm. Price, M. 5.20.

The intent of the authors is made clear in the preface of this booklet. The increasing number of applications of the interferometer to scientific and technical investigations justifies the special consideration of procedures and principles already described in the literature as well as additional new titration methods developed by the authors. Some of the topics discussed include (a) methods of measurement by the interferometer; (b) principle and construction of interferometers and their four general topics.

I. The gas interferometer.
    a Innovations in construction.
    b Calibration.
    c Calculations.
    d Absolute and relative calibration.
    e Selection of gases for comparison.
II. Possible application of the gas interferometer.
III. Interferometer for liquids.
IV. Field of application of the interferometer for liquids.

The special uses for these two types of interferometers described in the text are not given in detail. The reader is referred to original articles which are listed in each case. An exception to this is the application of the interferometer for liquids to various titrations. This is the special contribution of the authors and the description of this investigation constitutes one-half of the paper. The titrations include precipitation as well as neutralization reactions. Graphic representation of the data makes it possible to see at a glance the relative change of refractive index as the equivalence point of the titration is approached. From the many interesting examples given it is evident that the sensitivity of the interferometer makes possible the extension of the usual methods employed in Refractometry. The authors for the most part have given an applied rather than a highly theoretical presentation of the subject, The publication should prove to be interesting reading to those interested in technical and scientific applications of instrumental analysis.

VILLIERS W. MELOCHE

Select Methods of Metallurgical Analysis. By WILLIAM ARCHIBALD NAISH, Ph.D. (Eng.), A.R.S.M., B.Sc., P.I.C., M. Inst. M. M., and JOHN EDWARD CLENNELL, B.Sc. (London), Assoc. Inst. M. M. Introduction by Sir H. C. Harold Carpenter, F.R.S. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, 1930. xii + 495 pp. 32 figs. 15.5 × 24.5 cm. Price, $7.50.

In this book of five hundred pages a serious attempt has been made to give in concise form methods for the determination of all of the elements and analyses of most of the raw materials and products with which the metallurgical laboratory is confronted. The authors have taken up the elements alphabetically, giving selected and proved methods for their determination. In addition, methods are given for the complete analysis of ores and many metallurgical products, both ferrous and non-ferrous and including silicate analysis and fire assaying. Of course, it would not be possible within the scope of any ordinary sized book to take up in detail the complete analysis of all metallurgical materials, but the book is sufficiently complete to enable any reasonably trained metallurgical chemist to make chemical analysis of practically any metallurgical material. The book is so complete that it suffers somewhat from too great a condensation when giving analytical procedures. The chapter on "Electrometric Titration" is so condensed that it might almost as well have been left out, especially since the book does not make use of electrometric methods when describing the analytical methods used for each element. Perhaps the most outstanding omission in the book is its complete failure to include methods of gas analysis and its very sketchy two and one-half pages given to coal analysis. Neither is any mention made of water analysis.

From the point of pedagogy the chief criticism which the teacher of metallurgy will make will be directed against the almost complete absence of any discussion of the laws of physical chemistry as applied to the equilibria involved in the analytical procedures. This would be a serious matter if it were not for the fact that the teacher will have to drill the students in these matters anyhow. On the other hand, the authors are to be complimented on their thorough and uncompromising effort to give the chemical facts involved in analytical separations. There is all too great a tendency to neglect the facts and deal too much in theory in present-day pedagogy and book writing.

The most notable advance taken in this book is its up-to-date treatment of the application of spectrum analysis to the work of the metallurgical laboratory, because it is certainly true that metallurgists and metallurgical chemists must become "spectrum conscious." Since physical methods of analysis have been introduced in this chapter it would seem that the authors should have gone further and have included microscopic methods of analysis. The book is very thorough in its bibliography work, which will enable the users of it to get easily the details of procedure which the authors have been forced to omit.

This work will be frequently used in the reviewer's laboratory and will surely find a wide usefulness in the metallurgical world.

D. J. DEMOREST

Soap Films. A Study of Molecular Individuality. By A. S. C. LAWRENCE. **Foreword by Sir William Bragg, F.R.S. *G.* Bell and** Sons, **Ltd., Portugal** St., **London,** W. C. 2, England, 1929. xi + **141 pp. 61 figs. 14 × 22.5 cm. Price, 12s. 6d. net.**

Everyone interested in the intriguing subject of soap films—and everyone who dips into the pages of this unusual little book will find he is fascinated by it—will be under a debt of gratitude to Mr. A. S. C. Lawrence for having brought together in such readable form so much material of high scientific value which is not available elsewhere.

It is only those who have had the privilege of attending in person the Discourses at the Royal Institution, who will fully appreciate the opening sentence of Sir William Bragg's Introduction: "The researches of the late Sir James Dewar on the properties of soap films are well known for their variety, beauty and importance." The unrivaled practical experience in the demonstration of the properties of soap films and the production of black bubbles accumulated there through the course of many years was supplemented by the repetition of the more important studies of other investigators. The whole is vividly described and carefully discussed and systematized by the author, who was Lecture and Research Assistant to Sir James Dewar. The co-relation of these phenomena and the attempt to link them with existing theory represents, in itself, a substantial advance in this subject and will undoubtedly lead to further rapid developments. Amongst the subjects treated are discussions of surface tension and its inadequacy to explain the phenomena of soap films, reflection and interference of light by films, constitution of soap solutions and their surfaces and the remarkable phenomena presented by black and stratified films.

PROPERTIES OF DIPHENYLAMINE AND DIPHENYLBENZIDINE AS OXIDATION–REDUCTION INDICATORS

BY I. M. KOLTHOFF AND L. A. SARVER

RECEIVED MARCH 4, 1930 PUBLISHED NOVEMBER 5, 1930

Introduction

Knop[1] was the first to propose the use of diphenylamine as an indicator in the titration of ferrous iron by potassium dichromate, whereas Cone and Cady[2] recommended either diphenylamine or diphenylbenzidine as internal indicators in the titration of zinc by ferrocyanide. Several workers[3] have since shown that these indicators are reliable and useful in oxidation–reduction titrations, but Sarver[4] pointed out that end-points are often passed without any color formation, whereupon the addition of a trace of ferrous iron will then produce it instantly. Moreover, Watson[6] has recently shown that mercuric chloride has a powerful inhibiting effect on the color production.

Since diphenylamine and diphenylbenzidine now belong among the common analytical laboratory indicators it appeared desirable to make an extensive study of their properties in order to know in what cases they can be applied, under what conditions they give reliable results, and what corrections must be made under different circumstances. The physico-chemical part of this investigation will be presented here, while the analytical significance of the work will be reserved for a future paper.

I. Speed of Color Development.—Pure products of diphenylamine (m. p. 52–53', uncorr.) and diphenylbenzidine (m. p. 242–243°, uncorr.) have been used throughout this work, stock solutions being prepared by dissolving 0.1 g. of the substance in 100 cc. of concentrated sulfuric acid.

---

[4] L. A. Sarver, THIS JOURNAL, 49, 1472 (1927).

[5] F. J. Watson, *Chem. Eng. Min. Review*, 20, 355, 396 (1928).

The oxidation was first studied qualitatively, various amounts of acid, indicator and dichromate being mixed at different temperatures, and the time noted at which the color first became perceptible. The results were not very exact since it was hard to perceive the first tinge of violet, due to a green which often accompanied it. The hue is somewhat dependent upon the acidity, being violet at low hydrogen-ion concentrations, and more blue in acid concentrations higher than 4 N.

The speed of oxidation is approximately proportional to the amount of dichromate added for a given amount of indicator, and to the amount of indicator used for a given amount of dichromate. Furthermore, the reaction velocity increases rapidly with the temperature, being about four times as great at 55 as at 25°.

Acids increase the speed of reaction very markedly, and the color develops much more quickly in hydrochloric than in sulfuric acid of the same normality, on account of the greater activity of the hydrogen ions in the former. This increased speed of oxidation in larger hydrogen-ion concentrations is explained by the fact that the oxidation potential of the dichromate increases rapidly with the acidity, whereas as we shall see later the potential of the system diphenylbenzidine and its violet oxidation product is practically independent of the concentration of the hydrogen ions. This explanation is supported by the behavior of diphenylamine and diphenylbenzidine with stronger oxidizing agents; e. g., with potassium permanganate the violet appears instantly at all acidities.

Mercuric chloride has a pronounced inhibiting effect, whereas traces of ferrous iron show an enormous accelerating effect; when both are present at the same time the iron only partially neutralizes the adverse action of the mercuric chloride. It may be mentioned that ferric iron is without any effect. Hence the oxidation is induced by the reaction between ferrous iron and potassium dichromate, which is in harmony with the primary oxide theory of Manchot. First, the ferrous ion is oxidized to an intermediate unstable higher oxidation state than ferric iron, which in turn reacts rapidly with diphenylbenzidine.

Finally it should be mentioned that in all cases where a large excess of oxidant was added, the violet color was quickly destroyed, becoming first red, then yellow, with dark flocks precipitating out after standing for some time, leaving a colorless solution in which it was impossible to get the violet again. The diphenylbenzidine violet is therefore decomposed in an irreversible way by excess oxidant.

II. Light Absorption by Diphenylbenzidine Violet.—The light absorption of the violet oxidation product of diphenylamine and diphenylbenzidine (which will be called diphenylbenzidine violet and abbreviated D.B.V.) in hydrochloric and sulfuric acids of various concentrations was determined by means of a Keuffel and Esser spectrophotometer and, in agreement with the experiments of Thiel,[6] the curves were found to be nearly flat between 5400 and 5700 Å., the absorptions differing by less than 1% over this range. The intensities of the colors increased more or less slowly with the time, according to the concentration of the acid, and later decreased, so that it was difficult to obtain comparable readings for the whole absorption curve at one time: at one stage they were practically constant for a few minutes, however, and by working rapidly fairly comparable values were obtained; but it was not possible to derive transmission coefficients under these conditions. A definite shift of the absorption maximum toward the longer wave lengths was observed in the stronger acid solutions, from 5600 Å. for the colored oxidation product from either indicator in 0.5 N hydrochloric or sulfuric acid to 5850 Å. for 6 N acid solutions. This agrees well with Thiel's value of 5870 Å. for diphenylamine in 50% sulfuric acid, considering that he worked at a still higher acidity. The fact that the colored oxidation products of both diphenylamine and diphenylbenzidine have identical absorption spectra is one proof that the two bases give identical compounds (see discussion, Section V).

III. Solubility of Diphenylbenzidine and the Order of its Ionization Constant.—The solubilities of diphenylbenzidine in water, in various concentrations of hydrochloric acid, sulfuric acid and sodium chloride, and in saturated mercuric chloride have been determined by a nephelometric method. A freshly prepared solution containing 0.04 mg. of diphenylbenzidine per cc. in a mixture of concentrated sulfuric and glacial acetic acids (10 and 90% by volume, respectively) was dispensed from a microburet, 0.01 cc. at a time, into 50 cc. of water or solution contained in a small beaker.[7] After each addition the solution was stirred, poured carefully (to avoid formation of air bubbles) into Nessler tubes, and compared with other tubes containing only the solvent, in a dark room in a simple nephelometer constructed from a photographic dark-room lamp. Solubilities were estimated from the minimum volume of standard solution required to give the faintest perceptible permanent cloud, and could be reproduced with an accuracy of about 10%, which is quite satisfactory for such extremely small values; the concentrations were so low that the solutions did not show any perceptible color with oxidizing agents. Solubilities estimated in this way for water both at room temperature and at 50° were 0.06 mg. per liter, while those for 0.5 N and N sodium chloride, and saturated mercuric chloride were 0.05 mg. per liter. Solubilities of diphenylbenzidine in various concentrations of hydrochloric acid and the corresponding hydrolysis constants of the base are given in Table I.

Although diphenylbenzidine is a diacid base, its first ionization constant

---

[6] A. Thiel, *Z. Elektrochem.*, 35, 274 (1929).

[7] Soon after the preparation of diphenylbenzidine standard solutions, a green compound separated out; hence it was necessary to use fresh solutions.

TABLE I

SOLUBILITIES IN HYDROCHLORIC ACID AND HYDROLYSIS CONSTANT OF *DIPHENYLBENZIDINE* AT 25°

Normality of HCl	Mg. D.B. per liter	Mg. D.B.H$^+$ per liter	$K_{\text{Hydrolysis}}$	$K_{\text{Hydrolysis}}$ (corr. for salting out)
0.1	0.07	...	...	...
.25	.09	0.03	0.50	0.50

1.0	.17	.11	.55	.50
2.0	.28	.22	.55	.51

is so small that the solubility in acids will be mainly determined by the magnitude of this constant, according to the equations:

$$\textit{Diphenylbenzidine} + \mathrm{H}^+ \rightleftharpoons \textit{Diphenylbenzidine}\,\mathrm{H}^+ \tag{1}$$

and

$$\frac{[a\mathrm{D.B.}][a\mathrm{H}^+]}{[a\mathrm{D.B.H}^+]} = \frac{[a\mathrm{D.B.}][\mathrm{H}^+]f\mathrm{H}^+}{[\mathrm{D.B.H}^+]f\mathrm{D.B.H}^+} = K_{\mathrm{Hydrolysis}} \tag{2}$$

where $[a\mathrm{D.B.}]$ is the activity of diphenylbenzidine and equals the solubility in water, $[a\mathrm{H}^+]$ is the activity of the hydrogen ion and $[a\mathrm{D.B.H}^+]$ that of the diphenylbenzidine cation. Since $f\mathrm{H}^+$ and $f\mathrm{D.B.H}^+$ represent the activity coefficients of univalent ions at the same ionic strength, their magnitude will be of the same order, and the ratio of activities can be assumed to be equal to the ratio of ionic concentrations; this may introduce an uncertainty of 5–10% at higher acidities, but it is not serious when the approximate nature of the solubility determinations is considered. The concentration $[\mathrm{D.B.H}^+]$ is equal to the difference between the solubilities of diphenylbenzidine in acid and in water, but should be corrected for the salting out effect of the electrolyte. In order to approximate the magnitude of this correction, the solubility of diphenylbenzidine was determined in N and 0.5 N sodium chloride solution, and the salting out effect was assumed to be the same in hydrochloric acid of corresponding concentrations. The activity of the diphenylbenzidine is not changed by the salting out, although the actual concentration may be reduced; hence it may be assumed to be equal to the solubility in water. So it follows that

$$\frac{[S_{\mathrm{W}}]\cdot[\mathrm{H}^+]}{[S_{\mathrm{A}} - S_{\mathrm{W}}]} = K_{\mathrm{Hydrolysis}}\ \textit{(uncorrected)} \tag{3}$$

and

$$\frac{[S_{\mathrm{W}}]\cdot[\mathrm{H}^+]}{[S_{\mathrm{A}} - S_{\mathrm{S}}]} = K_{\mathrm{Hydrolysis}}\ \text{(corrected)} \tag{4}$$

where S_{W} represents the solubility of diphenylbenzidine in water, S_{A} the solubility in acid and S_{S} that in salt solution, while the hydrogen-ion concentration is assumed to be equal to the normality of the acid.

In this way the hydrolysis constant (corrected for salting out effect) has been determined and found to be remarkably constant in acid concentrations between 0.1 and 2.0 N, with an average magnitude of 0.50 at 25°.

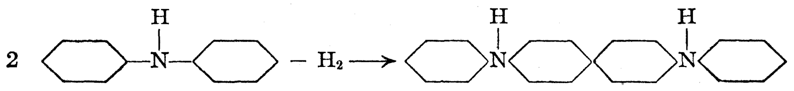
Hence the constant of the first ionization of diphenylbenzidine is 2×10^{-14} at 25°, whereas Thiel[6] found a value of 7.6×10^{-14} for diphenylamine at 15°.

The solubility of diphenylbenzidine in sulfuric acid is much smaller than in hydrochloric acid of corresponding normality, on account of the lower activity of the hydrogen ions in the former acid. In 4 *N* hydrochloric acid and 6 *N* sulfuric acid the solubility of diphenylbenzidine is much greater than could be expected from its behavior as a monoacid base; the activity of the hydrogen ions in these strongly acid solutions is much larger than the corresponding concentrations, and also the second basic group may play an important part in strong acid medium.

Finally, it is of interest to point out that since the solubility of diphenylbenzidine in saturated mercuric chloride is approximately the same as in water, we cannot explain the great inhibiting effect of this salt on the color development by the formation of a complex between it and diphenylbenzidine; so it seems more reasonable to suppose that it reacts in some way with the colored compound or intermediate products.

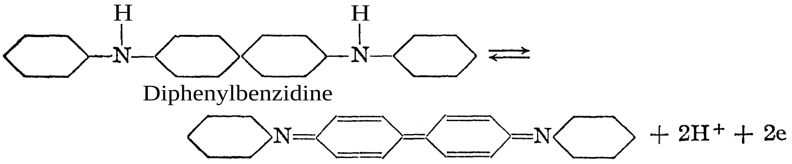
IV. Potentiometric **Titrations.**—Freshly prepared solutions of diphenylamine and diphenylbenzidine in various concentrations of sulfuric acid were titrated potentiometrically with 0.01 *N* potassium dichromate solutions containing the same concentrations of sulfuric acid as the titration mixtures, both at room temperature (24–30°) and at 50°. The bright platinum gauze electrode was ignited before each titration, and used in conjunction with a saturated calomel electrode with salt bridge of agar and saturated potassium chloride.

The experiments were not very satisfactory from the stoichiometric point of view, because of the slowness with which equilibrium is established and the occurrence of side reactions. However, it was found that the main reactions could be represented thus



Diphenylamine Diphenylbenzidine

(5)



Diphenylbenzidine

Diphenylbenzidine violet

(6)

The oxidation of diphenylamine to diphenylbenzidine is irreversible, and it even seems doubtful whether the reversible system, diphenylbenzidine $\rightleftarrows$ diphenylbenzidine violet, ever reaches a constant potential. In the first place they react with each other to form an extremely slightly soluble green meriquinoid (a molecular compound of diphenylbenzidine and diphenylbenzidine violet). Moreover, the diphenylbenzidine violet itself easily undergoes further oxidation by an irreversible reaction. Therefore the potentials observed in direct titrations depend upon the time which has elapsed since the addition of the oxidant, the temperature, the acidity and the amount of excess oxidant. Yet it is possible to obtain reproducible results when the titrations are made under similar conditions. When the dichromate is added rapidly the violet appears before complete oxidation of diphenylamine to diphenylbenzidine, but the color fades on standing and the potential drops. After the quantitative formation of the diphenylbenzidine, a continued addition of dichromate oxidizes it to diphenylbenzidine violet, but part of this reacts with unchanged diphenylbenzidine to form the green meriquinoid. This meriquinoid formation is less at higher temperatures than at room temperature.

The potentials observed during the oxidation of diphenylamine to diphenylbenzidine have no exact significance, because the reaction is irreversible and the electrode behaves more or less like an oxygen electrode, with the values decreasing on long standing. At the beginning of the oxidation of diphenylbenzidine to diphenylbenzidine violet the potentials are reproducible, although the meriquinoid formation and the decomposition of the violet are responsible for the fact that the potentials are never constant for an indefinite time.

In Table II a summary is given of the results found in a few examples taken from a large number of direct titrations of 1.69 mg. of diphenylamine with 0.01 *N* potassium dichromate at different acidities and temperatures.'. The table is self-explanatory with the exception of the last two columns; of these, the former gives the number of equivalents of oxidant added before a violet color was perceptible in the solution (which point could be only approximated, since the green greatly obscured the violet), and the latter column indicates the potential (against saturated calomel electrode) at which the violet was first visible in the solution. Probably there was already some violet in the solution before it could be perceived, on account of being masked by the green; this could be inferred from the results of the back titrations, as will be shown later. The violet was generally first observed at potentials of 0.510–0.525 v. (against saturated calomel electrode) when the titrations were made in the presence of ferrous iron.

These results show that in the direct titration of diphenylamine two jumps in potential are observed under the proper conditions, the first corresponding to the complete oxidation of diphenylamine to diphenylbenzidine, the second to the complete oxidation of the latter to diphenylbenzidine violet. The last does not correspond exactly to the stoichiometric value on account of the fact that the green insoluble meriquinoid formed during the titration is attacked very slowly (tending to cause low

results), and because part of the diphenylbenzidine violet is oxidized irreversibly to other products (tending to cause high results).

Similar titrations have been made with diphenylbenzidine under the same conditions of time and acidity, which confirm the results obtained with diphenylamine; but, owing to the slight solubility of the former, still more difficulties were encountered. Of course, only one jump in potential occurs in this titration, after the complete oxidation to diphenylbenzidine violet.

On account of the fact that equilibrium is established fairly slowly in direct titrations, with much opportunity for side reactions, it was thought desirable to add the diphenylamine or diphenylbenzidine to a small excess of dichromate and then back-titrate as quickly as possible. It is inevitable that some of the diphenylbenzidine violet will be further oxidized by the excess dichromate when working in this way; but by making the excess small and working rapidly it has been possible to obtain reproducible results which confirm the proposed theory of the reaction mechanism. The oxidized solutions were kept at room temperature until the excess dichromate had been reduced with ferrous iron, in order to minimize further oxidation of the diphenylbenzidine violet; they were then warmed to 50° for the rest of the titration, to hasten the establishment of equilibrium. Two jumps in potential were observed, the first corresponding to the complete reduction of the excess dichromate, and the second to the completion of the reduction of the diphenylbenzidine violet to the meriquinoid, diphenylbenzidine green. Averaging the results of a large number of titrations of diphenylamine at different acidities, it was estimated that after the removal of excess dichromate, 2.01 equivalents of the oxidant had been consumed by the diphenylamine (calcd., 2.0), and that the potential at the equivalence point was 0.575 v. (against saturated calomel electrode); likewise, the second jump, corresponding to the complete reduction of the diphenylbenzidine violet to diphenylbenzidine green, indicated that 1.62 equivalents of oxidant were required to oxidize the original diphenylamine to diphenylbenzidine green (calcd., 1.5), and the potential at this equivalence point was 0.510 v. (against saturated calomel electrode). Such a back-titration is shown graphically in Fig. 1, where the first part of the curve represents the reduction of the excess dichromate by ferrous sulfate, and the portion following the first break shows the reduction of diphenylbenzidine violet to the meriquinoid, diphenylbenzidine green, the second break indicating this equivalence point.

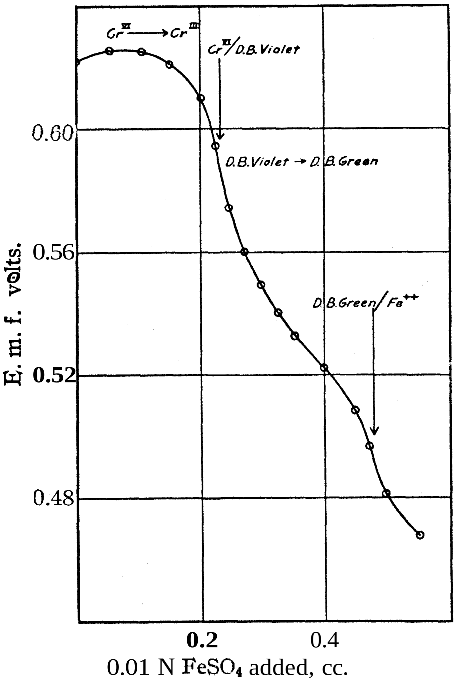

Fig. 1.—Back titration of diphenylbenzidine violet and excess potassium dichromate in 0.6 N sulfuric acid.

Similar experiments were made with diphenylbenzidine, but were less satisfactory from the stoichiometric point of view, for the reasons previously given; in all cases, however, the color change from violet to green took place at the same potential as with diphenylamine, 0.51 ± 0.01 v. (against saturated calomel electrode), or 0.76 ± 0.01 v. (against normal hydrogen electrode). It is striking that the potential at which this color change takes place is very constant, and quite independent of the acidity. Hence, it may be concluded that diphenylamine and diphenylbenzidine give their violet oxidation product in solutions having higher oxidation–reduction potentials than those mentioned above, at all reasonable acid concentrations. In general, the curves representing the potentials during the reduction of diphenylbenzidine violet to diphenylbenzidine green have the same shape, and corresponding points have the same potentials at all acidities between 0.1 and 1.0 N.

Further, although the results have no exact quantitative significance, they confirm the reaction mechanism represented by Equations 5 and 6.

V. Discussion.—1. The potentiometric experiments show that upon slow addition of a strong oxidizing agent to a solution of diphenylamine in an acid medium, one equivalent of oxidant is consumed before the violet is formed. Moreover, before the solution becomes colored, a milky cloudiness is observed, probably from diphenylbenzidine, which is very slightly soluble. That diphenylbenzidine is indeed the first oxidation product obtained from diphenylamine was proved by the following experiment. To a liter of a solution of 100 mg. of diphenylamine in 0.1 N sulfuric acid, 90% of the theoretical amount of dichromate necessary for the oxidation to diphenylbenzidine was added slowly at 50°. The solution soon became opalescent, with a tinge of green from the chromic salt formed. The white insoluble substance coagulated immediately upon boiling, and was filtered off and washed first with water and then alcohol. The residue was recrystallized from boiling toluene and dried at 105°. The melting point of this product was 244–245° (uncorr.), and the same value (within 2°) was found for a mixture of this with pure diphenylbenzidine.[8]

This experiment partly confirms the important work of Kehrmann and Micewicz,[9] who were the first to clear up the reaction mechanism in the oxidation of diphenylamine. Although the colored oxidation products of diphenylamine had been known and studied for a long time, the interpretations of the reaction given by various writers[10] were quite contradictory. Kehrmann and Micewicz obtained tetraphenylhydrazine, then diphenylbenzidine, then a green oxidation product of diphenylbenzidine which they called a half-quinoid salt, or quinhydrone, and, finally, the blue holoquinoid salt. Further strong oxidation gave a yellow solution, and then, by molecular rearrangement, a red solution. Dilute acid solutions of all these quickly became colorless, with precipitation of greenish-black flocks. These results were confirmed in the main by a number of writers, especially Marqueyrol and Muraour,[11] except that the latter obtained only traces of

---

[8] It should be mentioned that there is some confusion in the literature as to the correct melting point of diphenylbenzidine. R. Gnehm and H. Werdenburg [*Z. angew. Chem.*, 43, 1027, 1051, 1128 (1899)] gave it as 246–248°; V. Kadiera [*Ber.*, 38, 3575 (1905)] reported it as 242°, corrected; and M. Marqueyrol and H. Muraour [*Bull. soc. chim.*, 15, 186 (1914)] found 250.5–251.5°.

diphenylbenzidine when tetraphenylhydrazine was taken as the starting substance. At first Wieland believed that each molecule of diphenylamine splits off one molecule of hydrogen (as H_2O) upon osidation, to give the bivalent radical $[Ph—N{=}C_6H_4]{=}$, which then polymerizes to the blue product $Ph—N{=}C_6H_4{=}C_6H_4{=}N—Ph$; but Marqueyrol and Muraour showed by quantitative experiments that diphenylbenzidine is indeed the main product, and Wieland later concurred in their conclusions.

An interpretation similar to the original one of Wieland has recently been offered by Thiel,[6] but he assumes that not the free amines, but the corresponding cations, enter into reaction. Although it is quite possible that the formation of the bivalent cation depends upon working conditions (acidity, temperature, solvent, etc.), the present paper shows definitely that at fairly low acidities (0.1–2.0 N) with slow addition of the oxidizing agent, diphenylbenzidine is the first product which can be isolated.

Hence, it is felt that the first stage in the oxidation of diphenylamine is correctly represented by Equation 5 (Section IV), since the formation of diphenylbenzidine in nearly stoichiometric amounts has been proved, while no evidence of the formation of intermediate compounds has been found.

2. Diphenylbenzidine may be further oxidized to the violet or blue holoquinoid salt, diphenylbenzidine violet, by a reversible reaction Equation 6, (Section IV). This diphenylbenzidine violet is a very unstable compound, and is easily oxidized further to yellow or red compounds whose composition is as yet unknown; or it may react with unchanged diphenylbenzidine to form the greenish-black meriquinoid, diphenylbenzidine green. In fact, it is possible to titrate the color out of an oxidized diphenylbenzidine solution by adding a solution of pure diphenylbenzidine. While it is impossible to state with certainty, it is believed that diphenylbenzidine green is an equimolecular compound of oxidized and unoxidized diphenylbenzidine.

3. This meriquinoid, diphenylbenzidine green, which was first mentioned by Kehrmann and Micewicz,[9] is an extremely slightly soluble green substance, and obscures the perception of the violet in the solution. A saturated solution of it in water or acid is colorless, and contains so little diphenylbenzidine that it is not colored by an oxidizing agent. A suspension of the green product is, however, changed to violet by dichromate or any strong oxidizing agent, which shows the presence of diphenylbenzidine in the compound. On account of its extremely slight solubility, it is hard to reduce it with ferrous sulfate, but stronger reducing agents like stannous chloride discharge the color rapidly, and a milky white opalescence from the diphenylbenzidine remains. If diphenylbenzidine violet is titrated potentiometrically with ferrous sulfate, a jump in potential occurs at the point where all the violet has been reduced to the green meriquinoid; if, however, the ferrous sulfate is added very rapidly, the formation of the

green product is prevented, and the reduction goes as far as diphenylbenzidine. The stability of a suspension of the meriquinoid decreases with the temperature; at 50° it shows a weak violet color, which indicates that the dissociation of the molecular compound is greater at 50° than at room temperature.

4. If a small excess of potassium dichromate is added either to diphenylamine or diphenylbenzidine, both indicators behave identically upon back-titration with ferrous sulfate, which shows that the oxidation product is the same in both cases; this conclusion is also confirmed by the similarity of the absorption spectra (Section II).

5. It seems very remarkable that the potential at which the violet changes to green is independent of the acidity, at about 0.51 ± 0.01 v. against saturated calomel electrode, or at about 0.76 ± 0.01 v. against the normal hydrogen electrode, even the temperature having a negligible effect on this value. It was shown by special experiments that even at PH values of 3 to 4, the change from violet to green takes place at approximately the same potential, although the diphenylbenzidine violet itself is extremely unstable at these low acidities.

According to Equation 6 (Section IV) the oxidation–reduction potential should be

$$E = E_0 + \frac{0.060}{2} \log \frac{[a\text{D.B.V.}][a\text{H}^+]^2}{[a\text{D.B.}]}, \text{ at } 30^\circ \qquad (7)$$

where a designates the activity of the specified substance or ion. Therefore one would expect that E would increase 60 millivolts for each decrease of 1 in the PH.

Now if we consider the system diphenylbenzidine violet $\rightleftarrows$ diphenylbenzidine green, especially at the moment when the violet changes to green, we can safely assume that [aD.B.] is a constant, because diphenylbenzidine is very slightly soluble and its activity in a saturated solution will be a constant (cf. Section III). The diphenylbenzidine violet, on the other hand, had a variable concentration; further, part of it is present as cation (also violet or blue), and part as the free base, the latter determining the potential, according to the equations

$$\text{D.B.V.} + 2\text{H}^+ \rightleftarrows \text{D.B.V.H}_2^{++} \qquad (8)$$

$$[a\text{D.B.V.}] = \frac{[a\text{D.B.V.H}_2^{++}]}{[a\text{H}^+]^2} \cdot K \qquad (9)$$

Now, if diphenylbenzidine violet is a relatively strong base, as compared with diphenylbenzidine itself (which seems probable), practically all the dyestuff will be present as cation in the fairly strong acid solution. Therefore, if we consider the [D.B.V.] at different PH values, but at the same total concentration of dyestuff (free base + ions), then we may assume that [D.B.V.H_2^{++}] is practically the same in all the solutions, while the concentrations of the free base are quite different.

Assuming [aD.B.] a constant, we have from Equation 7

$$E = E_0' + \frac{0.060}{2} \log\, [a\text{D.B.V.}][a\text{H}^+]^2 \tag{10}$$

or, since

$$[\text{D.B.V.}] = \frac{[\text{Total dyestuff}]}{[a\text{H}^+]^2} K \text{ approximately} \tag{11}$$

we derive by substitution

$$E = E_0'' + \frac{0.060}{2} \log \frac{[\text{Total dyestuff}][a\text{H}^+]^2}{[a\text{H}^+]^2} = E_0' + 0.03 \log\, [\text{Total dyestuff}] \text{ approximately} \tag{12}$$

It thus becomes comprehensible why the oxidation–reduction potential is independent of the acidity, although it must be emphasized that the above relations hold only approximately.

6. It has already been mentioned that diphenylbenzidine violet can be oxidized to other products; at low acidities, especially, it is very unstable. In solutions with a P_H of 7 to 2, potassium dichromate is not able to oxidize diphenylamine or diphenylbenzidine to the violet; but potassium permanganate, on the other hand, oxidizes both indicators easily at these acidities, due to its higher oxidation–reduction potential. The violet is the more easily destroyed, the lower the P_H and the higher the oxidation–reduction potential; in acetic acid medium, the violet produced by oxidizing diphenylamine with permanganate disappears almost instantly.

7. Potentiometric titrations have been made in the presence of mercuric chloride in order to see whether this substance has a specific effect upon oxidation–reduction potentials, but it was not possible to make satisfactory measurements. Even the ferrous iron–dichromate titration was impossible; the electrode was slow, and no jump in potential occurred at the equivalence point. It seems that the electrode takes up some mercury by polarization, and does not respond quickly to excess of oxidant. This may be of significance in the use of a bimetallic electrode system.

Summary

1. At acidities between 0.1 and 2.0 N, diphenylamine is oxidized quantitatively to diphenylbenzidine by potassium dichromate if the oxidant is added slowly to the former solution. Further addition of dichromate oxidizes the diphenylbenzidine to a violet quinoid salt, which quickly combines with unchanged diphenylbenzidine to form an extremely slightly soluble green meriquinoid salt.

2. In titrating diphenylbenzidine violet with ferrous sulfate the color change, violet to green, takes place at a potential of about 0.51 v., against saturated calomel electrode; or at 0.76 v., against the normal hydrogen electrode, regardless of the hydrogen-ion concentration of the solution. An explanation has been offered to account for this.

3. The results of the analytical study are not very satisfactory from the stoichiometric point of view, because side reactions may occur, diphenylbenzidine and diphenylbenzidine green are very slightly soluble, and diphenylbenzidine violet decomposes rapidly, especially at low acidities.

4. The absorption spectra of oxidized diphenylamine and diphenylbenzidine solutions have been determined and found to be identical; the maxima of the curves are very flat, and shift toward the longer wave lengths in stronger acid solutions.

5 The solubility of diphenylbenzidine in water is 0.06 ± 0.005 mg. per liter at 25–50°; and its ionization constant at 25° is of the order of 2×10^{-14}.

STUDIES IN INTENSIVE DRYING[1]

BY E. JUANITA GREER[2]

RECEIVED JUNE 16, 1930 PUBLISHED NOVEMBER 5, 1930

The following is an account of an experimental study of the intensive drying, and therewith "the catalytic" effect of small traces of water, mainly in liquid benzene, which leads to an explanation of the phenomenon observed. Since Baker's work was published in 1922 there has been a constant stream of theoretical explanations of intensive drying, as well as a large number of experimental studies dealing with this strange phenomenon.

It is unnecessary in this paper to give even a synopsis of either the theoretical or the experimental aspects of this problem, inasmuch as quite recently this whole subject has been carefully and most adequately reviewed in book form under the title of "The Effects of Moisture on Chemical and Physical Changes," by J. W. Smith.[3]

Suffice it to say that since Baker's[4] paper data have accumulated which tend to support, and lately some as justly to contest, the view that when the last traces of water are removed from certain liquids, there occur physical changes in the latter that are consistent with the assumption of an association of the molecules in the liquid. The properties investigated have been such as the boiling point, freezing point, density, vapor density, surface tension, latent heat of vaporization and vapor pressure. However,

from a theoretical and practical consideration of the work of other investigators, it was assumed when this work was begun in 1927 that the vapor pressure of the liquids was the property the least open to misinterpretation and also the most reliable from the standpoint of experimental technique. This work began with the purpose of finding a means of producing liquids exhibiting the intensive drying effect in a shorter time than previously in order that the phenomenon might be more readily investigated.

Experimental Part

The Possibility of Compound Formation with Phosphorus Pentoxide and Benzene.—In the course of the preliminary work, benzene that had been purified by the method used by Hill[5] was found to produce color in pure phosphorus pentoxide when the mixture was stored in the light. The phosphorus pentoxide was prepared by resubliming Baker's pure phosphoric anhydride in a current of pure oxygen according to the method of Finch and Fraser[6] and the product satisfied the requirements of Baker[7] and of Finch and Peto[8] for purity.

Experimental investigation indicated that small traces of impurities in benzene—mainly sulfur compounds such as thiophene and carbon disulfide—are capable of imparting color to phosphorus pentoxide, varying from pale grayish-pink to yellow, when a mixture is stored in the light.

An investigation of the methods more generally used for the purification of benzene rarely revealed attempts to eliminate carbon disulfide which along with thiophene is one of the chief contaminants of commercial benzene.

Rigid purification of benzene either by an extension and combination (1) of the methods of Goldberg[9] and Haller and Michel[10] or (2) of the methods of Goldberg and Victor Meyer[11] which proved to be the more convenient method—gave a product which distilled within 0.01° and failed to impart any color to the phosphorus pentoxide upon heating or after a year's exposure to light.

The increased boiling points reported by Baker were ascribed by Balarew[12] possibly to the formation of compounds with phosphorus pentoxide and benzene. A search of the literature revealed that Giran[13] reported definite, solid, colored compounds insoluble in benzene resulting from the reaction of phosphorus pentoxide and benzene. As stated previously, impure

benzene did impart similar colorations to pure phosphorus pentoxide, but this present investigation indicated no such compounds as described by Giran with pure benzene and pure phosphorus pentoxide. Moreover, a fused glass apparatus containing a differential mercury manometer such as is described in the following section of this paper revealed no decrease in the vapor pressure of impure benzene dried with phosphorus pentoxide for two years. This would indicate that even if a compound were formed in the impure benzene, it was insoluble as Giran reported, and had no measurable vapor pressure, thus causing no change in the vapor pressure of the benzene.

Experiments with Phosphorus Pentoxide and Fused Glass Apparatus.—In 1926, Smits[14] reported that capillary-free glass hastened the drying of liquids with phosphorus pentoxide. His glass surfaces were fused and then cleaned with chromic acid, washed, steamed and dried. This chromic acid treatment has been shown by other investigators[15] to etch the surface of the glass. In order to preserve the beneficent effects of a fused pyrex glass surface, the apparatus used in the present investigation was first cleaned with chromic acid and, in the usual manner, washed with water and dried. It was then fused by an expert glass blower who melted the glass completely and then shaped it, blowing at all times through a tube of phosphorus pentoxide to avoid the access of water to the apparatus.

The entire apparatus of the circulating and of the static types similar to those used by Smits,[14] was constructed of fused glass and contained a differential mercury manometer to indicate the difference in pressure between the benzene being dried with phosphorus pentoxide on the one side, and a sample of the same normal benzene in a fused glass bulb on the other side. The vessels were filled under moisture-free conditions by the passage of a stream of air dried with phosphorus pentoxide. The liquids were frozen with solid carbon dioxide and ether when the apparatus, evacuated thoroughly by using a mercury diffusion pump in series with a high vacuum oil pump, was sealed off. The manometer was then filled with dry mercury from a reservoir in the apparatus by tilting the latter slightly.

No difference between the vapor pressures on the two sides of the pieces of apparatus has been observed even after three years in one case and twenty-seven months in two other cases. Moreover, in defense of Baker when his work was attacked by Balarew,[12] Smits[16] reported that he could detect no vapor pressure change in some of his pieces of apparatus after two years' drying.

Experiments with Silica Gel and Benzene.—A preliminary experiment

---

[15] **Frazer, Patrick** *and* Smith, *J. Phys. Chem., 31,* 897 *(1927)*

[16] Smits, *Z. physik. Chem.*, **129**, **33** *(1927)*

using pure, activated silica gel as the drying agent indicated a definite decrease in the vapor pressure of benzene. This drying effect appeared within twenty-four hours and seemed to have reached complete equilibrium after being kept for five days in a thermostat at 25°.

Apparatus of the type shown in Fig. 1 was constructed and joined in ring form. The differential manometer M contained pure mercury which was heated in the manometer with pumping for several hours to remove dissolved air and moisture. The pumps continued while the whole apparatus was heated well with a carbon flame to remove surface moisture and tested for leaks with a spark coil.

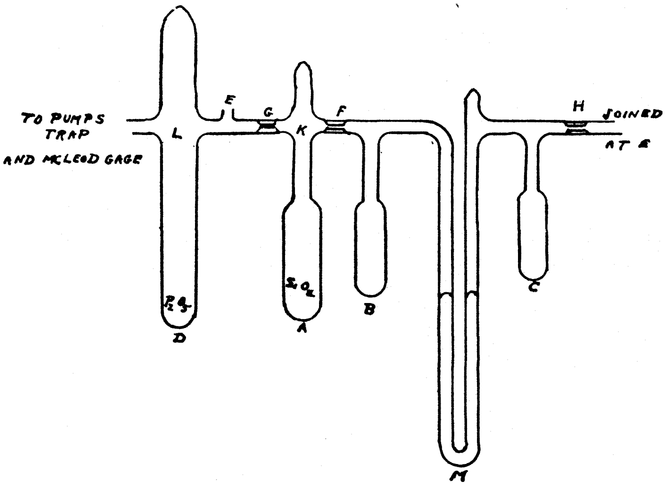

Fig. 1.

After the purified silica gel,[17] activated at 500°, was sealed up in vessel A, tube D was cracked and filled with pure phosphorus pentoxide and benzene, purified by the methods recommended earlier in this paper. Point L was plugged with glass wool to retain the phosphorus pentoxide used for the preliminary drying of the benzene. Tube D was quickly sealed while its contents were frozen with liquid air. The system was then evacuated to 10^{-5} mm. using an oil pump in series with a two-stage mercury diffusion pump. The liquid in D was melted, boiled, frozen with liquid air and opened to the pumps to remove dissolved air. This deaeration was repeated at least three times, or until no further air was removed by the process. The benzene was then distilled from D into vessels B and C simultaneously by immersing them in liquid air and removing the refrigerant from D. The apparatus was then pumped down to 10^{-5} mm. while the silica gel was heated to remove adsorbed liquid. The apparatus was sealed off at H while the pump continued and the silica gel in A was then

[17] Patrick, Frazer and Rush, *J. Phys. Chem.*, 31, 1511 (1927).

heated for half an hour with a large air flame which was kept in constant motion to prevent collapse of **A.** The apparatus was sealed off at G at a pressure of 10^{-5} mm. of mercury. The liquid air was removed from B and C when the silica gel had become cold and the benzene in B was allowed to distil onto the activated silica gel.

This method was used with pure benzene, pure carbon tetrachloride and pure carbon disulfide. With each a decrease in vapor pressure was observed upon drying the liquid with activated silica gel. Out of the nine pieces of apparatus that lasted through the above treatment without breaking, only one failed to manifest a decrease in pressure on the dry side.

Results.—These vapor pressure differences were measured at constant temperatures by means of a cathetometer and were checked to be certain that equilibrium had been attained. The vapor pressure differences observed for one liquid varied somewhat from one apparatus to another, as for example

Liquid	*T*, °C.	AP, mm.
CCl_4	0	3.67
CCl_4	0	3.30

Likewise, the vapor pressure differences varied among the different liquids as is shown by examples in Table I and plotted in Fig. 2. These values were taken at definite points as the temperature of the thermostat was raised from 20 to 50°, and were checked as it was lowered from 50 to 20°.

TABLE I

VAPOR PRESSURE DATA

Liquid (1) Benzene		Liquid (2) Carbon Tetrachloride		Liquid (3) Carbon Disulfide	
T, °C.	AP, mm.	T, °C.	AP, mm.	*T*, °C.	AP, mm.
−80.0	0.0	−80.0	0.0	−180.0	0.0
0.0	3.13	0.0	3.67	0.0	3.35
5.7	5.07	21.8	6.53	10.5	7.00
11.0	5.92	31.1	6.88	14.8	10.20
20.8	7.54	40.8	7.24	16.4	11.92
25.6	8.40	48.3	7.54	18.9	13.84
27.2	8.83			21.0	15.85
34.7	10.33			23.2	18.46
38.3	11.24				
45.5	12.71				
50.6	13.76				

These differences are all of similar order of magnitude and in the same direction as those reported in the De Liefde dissertation,[18] and there were no differences manifested at −180.0 and −80.0°, showing that the systems were air-free and that the differences were not due to dissolved air or gas.

---

[18] W. C. De Liefde, "Dissertation," Amsterdam, 1927,

Experiments with Liquids Dried with Silica Gel.—In the course of the investigation of these liquids dried with silica gel, attempts were made to study the effect of the replacement of water, the "catalyst," which according to the theory of Smits[19] and Baker[20] is removed by prolonged or intensive drying and causes measurable changes in the molecular complexity of certain substances.

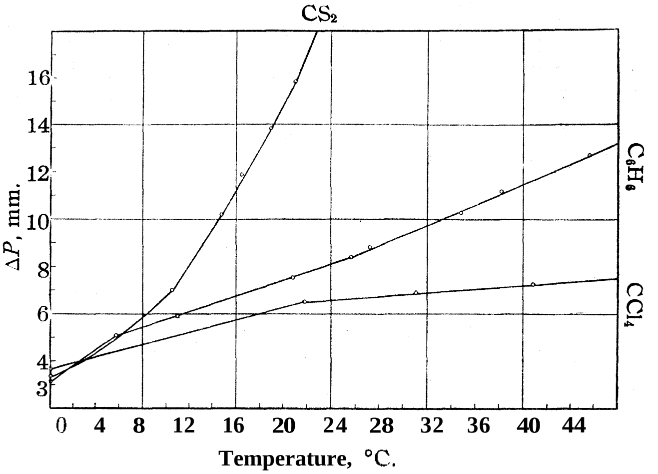

Fig. 2.

In order to effect the addition of moisture to benzene, the silica gel bulb was removed from the dry side of one piece of apparatus which was sealed to a series of bulbs and the pumping system. The mercury manometer had been frozen to act as a seal between the two sides of the apparatus. Silica gel at a saturated vapor tension of 4.5 mm. of water was added to the dry liquid, frozen with liquid air and the system was evacuated. The manometer which should have been level because of the replacement of the "catalyst" showed, however, a pressure difference of roughly 2.5 mm. at room temperature instead of the previous 7 mm. with the dry material alone. After distilling the benzene onto phosphorus pentoxide to remove the moisture and sealing off the silica gel that had been added, the benzene again manifested the previous 7 mm. pressure difference at 20°.

Discussion

The behavior studied in the above experiments in intensive drying indicated no catalytic action, but merely the addition of the partial pressure of water. It strengthened the theory that the difference in vapor pressure was due, not to the catalytic effect of the removal of water from the benzene

---

[19] Smits, *Z. physik. Chem.*, 100, 477 (1922).

[20] Baker, *J. Chem. Soc.*, 949 (1927).

on the dry side, but to the presence of a minute trace of moisture in the benzene on the normal side.

Objections to the above view on the basis of Raoult's law are precluded because that relation demands a large mole fraction of water to produce a partial pressure equal to the pressure differences manifested in this set of investigations where the phenomenon was observed only in liquids in which water is very insoluble, as benzene, carbon tetrachloride and carbon disulfide.

In this work the amount of normal benzene used for comparison with the dried material was very small, varying from one to three grams in the different pieces of apparatus. The solubility of water in benzene at 20° is reported in the "International Critical Tables" as 0.057%. A rough calculation shows that the production at 20° of a partial pressure of 7 mm. of water vapor in one gram of benzene requires only 2.29×10^{-4} g. or 1.27×10^{-5} mole of water. This follows from the relation $P_p/P_s = X/X_s$ where $P_p = 7$ mm., $P_s = 17.363$ mm., the vapor pressure of water, necessary to saturate one gram of benzene at 20°; and $X_s = 0.00057$ g. of water.

However, according to Raoult's law, one gram of benzene requires 9.28×10^{-2} g. or 5.16×10^{-3} mole of water to produce a partial pressure of 7 mm. of water. This concentration of water is 405 times greater than that calculated from the solubility data above.

Moreover, upon analysis of Fig. 2, the curves for carbon disulfide, benzene and carbon tetrachloride seem very definitely to represent the vapor pressure of solutions of water in those liquids. The three curves show that the vapor pressure deviations from the normal are within a close range at 0°. From this point they converged and diverge again according to the extent of saturation and the change in solubility of water in the liquid with increasing temperature. The curve for benzene with its abrupt change in slope at the melting point of benzene is an excellent illustration of the increasing solubility of water in benzene with temperature.

An explanation of the mode of access of the minute quantities of water required to produce the effects may lie in any of several factors. However, it cannot have come from the benzene, which was dried with phosphorus pentoxide and distilled from it. The moisture may have come from the activated silica gel when it was heated before vessel C of Fig. 1 was sealed off, or from the glass during the sealing process.

In either case, the liquid air with which vessel C and its normal contents were frozen is a very powerful dehydrating agent and might easily have condensed a trace of moisture before it reached the pumps. Another source, despite the preheating described, is the deeper seated moisture in the walls of vessel C. This possibility is compatible with the conditions and observations of this investigation, since the vapor pressure difference was not always immediately apparent. It is supported by the investigation of Baker,[21] who by using sodium amalgam in a glass bottle dried at 150° found that bubbles of hydrogen began to appear after two days and concluded that "since these did not appear within twelve hours, their formation could not be ascribed to surface water," but to the deeper seated moisture.

The gradual emerging of the deeper seated moisture may possibly account for some of the vapor pressure differences observed in intensive drying experiments by other investigators. An experiment in which pure, dry air-free benzene was distilled from phosphorus pentoxide onto pure silica gel—originally saturated with water—which had been pumped down to 10^{-4} mm. pressure, showed that the benzene can displace some of the water adsorbed in the gel, for within six hours a steady pressure of 1 mm. was manifest in one case and 1.4 mm. in another case.

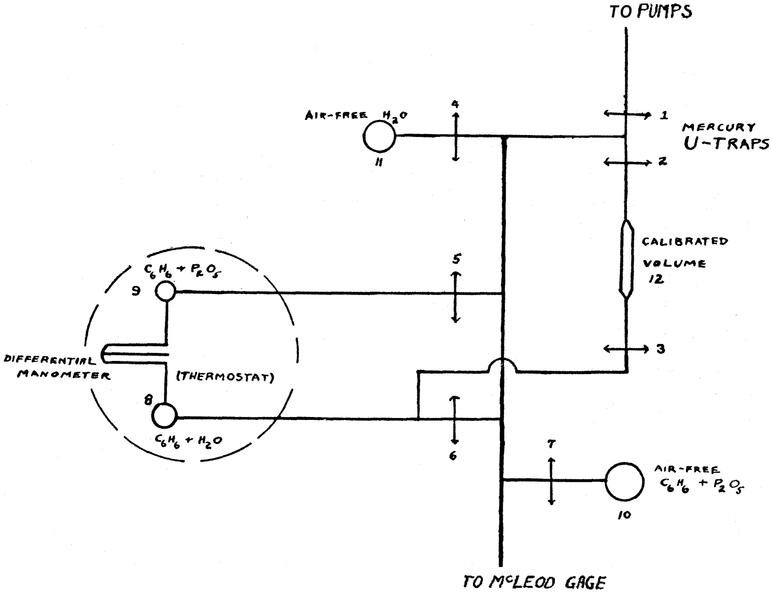

Fig. 3.

Experiments **with** Solutions of **Water** in Benzene.—As a confirmation of the calculations and experiments with silica gel and in an effort to test the theory that the vapor pressure changes observed were due to the presence of minute traces of moisture in the normal liquid instead of to intensive drying effects in the dried material, an apparatus was constructed to measure the change of vapor pressure of benzene with the addition of known amounts of water.

A diagram of the apparatus is shown in Fig. 3. The previous experiments had indicated the need of an absolute as well as a differential manometer which resulted in a three branched instrument, as shown, carefully

---

[21] Baker, *J. Chem. Soc.*, 1663 (1929).

filled in *vacuo* with pure, redistilled, dry, air-free mercury. The air-free water and the air-free dry benzene were prepared by intermittent boiling and pumping the liquids until the residual air pressure could not be measured with the pressure gage. The mercury U-traps (1) through (7) were filled with pure mercury which was boiled out in the trap to remove moisture and air.

The glass was cleaned with chromic acid and washed with distilled water before use and the apparatus was carefully heated all over before being used for the experiment.

The pumping system consisted of a high-vacuum oil pump in series with a two-stage mercury diffusion pump.

The thermostat was constructed elevator style so that the tank could be raised and lowered when large temperature changes were necessary. It was set at 20.89° and with continuous cooling, intermittent heating and rapid stirring was regulated to 0.005°—never more than 0.01°—by a mercoid relay and a metastatic regulator. The thermostat was always kept at least 2.5" cooler than the room in order to prevent condensation outside of the bath.

The volume of vessel (8) was etched in increments of about 1 cc. and was calibrated by weighing water; and calibrated volume (12) was determined directly as 65.578 cc. by use of a gas buret.

Rigidly purified benzene, dried with phosphorus pentoxide was used as the liquid to be studied.

Manipulation and Results.—After the system had been dried out and evacuated to 10^{-5} mm. of mercury, the benzene in storage vessel (10) was frozen with ice and benzene was distilled into vessel (9), containing phosphorus pentoxide, and vessel (8) which were immersed in ice and salt. The vessels were then closed off with mercury traps and the remainder of the system was evacuated to 10^{-5} mm. A preliminary determination of the vapor pressures of the benzene in (8) and (9) at 20.89° showed both to be equal to 7.88 cm., so there was no moisture present at the beginning. Vessel (8) contained 25.635 cc. of pure benzene at 20°.

Water was then added in small quantities, representing about one-tenth of the saturation value, to the benzene in (8) by closing trap (1) and opening the calibrated volume (12) to the air-free water stored in (11) at 25°. After closing the traps and measuring the pressure and temperature of the known volume of water vapor in (12), trap (3) was opened and the water vapor was condensed in (8) which was frozen with a mixture of carbon dioxide and ether. The room temperature during this operation was always 25° or above. Trap (3) was closed and the remainder of the system was evacuated after each addition of water vapor.

The total volume between (8) and traps (3) and (6) was determined from the relation $P_1/P_2 = V_2/V_1$ at 24.2' by condensing water vapor of known pressure and volume (12) into empty vessel (8) by the method described in the preceding paragraph. The volume of liquid benzene was subtracted from this value and the difference was 116.2 cc., the volume of vapor in equilibrium with the liquid. By use of the relation $PV = nRT$ the amount of water present in the vapor and that dissolved in the liquid benzene in the successive solutions was calculated. Equilibrium was attained very slowly.

Results

TABLE II

EXPERIMENTAL DATA

Volume of benzene, 25.635 cc.; volume of vapor, 116.2 cc.; average temperature of vapor, = 22°.

	Total mole H_2O added	Partial press. of Hz0 in mm. at 20.89°	Mole H_2O in vapor	Mole H_2O in benzene
1	8.77×10^{-5}	1.87	1.17×10^{-5}	7.60×10^{-5}
2	1.75×10^{-4}	3.88	2.43×10^{-5}	1.51×10^{-4}
3	2.6×10^{-4}	5.52	3.45×10^{-5}	2.25×10^{-4}
4 & 5	4.27×10^{-4}	9.62	6.1×10^{-5}	3.66×10^{-4}
6 & 7	6.03×10^{-4}	13.22	1.01×10^{-4}	5.02×10^{-4}
8 & 9	7.78×10^{-4}	16.79	$1\ 05 \times 10^{-4}$	6.73×10^{-4}
	Extrapolation	18.33		$7.15 \pm 0.05 \times 10^{-4}$

By extrapolation to 18.33 mm., the vapor pressure of water at 20.89°, the curve shown in Fig. 4 indicates that 7.15×10^{-4} mole of water is required to saturate 25.635 cc. of benzene. When this, saturation value is interpreted in grams, the figure reduces to 0.00057 g. of water per gram of benzene, or 0.057%, which checks the value given in the "International Critical Tables."

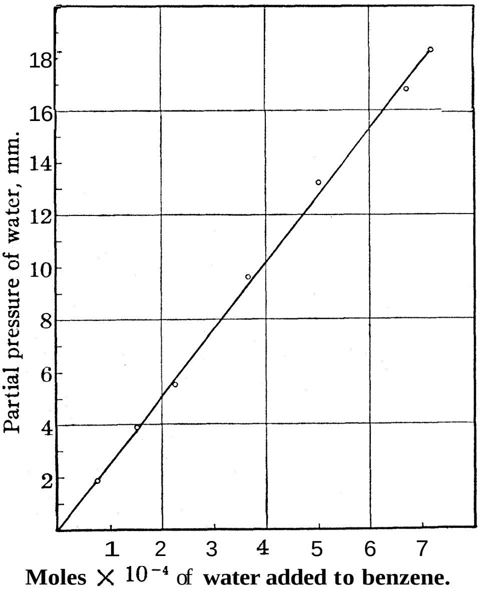

Fig. 4.

From the experimental data presented in Table II and in Fig. 4, it is evident that the solution of water in benzene follows Henry's law rigidly but not Raoult's law. However, the results for benzene at the saturation value and below may be expressed by the equation

$$P = \frac{x}{x_{\text{satd.}}} P_{\text{satd.}} \text{ at constant temperature}$$

where x is mole fraction of water present and $x_{\text{satd.}}$ is mole fraction of water required to saturate the benzene. The average deviation of the observed pressures from this relation is 0.19 mm. pressure or 2.28% of the calculated value.

It seems reasonable to expect that this relation would be fundamental for solutions of water in carbon tetrachloride and carbon disulfide, or for solutions of any two other mutually very insoluble liquids.

In conclusion, the author wishes to express her sincere appreciation to Dr. W. A. Patrick, under whose guidance this problem was completed, and to Dr. J. C. W. Frazer, who in conjunction with Dr. Patrick suggested and cooperated in the investigation.

Summary

1. Benzene free from impurities does not impart color to pure phosphorus pentoxide nor does it form such addition compounds with phosphorus as were described by Giran.
2. Methods have been found that produce benzene free from the usual sulfur compounds of which carbon disulfide has been found to be as undesirable as thiophene, though it is more commonly ignored than the latter.
3. Benzene that has been dried with phosphorus pentoxide in *a* fused glass apparatus for three years has not shown any change in vapor pressure with respect to the normal liquid in the same apparatus.
4. Within twenty-four hours, benzene, carbon tetrachloride and carbon disulfide dried with activated silica gel manifested vapor pressure differences or decreases, as compared with the normal liquids, that were finally comparable in magnitude and direction with those reported by other investigators in the field of intensive drying.
5. Experimental evidence has been submitted and discussed to support the theory that the vapor pressure decreases or differences from the normal may be explained by assuming the presence of minute traces of water vapor in the normal liquid rather than any catalytic effect due to the removal of water from the dried liquid.
6. Calculations from solubility data show that only 0.000229 g. of water is required to produce a partial pressure of 7 mm. of water in one gram of benzene at 20°. This value deviates from Raoult's law, which requires 405 times more water than is actually effective.
7. The partial pressures of solutions of water in benzene at 20.89° have been measured and plotted. Extrapolation of the curve gives a value of the solubility of water in benzene at 20° which checks that given in "International Critical Tables."
8. The relation of the partial pressures to mole fractions in solutions of water in benzene may be expressed by the equation $P = (x/x_{\text{satd.}})P_{\text{satd.}}$.

THE SYSTEM Na_2SO_4–NaF–NaCl–H_2O. I. THE TERNARY SYSTEMS WITH WATER AND TWO SALTS[1]

BY H. W. FOOTE AND J. F. SCHAIRER

RECEIVED JUNE 20, 1930 PUBLISHED NOVEMBER 5, 1930

Before investigating equilibrium relations in the quaternary system Na_2SO_4–NaF–NaCl–H_2O, it was necessary to determine first these relations in each of the three ternary systems of two salts and water. The data for the ternary systems are given here and the data for the quaternary system will be published in Part II.

Sodium sulfate and sodium chloride were purified by the usual methods. Sodium fluoride forms an acid fluoride in the presence of only a small excess of hpdrofluoric acid.[2] To obtain pure sodium fluoride, recrystallized sodium carbonate was dissolved in a small volume of water and neutralized with the smallest possible excess of hydrofluoric acid. After warming to remove carbon dioxide, the solution was cooled and the precipitated sodium fluoride filtered and washed with alcohol. An analysis by conversion to the sulfate and an optical examination with the petrographic microscope checked its purity.

For the determination of solubility isotherms appropriate mixtures of salts and water were placed in hard rubber bottles and shaken at constant temperature in a water thermostat for at least twenty-four hours. A check upon the attainment of equilibrium was made by running duplicate determinations held at constant temperature for longer periods of time. Solutions for analysis were removed through filters of glass wool directly into weighing tubes. Depending on the solid phases present and whether a wet or dry residue was desired, different procedures were followed. The solid phases, or "residues," which were in equilibrium with the solutions, were either pressed between filter papers until dry, or washed quickly with alcohol on a Gooch crucible and then dried between filter papers. Both methods have disadvantages, and in general it is not possible to obtain the composition of the residues as accurately as that of the solutions. In some cases wet residues were analyzed and the composition of the solids determined by the graphic method of Schreinemakers.[3]

In the analysis of solutions and solids, sodium chloride was determined by titration with silver nitrate solution, using potassium chromate as the indicator. The determination of sulfate as $BaSO_4$ is entirely unreliable in

---

[1] The data presented in this paper constitute a portion of a Dissertation presented to the Graduate School of Yale University by J. F. Schairer, in partial fulfilment of the requirements for the degree of Doctor of Philosophy, June, 1928.

[2] Jehu and Hudleston, J. Chem. *Soc.*, **125**, 1451–1456 **(1924).**

[3] Schreinemakers, *Z. physik.* Chem., **43**, 307 (1903).

the presence of fluorides. Sodium fluoride was determined by converting the salts to sodium sulfate with sulfuric acid and igniting in a current of air containing ammonia, and sodium sulfate determined by difference. On account of the considerable difference between the equivalent weights of sodium fluoride and sodium sulfate, this method of indirect analysis is much more accurate than is commonly the case with indirect methods. The formula used in calculating the weight of sodium fluoride is: $x = 1.4468 (b - a) - 0.3113 c$, in which a, b and c represent, respectively, the weight of mixed salts, the weight of sodium sulfate after the conversion of chlorides and fluorides to sulfate, and the weight of sodium chloride.

Eutectic points with ice as one of the solid phases were determined in a small vacuum-jacketed flask, by shaking a mixture of wet crushed ice with an excess of the salt or salts in question. After removal of a sample of the solution for analysis, more of each solid phase was added and the temperature again observed. The thermometers were calibrated with care and the eutectic temperatures are probably in error by not more than 0.1'. Transition temperatures were determined by the same general method as eutectic temperatures.

The System Na_2SO_4–NaF–H_2O.—In the system Na_2SO_4–NaF–H_2O a double salt $Na_2SO_4 \cdot NaF$ forms. Wolters[4] found this double salt at high temperatures in his investigation of the fusion relations in the ternary system Na_2SO_4–NaF–NaCl. Below a transition temperature (17.5') the double salt breaks down into sodium fluoride and the decahydrate of sodium sulfate. Above the transition temperature of sodium sulfate (32.38°), a solubility isotherm consists of three branches meeting in two univariant points at which two solid phases (sodium fluoride and double salt or sodium sulfate and double salt) are in equilibrium. The transition temperature of sodium sulfate decahydrate in the presence of the double salt (32.36') is almost identical with that of the pure decahydrate, on account of the slight solubility of sodium fluoride. Between 32.36° and the transition point of the double salt (17.5°), a solubility isotherm consists of three branches, with sodium sulfate present as the decahydrate. Below 17.5°, an isotherm consists of two branches meeting at a point where the two single salts coexist as solid phases. The solubility data obtained at four temperatures are given in Table I. Where less than 0.1% of a salt was found in solution it is reported as a trace (tr.).

The solid phases present in the residue were determined in the usual manner by plotting the composition of solutions and residues on an equilateral triangle. The nature of the solid phases was checked by an examination with the petrographic microscope. The identity of the solid phase or phases in equilibrium with a given solution is noted in Table I. Ds indicates the double salt $Na_2SO_4 \cdot NaF$.

[a] Wet residue analyzed. [b] Ds = $Na_2SO_4\cdot NaF$ (double salt).

The data for eutectic and transition temperatures are given in Table II. The two eutectics with ice and a single salt have been determined before.[5]

---

[5] Guthrie, *Phil. Mag.*, **6**, 40 (1878); De Coppet, Z. *physik. Chem.*, 22, 239 (1897); Chretien. *Caliche*, 9, 248 (1927).

The transition point where the solid phases are $Na_2SO_4\cdot 10H_2O$, NaF and $Na_2SO_4\cdot NaF$ is somewhat difficult to obtain. Solubility isotherms indicated that this transition temperature was between 15 and 25°. A mixture of sodium fluoride, decahydrate of sodium sulfate and a small amount of the double salt $Na_2SO_4\cdot NaF$ and water was placed in a vacuum flask at 21° and the temperature observed. The temperature slowly dropped, finally remaining constant for several hours. The reverse of this determination, starting below the transition temperature, did not give a sharp result.

TABLE II

EUTECTIC AND TRANSITION TEMPERATURES—SYSTEM Na_2SO_4–NaF–H_2O

Solid phases	Temp., °C.	Solution % Na_2SO_4	Solution % NaF	Corresponding point in the diagram (Fig, 1)

[a] "International Critical Tables," 1926, Vol. I, p. 66. [b] *Ibid.*, 1928, Vol. III, p. 371.

These data cannot be properly shown as a projection on a triangular base. The results are, therefore, represented in a space figure (Fig. 1),

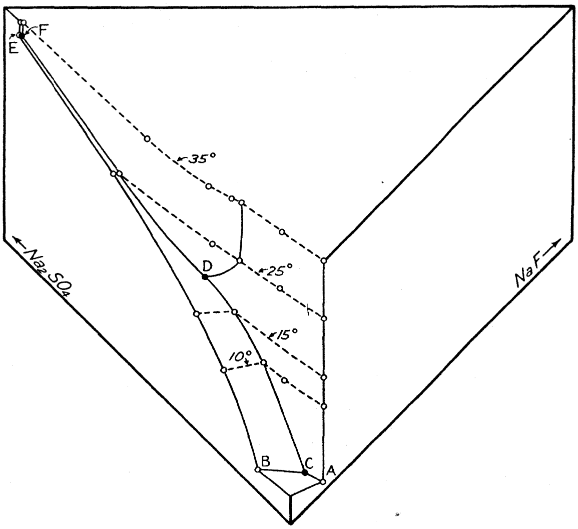

Fig. 1.—System Na_2SO_4–NaF–H_2O. Space model.

plotting temperatures vertically from a triangular base. The eutectic and transition temperatures (Fig. 1) are lettered to correspond with the data in Table II. Solubility isotherms are represented as dotted lines. The results given in the tables for invariant and univariant points have been averaged for representation in Fig. 1.

The Double Salt $Na_2SO_4 \cdot NaF$.—The double salt $Na_2SO_4 \cdot NaF$ was first described by Marignac[6] who obtained it by evaporation of the mother liquor from a preparation of sodium fluoride with hydrofluoric acid containing some sulfuric acid. He describes it as occurring in hexagonal plates twinned parallel to the base. The crystals were a combination of the base and four rhombohedrons. The crystals gave poor signals on the goniometer. Marignac assigns the crystals with some doubt to the rhombohedral class of the hexagonal system.

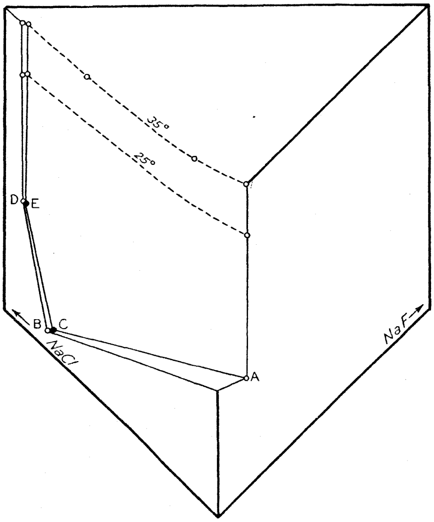

Fig. 2.—System NaF–NaCl–H_2O. Space model.

Wolters[7] prepared the double salt from water solution at 35° and claims that it is pseudo-hexagonal up to 105° (±2°), where it becomes hexagonal. This transition temperature is above the range of temperatures studied by us.
