Crystals of the double salt were prepared by isothermal evaporation at 35°. Five crystals were measured on a two circle goniometer. The crystals appeared bright and sharp but did not give good signals. The crystals are tabular with hexagonal outline and decided trigonal symmetry. The base is rough and the other faces, although very definite, usually gave many goniometric signals in the zone with the base. Twinning on the base is common. The results of our measurements on five crystals give

$$c = 1.77$$
$$(0001) \wedge (10\bar{1}1) = 63.9°; \quad (0001) \wedge (01\bar{1}2) = 45.7°$$
$$(0001) \wedge (03\bar{3}2) = 72.0°$$

The double salt $Na_2SO_4.NaF$ is uniaxial, optically positive, $\epsilon_{Na} = 1.430$, $\omega_{Na} = 1.436$ with a cleavage parallel to (0001).

The System NaF–NaCl–H_2O.—The solubility isotherms at 25 and 35°, taken in connection with the composition of the residues, show that no double salt forms and that solid solution, if present, is too slight to be

detected. The transition temperature of sodium chloride dihydrate has been determined repeatedly by others, though the results in the literature do not agree closely. We found it sharp and easily obtained. Sodium fluoride lowers this transition temperature but slightly on account of its slight solubility in the presence of sodium chloride.

The results obtained are given in Tables III and IV and are represented in Fig. 2.

Summary

Solubility determinations were made on the ternary system Na_2SO_4–NaF–H_2O at 35, 25, 15 and 10°, and on the ternary systems NaF–NaCl–H_2O and Na_2SO_4–NaCl–H_2O at 35 and 25°. The necessary eutectics and transition temperatures were determined to define each ternary system between its ternary eutectic and 35°. These data are presented by tables and graphically by space models.

The nature and identity of the various solid phases was checked with the petrographic microscope. The crystallographic and optical properties of the double salt $Na_2SO_4 \cdot NaF$ were measured.

THE SYSTEM Na_2SO_4–NaF–NaCl–H_2O. II. THE QUATERNARY SYSTEM AT 25 AND 35°[1]

BY H. W. FOOTE AND J. F. SCHAIRER

RECEIVED JUNE 20, 1930 PUBLISHED NOVEMBER 5, 1930

The quaternary system Na_2SO_4–NaF–NaCl–H_2O is derived from three ternary systems, each composed of two of the above salts and water. The data on these three systems were presented in the first part of this paper.[2] At a given temperature, proceeding from each univariant point in these systems, where two solid phases coexist, there is a solubility curve ending at a point where a third solid phase appears. We have determined the solubility relations and the solid phases for the quaternary system at the temperatures 25 and 35°.

The chief experimental difficulty in the investigation was to obtain the gross composition of the residues, because it is impossible to free them entirely from solution. At 35°, since all the solids are anhydrous, it was possible to filter the solids rapidly on a warmed Gooch crucible, after removing a sample of the solution for analysis. The solids were washed quickly with alcohol and dried between filter papers. At 25°, except where noted, we analyzed wet residues. Since the composition of the solution is known, the gross composition of the solid residues may be calculated.[3] By making a sufficient number of such determinations, it is possible to decide whether one is at a univariant point (with three solid phases and constant solubility) or on a divariant curve (with two solid phases and varying solubility). We made use of the optical properties of the crystals to determine qualitatively the number and kind of solid phases as a check on the analytical data.

The results are given in Table I. The composition of the residue free from mother liquor is given in all cases, whether determined directly by analysis or calculated after analysis of solution and wet residue. Sodium fluoride is only slightly soluble in the more concentrated solutions of sodium sulfate and chloride. Whenever less than 0.1% was found, it is reported as a trace.

To show the results in a diagram, we have plotted the solubilities of the three salts along three axes which make an angle of 120° with each other. In ternary systems it is convenient to represent isotherms in an equilateral triangle in which composition of both solutions and residues may be plotted.

14	7.71	0.69	6.98	77.17	22.83	None	Ds

[a] Ds = double salt $Na_2SO_4 \cdot NaF$. (This is capable of taking up a limited amount of NaCl in solid solution which replaces an equivalent quantity of NaF. The pure double salt contains 77.18% Na_2SO_4.)

[b] This residue was air dried for analysis. The others were analyzed wet and the composition of the dried residues, as given in the table, was calculated.

However, in a quaternary system, it is not feasible to represent the composition of both solutions and residues by a single diagram. We have therefore represented the composition of residues by means of a separate triangular diagram used in conjunction with the solubility diagram to show the relations of residues to their solutions. This is entirely satisfactory when the residues are anhydrous, which is the case at 35°. At 25° this method of representing residues cannot be used, as both anhydrous Na_2SO_4 and $Na_2SO_4 \cdot 10H_2O$ are present.

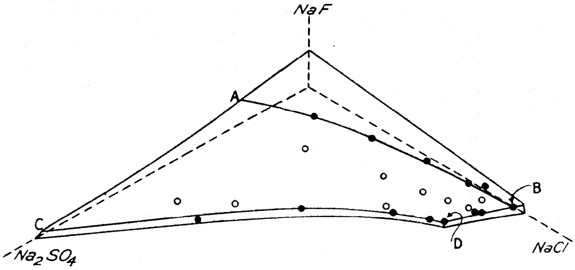

Fig. 1.—System Na_2SO_4–NaF–NaCl–H_2O. Solubility isotherm at 35°.

The solubility data are plotted in Figs. 1 (35° isotherm) and 2 (25° isotherm). At univariant points, the average result of the several determinations is represented. Some univariant points taken from the ternary systems have been displaced outward slightly to make the diagram clear, since they almost coincide with the corresponding quaternary points.

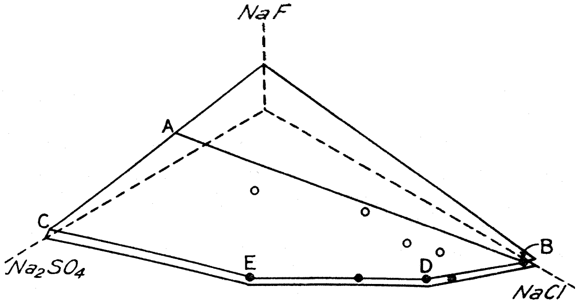

Fig. 2.—System Na_2SO_4–NaF–NaCl–H_2O. Solubility isotherm at 25°.

At 35° (Fig. 1) the double salt (in which some NaCl replaces NaF) is stable throughout the area ABDC. The solubility results obtained in this area (Nos. 17–25 in Table I) are plotted as circles. At the univariant points B and D, three solid phases coexist in equilibrium with solution. Univariant points and points on the three curves are plotted as black dots. At 25° (Fig. 2), the relations are similar but an additional univariant point E exists, where the solid phases are double salt, Na_2SO_4 and $Na_2SO_4 \cdot 10H_2O$.

At this point the double salt contains no appreciable amount of NaCl. Only a few determinations were made at 25°, since the general relations were already clear.

The residues at 35°, so far as they contain all three salts, are plotted in Fig. 3. In considering this diagram, it must be remembered that the double salt can take up a limited amount of chloride in solid solution, which replaces an equivalent amount of fluoride. This replacement only becomes appreciable in the presence of considerable amounts of sodium chloride in solution. (Nos. 22–25 of Table I.) The composition of the double salt is therefore variable and represented by the line ABC. The maximum amount of solid solution, represented by C, is not accurately known, but is undoubtedly a function of temperature. The solution yielding the maximum is very probably at the univariant point where the solid phases are Na_2SO_4, NaCl and double salt. In the table of data at 35° (Table I), Nos. 17–21 contain little or no chloride in the double salt and their composition falls very close to the point A of Fig. 3. The other residues consisting of double salt showing appreciable solid solution (Nos. 22–25, Table I) are plotted. Two of them are somewhat off the line AC, showing that these were slightly contaminated with sodium chloride from the solution, though their solubility shows quite definitely that but a single phase was present. The areas ACD, ABE and BCF (Fig. 3) correspond to mixtures of Na_2SO_4 with double salt, NaF with double salt and NaCl with double salt, respectively. The numbered points refer to the numbers in Table I at 35°.

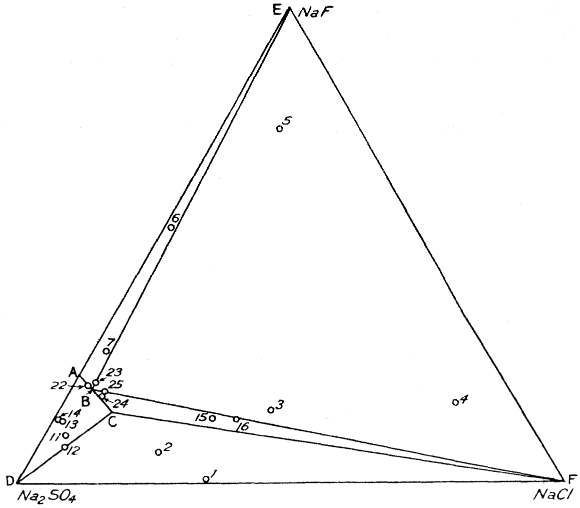

Fig. 3.—Composition of solid phases in equilibrium with solutions at 35°.

The residues in equilibrium with solutions at 25° show the same general relations. Complete representation of the residues on an equilateral triangle is not possible because anhydrous Na_2SO_4 and $Na_2SO_4 \cdot 10H_2O$ are present in some mixtures.

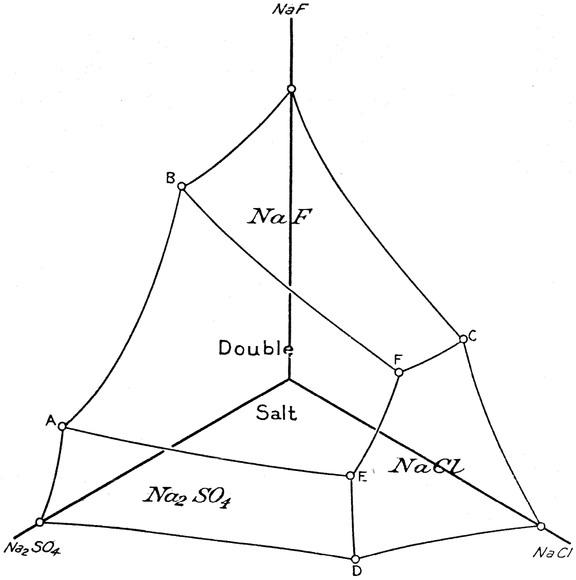

Fig. 4.—Hypothetical quaternary isotherm assuming that no triple salt appears.

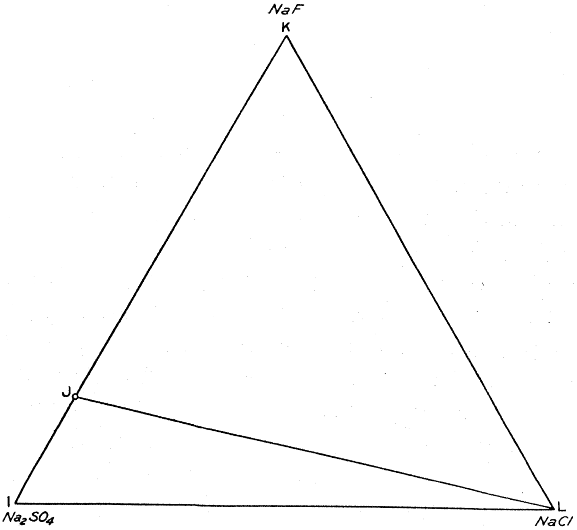

Fig. 5.—Composition of solid phases in equilibrium with solutions of Fig. 4.

There was a strong probability at the outset of the work that the mineral sulfohalite ($2Na_2SO_4 \cdot NaCl \cdot NaF$) might appear as one of the solid phases at the temperatures investigated. If this had appeared, it should be one of the solid phases in a portion of the area ABDC (Fig. 1). Then at the point B and possibly at D it would be one of the three solid phases. There would also be two other univariant points each with three solid phases and the corresponding divariant curves. It can be shown by considering the relation between solutions and residues that the solid phase $2Na_2SO_4 \cdot NaCl \cdot NaF$ did not appear at the temperatures investigated and that the solid phase in the area ABDC (Figs. 1 and 2) of the two investigated isotherms is not pure double salt $Na_2SO_4 \cdot NaF$ but a solid solution in which a limited part of the fluoride is replaced by chloride.

Let us assume that no triple salt appears in the quaternary system and that only the double salt $Na_2SO_4 \cdot NaF$ (with no solid solution) and the three single salts appear. Then the hypothetical solubility relations at some constant temperature are represented diagrammatically in Fig. 4. The assumed values for solubilities used to prepare Fig. 4 were so chosen as to prevent crowding of lines and points for clarity in presentation. Then the residues in equilibrium with such solutions may be shown on an equilateral triangle, Fig. 5. J represents the composition $Na_2SO_4 \cdot NaF$. If the assumed solubility relations were correct, all residues whose composition lay in the area IJL (Fig. 5) should have the same solubility (represented by E of Fig. 4) and similarly all those in the area JKL (Fig. 5) should have the solubility represented by F (Fig. 4).

By examining the actual data given in Table I and presented graphically in Figs. 1, 2 and 3, we find that the experimental data do not fit the assumption we have made.

If we assume that a triple salt $2Na_2SO_4 \cdot NaCl \cdot NaF$ appears and that the other solid phases in the quaternary system are pure double salt $Na_2SO_4 \cdot NaF$ and the single salts, these hypothetical relations can be shown diagrammatically in Fig. 6 (assumed values chosen to prevent crowding in the figure). The composition of all residues may be shown in Fig. 7. J represents the composition $Na_2SO_4 \cdot NaF$ and M the composition $2Na_2SO_4 \cdot NaCl \cdot NaF$. If the assumed solubility relations were correct, all residues whose composition lay in the areas IJM, JMK, MKL and IML (Fig. 7), respectively, would have the solubilities H, G, F and E (Fig. 6), respectively.

Again, examining the actual data given in Table I and presented graphically in Figs. 1, 2 and 3, we find that the experimental data are not in accord with the assumption made.

The experimental data show that at the temperatures investigated no triple salt forms and that in the quaternary system the double salt $Na_2SO_4 \cdot NaF$ has a limited part of its fluoride replaced by chloride. This fact was confirmed by microscopic examination. The replacement of fluoride by chloride raises the indices of refraction of the double salt.

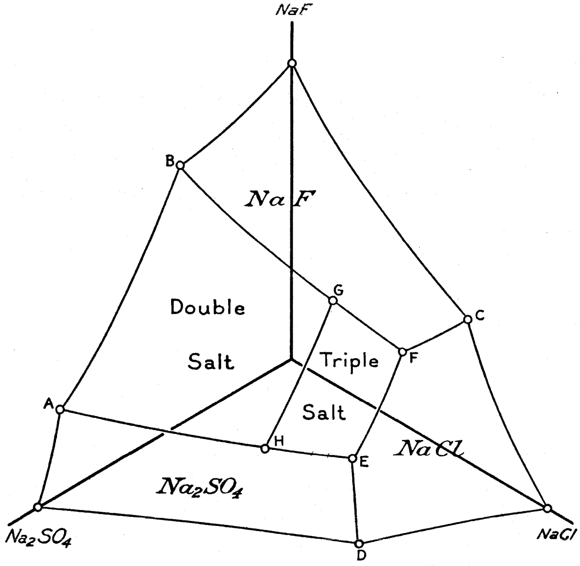

Fig. 6.—Hypothetical quaternary isotherm assuming existence of a triple salt $2Na_2SO_4 \cdot NaF \cdot NaCl$.

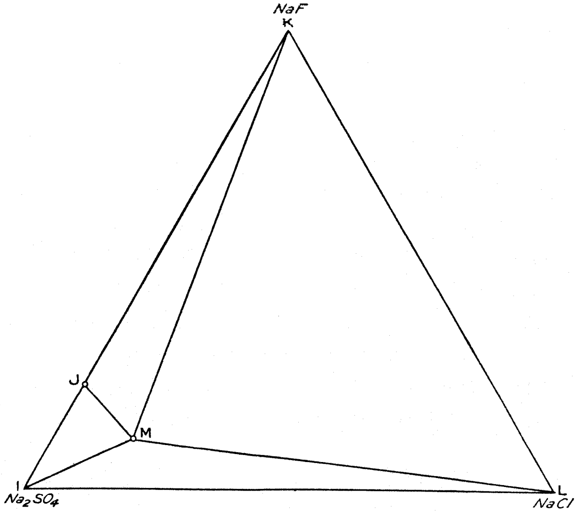

Fig. 7.—Composition of solid phases in equilibrium with solutions of Fig. 6.

In two cases after equilibrium had been reached at the points B and D (Figs. 1 and 2), we introduced a small amount of the natural mineral (sulfohalite $2Na_2SO_4 \cdot NaF \cdot NaCl$ from Searles Lake, California) into the equilibrium bottles, which were again shaken at constant temperature. This was done to overcome any possible metastable condition and was without effect on the solubility or nature of solid phases present.

Sulfohalite.—We obtained several small crystals of the natural mineral, sulfohalite, from the U. S. National Museum (Museum No. 93,659). These crystals from Searles Lake, California, all proved quite unsuitable for chemical study owing to the very numerous and well distributed tiny laths and grains of an impurity. The sulfohalite crystals were sharp octahedrons, optically isotropic, $n_{Na} = 1.454$. Sulfohalite is undoubtedly a distinct mineral. It is well crystallized and optically distinct from all other mineral species. Both Penfield[4] and Gale and Hicks[5] give its composition as $2Na_2SO_4 \cdot NaF \cdot NaCl$. It might be supposed that the mineral represented an extreme case of solid solution in which the replacement of fluoride by chloride was by chance 1:1. The mineral, however, is isometric while the solid solution is hexagonal rhombohedral. It seems very unlikely that sulfohalite might appear at a transition temperature above 35°, since Teeple[6] has shown that the brine which permeates the entire salt deposit at Searles Lake is uniformly at 23° throughout the year. Our isotherms show no indication of the mineral between 25 and 35°. If it exists in stable equilibrium, it is likely that this can only be the case below 25°, which can be determined by further isotherms at lower temperatures.

Summary

Solubility isotherms for the quaternary system Na_2SO_4–NaF–NaCl–H_2O have been determined at 25 and 35°. At these temperatures, the double salt $Na_2SO_4 \cdot NaF$ forms a solid solution in which fluoride is replaced by chloride to a limited extent.

No indication of the mineral sulfohalite $2Na_2SO_4 \cdot NaF \cdot NaCl$ has been obtained at these temperatures.

A graphic method has been developed to show the relation of the composition of anhydrous solid phases to the solutions in equilibrium with such phases in quaternary systems composed of water with three salts containing a common ion.

New optical and crystallographic data are recorded for the compound $Na_2SO_4 \cdot NaF$.

THE HEATS OF DILUTION OF POTASSIUM CHLORIDE IN SUCROSE AND UREA SOLUTIONS AS SOLVENTS BELOW 0.1 M AT 25°[1]

BY E. LANGE AND A. L. ROBINSON

RECEIVED JULY 8, 1930 PUBLISHED NOVEMBER 5, 1930

Introduction

With the use of a sensitive differential calorimeter,[2] the integral heats of dilution of a number of strong electrolytes in water in the concentration range 10^{-1}–10^{-5} M have been measured in this Laboratory.[3] The thermodynamic usefulness of such quantities is illustrated, for example, in Latimer's treatment of the problem of aqueous ionic entropies.[4] For an exact comparison of the measurements with theoretical heats of dilution[5] calculated in accordance with the Gronwall, La Mer and Sandved[6] development of the fundamental theory of activity coefficients of Debye and Hückel,[7] an exact knowledge of dD/dT for the solvent is necessary. Unfortunately, the measurements at hand, even for water, show such discrepancies among the different series of results that such a comparison is at present somewhat uncertain.[8] The experimental results obtained with a number of 1–1 type salts may be summarized as follows: (a) the integral heat of dilution (V_c) is positive and is proportional to the square root of the concentration (expressed in moles of salt per liter of solution) from the most extreme dilution up to a concentration of about 0.01 M on the average; (b) the different salts have individual slopes in this concentration range $(V_c = A\sqrt{c})$, the individuality persisting down to the lowest measured concentration; (c) the values of the initial slopes A range from 280 to 430, which values correspond to 'a' values (apparent ionic diameters) of a reasonable order of magnitude, although, as mentioned, the uncertainty in the dD/dT value does not permit a more definite evaluation of these parameters.

It was thought of interest to extend these measurements to non-aqueous

solvents where from all theoretical considerations the dielectric constant and dD/dT for the solvent in question should be the influencing factors in determining the values of the integral heats of dilution. The experimental difficulties are not much greater than in the case of aqueous solutions and it is intended to carry out such measurements in the near future. There is also the possibility of using as solvents aqueous solutions of non-conducting substances which alter the dielectric constant and dD/dT of water. In comparing the results obtained with aqueous solutions with the demands of the theory, the D and dD/dT values for pure water have been used; a justification for this usage has been shown by Debye and Pauling.[9] By the use of solvents such as those used in these measurements, it was hoped to bring further evidence to test whether the dielectric properties of the medium are the constants to be used for dilute salt solutions. In this paper are reported measurements of the integral heats of dilution of potassium chloride in a 15 weight per cent. aqueous solution of sucrose and a 5 weight per cent. aqueous solution of urea; for these two solvents there are dielectric constant and dD/dT measurements by Kockel.[10]

Experimental Results

Materials.—The potassium chloride was a de Haen guaranteed pure preparation which after drying was used without further purification. Previous experience with this salt had shown that traces of impurities did not influence the measured heats of dilution beyond the calorimetric error of ±2%. A fresh solution was prepared for each new concentration measurement.

Ordinary lump sugar was found to give results indistinguishable from a Kahlbaum preparation for thermochemical determinations and was, therefore, used for most of the sugar solution measurements.

The urea used was partly a pure preparation from Kahlbaum, and for a portion of the measurements a doubly purified preparation from de Haen. The two gave entirely concordant results.

Measurements.—For details of procedure in carrying out the measurements we refer the reader to previous publications.[11] The metal pipets containing the solution to be diluted had, respectively, volumes of 24.6 ± 0.1 cc. in the left half (l) of the calorimeter and 24.9 ± 0.1 cc. in the right half (r). The calorimeter halves were filled with 800 cc. (l) and 810 cc. (r) of solvent. After the solutions in both halves had been diluted, the pipets were pumped out and refilled with the same solution, so that so-called "second dilutions" could be carried out. As the concentrations in Tables I and II show, the end concentration after a "second dilution" was, with sufficient exactness, the same as the end concentration after a "first dilution" with a solution of double initial concentration, so that all measurements could be plotted on a common curve, practically without interpolation. Column 4 in the same tables shows the heat given to the opposite half—since all dilutions produced an evolution of heat—as compensation by electrical heating during the dilution, so that the temperature difference between the two calorimeter halves could be kept as small as possible. Column 6 gives the uncertainties in the

errors which may have been present. The latter may take the form of absorption heats, but from various considerations[12] we believe that such disturbing factors were not present. Moreover, the inner walls of the Dewar vessel were covered with a thin layer of pure vaseline. Controls in the form of blank runs repeatedly gave a zero galvanometer deflection when both pipets (filled with solvent or with the same solution that was contained in the calorimeter) were opened simultaneously. The sensitivity of the galvanometer was 0.0007 cal. per mm. of deflection or about 8×10^{-7}° per mm.; a greater sensitivity was not required for these measurements. The average reproducibility of the individual measurements was ±0.0004 cal., corresponding to about 4.5×10^{-7}°.

From the experimental data curves were plotted which showed, below 0.008 M, a proportionality with $\sqrt{c}$ within the limit of experimental error, and which were therefore extrapolated linearly to $c = 0$. The A values obtained by extrapolation are 386 ± 3% for the 15% sugar solution as solvent and 332 ± 3% for the 5% urea solution as solvent, as compared with 376 ± 3% for potassium chloride in pure water.[13] From the smooth curves the values for the integral heats of dilution given in Table III were ob-

[13] Lange and Leighton, ibid., 34, 566 (1928).

tained. These values we believe to be exact to within ±2% plus an additive uncertainty of 0.5 cal. introduced by the extrapolation.

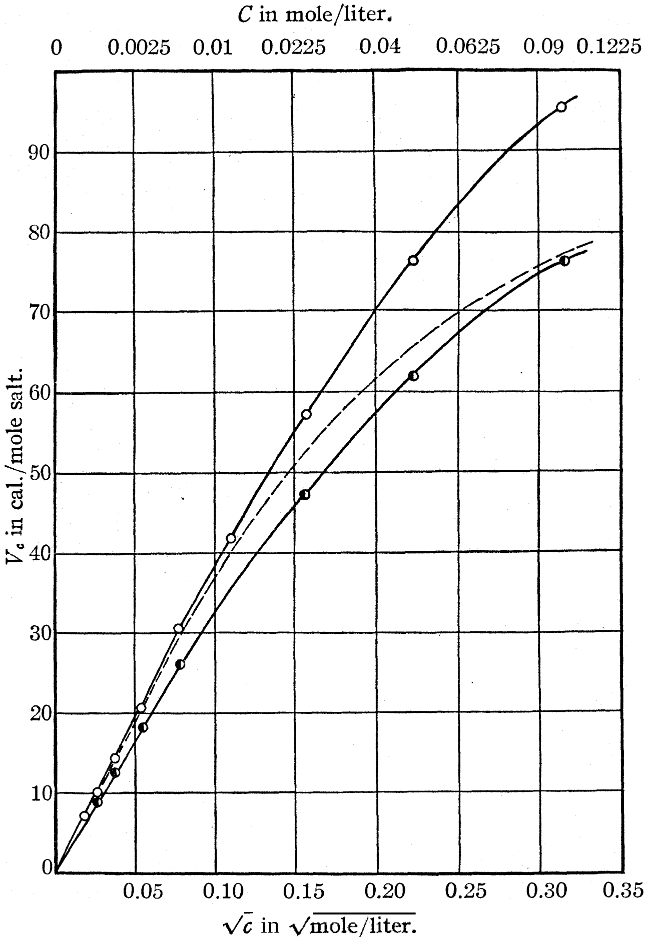

Fig. 1.—○, 15% sucrose; ◐, 5% urea; — — — —, water.

Discussion of Results

At first glance it is seen that the two measured dilution curves are entirely similar in their general nature to the previously obtained curves for potassium chloride and other 1–1 type salts in water; there is the same initial linearity with $\sqrt{c}$ and the initial slopes correspond well with the values mentioned above. However, the differences between the curves for the sugar and urea solutions as solvents and that for pure water, partly at low concentrations and partly at higher concentrations, are real and entirely outside of the experimental error. In the case of the sugar solution there is considerable evidence[14] to indicate that the sucrose molecules are hydrated, probably with approximately six water molecules, and the higher heats of dilution of the potassium chloride in this solvent might be explained as being caused by an increase in the potassium chloride concentration due to the removal of (6 × moles of sucrose) moles of water. A simple calculation shows that this explanation is inadequate, accounting at the most at a potassium chloride concentration of 0.1 M for but 10% of the observed difference. From the classical point of view another possible explanation is that the dielectric constant of this solution is, according to Kockel's measurements, about 5% lower than that of pure water and that if in these dilute solutions undissociated potassium chloride molecules are present, a larger number of such molecules might be expected in the solvent of lower dielectric power, accounting for the more positive values of V_c. But this explanation demands a positive dissociation heat for potassium chloride, which does not agree with the case for potassium chloride in pure water, where the effect of the hypothetical association at higher concentrations is to produce more negative heats of dilution.

There is also the possibility to consider of compound formation between the ions and the sugar or urea molecules, similar to the more or less stable binding of water molecules by the ions. In terms of the interionic theory this could be interpreted as a change—very likely an increase—in the '*a*' value for potassium chloride. A further discussion of this possibility does not seem possible in view of the lack of experimental facts.

Assuming that such effects are not present, an explanation for the experimental curves, not explainable by hydration of the sucrose molecules or an increased association of the potassium chloride, may be sought in a consideration of the dielectric properties of the solvents.

The relation of the initial slope ***A*** to the dielectric properties of the medium (limiting Debye–Hückel case) is shown by the equation

$$V_c = -1.66116 \times 10^7 \times 1/D \times 1/\sqrt{DT}(1 + T/D\ dD/dT)\sqrt{c} = A\sqrt{c}\ \text{cal./mole of salt}$$

Plotting Kockel's data, we have obtained the following values at 25°: for a 15% sugar solution D = 74.25 and dD/dT —0.38, for a 5% urea solution D = 82.8 and $dD/dT = -0.20$. The calculation of ***A*** gives +532 for the sugar solution and —228 for the urea solution as compared with +661 for pure water (again using Kockel's measurements for the sake of comparison). The great sensitivity of the factor $(1 + T/D \times dD/dT)$ to small changes or uncertainties in dD/dT makes impossible any certain decision in the case of the sugar solution, and water curves but, if Kockel's values for the urea solution are even only approximately correct, we should get a curve with a negative instead of a positive slope. The evident contradiction in this case could be avoided by using the D value for water, and

---

[14] McBain **and** Kistler, *J. Phys. Chem.*, **33,** 1806 (1929).

not the D for the urea solution. On the other hand, there has been no doubt as yet in investigations of the activity coefficients of strong electrolytes in non-aqueous solvents that the D value of the particular solvent should be used.[15] Accordingly we should use the dielectric constants of these two solutions in question and in view of the unexplainable discrepancy in the case of the urea solution we might conclude that there is an error in the measured dD/dT value, although Kockel reported reproducible measurements in the temperature range 5–35'. The question seems to be interesting enough to warrant further accurate measurements of dD/dT for aqueous solutions of non-conducting substances, at least relative to the value for water, since the corresponding heat of dilution measurements can be made accurately and without great difficulty.

We thank the Notgemeinschaft der Deutschen Wissenschaft and the Kaiser Wilhelm Institut für Physik for their support in this work through the furnishing of necessary apparatus. One of us (A. L. R.) was on leave of absence from the University of Pittsburgh during the course of this work.

Summary

The integral heats of dilution of potassium chloride in a 15% sucrose solution and a 5% urea solution as solvents have been measured in the concentration range 10^{-1}–10^{-4} M at 25° with an exactness of ±2% plus an added uncertainty of 0.5 cal. introduced by the extrapolation to infinite dilution.

The curves are of the same general nature as those obtained for a number of 1–1 type salts (including potassium chloride) in water, but the deviations from the curve obtained for potassium chloride in pure water throughout the entire measured concentration range are outside of the limit of error.

It does not seem possible to explain these deviations in terms of concentration or association effects (if the formation of compounds between potassium chloride and sucrose or urea molecules is excluded). The differences are possibly due to the different dielectric properties of the solvents used, although uncertainties in the values of these constants make an exact comparison impossible.

THE IGNITION OF CARBON MONOXIDE–OXYGEN MIXTURES: THE EFFECT OF IMPURITIES

BY A. KEITH BREWER AND W. EDWARDS DEMING

RECEIVED JULY 16, 1930 PUBLISHED NOVEMBER 5, 1930

Introduction

In a previous communication[1] it was shown that when a $2CO–O_2$ mixture was ignited by a condensed discharge a hyperbolic relationship existed between the gas pressure and the condenser voltage, i. e.,

$$V = k/P \qquad (1)$$

where V is the minimum voltage necessary for flame propagation and P is the pressure of the explosive mixture. The effects of various impurities on the ease of ignition were also discussed and an attempt was made to establish a mathematical relation between the amount of impurity and the energy of ignition.

In the present paper it is proposed to extend the hyperbolic relation between voltage and pressure to other explosive mixtures and to establish a more exact mathematical relation between the quantity of impurity present and the ignitibility of the gas.

Finch and Cowen[2] have shown that the ignition current in a $2H_2–O_2$ mixture is a hyperbolic function of the pressure over an appreciable pressure range. From this they drew the conclusion that "ignition is determined solely by the attainment in some portion of the gas traversed by the discharge of a certain definite concentration of suitable ions or electrically charged particles."

The study of the effect of impurities on the ignitibility of explosive mixtures has largely been confined to that of water vapor on the $2CO–O_2$ mixtures. This problem has been investigated by W. A. Bone and his co-workers[3] who have shown that as water vapor is progressively removed the ignitibility rapidly diminishes, the minimum spark energy for a mixture dried with calcium chloride being about thirty-fold that required to ignite the same mixture when saturated with water. They have also shown that gas dried for a year over phosphorus pentoxide is ignitible in a sufficiently powerful condensed discharge although the reaction does not go to completion.

Apparatus

The type of apparatus used in these researches was briefly described in the former article. It consisted of an explosion chamber of 56 cc. capacity which was connected

to separate gas trains, one for the admission of the moist or dried $2CO-O_2$ mixture, and the other for the admission of the various impurities tested.

Open-end mercury manometers were used to determine the gas pressures. A McLeod gage was unsuitable since most of the impurities tested were vapors. The glass walls of these manometers can be kept clean by admitting hydrogen to the system from time to time and then passing an electric discharge from the mercury to a suitably placed auxiliary electrode. The H_2^+ ions and atoms formed in the discharge readily reduce the oxides contaminating the walls.

A Hyvac pump capable of giving a pressure of less than 0.1 mm. was used for evacuation. The explosion chamber was flushed out before admitting fresh gas.

Connection to the explosion chamber was made through ground-glass stopcocks lubricated with high vacuum stopcock grease. No effect whatsoever could be attributed to the use of the grease. Its lower vapor pressure and its greater freedom from leaks render it far more satisfactory than the sirupy phosphoric acid often used in this type of work.

The ignition was brought about by a discharge from eleven 1-mf. condensers placed in parallel. The condensers could be charged to any desired voltage by a high voltage d. c, generator placed across a suitable potentiometer. The charging voltage was read with a 750 voltmeter, which could be used with a 10^5-ohm resistance in series when necessary.

The spark gap was made from two platinum balls about 2.0 mm. in diameter; one was fastened directly to a 60-mil tungsten lead while the other was fastened to a strip of flexible platinum spot welded to a tungsten lead on one end while the other end was connected to an iron weight enclosed in glass. The discharge 'was caused to pass by means of an electromagnet attracting the iron weight on the flexible platinum. The electrodes were removed from time to time and the balls re-rounded with an oxy-hydrogen flame; the shape of the electrodes had little effect, however, except when they were badly burned away.

The carbon monoxide was prepared by the action of formic acid on sulfuric acid. Electrolytic oxygen was used from which the hydrogen was removed with heated copper oxide and the water with sulfuric acid. The organic vapors were all dried and purified by the usual methods.

The $2CO-O_2$ mixture was dried by allowing the preliminary dried gases to stand over fresh sulfuric acid for about twenty-four hours, and then by passing the mixture through a deep tower filled with sulfuric acid and glass beads before entering the explosion chamber. Any sulfuric acid mist was removed with glass wool. Water was substituted for the acid when it was desired to have the mixture saturated with moisture.

Method of Procedure

In preparing the explosion chamber for a filling with a water-saturated $2CO-O_2$ mixture, no precautions were necessary after evacuation except to flush the chamber out with a small amount of gas before filling to the desired pressure. In the experiment, when the dry gas was used, the explosion chamber was baked out with a flame to remove all adhering moisture from the walls before starting the experiment. After the system was once thoroughly dried, further baking out was unnecessary during a single series of runs.

In testing for the effect of impurities it was found that *a* thorough mixing of the gases, as well as a more accurate pressure reading, could be obtained by admitting the impurities to the reaction chamber first. When necessary, the gases were agitated in the explosion chamber by swinging the flexible electrode with the electromagnet.

In determining the minimum ignition voltage, it was found necessary to obtain the approximate voltage first. This was done by starting at some low voltage and gradually raising the sparking voltage until the gas ignited. Since the sparking potential fluctuates statistically about a definite value for a given set of conditions, several tests had to be made at each voltage. It was found, in general, that if a gas mixture would ignite at a given voltage it would do so within three or four trials. After the approximate ignition voltage was found, the true voltage was obtained by starting the ignition tests just under the first value. Since some oxidation took place in the path of any spark the products of reaction formed before the ignition voltage was reached often caused these two values to differ by an appreciable quantity.

Results

Pure Explosive Mixtures.—The pressure ignition-voltage curve for an explosive mixture of ethyl ether and oxygen is illustrated in Fig. 1. The results obtained with explosive mixtures of oxygen with carbon disulfide, ethyl alcohol and carbon monoxide are similar. In most instances the points on a given curve checked within ±5 volts.

When the ignition voltage was plotted against the reciprocal of the pressure the points all fell closely on the straight lines illustrated in Fig. I. This indicates that a hyperbolic relationship exists between ignition voltage and pressure which may be expressed as $V = k/P$. It will be noted that while the values of k differ widely for different reactions, the lines all intersect the voltage axis some place between 15 and 20 volts.

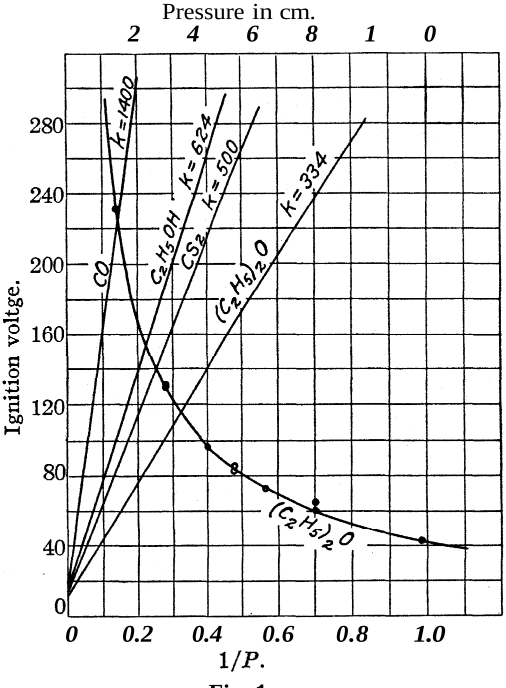

Fig. 1.

Effect of Impurities.—Impurities may be divided into two distinct classes with respect to their effect on the ignitibility of *a* $2CO–O_2$ mixture; namely, as positive and negative catalysts. The former are those that when added to the explosive mixture in almost any proportion lower the energy necessary for ignition, and the latter are those that raise the ignition energy.

In Fig. 2 is illustrated the effect of adding various amounts of impurities on the voltage necessary to explode a mixture containing 12 cm. $2CO + O_2$ and 2 cm. water vapor.

It will be noted that ether up to 3.0 mm. and ethyl alcohol up to 6.0 mm. partial pressure lower the ignition energy, and thus behave as positive catalysts. Above these pressures the vapors of both behave as powerful negative catalysts.

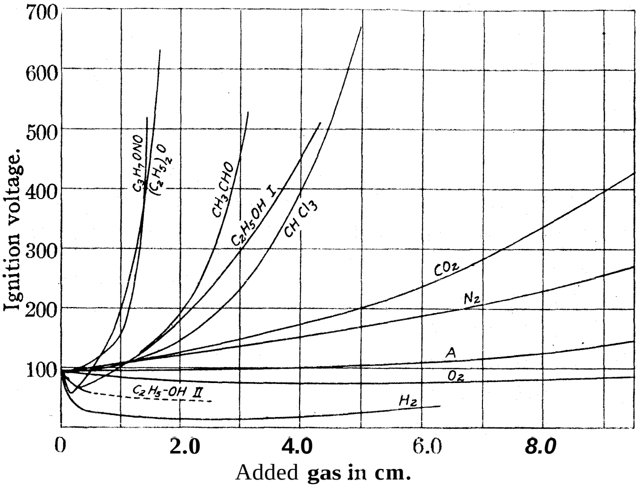

Fig. 2.

The ethyl alcohol curve is divided into two sections: Part I represents the addition of alcohol vapor alone, while Part II represents the effect produced when sufficient oxygen to burn the alcohol is also added. The effect of ether with additional oxygen is the same. Hydrogen also behaves, in this respect, like alcohol and ether, but the effect is not so pronounced. The reason is probably that the hydrogen burns even without additional oxygen because it ignites more readily than the carbon monoxide and requires much less oxygen per volume than alcohol or ether. Thus it will be seen that whether these vapors are to be considered as positive or negative catalysts depends entirely on whether or not they burn in the explosion; if they burn, they are positive catalysts, while if oxygen is insufficient for their combustion, they are negative catalysts.

The data in Fig. 1 show that gases differ widely in their negative catalytic properties. To illustrate, the amount of impurities in centimeters of mercury that must be added to a given explosive mixture to raise the ignition voltage from 95 volts to 150 volts is as follows.

Impurity	Cm of Hg	Impurity	Cm. of Hg
A	9.75	C_2H_5OH	1.7
N_2	4.0	CH_3CHO	1.6
CO_2	3.0	C_3H_7ONO	0.95
$CHCl_3$	2.2	$(C_2H_5)_2O$	.80

It will be seen from the foregoing that the ability of an impurity to inhibit ignition is a function of the complexity of the molecule; indeed it is almost directly proportional to the number of atoms in the molecule. An exact mathematical relationship between the number of atoms and the ignition voltage is difficult to establish, since many of the impurities such as hydrogen and alcohol behave both as positive and negative catalysts, depending on the amount present.

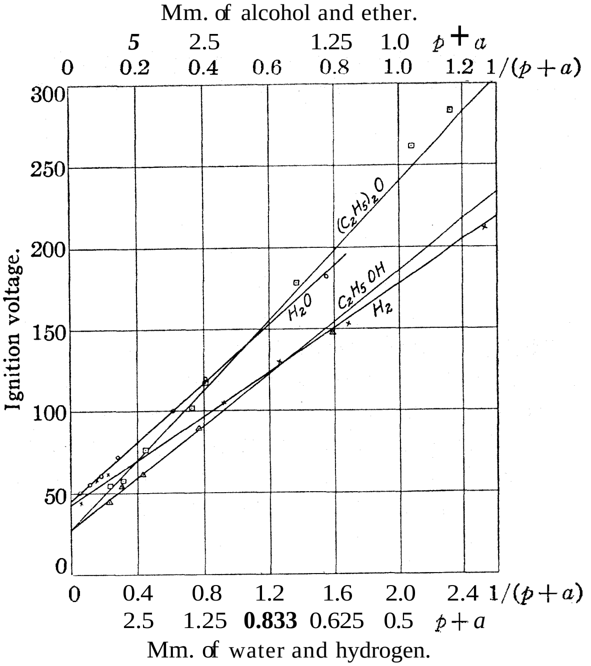

Fig. 3.

Quantitative Effects of Four Positive Catalysts.--The effect of adding explosive mixtures of oxygen with hydrogen, water, alcohol and ether vapors as impurities to the dry $2CO-O_2$ explosive mixture at 14 cm. pressure is exhibited in Fig. 3. The abscissas are $1/(p + a)$, where p mm. is the observed pressure of gas added, and a is a constant that differs from one gas to another. The ordinates are the voltages necessary to ignite the mixture when the p mm. of gas have been added; p and V seem to satisfy the relation

$$V = \frac{c}{p + a} + b \qquad (2)$$

This is the equation of the lines drawn in the figure. The values of a, b, c are tabulated below.

Gas	a (mm)	b (volts)	c (mm. volts)
Water	-0.35	45.4	90.2
Hydrogen	.10	42.7	67.6
Alcohol	.67	27.3	158.9
Ether	.46	27.4	213.8

These values were worked out by least squares, throwing all the errors of observation on to p, and giving the higher values of p several times as much weight as the lower values.

It is interesting to observe that the points satisfy this relation as closely as they do, that the V intercepts for hydrogen and water are nearly equal, and that those for alcohol and ether are equal. These curves, if extended, would not be straight lines throughout their entire course; at their upper ends they must all become asymptotic to the ignition voltage for the pure $2CO-O_2$ mixture at 14-cm. pressure. At the lower ends beyond the last experimental points, their shapes cannot be predicted with certainty, but the curve for water will turn up and become asymptotic to the V axis. Over the range of these experiments the data are well represented by the relation (2).

An explanation of the constant a that enters the above relation can be found from the following reasoning. The impurity was always admitted to the explosion chamber and its pressure p read before the explosive mixture was turned in. The pressure of the impurity was in most cases comparatively small—from 0.2 mm. to 20 mm.—and if a few tenths of a millimeter of the gas condensed on the walls after it was read, or if some that had already condensed before its pressure was read was displaced by the carbon monoxide or oxygen, then the pressure of the impurity actually in the gas phase at the moment of explosion would differ from the value recorded for #. It seems plausible to consider that a represents the average discrepancy between p and the actual pressure $p + a$ of the impurity at the moment of explosion. $1/(p+a)$ could then be considered the specific volume (in arbitrary units); and since the curves are straight lines it appears that the change in ignition voltage is proportional to the change in the specific volume of the impurity present at the moment of ignition.

Discussion

A consideration of the ignition process is helpful to an understanding of the mechanism. A critical voltage exists for each explosive mixture, and propagation never takes place at lower voltages. Chemical action does take place, however, directly in the path of the spark at a voltage far below that necessary for propagation. The amount of gas burned in the non-propagating sparks was measured by the change in pressure following the spark; when low voltages were used it was found necessary to measure the pressure after several sparks had been sent through the gas. In gases with a low ignition voltage, the amount that can be burned in a non-propagating discharge is small, but for a dried $2CO-O_2$ mixture, which has a high ignition voltage, a discharge wherein slightly over one cubic centimeter of gas, at the pressures used, is burned in the spark can be sent through the gas without propagation. For the moist mixture the gas that could be burned in a non-propagating spark was of the order of 1 to 5 cubic millimeters; the size of the ball of gas burning in the path of the spark increases with the decrease in percentage of moisture. It appears, therefore, that a certain amount of the mixture must be burned in the spark before the combustion will go to completion; the higher the ignition voltage the more must be burned in the spark.

In the case of the added impurities, it will be seen in Fig. 2 that both alcohol and ether in themselves are strong negative catalysts in the oxidation of carbon monoxide, while in Fig. 3 both of these vapors, in the presence of sufficient oxygen for their combustion, appear as powerful positive catalysts. From this it appears that ether and alcohol molecules, as such, are negative catalysts and that the burned product is the positive catalyst. Since carbon dioxide, as will be seen in Fig. 2, shows only negative catalytic properties, it follows that the positive action of both alcohol and ether as well as hydrogen is largely due to their ability to furnish water to the reaction. No doubt the heat liberated in this oxidation is also a contributing factor, but is of minor importance compared to the formation of water.

A comparison of the slopes of the lines in Fig. 3 shows that per total water molecules formed there is a decreasing efficiency per molecule in the order water, hydrogen, alcohol and ether, probably because the effective water concentration is materially less than the total number formed in the explosion, since the rate of burning of carbon monoxide is appreciable compared with that of the hydrogen, alcohol or ether. In the two latter cases the apparent efficiency of the water is also impaired by the presence of carbon dioxide.

These observations confirm the relation that has been shown to exist between ignition voltage and pressure. The equation $V = k/P$ shows that the ignition voltage is inversely proportional to the pressure and hence to the number of molecules in the path of the spark. Thus for propagation it appears that a definite number of molecules must be burned in the path of the spark, the exact number being specific for each reaction. While the number of molecules that must he burned for propagation cannot be told, the relative number for different mixtures may be obtained from the values of k; since the slopes of the lines of V vs. $1/P$ are 1400 and 334 for carbon monoxide and ether, respectively, we can say that the number of molecules that must be burned for propagation in the two mixtures are in the ratio 1400:334. This statement assumes that density is proportional to pressure, and that the lines all have the same intercept on the V axis, both of which are not strictly true but introduce only small corrections. k can therefore be used as a measure of the ease of ignition in various explosive mixtures and may be termed the *ignitibility constant.*

In a condensed discharge, such as was used in this work, the quantity of electricity passing across the spark is proportional to the voltage, since $Q = CV$, where Q is expressed in coulombs, C is the condenser capacity, which was kept constant, and V is the voltage. The word *quantity,* therefore, can be substituted in the place of *voltage,* in these discussions.

In this connection it is of interst to recall that in a former article[1] it was shown that when the capacity was varied a 600% increase in C resulted in only an 18% decrease in Q. From this it will be seen that the ignition is actually established by the quantity of electricity flowing and is at most only slightly related to the voltage. The slight increase in Q with increased V and decreased C is probably because the ionizing efficiency of an electron is slightly less than proportional to the voltage. From these considerations it seems very probable, as was pointed out by Finch and Cowen,[2] that ignition results from the attainment of a definite ion density as determined by Q at some point in the gas.

The fact that the lines for the various gases listed in Fig. 1 intersect the voltage axis at a point that is very close to the ionization potential for the gases used indicates that ionization is necessary for ignition. In this respect the results are very similar to those obtained in the glow discharge, for the oxidation of hydrogen[4] and the oxidation of carbon monoxide,[5] wherein it was possible to trace the oxidation from a simple ionic reaction through chain reactions to the ignition point.

Laws of Ignition.—These observations, when interpreted in the light of the hyperbolic relation between pressure and ignition voltage, may be summed up in the following rules for ignition.

Equation 1 may be interpreted as: *(I) the voltage necessary to ignite a given explosive mixture is inversely proportional to the number of molecules in the path of the spark.* Similarly, Equation 2 may be interpreted: *(II) the ability of a positive catalyst to lower the voltage necessary to ignite a given explosive mixture is, over a wide range, proportional to the number of its molecules in the path of the discharge.* The data tabulated in Fig. 1 may be interpreted as: *(III) the ability of a negative catalyst to raise the ignition voltage is a direct function of the complexity of its molecule.*

Summary

The hyperbolic relation $VP = k$ between ignition voltage and pressure of the mixture, noted by Brewer in 1927, working with a $2CO-O_2$ mixture,

---

[4] Brewer and Westhaver, *J. Phys. Chem.*, 34, **2343** (1930).

[5] Brewer and Kueck, *ibid.* (in press).

is shown to hold also for explosive mixtures of oxygen with ethyl alcohol, ether and carbon disulfide. Arguments are advanced to prove that this is a general law of ignition. k is different for each mixture.

Impurities in the explosive mixture are divided into two classes, positive and negative catalysts; the former lower the ignition voltage and the latter raise it. Vapors that burn to form water as one product of combustion will be positive catalysts when present in a small amount and negative catalysts when present in a greater amount. The positive action of a catalyst probably comes from the water formed in its combustion, which precedes the ignition of the main mixture. All impurities that form water seem to act as positive catalysts when present in *any* amount provided there is sufficient extra oxygen to burn the catalyst.

A quantitative relation, also hyperbolic, is worked out for impurities that act as positive catalysts. It is

$$(V - b)(p + a) = c$$

$p + a$ is the pressure of the explosive mixture added as impurity, V the ignition voltage, and b and c are constants for each catalyst.

The two hyperbolic relations explained can be restated thus: *(I) the voltage necessary to ignite a given explosive mixture is inversely proportional to the number of molecules in the path of the spark. (II) the ability of a positive catalyst to lower the voltage necessary to ignite a given explosive mixture is, over a wide range, proportional to the number of its molecules in the path of the discharge.*

A study of curves for several catalysts shows that, *(III), the ability of a negative catalyst to raise the ignition voltage is a direct function of the complexity of its molecule.*

THE ANHYDROUS LOWER BROMIDES OF TITANIUM

BY RALPH C. YOUNG WITH WALTER C. SCHUMB

RECEIVED JULY 18, 1930 PUBLISHED NOVEMBER 5, 1930

Considerable work has been done on the anhydrous trichloride and dichloride of titanium, and the di-iodide and trifluoride have been prepared, but we have been unable to find any data concerning the anhydrous lower bromides. The present work had for its purpose the preparation of these latter compounds and a study of some of their properties.

Three methods of preparation were considered and tried: (1) reduction of the tetrabromide by hydrogen; (2) the action of hydrogen bromide on titanium; (3) reduction of the tetrabromide by metals with and without a solvent.

For the preparation of titanium tetrabromide, dry carbon dioxide was allowed to pass through an intimate mixture of pure titanium dioxide (1 mole) and charcoal (2 moles) which was heated in a combustion furnace. After the water vapor was expelled, the carbon dioxide was directed through liquid bromine and the temperature of the furnace was raised until the pyrex tube showed signs of softening. The titanium tetrabromide was collected in a pyrex flask connected to the reaction tube. It was later freed from bromine by being kept in a liquid condition while carbon dioxide was allowed to bubble through it. It was distilled in an atmosphere of carbon dioxide and collected in tubes which were then sealed The portion distilling at 230° was used. Titanium tetrabromide prepared by the action of hydrogen bromide on titanium was also used in some of the experiments.

In applying method (1) above mentioned, on account of the reversibility of the reaction between titanium tetrabromide and hydrogen, it seemed advisable to employ the hot–cold tube principle which was used in the preparation of the trichloride by Georges and Stahler.[1] Hydrogen, dry and freed from oxygen by passage over hot platinized asbestos, was allowed to bubble through liquid titanium tetrabromide in a 50-cc. flask, (A Fig. 1), sealed directly to a 30-mm. pprex tube, 66 cm. long, B, through the center of which passed an 8-mm. tube, C. Cold water was conducted to the end of tube C by a 4-mm, tube, D. By this means a temperature gradient in the outer tube of about 750 to 22° was obtained. A hinged type electric furnace was used for heating, the temperature of which was controlled by a rheostat and measured by means of a pyrometer.

Preparation of Anhydrous Titanium **Tribromide.**—The apparatus was first swept out with hydrogen which entered through a tube sealed to the neck of the flask. After the reaction tube had been heated to redness, the gas was directed through the titanium tetrabromide, which was heated with a burner to such a temperature that about 15 g. per hour was vaporized and passed into the large tube. It was found necessary to employ a rapid stream of hydrogen (about 200 cc. per minute) to insure appreciable yields of product. A dark deposit could be noticed almost immediately at the end of the cold tube. This grew in length and thickness. Some of the reduced product was carried along with the unchanged titanium tetrabromide and hydrogen through tube E into a flask, F, by means of which the unchanged titanium bromide could be recovered.

The deposit on tube C soon assumed a crystalline character. Lustrous blue-black needles extended from the portion adhering to the cold tube to within a few mm. of the walls of the outer tube. Interspersed among the needles were small hexagonal plates. This formation of needles and plates was allowed to continue for about two hours or until it had extended for a distance of about 10 cm. along tube C. The passage of the hydrogen

---

[1] Georges and Stähler, *Ber.*, 42, 3200 (1909).

through the titanium tetrabromide was discontinued and the gas allowed to go directly into the reaction tube. The burner and the furnace were shut off and the reaction tube cooled to 250° and then the water flow was discontinued. Any titanium tetrabromide which had condensed on the cooling tube now volatilized. The furnace was next allowed to cool down to room temperature. All the titanium tetrabromide was driven by means of a free flame into the flask, F. Then a current of dry carbon dioxide was substituted for the hydrogen and after the hydrogen was displaced, the tube leading into the flask F was sealed at K. The empty cooling tube was next partly withdrawn through the cork stopper which held it in the large reaction tube. During this process a lively stream of carbon dioxide prevented air from entering through the cork. The black product for the most part fell to the bottom of tube B and by means of tipping and shaking could be brought into tube E without any appreciable hydrolysis taking place. After the flow of carbon dioxide had been stopped, the tube E was sealed at G and the product thus obtained in an atmosphere of carbon dioxide.

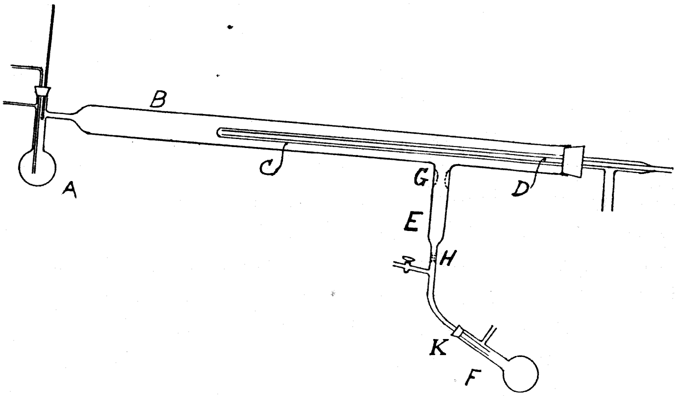

Fig. 1.—Apparatus for the preparation of titanium tribromide.

The tube with contents (carbon dioxide and the bromide of titanium) was weighed, opened and the product immediately dissolved in cold water. The familiar violet solution of trivalent titanium was obtained. There was a slight residue of titanium dioxide which amounted to 0.0035 g. in about 0.50 g. of the product. The titanium was removed from solution by precipitation with ammonium hydroxide as the hydrated oxide, which was afterward ignited and weighed as titanium dioxide. The bromine was determined as silver bromide.

ANALYSES

	I	II	Calcd. for $TiBr_3$
Ti, %	16.6	16.6	16.7
Br, %	83.0	82.9	83.3

The solution had the usual reducing properties of trivalent titanium. Ammonia produced a bluish-black precipitate which evolved hydrogen and gradually turned white.

During the course of one hour about one gram of the tribromide was produced and the tetrabromide which passed through the tube unchanged was recovered practically quantitatively.

An examination of the plates and needles was kindly made by Professor M. J. Buerger of the Geology Department of this Institute, who reported as follows. "The plates were hexagonal. The needles were studied with a petrographic microscope, carbon tetrachloride being used as the immersion liquid. The following characteristics were observed. With the light vibrating parallel to the length they were opaque, while they appeared blue with the light vibrating normal to the length. The interference colors can be described as anomalous. The needles possessed parallel extinction which denoted them to be hexagonal, tetragonal or orthorhombic. The formation of two kinds of crystals by a single substance in a reaction where a large temperature gradient is present is described by Tutton[2] in the case of antimony trioxide." The plates dissolved a little more slowly than the needles but gave the same violet solution. They seemed more compact and denser than the needles. Slight hydrolysis and oxidation brings about a somewhat violet appearance which deepens to red if allowed to continue.

Preparation of Anhydrous Titanium Dibromide.—The sealed tube containing a sample of the tribromide was evacuated with a high vacuum pump and heated in an electric furnace, the small end being immersed in ice water or in a mixture of alcohol and solid carbon dioxide. In decomposing the titanium tribromide, according to the equation $2TiBr_3 \qquad TiBr_2 + TiBr_4$, a temperature not greatly exceeding 400° was used in order to prevent as far as possible the decomposition of the dibromide; a 0.5-g. sample required eighteen hours for complete reaction. The proportions of dibromide and tetrabromide obtained from a known weight of the tribromide corresponded fairly closely to the requirements of the above equation. The titanium dibromide proved to be a deep black powder.

The end of the tube containing the volatilized titanium tetrabromide was sealed at H, the tube containing the dibromide was opened in an atmosphere of carbon dioxide and the contents dissolved in cold water saturated with carbon dioxide. A small residue remained undissolved which amounted to 0.0060 g. for 0.2100 g. of the product. Analysis gave the following results.

ANALYSES

	I	II	Calcd. for $TiBr_3$
Ti, %	77.5	77.3	76.8
Br, %	22.3	22.8	23.1

---

[2] Tutton, "Crystallography and Practical Crystal Structure," p. 1256.

The black powder was very reactive, with strong reducing properties. It caught fire when exposed to moist air and dissolved in water with the evolution of hydrogen. In a mixture of ice and water saturated with carbon dioxide the reaction was much slower but nevertheless noticeable. On heating, titanium dibromide was found to decompose into titanium and titanium tetrabromide. This reaction takes place very slowly at 500°, but at 650° at such a rate that 0.2 g. decomposed in six hours. There was no evidence of hydrogen or hydrogen bromide being formed by the decomposition, which rules out the possibility of hydrogen being a part of the compound; nor was there any appearance of free bromine.

The following equations indicate two possible ways in which titanium tribromide could be formed from the tetrabromide:

$$2TiBr_4 + H_2 \rightleftharpoons 2TiBr_3 + 2HBr \qquad (1)$$

$$TiBr_4 + TiBr_2 \rightleftharpoons 2TiBr_3 \qquad (2)$$

The surface of the reaction tube in the hot zone is considerably attacked and black metallic titanium is first formed thereon. This then appears to react with the glass. It is reasonable to suppose that titanium dibromide is formed by reduction in a somewhat cooler zone and it was proved by a separate test that titanium tribromide can be formed with the furnace at 400°. In other experiments, a thermocouple enclosed in a pyrex tube in the reaction zone midway between the cooling tube and the inner surface of the large tube, which was heated to 750°, registered 400°. No reduction product was obtained on the side toward the hot surface of the large tube, while the product did form between the tube containing the thermocouple and the inner cold tube. The formation therefore took place below 400°.

A study was made of Reaction 2. In the same apparatus used for the preparation of titanium tribromide, titanium dibromide was formed in an atmosphere of hydrogen according to the equation $2TiBr_3 \qquad TiBr_4 + TiBr_2$, at 450°, no water having been allowed to circulate in the cooling tube. The needles and plates ($TiBr_3$) changed to a very black powder. Titanium tetrabromide was then passed with hydrogen through the furnace and the temperature gradually raised from room temperature. At 280° there developed the distinctive bluish-black appearance of the tribromide and at 380° all appeared to be changed over. The product dissolved in water to form a solution which possessed the properties of trivalent titanium.

Action of Hydrogen Bromide on the Lower Bromides of Titanium and Titanium Metal.—Titanium tribromide was made as described previously and hydrogen bromide, prepared as usual from hydrogen and bromine with the aid of a platinized asbestos catalyst, and carefully freed from bromine by ferrous bromide and from water by calcium bromide, was passed through the reaction tube containing the solid. The furnace temperature was gradually raised; at 250° reaction took place slowly with the formation of titanium tetrabromide and hydrogen and above 350° became very rapid.

Likewise, titanium dibromide was produced in the large pyrex reaction tube in the manner described above, hydrogen bromide was passed over it, and the temperature of the furnace gradually raised. The black titanium dibromide began to assume the brilliant blue-black color of the titanium tribromide at 160° and some titanium tetrabromide was also produced. The non-volatile product was dissolved in water and proved to be titanium tribromide.

Titanium metal was found to react with hydrogen bromide at 300° and very slowly slightly below this temperature. Experiments were conducted at 450° and at 300° to see in which case more of the non-volatile bromides were produced. At 450° the proportion of non-volatile product to volatile titanium tetrabromide, calculated in moles, was 1 to 20, while at 300° the proportion was 1 to 2 and only in the latter case was there evidence of the presence of the dibromide. Consequently the formation of incompletely halogenated products is favored by low temperature, a result which is similar to that noted in the action of hydrogen bromide on silicon.[3]

Finally, the reduction of titanium tetrabromide by means of metals, namely, titanium, mercury and silver, was studied. Titanium tetrabromide was heated with titanium in a sealed tube at 300° for four hours. Black needles of titanium tribromide, of the same general appearance as already described, were formed. Mercury was also found to reduce titanium tetrabromide when the two substances were heated in a sealed tube at 300°. If a sealed tube containing a benzene solution of titanium tetrabromide and mercury is rotated, the reduction to titanium tribromide and mercurous bromide is practically quantitative,* both products being insoluble in benzene. Attempts to separate the two by sublimation were not successful. Water dissolved the titanium compound and the solution gave the usual tests for trivalent titanium. Silver was found to react in a manner similar to mercury.

Summary

Anhydrous titanium tribromide was prepared in a mixture of two crystalline forms by reduction of the tetrabromide with hydrogen by the use of the hot-cold tube principle. In the study of its properties, it was found to decompose at 400° into titanium tetrabromide and titanium dibromide. The reverse reaction was also carried out by the passage of vapors of the tetrabromide over heated titanium dibromide. Titanium dibromide de-

---

[3] Schumb and Young, THIS JOURNAL, 52, 1464 (1930).

[4] The titanium tribromide formed from 4 g. of titanium tetrabromide by reduction with 10 g. of mercury in 20 cc. of benzene reduced 26.5 cc. of 0.4 N ferric alum solution. This is equivalent to a yield of tribromide of about 97%.

composes into titanium metal and titanium tetrabromide, very slowly at 500° but rapidly at 650°.

Both the di- and tribromide react with hydrogen bromide to produce the tetrabromide. Titanium metal reacts with hydrogen bromide to produce a greater proportion of non-volatile bromides ($TiBr_2$ and $TiBr_3$) to the tetrabromide at 300° than at 450°.

At 300° titanium metal suspended in titanium tetrabromide brings about partial reduction to the tribromide. Silver and mercury reduce titanium tetrabromide, dissolved in benzene, to titanium tribromide; in the case of the latter metal the reduction is practically quantitative.

THE THERMODYNAMIC TREATMENT OF CHEMICAL EQUILIBRIA IN SYSTEMS COMPOSED OF REAL GASES. III. MASS ACTION EFFECTS. THE OPTIMUM HYDROGEN: NITROGEN RATIO FOR AMMONIA FORMATION IN THE HABER EQUILIBRIUM

BY LOUIS J. GILLESPIE AND JAMES A. BEATTIE

RECEIVED JULY 24, 1930 PUBLISHED NOVEMBER 5, 1930

Although the mass action law has often been applied to experimental studies of gaseous equilibrium, there is little or no direct evidence of its inadequacy for gases. This is doubtless due to the fact that most studies have been made at low pressures. and sometimes also at high temperatures, conditions which favor the applicability of the ideal gas laws to real gases.

A recent exception has been furnished by the data on the Haber equilibrium obtained by Larson and Dodge and by Larson.[1] Here it has been found that K_p, the mass action function in terms of ideal gas partial pressures, is not constant at constant temperature, as required by the theory of ideal gases, but increases definitely with the pressure. As already pointed out[2] we must therefore believe that K_p will vary if the concentrations are varied at constant temperature and pressure—in other words, that K_p is not strictly constant with respect to any change of condition whatever.

The contributions of previous investigators to the theory have been discussed at length in Part I of the present series[3] of three papers. Here we shall repeat only the previous results of present interest.

---

[1] Larson and Dodge, THIS JOURNAL, 45, 2918 (1923); Larson, *ibid.*, 46,367 (1924).

[2] Gillespie, *ibid.*, 47, 305 (1925).

[3] Gillespie and Beattie, Phys. *Rev.*, 36, 743 (1930); Part II, *Phys. Rev.*, 36, 1008 (1930). In this part the heat of reaction was calculated at various temperatures and pressures, and the entropy and energy constants of ammonia were found.

In brief, a general mass action equation has been derived[4] by assuming that certain properties[4,5] of ideal gases hold also for real gases at very low pressures. By assuming further that the equation of state of a gas mixture may be obtained by means of a "linear combination of constants" and that the Beattie–Bridgeman equation of state[6] is to be used for the separate gases a mass action equation has been derived[7] in which all the integrations have been carried out, in terms of the volume of the mixture.

Subject to the same assumptions and to some simplifying assumptions, which should be valid at pressures not too high, the following approximate mass action equation has been derived[8]

$$\ln K_p = \ln K_p^* - \{\Sigma\nu_i[B_{0i} - A_{0i}/RT - C_i/T^3] + \Sigma\nu_i[(A_{0i}^{1/2} - \Sigma x_i A_{0i}^{1/2})^2/RT]\}p/RT \quad (1)$$

K_p^* is the limiting value of K_p when the gaseous mixture is maintained in equilibrium and its pressure reduced to zero. It is determined by the temperature alone for a given chemical equation.

An approximate equation similar to Equation 1, but without the constant c, has been obtained by Keyes[9a] from the kinetic considerations leading to the Keyes equation of state.[9b]

The chemical equation for the Haber equilibrium is

$$1/2N_2 + 3/2H_2 = NH_3 \quad (2)$$

From the definition of K_p we have

$$\log K_p = \log x - 1/2 \log x_N - 3/2 \log x_H - \log p \quad (3)$$

where x, x_N and x_H are the mole fractions of ammonia, nitrogen and hydrogen, respectively, in the equilibrium mixture, and p is its pressure.

Equation 1 gives us for the Haber equilibrium, after substituting numerical values[3] for the equation of state constants A_{0i}, B_{0i} and C_i

$$\log (K_p/K_p^*) = p[0.1191849/T + 25122730/T^4 + 38.76816\Sigma(x_i A_{0i}^{1/2})/T^2 + 64.49429(\Sigma x_i A_{0i}^{1/2})^2/T^2] \quad (4)$$

where the values of $A_{0i}^{1/2}$ for ammonia, nitrogen, hydrogen and argon are 1.546932, 1.159526, 0.4444097 and 1.136090 liter-(atmosphere)$^{1/2}$ per mole, respectively, and log refers to the base 10.

In Part I of the present series, Equation 4 was applied to the existing data of Haber,[10] of Larson and Dodge, and of Larson, and was found to represent the effect of pressure on the yield of ammonia within the experimental error at all temperatures.

[10] Haber. Z. Elektrochem., 21, 89 (1915).

The temperature variation was expressed by the equation

$$\log K_p^* = -2.681122 \log T - 5.519265 \cdot 10^{-5} T + 1.848863 \cdot 10^{-7} T^2 + 2001\,6/T + 2.6899 \qquad (5)$$

of which the last two constants, and these only, were arbitrary and chosen to fit the whole body of data.

Theory

Equation 5 rests on the assumptions that the specific heats of the gases at extremely low pressures may be expressed over the necessary temperature interval a .functions of the temperature in series, and that the temperature variation of K_p is the same for real gases at extremely low pressures as for ideal gases.[11] There would be no point here in questioning the validity of these assumptions. The use to which we put Equations 4 and 5 in this paper depends, however, on the validity of Equation 1 or 4.

We believe that we are in a very good position to calculate the effects of varying composition in the Haber equilibrium by the use of the numerical equation 4 in connection with Equation 5, which serves to eliminate log K_p^* from Equation 4, for the following reasons: (1) the general assumptions underlying the mass action equations discussed above are supported abundantly by experimental evidence other than that relating to the Haber equilibrium, as has been discussed in Part I. (2) The agreement of the approximate equation (1) or (4) with the Haber equilibrium data indicates that the simplifying assumptions which have been used to obtain them are not too severe. (3) The composition terms in $\Sigma(x_i A_{0i}^{1/2})$ occurring in Equation 1 or 4 must be supposed approximately correct, since a mass action equation, which may be considered to be based on the Lewis and Randall rule[12] of fugacities, and which differs from Equation 1 principally by the omission of these composition terms, has been applied to the Haber equilibrium data and found to fail badly at 300 atmospheres to represent the pressure variation of K_p, though the representation at lower pressures was good.[4]

A mass action question of unique interest is the following: At what mole ratio, hydrogen:nitrogen, will there be at given temperature and pressure the largest mole fraction of ammonia in the equilibrium mixture?

When the function K_p is constant at constant temperature and pressure, as is the case not only for ideal gases but also for the case that the Lewis and Randall rule is exact,[4] the optimum ratio is exactly three (provided neither reactant is contaminated with an inert gas), as may readily be shown mathematically by equating to zero the derivative of log K_p with respect to the ratio H_2:N_2. But according to Equation 1 or 4, or indeed according

---

[11] For a very simple choice of necessary assumptions for the discussion of thermodynamic equilibrium in real gases, see Beattie, Ref. 5.

[12] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923.

to any equations which are not based on the ideal gas laws and which differ from the Lewis and Randall rule,[4] K_p varies with composition at constant temperature and pressure, and naturally a value different from three will be expected for the optimum ratio, as already suggested.[13]

By examination of the derivative of the mole fraction of ammonia at equilibrium, below always denoted by x, with respect to r_e, the equilibrium value of the ratio H_2:N_2. the following equation is found for the optimum value of r_e when no argon is present in the reactant gases.

$$r_e = 3 - \frac{2}{M}(A_{0N}^{1/2} - A_{0H}^{1/2})\frac{r_e}{(1 + r_e)}(1 - x)\left[38.768 + 128.99\Sigma(x_iA_{0i}^{1/2})\right]\frac{p}{T^2} \qquad (6)$$

Here A_{0N} and A_{0H} are the cohesive pressure A_0 constants in the Beattie–Bridgeman equation of state for nitrogen and hydrogen, respectively. The summation $\Sigma(x_iA_{0i}^{1/2})$ is obtained by adding the terms $x_1A_{01}^{1/2} + x_2A_{02}^{1/2} + \ldots$, etc., taking the square roots of the cohesive pressure constants, and x_1, x_2, etc., the mole fractions, for all gases present in the equilibrium mixture. M is the modulus of logarithms, 0.43429 . . ., p is the pressure in atmospheres (normal) and T is the absolute temperature ($t° + 273.13$).

At zero pressure $r_e = 3$. At other pressures the sign of the correction depends on the term $(A_{0N}^{1/2} - A_{0H}^{1/2})$, which is $+0.7151163$. Hence the optimum ratio lies at less than 3 for all pressures not zero within which the simplifying assumptions used in deriving Equation 1 are valid.

Although r_e appears on both sides of Equation 6, this does not cause any serious difficulty, as the quantity to be subtracted from 3 is small, and hence the use of an approximate value of r_e on the right-hand side of the equation will lead to a good value. More serious is the fact that x and $\Sigma(x_iA_{0i}^{1/2})$ must be consistent with Equation 4. Hence several trials are necessary to arrive at good numerical values of x and r_e. We have used Equation 6 only for checking the results of other computations.

It appeared somewhat more interesting to calculate the best initial value of the ratio H_2:N_2, which initial ratio we shall designate by r, in a reactant mixture of hydrogen and nitrogen when the nitrogen contains c mole per cent. of argon.

If in such a reactant mixture containing originally no ammonia there is formation of ammonia subject to Equation 2, then the mole fractions of the various gases at any time, for instance at equilibrium, will be related to each other and to r and c by Equations 7

$$\left.\begin{array}{ll} x_{NH_3} = x & x_N = \dfrac{(1 + x)}{(1 + c + r)} - \dfrac{x}{2} \\ x_{Ar} = \dfrac{c(1 + x)}{(1 + c + r)} & x_H = \dfrac{r(1 + x)}{(1 + c + r)} - 3\dfrac{x}{2} \end{array}\right\} \quad (7)$$

These relations (7) will be applied only to the mole fractions at equilibrium

From Equations 4, 5 and 7, log K_p, x_N, x_H and x_{Ar} may be eliminated,

---

[13] Gillespie, *J. Math. Phys., Mass. Inst. Tech.*, 4, 84 (1925).

giving an equation between r, x, c, p arid T, containing log K_p^* which is a function of the temperature. From this equation the derivative dx/dr at constant c, p and T may be found and put equal to zero. This gives finally the following equation for the value of the initial ratio r for which x is a maximum at given values of c, p and T.

$$r = 3(1 + c) - \frac{3cx(1 + c + r)}{2(1 + x)} - \frac{2}{M}\left[A_{0\mathrm{N}}^{1/2} - A_{0\mathrm{H}}^{1/2}(1 + c) + A_{0\mathrm{Ar}}^{1/2}c\right] \times \frac{(1 + c + r)}{(1 + x)} x_{\mathrm{N}}x_{\mathrm{H}}\left[38.768 + 128.99\Sigma(x_iA_{0i}^{1/2})\right]\frac{p}{T^2} \qquad (8)$$

For ideal gases the A_0 constants are zero, the last term of Equation 8 vanishes. and we have

$$r = 3 + 3c\,\frac{1 - x - 0.5cx}{1 + x + 1.5cx} \qquad (9)$$

Thus even for ideal gases the best initial ratio is not three when nitrogen cannot be added without adding argon; although of all equilibrium mixtures containing the same mole fraction of argon, the one whose ratio H_2:N_2 is three contains the largest percentage of ammonia.

For any chosen values of c, p and T, Equation 8 may he solved for values of r and x which are also consistent with the mass action and stoichiometric requirements as expressed in Equations 3, 4, 5 and 7. For this purpose an equation may be found of the form $F = 0$, by elimination of log K_p and log K_p^* from Equation 4 by use of Equations 3 and 5. For any chosen value of r, a value of x may then be found by trial which will make the function F reduce to zero. Elimination of the mole fractions x_{N}, x_{H} and x_{Ar} is best made after calculation of their numerical values from Equations 7.

The **Present** Calculations

We have made calculations for the temperature 500°, a series of pressures, and an original mole fraction of argon in the nitrogen, $c = 0.012$. This is about the value of c when nitrogen is made from air and the argon not removed. The function to be reduced to zero is not so formidable as might be expected from the above, once T, p and c have been assigned numerical values, and the numbers have been collected and combined. Thus at 1000 atmospheres the equation we had to solve was

$$F = 0.7985342 + 0.06485898\Sigma(x_iA_{0i}^{1/2}) + 0.10789870\left[\Sigma(x_iA_{0i}^{1/2})\right]^2 + \frac{1}{2}\log x_{\mathrm{N}} + \frac{3}{2}\log x_{\mathrm{H}} - \log x = 0 \qquad (10)$$

subject to the relations (7).

At each pressure the optimum value of r was calculated by Equation 8, using approximate values of the mole fractions, and then an equation such as (10) was solved for x at values of r adjacent to this approximate optimum value. Finally Equation 8 was used to confirm or to locate more precisely the optimum value. The final ratio r_e was also computed from the equation

$$r_e = 3(1 + c) - \frac{2}{M}\left[A_{0N}^{1/2} - A_{0H}^{1/2}(1 + c) + A_{0Ar}^{1/2}c\right]\frac{(1 + c + r_e)}{(1 - x - 0.5cx)}x_N x_H \times \left[38.768 + 128.99\Sigma(x_i A_{0i}^{1/2})\right]\frac{p}{T^2} \qquad (11)$$

The optimum values of r, the initial ratio H_2:N_2, and of r_e, the ratio at equilibrium, are given in Table I. In Table II are given the percentages of ammonia in the equilibrium mixtures at the optimum value of r and also for r = 3. In Table III are given the optimum ratios, and in Table IV the percentages, for the case that no argon is present.

We have thought it of interest to calculate also the percentages at the initial ratios 2 and 4, and also to compare them with the yields that would be expected from the ordinary simple mass action law at the initial ratios 2 and 4 from the percentages for $r = 3$ as given by our improved mass action law. Argon was assumed to be absent.

The yields expected from the ordinary mass action law were obtained by solution of the equation

$$F' = \log p + \log K_p + 1/2 \log x_N + 3/2 \log x_H - \log x = 0 \qquad (12)$$

subject of course to the relations (7), when $\log K_p$ is the correct value of $\log K_p$ found from Equations 4, 5 and 7 for $c = 0$ for the given temperature and pressure.

1000	0.890	3	10.822	0.903	11.414

Discussion of the Results

Whether argon is present in the usual quantities or absent, the optimum initial value of the ratio $H_2:N_2$ passes through a minimum at about 600 atmospheres, at which it is only about 3% less than the value 3; but both the minimum and the smallness of the effect are due to the considerable change in the value of the ratio as a consequence of the extensive formation of ammonia at the higher pressures. The optimum value of the ratio at equilibrium passes through no minimum and reaches a value over 10% less than 3 at 1000 atmospheres.

Although reasons were given above for supposing that the approximate equation used for the calculation should give good results, it would not necessarily follow that pressure derivatives of functions such as the optimum ratio would be furnished correctly, as the terms neglected in deriving the approximate equation would affect the pressure derivatives. Nevertheless in calculations of the Joule–Thomson effect,[14] similar approximations were made and yet a correct slope was obtained of the curve for the inversion temperature *vs.* pressure.

Whether argon is present or not, the maximum mole percentage of ammonia formed at the optimum ratio exceeds the mole percentage formed at $r = 3$ by less than 0.07% of this mole percentage even at 1000 atmospheres. Hence the optimum ratio may safely be taken as 3 for practical purposes, though in point of theory it must be regarded as less.

This practical coincidence of the improved mass action law with the ordinary mass action law is, of course, due to the fact that the value of any

---

[14] Beattie, *Phys. Rev.*, 35,643 (1930).

function cannot change rapidly in the neighborhood of its maximum. From Table V it can be seen that if the ordinary mass action law be used to calculate the mole percentage of ammonia when $r = 2$ or 4, from the value given for $r = 3$, it will be found to produce errors which are 0.87 and 1.59% of the correct percentages, respectively, at 1000 atmospheres. Though the pressure here is high, the variation of composition is rather small.

Comparison of Tables II and IV shows that the yield at any pressure is better in the absence of argon. At 1000 atmospheres the improvement is about 0.63% of the yield.

Theoretically, the optimum mixture from nitrogen which contains argon may be improved by adding pure nitrogen. The best initial ratio depends but very slightly on the argon content, being the same for mixtures containing a constant initial mole fraction of argon equal to 0.003 as the figures listed in Table III for zero mole fraction of argon; but the effect on the yield of adding pure nitrogen in this way is small.

Summary

By means of an improved mass action equation, which had previously been found to represent the combined effects of variations of temperature and pressure together with such concomitant variations of composition as necessarily occurred in the displacement of equilibrium, calculations have been made of the effects on the yield of ammonia produced by systematic variation of the ratio of hydrogen to nitrogen. For the temperature 500° and for the pressures 100, 300, 600 and 1000 atmospheres, the optimum values of this ratio, both the initial values and the values at equilibrium, were found for pure hydrogen and nitrogen, as well as for pure hydrogen and atmospheric nitrogen from which the argon has not been removed.

Except at low pressures, the optimum value of the ratio is less than 3. The optimum value of the initial ratio falls to 2.90 at 600 atmospheres, and that of the final ratio at equilibrium to 2.68 at 1000 atmospheres, when no argon is present. The corresponding figures are 2.91 and 2.72 when atmospheric nitrogen is used.

The percentage of ammonia at the optimum ratio exceeds that at the ratio 3 by less than 0.1% of the percentage at 3 in any case.

The presence of argon is deleterious at any pressure. At 1000 atmospheres the yield when pure nitrogen is used is about 0.6% (of its value) greater than when atmospheric nitrogen is used.

For the case of pure nitrogen, the yields of ammonia were also calculated at the values 2, 3 and 4 at each pressure and at 500°. For comparison, the ordinary mass action law was used to calculate the yield of ammonia at each pressure and at the initial values 2 and 4 from the yield at the value 3, with errors which reached at 1000 atmospheres 1.5% of the yield at 3.

THE DIRECT DETERMINATION OF SODIUM IN THE PRESENCE OF ALUMINUM AND CHROMIUM

BY EARLE R. CALEY AND DARRELL V. SICKMAN

RECEIVED JULY 25, 1930 PUBLISHED NOVEMBER 5, 1930

The possibility of determining small amounts of sodium in the presence of large amounts of aluminum and chromium is of special interest due to the difficulties involved in the accurate separation of sodium from these elements. When aluminum and chromium are precipitated in the usual manner as hydroxides with the subsequent determination of sodium in the filtrate the results are far from satisfactory even with careful manipulation. Other methods of separation have been proposed but these likewise leave much to be desired. Since a direct analytical method is always desirable for the estimation of small amounts of a given element, the following experiments were performed to determine whether or not the magnesium uranyl acetate method for sodium could be applied satisfactorily to this problem.

General Procedure

In the experiments with pure salts, known volumes of standard sodium solution were added to solutions of known amounts of aluminum and chromium salts and, after evaporation to small volume, the sodium present was determined by the direct magnesium uranyl acetate method for sodium previously described.[1] The technique given in the first paper in this series was followed except for the following variations which further experience with the method has shown to be advisable. Where sulfates are present, which was the usual case in these experiments, precipitates should first be washed with two or three 5-cc. portions of reagent in order to prevent any precipitation of metallic sulfates by the alcoholic washing fluid. Experiment has shown that it is preferable to wash the sodium precipitate with a wash liquid prepared by freshly saturating 95% alcohol with the triple acetate precipitate rather than to wash with pure 95% alcohol and then apply a washing correction, since the latter varies with the amount of precipitate present and with the rapidity of washing. An important point to be noted is that the quantities of salts given in the original formula for the magnesium uranyl acetate reagent referred to the ordinary grades of uranyl acetate and magnesium acetate then obtainable on the market, the latter salt being in the form of so-called "dried" crystals containing less than the theoretical amount of water of hydration. This latter material has been found to differ in composition depending upon its source and since it has now been found possible to obtain clear crystallized magnesium acetate containing the theoretical percentage of water, it is preferable to

---

[1] Caley and Foulk, THIS JOURNAL, 51, 1664 (1929).

use this salt in the preparation of the reagent. Based on the employment of salts containing the theoretical percentage of water of hydration the formula of the reagent has been modified to read as follows.

SOLUTION A		SOLUTION B	
Uranyl acetate ($2H_2O$)	90 g.	Magnesium acetate ($4H_2O$)	600 g.
Glacial acetic acid	60 g.	Glacial acetic acid	60 g.
Water	to 1000 cc.	Water	to 1000 cc.

Prepared on this basis more uniform and satisfactory results are obtained.

Materials

Standard Sodium Chloride Solution.—This solution, used as the basis of the experiments, was made by dissolving 2.5418 g. of the purified and carefully dried salt in water and making the solution up to one liter. Each cubic centimeter of this solution contained 0.0010 g. of sodium.

Aluminum Sulfate.--Since it was not found possible to obtain a sample of this salt that did not contain appreciable quantities of sodium, the material had to be especially prepared. For this purpose a quantity of U. S. Bureau of Standards melting point aluminum was dissolved in dilute sulfuric acid and $Al_2(SO_4)_3 \cdot 18H_2O$ was crystallized from this solution and dried in the usual way. The salt thus prepared gave no flame test for sodium.

Aluminum Chloride.—There was used an exceptionally pure commercial material that contained no sodium as determined by the flame test.

Chromium **Sulfate.**—Kahlbaum's $Cr_2(SO_4)_3 \cdot 5H_2O$ was used. The sample employed contained a slight amount of sodium as determined by the flame test and by blank determinations, but the blank was sufficiently small to permit the use of the material in these experiments. The chromium content of the salt was checked and it was found to correspond nearly to the value required by theory.

Ammonium Sulfate.—For experiments on the effect of ammonium salts on the determination of sodium in sulfate solution there was used a sample of "C. P." salt that gave no flame test for sodium.

The Determination of Sodium in **the** Presence of Aluminum.—In the experiments shown in Table I the calculated amount of pure aluminum sulfate was added to the measured volume of standard sodium solution and the resulting solution was brought to a volume of from five to six cubic centimeters. The reagent was then added and the determination made in the usual way. In cases where 0.500 g. of aluminum was present, it was found necessary to add the reagent to the hot solution for salts separated on cooling due to their high concentration, but since the mixture was rapidly brought to the temperature for precipitation this variation did not affect the determinations. **A** similar set of experiments made with aluminum chloride gave like results. In neither case was it found that the presence of the aluminum salts resulted in the separation of any undesirable phase or otherwise influenced the practical accuracy of the sodium determinations, although duplicate values as shown by the weights of precipitates failed to agree as well as similar determinations made with sodium present alone.

[b] In these two samples the solutions were evaporated to 3 cc. before adding reagent.

in the determined weight of each precipitate, a procedure justified by the resulting consistency of the values thus obtained and by the fact that in separate experiments solutions of chromium salts free from sodium gave no precipitate with the reagent. The results show that chromium, in sulfate solution at least, does not affect the practical accuracy of the direct sodium determination.

The Influence of Ammonium Salts in Sulfate Solutions.—Since ammonium salts are liable to be present in actual determinations, it was thought advisable to determine the effect of rather high concentrations of ammonium salts, especially in sulfate solutions, this usually being the case in direct sodium determinations involving aluminum or chromium. It was found that moderate to high concentrations of both sulfate and ammonium sometimes resulted in the precipitation of the phase $(NH_4)_2SO_4 \cdot MgSO_4 \cdot 6H_2O$ along with the triple acetate precipitate. Experiments on this point (Table III) showed that such concentrations of ammonium and sulfate as can ordinarily be present in 5 cc. of test solution do not result in the precipi-

tation of this undesirable phase providing a sufficient volume of reagent is used. The precipitation of this double salt is, of course, not peculiar to sulfate solutions containing aluminum and chromium but is a general effect governed by the concentration of magnesium, ammonium and sulfate in the solution obtained by mixing test solution and reagent. In general this source of error may be avoided safely by keeping the ammonium salt concentration down to a minimum and using an ample volume of reagent when making direct sodium determinations in sulfate solution. When working with sulfate solutions containing aluminum or chromium it is desirable on another account to keep the ammonium concentration down to a minimum since the ammonium alums are difficult to keep in solution when evaporating to the small volume required by this procedure for sodium. In working with chloride solutions containing aluminum or chromium no particular precautions need be taken in regard to the ammonium salt concentration.

Applications.—In addition to the experiments detailed above, a number of determinations of sodium have been made in commercial samples containing aluminum or chromium, including metallic aluminum, minerals and salts. Satisfactory results have been obtained in these cases, showing that the direct method for sodium may be safely applied to a diversity of materials containing these elements.

Summary

1. It has been shown that the direct magnesium uranyl acetate method for sodium is applicable in the presence of aluminum and chromium.

2. The undesirability of having a high concentration of ammonium salts when making direct sodium determinations in sulfate solution has been pointed out.

THE MELTING CURVE OF SODIUM CHLORIDE DIHYDRATE. AN EXPERIMENTAL STUDY OF AN INCONGRUENT MELTING AT PRESSURES UP TO TWELVE THOUSAND ATMOSPHERES

BY L. H. ADAMS AND R. E. GIBSON

RECEIVED JULY 28, 1930 PUBLISHED NOVEMBER 5, 1930

Under atmospheric pressure sodium chloride dihydrate melts incongruently at 0.1°, forming solid sodium chloride and a saturated solution of that salt. Below this temperature the dihydrate is the stable solid phase in contact with a saturated solution of sodium chloride, although it exhibits such reluctance to appear that special methods are necessary to bring about its formation. A study of the system $NaCl-H_2O$, at 25° and under high pressure, which is being undertaken by one of us, required an answer to the question—at what pressures, if any, is $NaCl{\cdot}2H_2O$ the stable phase at 25°, a question which could best be answered by a determination of the influence of pressure on the melting point of the dihydrate.

A detailed study of this problem was also of interest as an example of the course of the melting curves of substances melting with decomposition. Although such substances are numerous, only a few such as $Na_2SO_4{\cdot}10H_2O$,[1] $Cd(NO_3)_2{\cdot}4H_2O$,[2] $Ca(NO_3)_2{\cdot}4H_2O$,[2] $CaCl_2{\cdot}6H_2O$[3] have been examined under pressure and none under pressures greater than 3 kilobars.[4] In the case of $Na_2SO_4{\cdot}10H_2O$ there is a maximum on the melting curve in the neighborhood of 500 bars, but in other cases no maxima were realized experimentally.

In this paper we shall give an account of the experimental determination of the following data about the transition point of sodium chloride dihydrate: the volume change at atmospheric pressure; the temperature of the transition point up to pressures of about 12 kilobars; and the volume changes which accompany the inversion at these pressures. We shall also calculate the heat of transition both from the melting curve under pressure and from the solubility curves at atmospheric pressure.

Experimental

Sodium chloride dihydrate, as has been mentioned, exhibits great reluctance to crystallize from solution, but, following a suggestion of Meyer-

[4] 1 bar = 10^6 dynes per sq. cm.; 1 kilobar = 10^3 bars (approx. 1000 atmospheres). See Adams and Gibson, J. *Wash. Acad. Sci.*, 20, 213 (1930).

hoffer and Saunders,[5] we found that it was possible to prepare the pure hydrate easily and in any desired quantity by cooling a solution of sodium chloride, saturated at room temperature, to below −5° and throwing on the surface of the solution a small amount of carbon dioxide snow. Immediately a cloud of fine crystals of the dihydrate appeared in solution. Below −5° the solubility of sodium chloride is much greater than that of $NaCl\cdot 2H_2O$, so that introduction of solid sodium chloride into the cold bath of dihydrate crystals results in immediate solution of anhydrous salt and precipitation of more dihydrate.

The mother liquor was removed from the crystals by decantation and suction through a chilled filter.

Change in Volume Accompanying the Melting of $NaCl\cdot 2H_2O$ at One Atmosphere.—It was difficult to dry the dihydrate completely; hence the dilatometer (a glass one of the usual kind) was filled with the moist salt. Any air was carefully pumped out and xylene introduced as index liquid. During all these operations the temperature of the salt was kept below 0°. When filled and sealed up the dilatometer was immersed in a cold bath and the heights of the meniscus of the xylene in the capillary at different temperatures were read. The changes in height of the meniscus, corrected for temperature of the capillary and irregularities in the bore, were converted to volume changes and plotted against temperature. From the curve was read the increase in volume accompanying the decomposition at 0.1°, which is the mean of the inversion temperatures as given in the literature (0.15°) and as determined by us (0.05°).

After each experiment the amounts of anhydrous sodium chloride and water contained in the dilatometer were determined, and hence with the knowledge of the solubility of sodium chloride at the inversion point we could calculate the actual amount of solid $NaCl\cdot 2H_2O$ whose volume change on melting was measured.

If A is the weight of salt and water and B the weight of salt in the dilatometer, x_2 and x_0 the weight fractions of sodium chloride in the saturated solution and the solid dihydrate, respectively, at 0°, and m_2 the unknown weight of solid dihydrate before inversion, we find that

$$m_2 = \frac{B - Ax_2}{x_0 - x_2}$$

x_2 was taken from the data of Berkeley[6] as 0.2633 and x_0 is 0.6187. Two experiments were performed, m_2 being 9.628 g. in the first and 8.846 in the second.

The results gave 0.0362 and 0.0377, or an average of 0.037 cc./g. of $NaCl\cdot 2H_2O$ as the increase in volume accompanying the transition, $NaCl\cdot 2H_2O \longrightarrow NaCl + \text{Satd. Soln.}$ at 0.1°. By taking Berkeley's value, 1.2090,

for the density of a saturated salt solution at 0°, and the density of sodium chloride as 2.168,[7] we calculated that the density of $NaCl \cdot 2H_2O$ at 0° is 1.630 g. per ml.

A few qualitative observations on the speed of the reaction may be noted here. The reaction did not proceed at any appreciable rate until the temperature was 1–2° above the inversion point, and even then the rate was slow. It required over an hour for the reaction to go to completion at a temperature of 4°. At constant temperature the reaction accelerated as more and more anhydrous salt was formed, reaching a maximum speed when about half the material had inverted.

The Effect of Pressure on the Transition Point. (a) Low-Pressure Experiments.—In order to examine the initial portion of the p–t curve of the melting of $NaCl \cdot 2H_2O$, a sample of the hydrate was enclosed in the bomb of the pressure dilatometer apparatus whose description has already been published in detail.[8]

The bomb was immersed in a low-temperature bath, a suitable pressure generated, and the system, bomb and pressure gage tightly closed. The criterion of the inversion proceeding in any direction was steady change of pressure at constant temperature. At first the temperature of the bath was raised to a point where rise of pressure indicated that the hydrate was decomposing. The temperature was then lowered to a point where falling pressure showed that re-formation of hydrate was taking place. After that the temperature was raised by short intervals, the trend of the pressure change being carefully observed until it was possible to shut the equilibrium temperature within limits of ±0.25°. The results are given in Table I. In this way the points at 180, 270, 550 and 850 bars on the curve in Fig. 2 were obtained. These points established the initial slope of the p–t curve for $NaCl \cdot 2H_2O$ to our satisfaction.

has already been described.[9] It consists essentially of a very heavy-walled steel cylinder or bomb in which the system under investigation is immersed in n-butyl ether, a liquid selected because of its high freezing pressure. A special type of leak-proof piston is forced into the open end of the cylinder and hydrostatic pressure generated in the butyl ether. The pressure is measured by an electrical resistance gage.

The apparatus is large and, although protected from minor temperature variations by an insulating housing, is approximately at the temperature of the room. The apparatus could be held constant for a day at temperatures between 17 and 26°, and by following a special procedure it was possible to determine the equilibrium pressures at these temperatures. A glass tube (see Fig. 1) was filled with slightly moist dihydrate, placed in a somewhat larger steel tube filled with butyl ether and kept for half an hour in a eutectic mixture of chloroform and carbon dioxide (approx. −80°). The tubes and their contents were introduced into the bomb and the pressure was raised as expeditiously as possible to the highest value. Five minutes elapsed between the removal of the capsules from the freezing mixture and the pressure on the dihydrate exceeding 7 kilobars. From auxiliary experiments at atmospheric pressure it was found that very little inversion of the salt would take place during the interval required for raising the pressure. A series of readings of pressure and piston displacement was taken when the apparatus came to temperature equilibrium. Rise or fall of pressure, temperature and piston displacement being constant, indicated decomposition or forma-

tion of the dihydrate and by prolonged observation we were able at temperatures up to 25° to estimate the inversion pressure to within the limits of error given in Col. 4 of Table II. It was also possible to make reliable estimates of the change in volume on inversion at these higher pressures. The results are recorded in Table II and the complete melting curve is illustrated in Fig. 2.

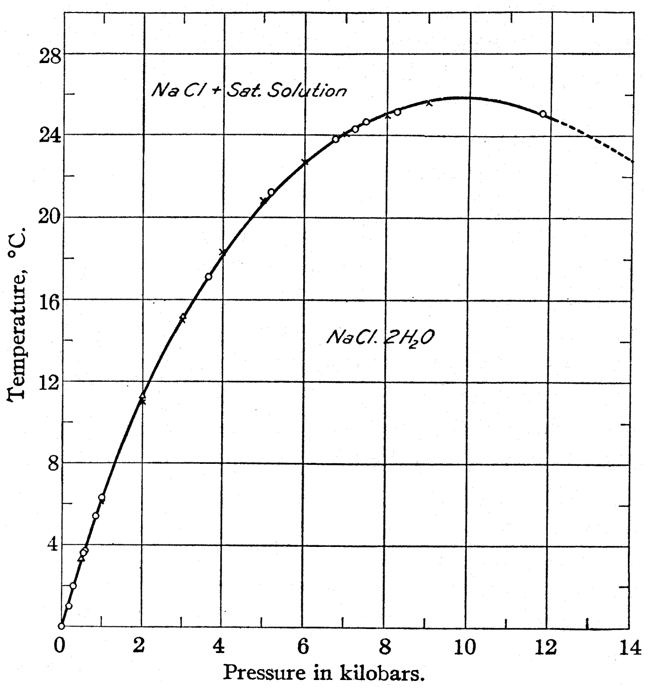

Fig. 2.—The influence of pressure on the incongruent melting of $NaCl{\cdot}2H_2O$.

Change in Volume at Higher Pressures.—At higher pressures the volume change on inversion, Av, which is proportional to the slope of the *p–t* curve, becomes very small. Even with the volume of the system under pressure reduced to a minimum, we had difficulty in fixing the inversion pressure and temperature at the higher pressures, and, indeed, it was almost impossible to obtain results by direct measurement between 8 and 11 kilobars. As one of the most interesting features of this work was the investigation of the possibility of a maximum on the melting curve, we decided to measure as accurately as possible the difference between the specific volume of $NaCl{\cdot}2H_2O$ and its decomposition products at pressures up to 12,000 bars. The maximum on the melting curve would occur at the pressure where Av is zero. Two methods were used to estimate Av. Method 1 consisted of determining the rise in pressure at constant volume or the increase in volume at constant pressure by direct observations near the actual inversion point at any temperature. Results were obtained in this way below 8 kilobars and are given in the second column of Table III. Method 2, being rather novel and depending on the fact that a mixture of sodium chloride and its saturated solution will remain in a metastable state several thousands of bars above the inversion point, will now be discussed in some detail. The piston displacements for a given amount of dihydrate at pressures from 6 to 12 kilobars were compared with the piston displacements for the decomposition products of the same sample of dihydrate (sodium chloride and saturated solution) at the same pressures obtained at the same temperature in such a way that errors due to hysteresis in the bomb were reduced to a minimum. The procedure may be illustrated by an example. A quantity of $NaCl{\cdot}2H_2O$ was placed in the bomb at 23.3°. The pressure was raised to exactly 12,400 bars and then reduced to 30 bars below 12,000 bars. A pause was made for temperature readjustment, and then the pressure was raised to as near 12,000 bars as possible. A reading of the piston displacement was taken. Similar observations of displacement and pressure at intervals of 1000 bars were made down to 7000 bars. The pressure was now lowered to 5700 bars, which is 500 bars below the inversion pressure at 23.3°. Readings were noted and a rise of pressure which was allowed to go on only for a short time indicated that $NaCl{\cdot}2H_2O$ was decomposing. The pressure was again raised to 12,400 bars and a second series of measurements was taken. The first run was made merely to put the apparatus through a definite hysteresis cycle. At the end of the second series the inversion was allowed to go to completion. Incidentally the rise of pressure at constant piston displacement gave a measure of Δv at 5700 bars.

After the reaction was entirely finished the pressure was again raised to 12,400 bars and a third series of pressures and piston displacements was observed.

This was followed by a fourth series of observations made in exactly the same way. By noting the differences between two successive runs made with the material in the bomb in the same state of aggregation we were able to make corrections for the small systematic difference between two successive series. The differences between the corrected piston displacements before and after the inversion when multiplied by the cross section area of the hole in the bomb and divided by the weight of dihydrate used gave the approximate change in volume per gram accompanying the inversion at pressures from 6 to 12 kilobars. Three experiments were made at temperatures of 23.3, 23.7 and 24°. In each case an additional value of Δv at 6000 bars was obtained by observation of the total rise in pressure during the inversion. In the experiments at 23.3 and 23.7° uncertainty arose as to the exact amount of dihydrate in the bomb. The results were calculated in such a way that the values of Δv at 7000 bars were made equal to that obtained in the experiment at 24°. All the results on volume changes are recorded in Table III.

TABLE III

INCREASE IN VOLUME OF $NaCl\cdot 2H_2O$ ON MELTING AT VARIOUS PRESSURES

Pressure, bars	Δv, cc./g., Method 1	Δv, cc./g., Method 2 1	2	3

Discussion of Results

Interpolation Formulas.—Two cubic equations

$$t = 7.047p - 0.7655p^2 + 0.035244p^3 \tag{1}$$

$$t = 0.06 + 6.512p - 0.5529p^2 + 0.06056p^3 \tag{2}$$

were found to express the melting temperature as a function of pressure. The temperature, t, is expressed in degrees centigrade and the pressure, p, is in kilobars. Equation 1 being passed through the points at lower pressures gives more accurately the initial slope of the pressure–temperature curve, but it does not represent the data very well above 4.5 kilobars. Equation 2, we consider, expresses the results accurately between 4 and 8 kilobars. Indeed, it applies very well to atmospheric pressure, which is surprising when it is mentioned that the lowest point used in computing this equation was that at 17.15° and 3.620 kilobars.

In Fig. 2 the circles represent the observed points, the crosses, points calculated from Equation 1, and the triangles, points calculated from Equation 2. Both equations are purely interpolation formulas and are not suited for extrapolation.

Maximum on Melting Curve.—From direct observations of melting we can say definitely that at 8000 bars sodium chloride dihydrate becomes the stable phase in contact with a saturated solution at 25°. The question as to whether the melting curve passes through a maximum and whether at some higher pressure sodium chloride is again stable at 25° may be answered from considerations of the volume changes. In Fig. 3 we have plotted points representing Δv per gram at different pressures as measured by our first method (triangles), and as determined by the second method (circles). The two series are fairly consistent, although the second method appears to give values which are somewhat lower than those given by the first. The curve passed through these points cuts the pressure axis at 9500 bars, showing that the melting curve passes through a maximum at this pressure. It should be mentioned that the values of Δv at the higher pressures are calculated on the assumption that the effect of temperature on the change in volume during the inversion is negligible when compared with the effect of pressure.

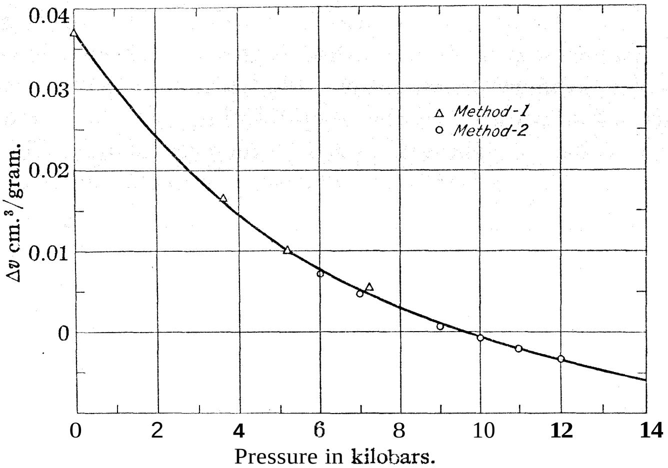

Fig. 3.—Volume change accompanying the melting of 1 g. of $NaCl \cdot 2H_2O$ at various pressures. Above 9500 bars the volume change is negative.

Confirmation of the maximum on the melting curve was obtained by direct observation of the decomposition of $NaCl \cdot 2H_2O$ at 12,500 bars and 25.1'. The pressure on the sample was first raised to 12,500 bars and dropped to 10,000 bars, where it was held until equilibrium was established. The pressure was then raised by steps of 500 bars and at each pause was carefully watched and its trend noted. Below 12,000 bars and above 10,000 bars the creep of pressure after the primary rise was always upward—there was no tendency to fall. This phenomenon will be referred to later. At 12,000 bars the pressure drifted down slowly but steadily and in the course of four hours dropped 80 bars. That this drop was due to the decomposition of $NaCl \cdot 2H_2O$ was shown when the pressure was finally lowered to 7000 bars (1000 bars below the low-pressure equilibrium value at 25') and the total rise at constant volume was about one-third that which would be obtained from the particular sample of uninverted dihydrate. As the pressure rose at constant volume at 11,500 bars, we were able to place the pressure coördinate of the melting curve at 25.1' between 11,500 and 12,000 bars.

The Compressibility of $NaCl \cdot 2H_2O$.—The volume of sodium chloride at any pressure is known from compressibility measurements,[9a] and recently the specific volumes of saturated sodium chloride solutions have been determined to 12 kilobars.[10] As we have measured around 25° the differences in volume between $NaCl \cdot 2H_2O$ and its decomposition products, it is possible to calculate the specific volume of the hydrate at pressures between 6 and 12 kilobars. It is assumed that the solubility of sodium chloride is not greatly altered by pressure in this range. The results are recorded in Fig. 4 where v_0, the specific volume, is plotted against the pressure. The slope of this curve, when divided by the specific volume of $NaCl \cdot 2H_2O$ at ordinary pressure, gives the fractional decrease in volume per bar increase of pressure, or the compressibility β. The average value of β between 6 and 12 kilobars is 4.8×10^{-6} reciprocal bars. This may be compared with 3.6×10^{-6}, the value of β for sodium chloride at 9 kilobars.

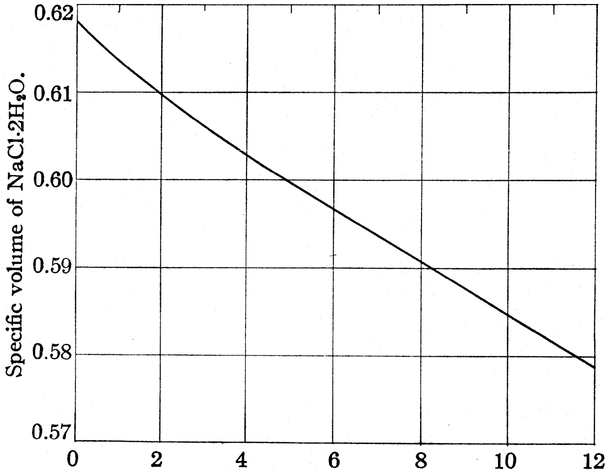

Fig. 4.—The specific volume of $NaCl \cdot 2H_2O$ as a function of pressure.

Heat of Inversion from the Melting Curve.—The initial slope of the melting curve is shown by Equation 1 to be 7.05° per kilobar. The volume change at atmospheric pressure is 0.037 cc. per gram of $NaCl \cdot 2H_2O$, and hence by the Clausius–Clapeyron equation the heat of fusion per gram, Ah, is 34.4 cal. In the same way, obtaining Av from the curve in Fig. 3 and dt/dp from Equation 2, we find that at 5 and 7 kilobars Ah is 36.4 and 33.1, respectively. The heat of fusion is not greatly influenced by pressure—a fact which is in accord with Bridgman's[11] observations on various materials.

---

[10] Adams, unpublished data.

[11] Bridgman, *Phys. Rev.*, 3, 190 (1914).

Secondary Increase of Pressure.—On all occasions when a charge of dihydrate was held at a pressure and temperature in the vicinity of the maximum on the melting curve a very curious phenomenon was observed. The pressure had been raised to somewhat above 10,000 bars, and, contrary to what was expected, it continued to drift slowly *upward* for an hour or more, the total increase of pressure being as much as 20 bars. The normal behavior of a system the pressure of which has just been increased is, of course, to show at first a small decrease of pressure—even in a pressure-tight apparatus. The immediate cause of this decrease may be the cooling subsequent to the heating by compression, or, in a multi-phase system, the transformation of one phase to another in accordance with the conditions of equilibrium. Similarly, a decrease of pressure is usually followed by a secondary increase. In the simple case of a mixture of solid and liquid in equilibrium an increase of pressure causes the production of more solid (in rare instances more liquid), and since this is accompanied by a decrease of volume, the pressure falls, finally coming back, if the primary increase is not too great and the substance is a pure material, exactly to the original pressure.

The abnormal behavior of the sodium chloride dihydrate, which at first seemed very puzzling, may be explained as follows. Suppose that a mixture of the dihydrate and its decomposition products is held at a temperature and pressure corresponding to the point *O* in Fig. 5, and that the pressure on the system is suddenly increased. The temperature will increase with the pressure, approximately isentropically, as shown by the dotted line. The material will then begin to cool, and the secondary pressure change will be the sum of two effects: (1) the effect due to cooling and (2) the effect due to transformation from one form to the other. In the present case the problem is much simplified because the inversion takes place relatively slowly so that during the time required for the temperature to return to its original value (about five minutes) very little of the material has changed its state. On the diagram, therefore, the temperature and pressure reach the point *a* while there is still present a mixture of the dihydrate and its decomposition products. Since at this point dihydrate is the stable phase, solution and salt will react to form dihydrate, which under the given conditions has the smaller volume, and hence the pressure will fall. Suppose, on the

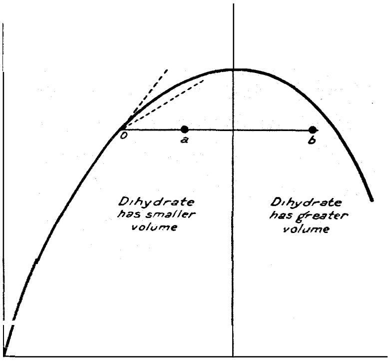

Fig. 5.—Diagram to accompany explanation of secondary increase of pressure.

other hand, that starting again with a mixture at O, the pressure is suddenly increased, attaining at the same temperature the pressure indicated by b. Here, as before, dihydrate is the stable phase, and more will be formed, but the pressure being now beyond the maximum, the dihydrate occupies more volume and the pressure therefore will rise. A secondary increase of pressure has been discussed by Tammann[12] in connection with the existence of maximum melting points, but Bridgman in a careful analysis of the problem points out that the conditions of equilibrium in a system make it impossible for Tammann's secondary increase of pressure to occur. According to Bridgman,[13] in a system composed of phases in equilibrium, and each in condition of internal stability, thermodynamical considerations require that the secondary pressure reaction be a decrease rather than an increase. That this result, however, does not contradict the opposite conclusion obtained as above from elementary principles becomes apparent when we recall that Bridgman's equation is valid only for *infinitesimal* changes and is not necessarily applicable to the *finite* changes here under discussion. It is only because we have increased the pressure a considerable distance beyond the equilibrium curve and into that part of the field which lies beyond the maximum that the secondary increase of pressure occurs. Expressed in other terms: we are here dealing with a non-equilibrium process, whereas the thermodynamical equations refer only to equilibrium states and their immediate vicinity. It should be noted that the above considerations apply equally well to the melting curve of a substance which does not decompose at its melting point.

Heat of Inversion from the Solubility Curves.—No direct measurements of the latent heat of the incongruent melting of $NaCl \cdot 2H_2O$ are available but it is possible to calculate this heat of inversion from solubility measurements of sodium chloride in water and from the known values of the chemical potential of sodium chloride in aqueous solution. The relation is

$$\Delta h = T(b_3 - b_2)\frac{\partial \mu_2}{\partial x_2}\frac{x_0 - x_2}{1 - x_2} \qquad (3)$$

Here Ah is the heat absorbed, when one gram of $NaCl \cdot 2H_2O$ inverts to *a* mixture of sodium chloride and saturated solution of sodium chloride in water, T is the absolute temperature, x_0 is weight fraction of sodium chloride in $NaCl \cdot 2H_2O$, x_2 is the weight fraction of sodium chloride in the saturated solution which is in equilibrium with sodium chloride and $NaCl \cdot 2H_2O$, b_3 is the slope dx_2/dT of the solubility curve for $NaCl \cdot 2H_2O$ as the solid phase, b_2 is dx_2/dT for the solubility curve with sodium chloride as the solid phase, and μ_2 is the chemical potential of Gibbs (or partial free energy of Lewis) referred to one gram of sodium chloride in solution.[14] In the expression

---

[12] G. Tammann, "Kristallisieren und Schmelzen," p. 87.

[13] P. W. Bridgman, *Phys. Rev.*, 3, 192 (1914).

[14] If it is desired to express the above equation in terms of activity and mole frac-

$\partial\mu_2/\partial x_2$ the temperature is constant. The derivation of the equation will be given in another paper from this Laboratory.

From a careful plot of the solubility data of sodium chloride in water as given in the "International Critical Tables," b_3 is found to be 0.00138 and b_2 0.00001. The solubility of sodium chloride, x_2, at the inversion point is 0.263, and x_0 is 0.619. The absolute temperature of the inversion, T_1, is 273.2°, and the value of $\partial\mu_2/\partial x_2$, as determined from freezing point, e. m. f., solubility and vapor-pressure data, and corrected to $t = 0.1°$, is taken as 165 calories. Substituting these numerical quantities in Equation **3** we have

$$Ah = 30 \text{ cal.}$$

for the heat absorbed by the incongruent melting of one g. of $NaCl{\cdot}2H_2O$.

This result is to be compared with 34 cal., the value obtained from the initial slope of the p–t curve and the volume change at $p = 1$. The agreement is none too close, but considering the complexity of the calculation, and the large variety of data involved, it is an interesting confirmation. Probably about equal weight should be given to the value of ***Ah*** obtained from the solubility curve and that derived from the initial slope of the melting curve.

Summary

The temperature of the incongruent melting of $NaCl{\cdot}2H_2O$ has been determined up to 12,000 bars (or c. g. s. atmospheres) by direct measurement and also indirectly from measurements of the volume changes. The melting curve starts at 0.1' at atmospheric pressure with an initial slope of 7.05' per kilobar. The slope decreases rapidly with increasing pressure, finally becoming zero, so that the curve passes through a maximum at 9500 bars and 25.8'.

The volume change was measured at one bar in a dilatometer, and at various pressures up to 12,000 bars by two different methods. From the volume change and slope of the melting curve the heat of fusion at several pressures was calculated. The density of $NaCl{\cdot}2H_2O$ at 0.1° and one bar

tions, this can be done by making use of the relation $d\overline{F}_2 = M_2 d\mu_2 = RT\, d \ln a_2$ at constant temperature, in which $\overline{F}_2$ is the partial molal free energy, M_2 the formula weight, a_2 the activity of component 2, and R is the gas constant. The transformed equation is

$$\Delta H = 3RT^2(B_3 - B_2)\,\frac{d \ln a_2}{dX_2}\,\frac{X_0 - X_2}{1 - X_2}$$

in which ΔH is the heat observed when one mole of $NaCl{\cdot}2H_2O$ inverts, X_2 is the mole fraction of sodium chloride in the equilibrium solution, X_0 is the mole fraction of sodium chloride in $NaCl{\cdot}2H_2O$, B_3 and B_2 are the values of dX_2/dt along the $NaCl{\cdot}2H_2O$ and sodium chloride curves, respectively, and a_2 is the activity of sodium chloride in solution. Moreover, the activity coefficient γ may be used in place of a_2 by making the substitution, $d \ln a_2/dX_2 = \nu\, d \ln (m\gamma)/dX_2$, ν being the number of ions into which one molecule of the solute is assumed to dissociate.

was found to be 1.630, and its mean compressibility between 6000 and 12,000 bars at about 22°, 4.8×10^{-6} per bar. A method for calculating the heat of fusion from solubility data gives a value which is in fair agreement with that determined from the initial slope of the melting curve, the average value being 32 cal. per g. of $NaCl\cdot 2H_2O$.

A secondary pressure increase, that is, a continued rise of pressure following a sudden increase, was observed at pressures near the maximum on the curve, and an explanation is given for this phenomenon.

THE SEPARATION OF YTTERBIUM BY ELECTROLYTIC REDUCTION.

OBSERVATIONS ON THE RARE EARTHS. XXXVI

BY ROBERT W. BALL[1] WITH L. F. YNTEMA

RECEIVED AUGUST 2, 1930 PUBLISHED NOVEMBER 5, 1930

Recently it was found that europium can be separated from a mixture of samarium, europium and gadolinium chlorides by electrolytic reduction in acid solution in the presence of the sulfate ion.[2] Europous sulfate, $EuSO_4$, precipitated as a white, finely crystalline compound, stable when heated in air at 65° and insoluble in dilute acids. It was readily oxidized by dilute nitric acid.

In 1929 Klemm and Schüth[3] reported the preparation of ytterbous chloride, $YbCl_2$, similar to samarous chloride, $SmCl_2$,[4,5] and europous chloride, $EuCl_2$[6,7] by treatment of ytterbium oxide, Yb_2O_3, with a stream of Cl_2–S_2Cl_2 at 600–620°.

These facts suggested the possibility of separating ytterbium from the other rare earths of the yttrium group by electrolytic reduction in the presence of the sulfate ion.

Experimental

I. Electrolysis of Rare Earths with Low Ytterbium Content.—Ten grams of pink yttrium group oxides, containing yttrium and erbium with small percentages of thulium and ytterbium, were dissolved in hydrochloric

acid. The excess acid was evaporated, the solution diluted to 400 cc. and 4 cc. of sulfuric acid (sp. gr. 1.84) was added.

This solution was put into the cathode compartment of an electrolytic cell with a mercury cathode.[2] The anode compartment was filled to the same level with approximately 0.05 N hydrochloric acid. A current of 0.1 ampere, corresponding to a current density at the cathode of 0.025 amp./sq. cm., was used. The voltage drop between electrodes was 110 volts.

The solution was electrolyzed almost continuously for one hundred and ten hours. The only interruptions were during the nights when enough of the hydrogen evolved would get into the salt bridge to shut it off. During the first hour of the electrolysis the solution became dark. This soon cleared up and after thirty-two hours the solution, which was originally pink, had become clear green in color. Visual examination of the solution with a hand spectroscope still showed the absorption spectrum of erbium while there was also general absorption in the red part of the spectrum. At the end of eighty hours a greenish-white crystalline precipitate started to form. At the end of one hundred and ten hours the precipitate was filtered off, washed with boiled distilled water and dissolved in nitric acid. It dissolved in concentrated nitric acid with the evolution of brown fumes, indicating that it was a reduced compound. Any heavy metals with which the precipitate might have become contaminated were removed with hydrogen sulfide. The rare earths were precipitated as oxalate and ignited to the oxide, which was white in color. A qualitative test showed that the anion of the precipitate was sulfate.

Photographs were made of the arc spectra on carbon electrodes of the original mixed oxides and of the oxide from the precipitate.

The more prominent lines on this photograph were examined. The results obtained are shown in Table I.

TABLE I

SPECTRUM LINES

Wave lengths in I. A.	Element	Intensity of line in original	Intensity of line in precipitate	Wave lengths in I. A.	Element	Intensity of line in original	Intensity of line in precipitate
4935.51	Yb	0	7	4422.60	Y	10	1
4900.11	Y	7	1	4398.03	Y	8	2
4883.69	Y	7	1	4374.95	Y or Er	10	5
4854.88	Y	7	1	4358.72	Y	6	1
4823.31	Y	2	0	4309.62	Y	10	4
4786.60	Yb	0	7	4305.97	Yb	0	5
4781.90	Yb	0	7	3933.67	Ca	4	7
4564.00	Yb	0	3	3906.34	Er	4	1

4515.15	Yb	0 -	4	3467.88	Y	3	1
4439.22	Yb	0	8				

From this examination it was concluded that, while the original material contained only 1 or 2% of ytterbium, the precipitate consisted of ytterbium with very little of the other rare earths (estimated at 1 or 2%).

The authors wish to express their appreciation to Mr. P. W. Selwood for his assistance in the examination of the arc spectra of the original and precipitated oxides.

II. Electrolysis of Rare Earths with High Ytterbium Content and Analysis of the Precipitate.—Samples of ytterbium-rich oxide which were white in color and, when dissolved in hydrochloric acid, showed no absorption in the visible region of the spectrum, were also electrolyzed. The same color changes and precipitate formation as noted above took place although much more rapidly than in the solutions containing less ytterbium. When one or one and a half grams of precipitate had formed, the solution was decanted and the precipitate collected on a sintered glass crucible. It was found that the precipitate dissolved slowly if left in contact with the solution with constant evolution of gas. The decanted solution was clear green and bubbles of gas formed through its entire volume. At the end of about fifteen minutes it became colorless and no more gas was evolved.

The precipitate was washed successively with freshly boiled distilled water, alcohol and ether, and heated to constant weight at 72°. It was found that the precipitate gained weight when exposed to air at room temperatures; the crucible was therefore transferred to a glass-stoppered

weighing bottle before cooling. The analysis was carried out as described in a previous publication.[2] The results are given in Table II.

The ratio of sulfate to ytterbium was always less than unity. It was found that the material which approximated closest to a 1:1 ratio for ytterbium and sulfate was precipitated when the current density was low, the solution was dilute and the hydrogen-ion concentration fairly high. In this investigation no attempt was made to determine the optimum hydrogen-ion concentration for precipitation. The acid concentration in the cathode compartment of the cell at the start of a run was **0.37** N and this was decreased by the electrolysis. Care must be exercised, however, to prevent hydroxide formation through too low acidity. It is supposed that ytterbium is precipitated as $YbSO_4 \cdot xH_2O$, in which the water content is unknown. The fact that the sulfate content is lower than is theoretically correct may be explained by assuming that there is hydrolysis after the precipitation has taken place. It should be pointed out that the completeness of separation is not affected by any change taking place in the precipitate after it has once formed.

It was noticed that ytterbous sulfate was only stable in the acid solution when current was flowing and the cathode was one with a high overvoltage. When the current was shut off, the precipitate slowly dissolved with the evolution of hydrogen. The reaction is probably

$$2YbSO_4 + 2H^+ \longrightarrow 2Yb^{+++} + 2SO_4^{--} + H_2$$

Of particular interest is the green coloration which always appeared when ytterbium salts were reduced. Examination with a hand spectroscope showed no absorption bands, but general absorption in the red. When europium salts were reduced there was no change in color. When ytterbium was present, even if only in small amounts, the green coloration always appeared. It appeared before any precipitate formed and remained as long as the electrolysis was continued. On shutting off the current, or decanting the solution into a beaker, bubbles of hydrogen formed throughout the clear green acidic solution and within fifteen minutes the solution had become colorless. The reaction is probably

$$2Yb^{++} + 2H^+ \longrightarrow 2Yb^{+++} + H_2$$

The ytterbic ion, Yb^{+++}, is colorless, but the ytterbous ion, Yb^{++}, appears to be green.

Attempts to reduce ytterbium, using cadmium or platinum cathodes, were not very successful.

Summary

1. Bivalent ytterbium sulfate may be precipitated from an acid solution by electrolytic reduction in the presence of the sulfate ion.

2. Arc spectrum analysis indicates that ytterbium of 98% purity may

be separated in one operation from mixed yttrium group material containing 2% ytterbium.

3. Analysis of the precipitate showed it to be of variable composition approaching the formula $YbSO_4 \cdot xH_2O$. It is a very light green crystalline compound. It is soluble in dilute acids with the evolution of hydrogen and in nitric acid with evolution of oxides of nitrogen.

4. The ytterbous ion, Yb^{++}, is green.

EQUILIBRIA IN THE Fe–H–O SYSTEM. INDIRECT CALCULATION OF THE WATER GAS EQUILIBRIUM CONSTANT

BY P. H. EMMETT AND J. F. SHULTZ

RECEIVED AUGUST 9, 1930 PUBLISHED NOVEMBER 5, 1930

In a previous paper[1] we have calculated the value of the equilibrium constant for the reaction

$$CO_2 + H_2 = CO + H_2O \qquad K_1 = (P_{CO})(P_{H_2O})/(P_{CO_2})(P_{H_2}) \qquad (1)$$

by combining the equilibrium constants obtained in our experiments[2] on the two reactions

$$Co + H_2O = CoO + H_2 \qquad K_2 = P_{H_2}/P_{H_2O} \qquad (2)$$
$$Co + CO_2 = CoO + CO \qquad K_3 = P_{CO}/P_{CO_2} \qquad (3)$$

The values so calculated were found to be in good agreement with those measured directly by Neumann and Köhler.[3] Such previous calculations made by Eastman and Evans,[4] Eastman[5] and Eastman and Robinson,[6] respectively, had, however, given values about 40% higher than the directly measured equilibrium constants. The first two of these calculations were based on the reactions

$$FeO + H_2 = Fe + H_2O \qquad K_4 = P_{H_2O}/P_{H_2} \qquad (4)$$
$$FeO + CO = Fe + CO_2 \qquad K_5 = P_{CO_2}/P_{CO} \qquad (5)$$
$$Fe_3O_4 + H_2 = H_2O + 3FeO \qquad K_6 = P_{H_2O}/P_{H_2} \qquad (6)$$
$$Fe_3O_4 + CO = 3FeO + CO_2 \qquad K_7 = P_{CO_2}/P_{CO} \qquad (7)$$

The calculations by Eastman and Robinson were made with the help of their own equilibrium data on the reactions

$$SnO_2 + 2H_2 = 2H_2O + Sn \qquad K_8 = P_{H_2O}/P_{H_2} \qquad (8)$$
$$SnO_2 + 2CO = Sn + 2CO_2 \qquad K_9 = P_{CO_2}/P_{CO} \qquad (9)$$

In view of the importance of knowing the correct values for the water gas equilibrium constant, as well as the values for the equilibria involving iron and its oxides, it seemed worth while to attempt to ascertain whether the above-mentioned discrepancy might be due to errors in previous determinations of the equilibria of Reactions 4, 5, 6 and 7.

Examination of the literature has shown that the equilibrium constants that have been obtained for Reactions 5 and 7 differ considerably among themselves but exhibit no regular variations. The most reliable values agree approximately with those chosen by Eastman.[5] However, values for equilibria involved in Reactions 4 and 6 vary in a somewhat regular manner; they can for the most part be divided into two groups. In Group I are those agreeing with the determinations of Eastman and his co-workers; when combined with equilibrium constants for Equations 5 and 7, they give values for the water gas constant that are 40% or so higher than those directly measured. In the second group are those agreeing approximately with the theoretical curve calculated by combining equilibrium constants of the Fe–C–O system (Equations 5 and 7) and the directly measured value of the constants for Equation 1. A study of the apparatus and procedure employed by these two groups of workers made it seem possible that the values in the first group constitute what might be termed false equilibria in that they may have been influenced by an abnormal consumption of hydrogen by the surface of the iron oxide specimens. Such surface effects had been observed by us during the determination of the equilibrium in Reaction 3. They had also been noted by a number of previous workers.[7]

It seemed that the use of a dynamic rather than a static method would eliminate this source of error. The present paper gives the results of a series of equilibrium measurements obtained by a dynamic method on Reaction 4, at temperatures between 600 and 1000°, and on Reaction 6 at 700 and 800°.

Apparatus and Procedure

The dynamic method used in the present experiments is almost identical with that reported in a previous paper.[1] It consisted essentially in passing steam–hydrogen mixtures over an iron–iron oxide mixture and analyzing the effluent gases for water vapor and for hydrogen. Equilibrium was approached both from the side of reduction and of oxidation.

The apparatus is shown in Fig. 1. It consisted of a saturator, A; a reaction tube, J; an electric furnace, B; and an analytical apparatus, C and D. The saturator consisted of two towers containing glass beads and immersed in a thermostat controllable to ±0.1°. Tank hydrogen, after being freed from oxygen by hot copper, was passed through a flowmeter and mixed with excess steam from a steam boiler; the steam–hydrogen mixture was passed through the thermostated saturator towers.

[7] Richardson, Vibrans and Bell, Science, 56, 27 (1922); Pease and Cook, THIS JOURNAL, 48, 1199 (1926); Taylor, *Chem. Met.*, 27, 1263 (1922).

The reaction chamber was a silica tube, flanged and ground at one end to fit tightly against a similar flanged and ground pyrex glass tube. The two tubes were drawn together by a brass clamp, padded by asbestos washers and were made gas-tight by a layer of de Khotinsky wax over the joint. The other end of the quartz tube was drawn down and sealed to a small quartz tube in order to decrease the dead space between the oxide mixture and the analytical apparatus. The quartz reaction tube was surrounded by a heavy copper jacket for a distance of about 20 centimeters and packed with 85% magnesia into the electric furnace shown in the diagram. The copper cylinder surrounding the reaction tube fitted tightly into the alundum tube upon which the nichrome heating element was wound. It was centrally located in the furnace, being about 15 centimeters from each end.

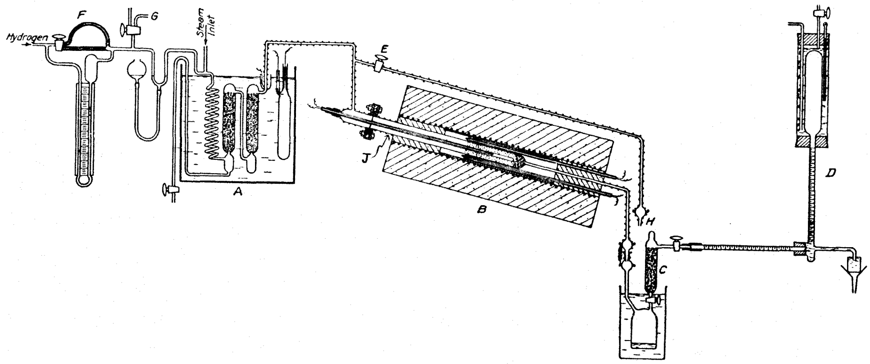

Fig. 1.—Apparatus.

In all of the final runs temperatures were measured by calibrated Pt–Pt-Rh thermocouples in conjunction with a Type K potentiometer. One couple was placed in a thin quartz thermocouple well in the center of the iron–iron oxide mixture, as shown in Fig. 1. The other Pt–Pt-Rh couple was placed in contact with the outside of the reaction tube. During each run it was moved along the tube to obtain the lengthwise temperature gradient. The gradient along the oxide mass was found to agree with that obtained on the outside couple, and was accordingly measured only a few times. The iron–iron oxide mass was about 5° cooler at each end than in the center. The gradient across the reaction tube was usually only one or two degrees; in a few runs it was as much as five degrees.

In the large number of preliminary experiments, alumel–chromel couples calibrated initially at 100 and 444° were used in conjunction with a portable potentiometer for measuring the temperature of 'the reaction tube. Unfortunately, during use the thermocouples became very brittle and broke before a final calibration over the range of temperatures used could be made.

The high reactivity desired in these measurements was obtained by using as a source of iron synthetic ammonia catalysts.[8] Sample A contained 0.5% ZrO_2 and 0.5% Al_2O_3. Sample B was a "pure iron" catalyst containing only 0.15% Al_2O_3.

The analytical apparatus was very similar to that previously described. The gas pipet D was of 250-cc. capacity and was water jacketed in order to eliminate any uncertainty as to its temperature. The weighing tube C was connected to the exit of the reaction vessel by a ground joint. All glass tubing between the thermostat and the reaction tube and at the exit of the reaction vessel was heated electrically to prevent

---

[8] Eastman, THIS JOURNAL, 44, 975 (1922).

condensation of any of the moisture present. Dehydrite was used in the weighing tube to catch any moisture not condensed in the main bulb of the tube. The specially designed gas pipet could be attached by a rubber connection directly to the weighing tube and exerted practically no back pressure in the line.

In carrying out the experiments, approximately 54 g. of the fused Fe_3O_4 was placed in the quartz reaction tube. The latter was packed into the furnace and connected as shown in the diagram. The iron oxide was then reduced completely by hydrogen at approximately 600°. At each furnace temperature at which runs were made the saturator was set at such a temperature as to give a steam–hydrogen mixture intermediate in composition between that of Curve I and that of Curve II, Fig. 2. Each run consisted in attaching the analytical apparatus to the exit of the reaction tube and determining the weight of water and volume of hydrogen in the exit gas passed during a given time. The composition of the entering gas was carefully checked at each saturator temperature to make certain that the steam–hydrogen mixture entering the reaction tube corresponded closely to that calculated from the temperature of the saturator. In the course of each experiment the following data were taken: temperature of catalyst, as measured by each of the thermocouples; flowmeter reading; temperature of the flowmeter, of the saturator bath, of the condenser surrounding the weighing tube, and of the gas in the pipet; the time of the run; the apparent volume of hydrogen collected; the height of final water level in the pipet above the water level at its exit; barometric pressure; and weight of water collected in the U-tube. The "U"-tube was always first carefully wiped with alcohol and then weighed to constant weight. From these data

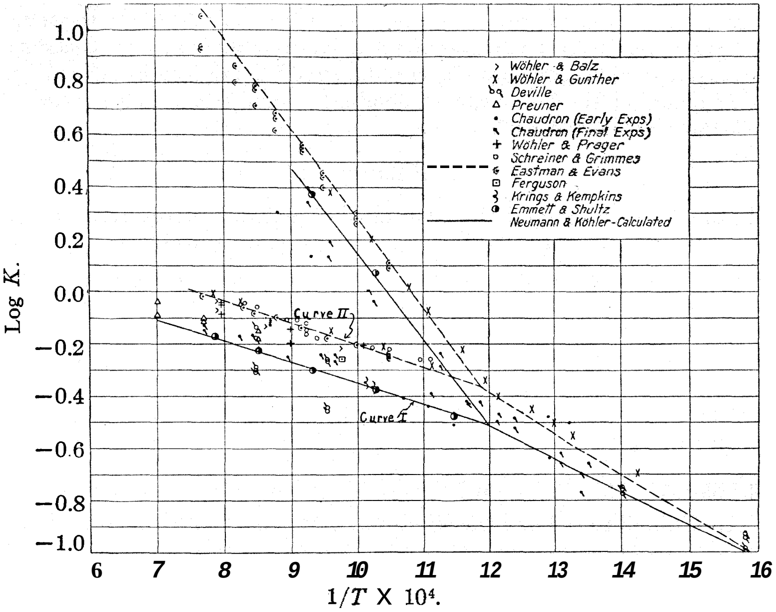

Fig. 2.—Variation with $1/T$ of log K, where $K = (H_2O)/(H_2)$ in equilibrium with FeO–Fe, Fe_3O_4–FeO or Fe_3O_4–Fe. Curve 1 is calculated by combination of the "best values" for the equilibrium constants of the Fe–C–O system and direct water gas constants as measured by Neumann and Kohler. Curve II is the experimental curve of Eastman and Evans.

the exit and entering steam–hydrogen ratios could be calculated. One could also calculate the average composition of the iron–iron oxide mixture in the reaction tube.

When the accumulation of oxide on the iron sample decreased the rate of attainment of equilibrium too greatly, the temperature of the saturator was dropped sufficiently to cause the entering steam–hydrogen ratio to be smaller than that corresponding to **Curve I**, Fig. *2*. Runs were then continued until most of the oxide was removed. Values of K_4 were determined in this way at intervals of 100° from 600° to 1000°, inclusive.

The two series of determinations of equilibria over $FeO–Fe_3O_4$ were carried out after oxidizing the Fe to FeO by long-continued steaming with a steam–hydrogen ratio a little too small to produce Fe_3O_4. This oxidation was continued until the exit steam–hydrogen ratio was identical with the entering, indicating that any iron remaining in the sample was covered effectively by a layer of FeO and would therefore have no influence on measurements of the $FeO–Fe_3O_4$ equilibrium. Equilibrium values were obtained over $FeO–Fe_3O_4$ at **700** and **800°**.

Results

In Table I are averaged the results of a number of preliminary experiments on the Fe–FeO system. The temperatures are those measured by the alumel–chromel couple at the center of the mass of iron–iron oxide.

TABLE I

PRELIMINARY EQUILIBRIUM DATA FOR REACTION 4 IN $H_2O–H_2–Fe–FeO$ SYSTEM

Temp., °C.		**600**	**700**	**800**	**900**	1000
Runs 40–329	$K = H_2O/H_2$	**0.343**	**0.413**	**0.493**	**0.591**	**0.679**
No. of runs averaged		**6**	40	**38**	**19**	**11**

In Tables II, III, IV, V and VI are given the data obtained in the final runs. In Cols. **3** and 4 are the inlet and exit steam–hydrogen ratios corresponding to the temperatures listed in Col. 2. In Col. 5 of each table are the equilibrium values corrected for convenience to 600, 700, 800, 900 and 1000°, respectively. The temperatures recorded in Col. 2 are the averages between the hottest point indicated by the outside couple and the coolest portion of the sample indicated by the inside couple.

In a number of the preliminary experiments the space velocity was lowered. No change in the exit ratio of steam to hydrogen was thereby produced. This constancy in composition of the exit gas at different rates of flow is further evidence that true equilibrium was being attained. All runs listed in Tables II to VI were made with an inlet hydrogen flow of about **23** cc. per minute.

The accuracy of the above equilibrium data depends upon the accuracy with which three measurements were made, the temperature of the iron–iron oxide, the volume of hydrogen passing through the reaction tube during a certain time, and the weight of water vapor passing in the same period of time.

The volume of hydrogen and the weight of water obtained per unit time were measured with considerable accuracy. The measurement of the

250 cc. of hydrogen could not, it seems, involve an uncertainty of more than ±0.5 cc. or 0.2%; this represents the summation of possible errors in reading the pressure, temperature and volume of gas in the pipet. Assuming an uncertainty of ±1 mg. in the weight of water obtained in each run, the total maximum errors that it seems might have been entailed in individual experiments in the analysis of the exit gas would accordingly range from ±1.9% at 600° to ±1.1% at 1000° for the Fe–FeO system, and from ±0.5% at 800° to ±0.7% at 700° in the FeO–Fe_3O_4 system.

In the experiments in which Pt–Pt-Rh thermocouples were used, together with a Type K potentiometer, the uncertainty in the temperature corresponding to a particular equilibrium value should not exceed ±6° at 600 and 700°, ±7° at 800 and 900° and ±9° at 1000°. The temperature at any particular portion of the reaction tube is known more accurately than this. A temperature uncertainty of this amount, however, results from the impossibility of ascertaining precisely which portion of the metal oxide mass determines the measured equilibrium value in a given run. The temperature uncertainty in the two series of runs on the FeO–Fe_3O_4 system, and in the preliminary runs on the Fe–FeO system is harder to estimate. The consistency of the values in the latter runs and their general agreement with those of the final runs would indicate that the temperatures measured with the alumel–chromel couples are probably correct to within ±10°.

When the above-mentioned errors are taken into consideration, the values of K_4 at 600, 700, 800, 900 and 1000" are 0.332, 0.422, 0.499, 0.594 and 0.669, respectively, each value being correct to ±0.012 unit. The values of K_6 at 700 and 800° are approximately 1.18 and 2.37, respectively. The above errors are estimated maximum errors that might exist in any one experiment. The probable errors calculated from the above data are of course very much smaller.

It will be noted in the above data that there is no difference between the values obtained with iron oxide, Sample A, and those obtained with Sample B. This observation was also apparent in the runs summarized in Table I. This indicates that the small content of Al_2O_3 or ZrO_2 does not materially affect the free energy of the iron samples.

In the above experiments the oxygen content of the samples was varied over wide limits with no influence on the equilibrium constant obtained. At one point equilibrium values taken from the high steam–hydrogen side remained constant, while the percentage of oxygen in the iron sample increased steadily from about 0.4 to about 5%. The first two runs after freshly oxidizing or reducing the sample were omitted in the above averages in order to exclude any possible surface effect from the final equilibrium values.

Discussion of Results

Logarithms of the values of K_4 and K_6 observed by various workers are plotted against $1/T$ in Fig. 2. Curve I was calculated by combining the "best values" chosen by Eastman[8] for the equilibria in Reactions 5 and 7 with the directly measured values of the water gas equilibrium of Reaction 1 as measured by Neumann and Köhler.[3] Curve II is one drawn by Eastman and Evans as being representative of their own values for the equilibria of Reactions 4 and 6. It is to be observed that the results of Eastman and Evans, of Schreiner and Grimmes[9] and of Wohler and Günther[10] agree fairly well with each other and with Curve II, but are about 40% higher than values lying along Curve I. The results of Van Groningen are said to be in agreement with these workers too, though his dissertation has not been available to us. The results of Wohler and Prager,[11] Wohler and Balz,[12] Chaudron,[13] Deville[14] and Preuner[15] lie, for the most part, between the two curves. The values obtained by the last three workers agree more closely with Curve I than with Curve II, though they are somewhat erratic. Finally, it will be noted, the values obtained in the present experiments are in excellent agreement with Curve I and are consistent with the maximum values of K_4 fixed by the experiments of Krings and Kempkens[16] and of Ferguson.[17]

Because of the importance of knowing the correct values for the equilibria of Reactions 4 and 6 and of gas–solid equilibria in general, it has seemed worth while to examine carefully the procedure and apparatus employed by the various above-mentioned workers with a view of ascertaining a possible cause of the large discrepancies that exist in the present equilibrium data.

The errors that may exist in the experimental determination of the equilibrium constant are of two kinds: (1) those resulting from incorrect observation of the temperature during a run, or faulty measurement of the partial pressure of water vapor or of hydrogen in the gaseous mixture at the end of an experiment; (2) those due to failure to obtain true equilibrium between the steam–hydrogen mixture and the solid phases indicated in Equations 4 and 6.

It seems very unlikely that the first type of error could be the entire cause of the above-mentioned discrepancies. In most cases the tempera-

ture of the sample was probably known with reasonable accuracy. The partial pressure of water could be in error only to the extent that there was any inaccuracy in measuring the temperature of the water in the thermostated bulb attached to the reaction tube in static experiments, or inaccuracy in determining the weight of water passing the iron samples per unit time in the experiments made by a dynamic method. No large uncertainties seem to have existed in either of these measurements. The principal error in measuring the partial pressure of hydrogen in static experiments arises from possible evolution of inert gas from the walls of the reaction tube of the metal sample during a run, or from possible leaking of air into the apparatus. Either occurrence would cause the total pressure and hence the apparent partial pressure of hydrogen to be too high; this would lower the apparent value of the equilibrium ratio of steam to hydrogen. Although this might explain some of the discrepancies between the various static experiments, it could not possibly account for the results of some of the static experiments being 40% higher than those obtained by the present dynamic method.

It has seemed to us that the cause of the discrepancy is of the second type. A careful consideration of the experiments of the various principal workers makes it appear probable that in the experiments performed by the static Deville method a false equilibrium has been measured—an equilibrium that differs from true equilibrium because of an abnormal consumption of hydrogen by a "surface oxide" present to a greater or less extent in all the static experiments carried out. Before discussing the work of the various authors it will be well to define what is meant by the "surface effect" here referred to.

Several instances are recorded in the literature in which the passage of a steam–hydrogen mixture over a freshly oxidized metal has resulted for a brief period in an exit steam–hydrogen ratio much higher than that corresponding to equilibrium with the massive metal–metal oxide phases. Conversely, passage of a steam–hydrogen mixture over freshly reduced metal surfaces has resulted in such an evolution of hydrogen that the effluent gas has for a short time possessed much less steam than corresponded to the normal equilibrium. Thus, Richardson, Vibrans and Bell noted the evolution of hydrogen in excess of equilibrium requirements when they passed steam over iron freshly reduced from iron oxide. Almquist and Black[18] and Emmett and Brunauer[19] have observed the definite formation of oxide on iron synthetic ammonia catalysts by ratios of steam to hydrogen much below equilibrium. Pease and Cook[7] noted excessive hydrogen evolution on passing steam over finely divided nickel and excessive hydrogen consumption in passing steam–hydrogen mixtures over

[19] Emmett and Brunauer, *ibid.*, 52, 2682 (1930).

freshly formed nickel oxide. The present authors[1] have called attention to similar phenomena in their study of the equilibria in Reactions 2 and 3. The effect is particularly observable in this latter system. In Fig. 3 is reproduced a diagram taken from the last mentioned paper. It clearly shows the manner in which such an effect can raise the ratio of CO_2/CO to a value much in excess of equilibrium if the surface of the oxide concerned is completely oxidized. The oxidation of the surface metal atoms by a gaseous oxidizing agent or reduction of the surface atoms of a metal oxide by a reducing gas thus appears to proceed with a greater decrease in free energy than does the oxidation of the massive metal to oxide or reduction of the normal oxide to massive metal. There are at present no data defining precisely the thickness of the "surface" to which such abnormal phenomena are restricted. All quantitative evidence available is, however, consistent with this "surface effect," being limited for the most part to the few outer layers of atoms of the metal or oxide.

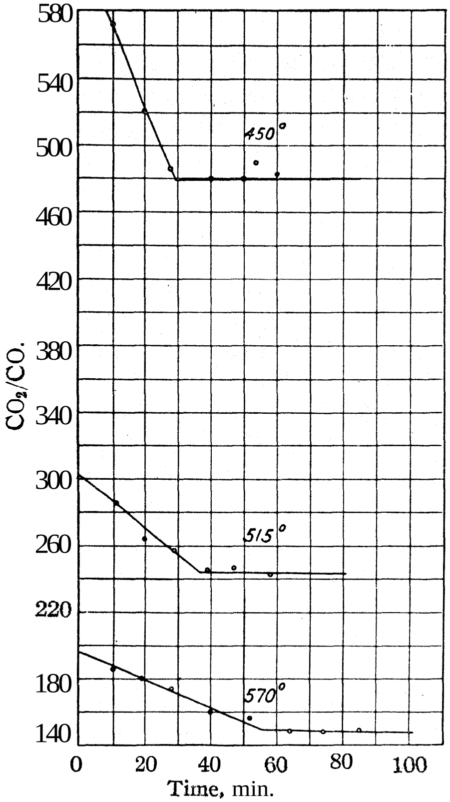

Fig. 3.—Typical curves showing the effect of surface oxide on the CO_2–CO equilibrium value over a cobalt–cobalt oxide mixture. The three series of runs shown were taken immediately after oxidation of the cobalt surface to CoO. The entering CO_2–CO ratios in the 570, 515 and 450° runs shown were 102, 194 and 324, respectively.

When the experiments of different workers are considered from the standpoint of the above-described surface effect, some interesting correlations appear.

Eastman and Evans, Schreiner and Grimmes, and Wohler and Günther used almost identical apparatus and procedure, and obtained values that are in good agreement with each other but are, in general, some 40% higher than those corresponding to Curve I in Fig. 2. The method used consisted in permitting water vapor from a thermostated water bulb to come in contact with samples of finely divided iron or iron oxide held in a quartz tube at some definite temperature. Equilibrium was said to have been reached when the total pressure indicated on an attached manometer became constant. These workers approached equilibrium from the reduction side by then merely increasing the temperature 25 or 50° after having obtained equilibrium from the oxidation side, and permitting the initially low steam–hydrogen ratio to adjust itself to the higher temperature. The samples of iron used were completely reduced in hydrogen initially and introduced into the quartz reaction tube as metallic iron. Evacuation of the apparatus was then carried out with the iron sample heated to free the apparatus from inert gases and decrease the pressure to that of the water vapor from the thermostated water bulb. In some of the experiments in which it was desirable to use a sample of known oxygen content, the iron samples were partially oxidized by continued evacuation until they were converted partially to oxide. In none of the experiments of these three authors was any mention made of approaching equilibrium from the reduction side by adding a large excess of hydrogen.

From this brief description of the procedure followed by these workers it will be apparent that at the start of every experiment mentioned by them iron samples had already been subjected to considerable exposure to steam. Hence each particle of iron must have been oxidized to some depth before the beginning of an experiment. Furthermore, in these experiments the final volume of hydrogen at equilibrium was of the order of only 2 or 3 cc. (S. T. P.) according to calculations based upon the internal volume of the apparatus and the final pressure of hydrogen present. It would seem, accordingly, that conditions were in each instance favorable for the operation of the "surface effect" mentioned above. The small volume of hydrogen in contact with a completely oxidized iron oxide surface would, in accordance with all of the above-mentioned instances, be expected to be partially consumed, thus resulting in a steam–hydrogen ratio much in excess of the true equilibrium value. The method used in approaching equilibrium from the hydrogen side would merely shift this surface effect to another temperature but still leave conditions suitable for it to be operative.

In marked contrast to the above-mentioned work is that of Deville, of Chaudron and of Preuner. They, in general, used a static apparatus similar to that of the first group of workers. However, the procedure employed was such as to eliminate partially the above-mentioned surface effect in at least some of their experiments. Deville and Preuner actually added excess hydrogen to the apparatus and observed the equilibrium resulting from the reduction of an iron oxide sample. Chaudron, in changing from the system $FeO–Fe_3O_4$ to the system Fe–FeO added excess hydrogen to the apparatus and after reduction evacuated it with the sample of iron cold. Any runs made immediately after such reduction without intervening evacuation with the sample hot should likewise not have been subject to a marked surface effect. Insufficient description of the exact procedure used by these three workers is given, however, to permit one to conclude definitely whether all of the discrepancy between this second group of workers and the first group is due to the influence of the surface effect, or is due in part to errors of Type 1.

Several interesting observations may be made in regard to the work of Deville and of Preuner.

Deville originated the static apparatus subsequently used by most workers in metal–metal oxidesteam–hydrogen equilibrium measurements. He obtained values at only two temperatures in the range covered by our own experiments, namely 907 and 767°, the boiling points of zinc and cadmium. His results at these temperatures are shown in Fig. 2. At 767° it will be noted that the four equilibrium values obtained by Deville fall distinctly into two groups. The two upper values obtained from the oxidation and reduction sides with the water-bath temperature at 15 and 15.4°, respectively, are in perfect agreement with each other, but differ greatly from two lower values obtained with the water-bath supposedly at 0°. No temperature measurements were made of the water in the inner bulb in the experiments of Deville, the temperature being assumed to be that of the surrounding water-bath. It is interesting to note that the four values at 767° are brought into perfect agreement by assuming that the water in the bulb attached to the reaction tube was at 4° instead of 0°. Since at 4° water has its maximum density, it does not seem improbable that in his experiments the water bulb was located at the bottom of an unstirred ice-bath where the temperature might easily have been 4°. Similarly at 907° the three low values were obtained with the water bulb immersed in an ice-bath, whereas the two upper values were obtained with the temperature of the water-bath at 15°. In this case, however, an assumed temperature of about 3° would be necessary to bring the two groups of results into agreement. It seems highly probable that this error in the temperature of the water-bath in the runs at 767 and 907° may have caused the discrepancies in his own experiments at these temperatures.

Preuner, working with a Deville type apparatus at temperatures of 900, 1025 and 1150°, obtained equilibrium values for Reaction 4. He, like Deville, took precautions to approach the equilibrium from the reduction side by actually introducing an excess of hydrogen and observing the pressure decrease. In Fig. 2 the higher of the values obtained by Preuner at each temperature are those in which equilibrium was approached from the high steam–hydrogen side. Those obtained from the reduction side are on an average only 5 to 10% above Curve I.

One observation not previously mentioned in connection with Preuner's work seems important. Figure 4 is a reproduction of Figure 24 of Preuner's paper. In his article in connection with this figure an experiment is described in which he merely wished to demonstrate the slowness with which a small amount of iron oxide would react with hydrogen at 900°. Water vapor at a pressure of 46.6 mm. was permitted to react in his static apparatus with a sample of completely reduced iron until the pressure had built up to 115 mm. A sufficient amount of hydrogen was then admitted to build up the pressure in the apparatus to about 130 mm. The pressure quickly dropped to an apparently constant value of about 125 mm. Preuner did not include this value in his equilibrium data, believing apparently that true equilibrium had not been attained. This is the only experiment in which after reaching equilibrium from the oxidation side he introduced hydrogen into the apparatus without further evacuation and resulting oxidation of the sample. As shown in Fig. 2, the equilibrium constant that we have computed from this one experiment agrees well with Curve I. It seems to be added evidence in favor of the validity of Curve I values and is apparently one static experiment in which the above-mentioned surface effect was entirely eliminated.

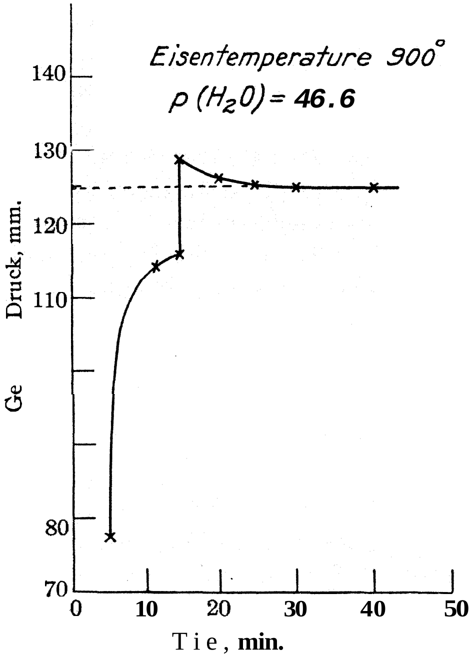

Fig. 4.—Variation with time of the P_{H_2O}/P_{H_2} over a sample of completely reduced iron in a static experiment by Preuner. The experiment is unique among all recorded static experiments on the Fe–H–O system in that after permitting the initially low steam–hydrogen ratio to increase nearly to equilibrium, an excess of hydrogen was added without intervening evacuation. The final steady state pressure shown in this figure corresponds to a value for K_4 in agreement with those of Curve I, Fig. 2.

The values obtained by Wöhler and Prager and by Wöhler and Balz agree much more closely with Curve II, Fig. 2, than with Curve I. The values obtained from the oxidation side are susceptible to the above-mentioned surface effect since evacuation of the reaction vessel and hot sample with its attendant oxidation of the surface of the iron was carried out before each run. However, equilibrium was approached from the reduction side by admitting an excess of hydrogen—"sometimes as much as 120 cc."—to an oxidized sample and permitting the pressure to decrease to a constant value. It is not clear why these latter equilibrium values should fail to agree more closely with Curve I.

Any surface effect occurring in a dynamic system is quickly eliminated by the large amount of steam and hydrogen passing through the reaction tube. Consequently, the equilibrium measurements reported in the present paper should be free from this error. They constitute the first measurements made upon Reaction 4 by a flow system in which the point of equilibrium was determined by analysis of the effluent gas from the reaction tube. The excellent agreement of the experimental points among themselves and with Curve I attests to their probable correctness.

The experiments of Krings and Kempkens and of Ferguson were also made by a flow method. They differ from our own experiments, however, in that the value of the equilibrium constant is deduced from the variation in composition of the iron or iron oxide samples when treated for a number of hours with a given steam–hydrogen mixture. The results of Krings and Kempkens shown in Fig. 2 represent ratios of steam to hydrogen that sufficed to form an appreciable amount of oxide on the iron samples used. Their measurements fix the upper limits to the values of K_4 at the temperatures used. Similar experiments performed with slightly lower steam–hydrogen ratios and with iron oxide as a starting material would fix the lower limit for K_4. Ferguson's measurements unfortunately were made upon a sample of pure electrolytic iron that had been heated in hydrogen for many hours at 900 to 1000°, and that was therefore doubtless extremely inactive and slow to oxidize. At 750°, after six hours exposure of the Samples of the iron to streaming mixtures of steam and hydrogen in which the ratios of steam to hydrogen were 0.476, 0.540, 0.568 and 0.595, respectively, the final samples analyzed 99.98, 99.9, 98.0 and 93.6% iron. These experiments of Ferguson definitely indicate that the value for the equilibrium constant for the conversion of Fe into FeO is not greater than 0.568 at 750°, assuming that the 2% oxygen content of this final sample is not present as solid solution. They cannot be considered, however, to contribute information as to the exact value of the equilibrium constant.

It is of course true that the surface effect mentioned and described above can be supposed to affect the equilibrium value only in case the duration of each experiment is insufficient to permit the true equilibrium value characteristic of the mass of iron–iron oxide to be attained. The slowness with which the establishment of true equilibrium throughout the mass of Fe–FeO takes place is evidenced by the fact that, according to the recent work of Krings and Kempkens, when a gas stream containing such a moisture content as to make its steam–hydrogen ratio slightly less than the equilibrium value for Reaction 4 above is passed over a sample of Fe_2O_3, complete reduction at 715° is not obtained for a great many hours. Thus, at the end of eight hundred hours, about 0.6% of oxygen still remained in such a sample.

Eastman and Evans observed that the equilibrium ratio of steam to hydrogen over an iron–iron oxide mixture at 775° decreased rapidly as the oxygen content of the solid phase fell below 5%. They interpreted this as being an indication that as much as 5% oxygen would dissolve in a sample of iron. However, Krings and Kempkens have recently determined the solubility of oxygen in iron and found it to be of the order of 0.1% or less. Possibly the decrease in the steam–hydrogen ratios in the experiments of Eastman and Evans at these low oxygen contents was the result of enough iron being exposed in the initial sample to eliminate partially the surface error outlined above and to cause the values for the equilibrium steam–hydrogen ratio to deviate more and more toward true equilibrium as the percentage of oxygen in the solid phase decreased.

The correlations mentioned in the above discussion are, we believe, significant and must somehow be explained. The tentative explanation here proposed, involving what has been termed "surface effect," seems consistent with most of the known experimental data. However, it cannot be accepted as final until conclusively demonstrated in a series of static experiments in which the exact technique necessary to produce the true equilibrium has been studied in detail. To this end additional experimental work is being undertaken at this Laboratory. An attempt will be made to prove the possibility of obtaining either false equilibrium values or true equilibrium values in a given static apparatus by merely changing one's procedure slightly. Further details as to the nature of this surface effect will accordingly be deferred to a later paper. At that time equilibrium data for steam–hydrogen over Fe–Fe_3O_4 and additional data for the FeO–Fe_3O_4 system will also be presented.

The Equilibrium Constant for the Water Gas Reaction

The value for the equilibrium constant for Reaction 1 can be calculated readily by combining equilibrium data for the Fe–C–O system of Equation 5 with the values of K_4 obtained in the present experiments. Such a calculation gives water gas constants agreeing with the directly measured values of Neumann and Kohler as closely as do the experimental values determined in the present paper agree with Curve I of Fig. 2. This calculation assumes the accuracy of the data for the Fe–C–O system. In Fig. 5 are shown the data for the Fe–C–O system. Curve I represents the "best values" as chosen by Eastman in his first paper.[8] The recent experimental values of Schenck and his co-workers[20] are also included. Curve II, Fig. 5, represents Eastman's[8] latest choice of the "best values" for this system.

In Table IX are summarized the values for the water gas equilibrium constants obtained in different ways. Columns 2 and 3 contain those obtained by the direct measurement of Hahn[21] and of Neumann and Kohler,

---

[21] Kahn, *Z. physik. Chem.*, 44, 5131 (1903); 48,735 (1904).

respectively. The values of the water gas equilibrium constant of Reaction 1 calculated by use of the steam–hydrogen and CO_2–CO equilibria with Co–CoO mixtures are shown in Col. 4. Those in Col. 5 were obtained by dividing the value of K_4 from our own Fe–H_2O–H_2–FeO equilibrium data, by K_5 as reported by Eastman. Column 6 contains the indirect calculation of Eastman and Robinson based upon their data for Reactions 8 and 9. This is the one remaining indirect calculation giving values for the water gas equilibrium constant that disagree with the directly measured values. The values in Cols. 3, 4 and 5 agree excellently with each other and we believe correspond to the true values of the water gas equilibrium constant over the range of temperature covered.

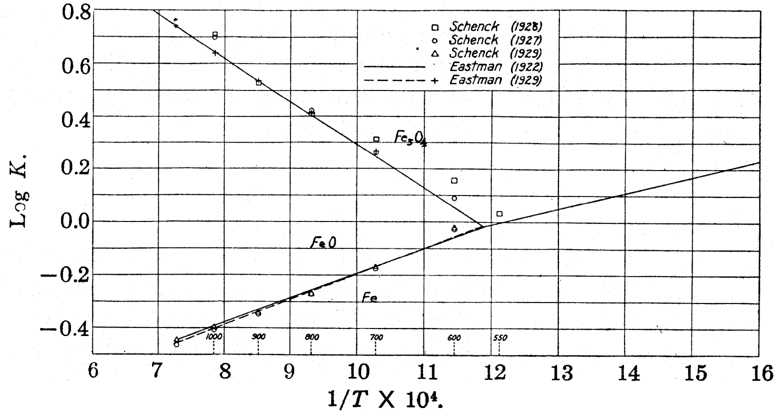

Fig. 5.—Variation with $1/T$ of log K, where K = $(CO_2)/(CO)$ in equilibrium with FeO–Fe, Fe_3O_4–FeO or Fe_3O_4–Fe.

TABLE IX

WATER GAS EQUILIBRIUM CONSTANTS

	Direct measurements			Calculated from	
Temp., t°C.	Hahn	Neumann and Köhler	Co–CoO system	Fe–FeO system	Sn–SnO_2 system
350		0.041			
400		.080

950	1.420	1.44			
1000	1.606	1.66		1.693	

Summary

1. The value of the equilibrium constant $K_4 = P_{H_2O}/P_{H_2}$ for the reaction $FeO + H_2 = Fe + H_2O$ has been determined by a flow method at 600, 700, 800, 900 and 1000" to be 0.332, 0.422, 0.499, 0.594 and 0.669, respectively.

2. The value of the equilibrium constant $K_6 = P_{H_2O}/P_{H_2}$ for the reaction $Fe_3O_4 + H_2 = 3FeO + H_2O$ has been determined by a flow method at 700 and 800° to be 1.18 and 2.37, respectively.

3. Combination of these values with the "best values" of Eastman for the Fe–C–O system gives values for the water gas equilibrium in good agreement with the water gas values determined directly by Neurnann and Kohler.

4. The so-called "surface effect" is presented as a probable reason for the discrepancies between the water gas values as obtained indirectly by other workers and the directly determined values.

A STUDY OF THE QUANTITATIVE PRECIPITATION OF CALCIUM OXALATE IN THE PRESENCE OF THE ARSENATE ION

BY J. T. DOBBINS AND W. M. MEBANE

RECEIVED AUGUST 9, 1930 PUBLISHED NOVEMBER 5, 1930

A study of the quantitative precipitation of calcium oxalate in the presence of the phosphate ion by Dobbins and Mebane[1] showed that the calcium ion could be quantitatively precipitated from a solution containing an excess of phosphate ions. Since the usual method of estimating calcium in calcium arsenate involves the same difficulties met in the phosphate analysis, a similar study was made of the quantitative precipitation of calcium in the presence of the arsenate ion. As the phosphate ion and the arsenate ion are chemically similar, the same method of study was used.

The study was based on the assumption' that the so-called tertiary calcium arsenate, which forms on the addition of ammonium hydroxide to the solution, having a much greater solubility product than calcium oxalate would go into solution and thus the calcium oxalate form. Consequently, if the solution be allowed to stand long enough for this metathesis to be complete, it should be possible to precipitate calcium oxalate in the presence of the arsenate ion. In order to determine the most favorable conditions under which to carry out the precipitation, several series of analyses were made to determine the time required for complete

---

[1] Dobbins and Mebane, THIS JOURNAL, 52, 1469 (1930).

transformation of calcium arsenate to calcium oxalate and the effect of temperature and alkalinity of solution at time of precipitation.

After first having found the minimum time necessary for the complete precipitation, determinations were made to determine the difference in results, if any, caused by adding the precipitating agent before and after the solutions were made alkaline with ammonium hydroxide and by varying the alkalinity of solution at time of precipitation. These series were run at 30 and 100°. An excessive amount of ammonium hydroxide, when added first to the solution, appeared to hinder the formation of calcium oxalate. Consequently two series were made using a slight excess of ammonia in one case and 10-cc. excess of concentrated ammonium hydroxide solution in the other, in order to determine the effect of the concentration of ammonium hydroxide on the solution.

Procedure.—A 0.1 N solution of calcium chloride was prepared by dissolving a weighed quantity of Iceland spar in hydrochloric acid. Approximately 0.1 N solutions of disodium arsenate and potassium permanganate were made. As the precipitating agent, a saturated solution of ammonium oxalate was used.

Twenty cc. of the standard solution was taken for each analysis. To this solution 25 cc. of the disodium arsenate was added to give an excess of arsenate ions, and then an excess of ammonium oxalate. The total volume of solution at this point was 80–100 cc. The precipitates were filtered, washed by decantation with distilled water containing a small amount of ammonium hydroxide and transferred on the filter paper to the precipitation beaker. The precipitates were dissolved in dilute sulfuric acid, the solution was brought almost to boiling temperature, and titrated rapidly with the 0.1 N permanganate solution in the usual way. As the precipitate was very finely divided, an inferior grade of filter paper could not be used in this determination. It was found that as accurate results were obtained by titrating the precipitate first formed as by following the usual procedure of dissolving and reprecipitating the calcium oxalate. The losses involved in redissolving the precipitate were as great as the error caused by the adsorption of ammonium oxalate by the precipitate.

TABLE I

Discussion

The formation of calcium oxalate in the presence of the arsenate ion was not as rapid as in the presence of the phosphate ion. Especially was this true at low temperature. Judging from other reactions of arsenates and phosphates, this was to be expected. Due possibly to adsorption of ammonium oxalate by calcium arsenate, the results of the titration were apt to be high if insufficient time were allowed for complete transformation of the calcium arsenate into calcium oxalate. This was also shown by the fact that good results were obtained in all cases where the precipitates were allowed to stand twenty-four hours before filtration or had been formed in solutions only faintly alkaline with ammonium hydroxide and digested at the boiling temperature for one hour. This heating seemed to destroy the flocculent nature of the previously precipitated calcium arsenate and made filtration very difficult, but good results were obtained by this method. The time of addition of ammonium hydroxide made no material difference in the analysis where the higher temperature was used. A large excess of ammonia gave high results in most of the analyses which were allowed to stand for an hour. This is possibly explained upon the difference in the adsorptive power of calcium arsenate which was formed in high concentrations of ammonium hydroxide and that which was formed in solutions only faintly alkaline. Those precipitates which were allowed to stand over for a twenty-four hour period gave uniformly good results. This was due to the complete transformation of the arsenate into the oxalate during this period of standing.

Recommended Procedure

Accurate results were obtained from the following procedure. The solution was made alkaline with ammonium hydroxide and a few drops excess added. After the addition of an excess of ammonium oxalate to the boiling solution, it was kept at incipient boiling temperature and occasionally stirred for ten minutes. After standing for an hour the precipitate was filtered off, washed with distilled water containing a small amount of ammonium hydroxide, transferred on the paper to the precipitation beaker, dissolved in 30 cc. of dilute sulfuric acid, diluted to 100 cc. and titrated rapidly with a 0.10 N potassium permanganate solution.

Summary

1. Calcium oxalate may be precipitated quantitatively in the presence of the arsenate ion.

2. The solution may be made alkaline either before or after the addition of ammonium oxalate, and a small excess of ammonium hydroxide added.

3. The best temperature for precipitation is 90–100°.

THE PHOTOCHEMICAL FORMATION OF CHLORINE DIOXIDE FROM CHLORINE MONOXIDE IN CARBON TETRACHLORIDE SOLUTION

BY ROSCOE G. DICKINSON AND CECIL E. P. JEFFREYS

RECEIVED AUGUST 18, 1930 PUBLISHED NOVEMBER 5, 1930

That chlorine monoxide, Cl_2O, is sensitive toward light has long been recognized. In recent years several quantitative investigations of the photochemistry of this compound have been undertaken. Bowen[1] studied the effect of light in the region 4100–4700 Å. on carbon tetrachloride solutions of chlorine monoxide; apparently on the assumption that the products of the reaction were simply chlorine and oxygen, he found from 0.81 to 1.02 molecules of the monoxide decomposed per quantum absorbed. He later measured[2] the effect of light on gaseous chlorine monoxide and concluded that in the gaseous state apparently two molecules of monoxide were decomposed for each quantum of blue and violet light absorbed.

---

[1] E. J. Bowen, *J. Chem. Soc.*, 123, 1199 (1923).

[2] Bowen, *ibid.*, 123, 2330 (1923).

The gaseous reaction was studied more extensively by Bodenstein and Kistiakowsky.[3] They concluded that two molecules of monoxide were decomposed per quantum absorbed irrespective of whether the light absorber was chlorine monoxide or added chlorine. They found further that the decomposition was accompanied by the formation of chlorine dioxide; this was shown by the fact that gaseous monoxide developed, on illumination, the absorption bands of the dioxide in the blue and violet. They believed, however, that the quantity of dioxide formed was very small, and they apparently did not regard its formation and presence as any important complicating circumstance in the measurement of the quantum yields.

The mechanism of the decomposition of chlorine monoxide (without reference to ClO_2 formation) has been discussed by Schumacher and Wagner.[4] They have shown that for 4350 Å. the absorption process may be either $Cl_2O + h\nu \longrightarrow Cl_2 + O$ or $Cl_2O + h\nu \longrightarrow ClO + Cl$, and regard the latter as more probable. The character of the absorption spectrum of gaseous Cl_2O[5] indicates that this wave length is energetically capable of producing either of at least two different dissociations.

In the present paper is described an examination of the reaction in carbon tetrachloride solution. It is found that chlorine dioxide is formed on illumination of the solution and that the amount formed is by no means negligible compared with the amount of monoxide decomposed. Moreover, the comparatively high light absorption coefficients of the dioxide make the presence of even small amounts of this compound a disturbing factor in the measurement of the quantum yield of the monoxide decomposition.

The Materials

Carbon Tetrachloride.—Some difficulty was experienced in preparing sufficiently good carbon tetrachloride. The starting point was commercial C. P. material; since this showed some photochemical reaction with chlorine, it was subjected to the following treatment.[6] The liquid was boiled for nine hours in an all-glass reflux apparatus, chlorine being bubbled through continuously. The chlorine was boiled off and the liquid treated with anhydrous sodium carbonate, and distilled twice from an all-glass still with a fractionating column. A middle fraction was used. This product was still found to develop acidity when chlorine was dissolved in it and the solution illuminated for four hours with the blue light source described below. (The acidity was detected by pouring the illuminated chlorine solution into an excess of potassium iodide, titrating to an end-point with thiosulfate and then adding iodate.) Finally some of this carbon tetrachloride which had been refluxed with chlorine was saturated with chlorine dioxide; after standing for several days it was again washed and fractionated. This product developed no acidity on four hours' illumination with chlorine and was used in the experiments described below.

Chlorine Monoxide.—The chlorine monoxide was prepared in carbon tetrachloride solution by adding an excess of mercuric oxide to carbon tetrachloride about half saturated with chlorine at room temperature. The oxide reacted quickly to give the brownish chlorine monoxide solution. The solid material was filtered off using asbestos in a Gooch crucible. Occasionally the preparations showed a small amount of free chlorine on analysis.

The mercuric oxide used in this preparation was obtained by adding a 50% solution of potassium hydroxide to a saturated solution of mercuric chloride at room temperature. The precipitated mercuric oxide was washed and then dried for two days or more at 120°.

Chlorine.—For the preparation of chlorine monoxide or for absorption measurements chlorine from hydrochloric acid and manganese dioxide, or from a tank, was purified by passing through a train of washing bottles with all-glass connections. The first two bottles contained potassium permanganate solution, the third concentrated sulfuric acid and a fourth glass wool to retain mist. Fresh materials were placed in the train before each experiment. The gas from the train was passed into carbon tetrachloride in a glass stoppered flask.

Chlorine Dioxide.—This was prepared according to the method of Bray.? Eight grams of potassium chlorate and **30** g. of oxalic acid were intimately mixed and moistened with 4 cc. of water in a flask with a side arm. The mouth of the flask was sealed and the mixture heated to 60°. The evolved gas was passed into carbon tetrachloride.

The Apparatus.—The arrangements for illuminating the solution and measuring its transmission are shown in plan in Fig. 1. Light from the quartz mercury arc A operated from a d. c. generator with a voltage regulator, passed, when the shutter B was opened, through a hole 1 cm. in diameter in a removable cap, C. It then passed through the filter box D through which water was flowed. The light filters E were submerged in this box. The light was then collimated by the lenses F.

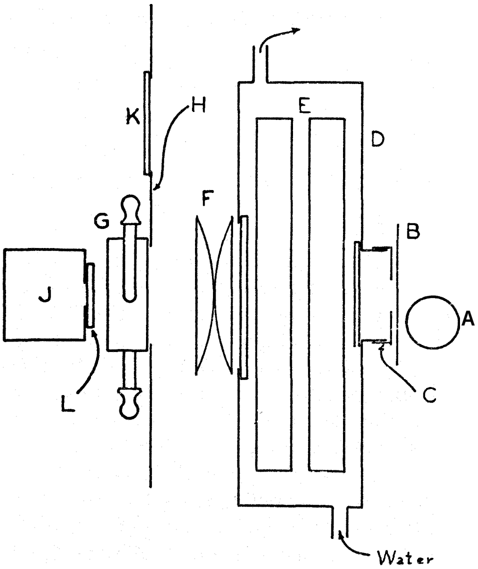

Fig. 1.—Plan view of photochemical apparatus.

The pyrex glass reaction cell G was 1.06 cm. thick internally with flat faces **3** cm. in diameter. The volume of solution which it held was 6.9 cc. The cell was provided with two capillary side arms for filling; these were fitted with ground glass caps.

Filters.—To remove infra-red, a 1-cm. layer of 6% copper sulfate solution was used.[8] To isolate λ4358, a 4-mm. piece of Corning G 585

---

[7] W. C. Bray, Z. *physik. Chem.*, 54, 592 (1906).

[8] W. W. Coblentz, ***Bur. Standards Bull.*, *9*,** 110 (1913).

was followed by a 2-mm. piece of Noviol A. On being photographed with a spectrograph, the radiation transmitted by these filters showed in addition to 4358 only the weak neighboring lines 4347 and 4339. To isolate 4047, a 1-cm. layer of 4% quinine hydrochloride was followed by a 5-mm. piece of Corning G 586 Å. Spectrographs of the radiation transmitted by this filter showed a trace of 4358 and various other lines down to 3900; most of the intensity, by far, was in 4047.

Spectroscopic Experiments.—Using a two-prism glass spectrograph we have photographed the absorption spectrum of chlorine monoxide in carbon tetrachloride solution. In agreement with Bowen the absorption was found to set in appreciably in the blue and to increase continuously toward the violet. After strong illumination of the solution with either white light or the line 4358 Å., a series of well-marked maxima of absorption situated at about 4350, 4240, 4130, 4020,... Å. developed. Since these absorption maxima are not attributable to chlorine, their source was sought in chlorine dioxide. It was found that chlorine dioxide solutions gave maxima in the same positions as the illuminated chlorine monoxide solutions; a 0.0015 molal chlorine dioxide solution showed the maxima to about the same extent as a 0.034 molal chlorine monoxide solution which had been exposed for three hours to our source of 4358 Å.

These experiments show that chlorine dioxide is produced in carbon tetrachloride solution by the illumination of chlorine monoxide but give only a rough suggestion of the quantity. We have accordingly attempted to estimate the number of molecules of chlorine dioxide produced per quantum absorbed and, taking account of the presence of chlorine dioxide, to reexamine the quantum yield in the decomposition of chlorine monoxide.

Absorption Coefficients.—Absorption coefficients of carbon tetrachloride solutions of chlorine, chlorine monoxide and chlorine dioxide were determined for the radiations 4358 and 4047 Å. Light from the mercury arc was passed through one of the filters described above, collimated, passed through a cell containing the solution, and then allowed to fall on a Moll thermopile connected with a galvanometer. The cell was removed and immediately replaced by a sheet of the same pyrex glass of which the cell was constructed. The ratio of the galvanometer readings for the two cases was taken as the transmission, I/I_0, of the solution. In Table I are given average values of the transmission for various solutions together with the absorption coefficients, a, defined by the equation

$$-\log_{10} I/I_0 = \alpha C$$

where C is the concentration in moles per liter. As our photochemical experiments were made in the same cell that was used for the absorption coefficients, these values are sufficient for our purpose. The thickness of the cell was 1.06 cm., so that the absorption coefficients, ϵ, defined by the equation

$$-\log_{10} I/I_0 = \epsilon C d$$

where d is the thickness of the cell in centimeters, are $\alpha/1.06$. In the case of chlorine, absorption coefficientswere also measured at the wave lengths 4358 Å. using a spectrograph and calibrated wire screens substantially as described by Winther.[9] The value of α obtained by this method, 2.40, is in agreement with that given in Table I.

TABLE I

ABSORPTION COEFFICIENTS IN CARBON TETRACHLORIDE SOLUTION

	,00135	4358	.530	203
	.00115	4047	.195	616
	.000428	4047	.551	605

Method of Analysis.—The carbon tetrachloride solutions, which in the general case were presumed to contain chlorine, chlorine monoxide and chlorine dioxide, were treated in the following manner. A weighed amount of the solution was run into a flask containing an excess of potassium iodide acidified with a known excess of standard acid. The iodine liberated by the following reactions was titrated with thiosulfate

$$Cl_2 + 21- = I* + 2Cl^-$$
$$Cl_2O + 41- + H_2O = 2I_2 + 2OH^- + 2Cl^-$$
$$ClO_2 + 51- + 2H_2O = 5/2I_2 + 4OH^- + Cl^-$$

The unused excess of acid was then determined by adding a small amount of potassium iodate and titrating with thiosulfate the iodine liberated by the reaction

$$IO_3^- + 51- + 6H^+ = 3I_2 + 3H_2O$$

Calling a the number of equivalents of thiosulfate used per liter of sample in the first titration, and b the number of equivalents of acid neutralized per liter of sample as determined by the second titration, it is evident that

$$a = 2(Cl_2) + 4(Cl_2O) + 5(ClO_2) \qquad (1)$$
$$b = 2(Cl_2O) + 4(ClO_2) \qquad (2)$$

where the parentheses indicate molal concentrations.

In those cases (as in the absorption measurements or at the beginning of the photochemical exposures) where one or more of the three substances was known to be absent, these titrations sufficed; but when all three substances were present, an additional independent relation between their

---

[9] C. Winther, Z. *wiss.* Phot., 22, 125 (1923).

concentrations was necessary. This was afforded by a measurement of I/I_0, the fraction of light transmitted by the solution when placed in the cell used for determining the absorption coefficients. The additional relation is, then

$$-\log I/I_0 = \alpha_1(\mathrm{Cl_2}) + \alpha_2(\mathrm{Cl_2O}) + \alpha_3(\mathrm{ClO_2}) \tag{3}$$

Simultaneous solution of Equations 1, 2 and 3 would give the desired analysis.

In practice it was found convenient to proceed slightly differently by using for the transmission measurements the radiation 4047 Å. For this wave length, the absorption coefficients of chlorine and chlorine monoxide are practically equal and much smaller than the coefficient for chlorine dioxide. If then no chlorine be allowed to escape from the solution during the photochemical reaction, any change in the transmission of the solution is ascribable to a change in $(\mathrm{ClO_2})$. If the solution initially contains no chlorine dioxide and has a transmission $(I/I_0)_i$, the concentration of chlorine dioxide corresponding to the transmission $(I/I_0)_t$ found after illumination is given by

$$-\log (I/I_0)_t + \log (I/I_0)_i = \left(\alpha_3 - \frac{\alpha_1}{2}\right)(\mathrm{ClO_2}) \tag{4}$$

From Table I, $[\alpha_3 - (\alpha_1/2)]$ has the value 607. We have accordingly followed, by transmission measurements, the concentration of chlorine dioxide in a sample of chlorine monoxide under illumination; using the final value of $(\mathrm{ClO_2})$ so obtained, we have determined the values of $(\mathrm{Cl_2})$ and $(\mathrm{Cl_2O})$ at the end by titration.

The experiments themselves afford two controls on this method of analysis. (1) The total chlorine in the solution, given by $(a - b)$, should be the same before and after illumination; this was ordinarily found to be the case to 1% or better which, in view of the small samples involved, is probably satisfactory. (2) From the analysis of the final solution, its transmission for 4358 Å. may be calculated and compared with a measured value. The calculated and observed transmission for this wave length agreed on the average to about 3%.

Measurement of Quantum Yields.—The chlorine monoxide solution, prepared as previously described, was placed in a small all-glass container built like a wash bottle. The exit tube from this container was ground into one of the capillary arms of the reaction cell. The cell was filled by blowing into the inlet tube of the container through a drying tube. The cell was then weighed, emptied into the titration flask, reweighed and immediately refilled. The initial composition of the $\mathrm{Cl_2O}$ solution was then determined by titration of the first sample. The second sample was then illuminated with 4358 Å. During this illumination, the cap C (Fig. 1) was removed to give a larger light source.

The illumination was interrupted at intervals for the measurement of

(1) the transmissions of 4358 and of 4047 and (2) the intensity of the 4358 as used for the reaction. The transmissions were measured as previously described. The light intensity was measured by noting the galvanometer deflection with C removed and the glass plate K in front of the thermopile; in this case a shunt was placed across the galvanometer to keep the deflection on the scale.

The thermopile had been calibrated with the aid of a carbon lamp calibrated by the Bureau of Standards; in the thermopile calibration the quartz window, L, was removed from the thermopile and the shunt from the galvanometer. The effect of the shunt had been determined by noting the deflections produced by a convenient white light source with and without the shunt.

The total number of quanta, Q, entering the reaction mixture in *t* minutes was calculated by the following formula

$$Q = 60t \times d \times f_1 \times f_2 \times f_3 \times E \times A \times f_4 \times f_5 \times q = 9.2 \times 10^{15} \times t \times d$$

d = galvanometer deflection in centimeters of scale as read with the shunt
f_1 = ratio of deflection without shunt to that with shunt
f_2 = rato of deflection with thermopile in plane of diaphragm and at its center. to deflection with thermopile in position used (the beam was slightly convergent) = 0.942
f_3 = ratio of average deflection over area of diaphragm to deflection with thermopile at center of diaphragm = 0.925
E = intensity of radiation giving unit scale deflection; ergs per sq. mm. per sec. per cm. scale deflection = 0.672
A = area of diaphragm opening in sq. mm. = 573
f_4 = reciprocal of transmission of quartz plate = 1.065
f_5 = reciprocal of transmission of one surface of pyrex plate = 1.035
q = number of quanta in one erg of radiation of wave length 4358 Å. = 2.217×10^{11}

The results of a number of experiments made by illuminating pure or nearly pure chlorine monoxide solutions of various concentrations are given in Table II. The initial and final amounts of chlorine monoxide and chlorine in the solutions are given in Cols. 3 and 4. The amount of solution was always 6.92 ± 0.02 cc. The amounts of chlorine dioxide present at various times (as computed from the transmission of λ4047) are given in Col. 5.

The total number of quanta having been absorbed by the system up to the time *t* (Col. 2) is given in Col. 9 and was calculated as follows. The number of quanta entering the reaction vessel in each interval of time was calculated from the average galvanometer deflection for that interval (Col. 8) as described above. This number was multiplied by $[1 - (I/I_0)]$ $[1 + r(I/I_0)]$ to give the number of quanta absorbed in the time interval. Here (I/I_0) is the average value of the transmission for λ4358 for the interval and ?(= 0.035) is the fractional reflection of radiation back into the cell at the rear window. (It may be noted that the small correction

$r(I/I_0)$ for rear-window reflection is not compensated in the absorption measurements.) The sum of the quanta absorbed in all intervals up to the time t is given in Col. 9.

The amount of chlorine dioxide formed in the various runs is shown in Fig. 2 plotted against the number of quanta absorbed. In a given run, the amount of chlorine dioxide formed increases less and less rapidly with the quanta absorbed as the exposure is prolonged. At least two reasons may be given for this: (1) chlorine dioxide already formed acts as an internal filter and partially screens its further formation; (2) chlorine dioxide is itself decomposed photochemically.[10] In addition there is the possibility of photochemical reaction between chlorine dioxide and chlorine monoxide.

When the various runs are compared with each other, it is found that for a given number of quanta absorbed, more chlorine dioxide has been formed the higher the initial concentration of chlorine monoxide. This effect

---

[10] H. Booth and E. J. Bowen, *J. Chem. Soc.*, 127,510 (1925).

again could obviously result from internal screening in both the formation and decomposition of the chlorine dioxide.

The simplest conditions evidently prevail at the beginning of the exposure where the material is substantially all chlorine monoxide. The initial (quantum) rate of formation of chlorine dioxide appears to be not markedly, if at all, dependent on the concentration of chlorine monoxide. The initial slope of the curves gives directly a quantum yield of about **0.35** chlorine dioxide formed per quantum absorbed.

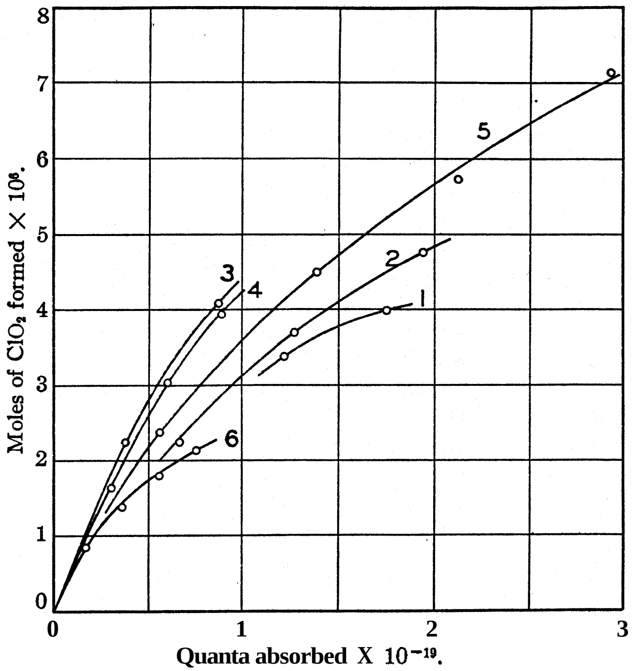

Fig. 2.—Amount of ClO_2 formed *vs.* number of quanta (4358 Å.) absorbed. The numbers on the curves are the experiment numbers of Table II. The initial concentrations of Cl_2O increase in the order 6, 1, 2, 5, 4, 3.

Our method of analysis supplied a knowledge of the chlorine monoxide present at only the beginning and end of a run. The number of molecules of chlorine monoxide decomposed in each entire run per quantum absorbed, irrespective of the absorbing substances, was computed from Cols. **3** and 9 and is given in Col. **10.** It may be seen that in Expts. **3** and 4, where the exposures were shortest and the proportion of chlorine dioxide at the end smallest, the yields were highest, *viz.*, 1.58 and 1.48, as against values around **1.2** in longer exposures. This suggests that shorter exposures would lead to still higher values for the initial yield; for after the decomposition of only a small amount of chlorine monoxide, the chlorine dioxide which had been formed played a considerable part in the light absorption. However, on account of the small titration differences already involved, experiments resulting in smaller decompositions did not appear feasible.

We have, therefore, calculated the number of molecules of chlorine monoxide decomposed per quantum absorbed by the chlorine monoxide. At any moment, the fraction of the absorption due to chlorine dioxide is $\alpha_3(ClO_2)/[\alpha_1(Cl_2) + \alpha_2(Cl_2O) + \alpha_3(ClO_2)]$. The denominator is equal to $-\log.(I/I_0)$ for λ4358. Hence the fraction of the entering quanta which are absorbed by other than chlorine dioxide is

$$\left[1 - \frac{\alpha_3(ClO_2)}{-\log\,(I/I_0)}\right][1 - I/I_0][1 + r(I/I_0)]$$

Values of this last expression were calculated for each time interval using average values of (ClO_2) and (I/I_0); these were multiplied by the number of quanta entering in the interval and summed over the entire run. The ratio of the number of molecules of chlorine monoxide decomposed to this sum is given in Col. 11. Strictly this is the yield per quantum absorbed by $Cl_2O + Cl_2$; however, the quantity of free chlorine was never large and its absorption coefficient for 4358 is small. These yields are comparatively constant, showing possibly a slight tendency to increase with decreasing exposure; the mean for the three longest runs is 1.69, while the mean for the three shortest runs is 1.81. In view of the uncertainty of extrapolation and of the small titration differences, it seems not impossible that the value for zero exposure and hence for pure chlorine monoxide solution may be as high as 2.

Summary

The effect of light of wave length 4358 Å. on solutions of chlorine monoxide in carbon tetrachloride has been investigated. It has been found that the decomposition of chlorine monoxide is accompanied by the formation of considerable chlorine dioxide. In solutions 0.014 to 0.054 molal in chlorine monoxide, the initial rate of formation of chlorine dioxide has been found to be about 0.35 molecule of chlorine dioxide per quantum absorbed. The initial rate of decomposition has been found to be at least 1.8 molecules of chlorine monoxide per quantum absorbed.

THE INTERACTION BETWEEN NITROGEN TRICHLORIDE AND NITRIC OXIDE AT −150". II. FURTHER EVIDENCE FOR THE FORMATION OF NITROGEN DICHLORIDE AND OF MONO-OXYGEN-DINITROGEN-DICHLORIDE

BY WILLIAM ALBERT NOYES

RECEIVED AUGUST 25, 1930 PUBLISHED NOVEMBER 5, 1930

In a paper published two years ago[1] it was shown that at −80°, in a solution of chloroform and carbon tetrachloride, two moles of nitric oxide react with one mole of nitrogen trichloride, giving one mole of nitrosyl chloride, one of nitrous oxide and two atoms of chlorine

$$2NO + NCl_3 = NOCl + N_2O + Cl_2$$

This was explained by assuming that the nitric oxide, having an odd electron, takes an atom of chlorine with an odd electron from the nitrogen trichloride to form the nitrosyl chloride. This leaves nitrogen dichloride with an odd electron and the latter combines with another mole of nitric oxide to form mono-oxygen-dinitrogen-dichloride, $O{=}N{-}NCl_2$. This last compound dissociates at −80°, giving nitrous oxide and chlorine. It was also found that at −130 to −140°, in petroleum ether, the reaction corresponds to the equation

$$NCl_3 + NO = N_2O + 3Cl$$

probably because hydrochloric acid formed by the action of nitrogen trichloride on the petroleum ether catalyzes a reaction between the nitrosyl chloride first formed and nitrogen trichloride, giving nitrous oxide and chlorine. It should be remarked, however, that this equation represents the final result of at least three or four reactions which occur consecutively or simultaneously.

To simplify the conditions and to eliminate, as far as possible, the catalytic effect of the hydrochloric acid and the reactions between nitrosyl chloride and nitrogen trichloride and between nitric oxide and chlorine, the reactions have been carried out in the presence of chloroform and carbon tetrachloride at −150°, the boiling point of nitric oxide.

Experimental Part

The apparatus used, shown in Fig. 1, was the same as that described in the first paper except that the bulb, F, in which the reaction was carried out, was surrounded with a second bulb sealed to it as shown in Fig. 2. Nitric oxide from a glass gasometer containing about 12 liters was condensed in the outer bulb by immersing it in liquid air. In some cases the solution containing a known amount of nitrogen trichloride was introduced by distilling it under low pressure from a glass bulb in which it had been frozen before

---

[1] Noyes, THIS JOURNAL, 50,2902 (1928).

connecting it with the apparatus at E. As the mixture distilled into the reaction bulb F, which was kept in liquid air, it froze on the walls of the bulb. In other cases the solution was allowed to flow slowly through a fine capillary tube down the inner wall of F. The latter method is considered better. This gave a large reacting surface for the mixture, and as the freezing point of nitrogen trichloride is lower than that of the mixture of chloroform and carbon tetrachloride, the trichloride was largely on the outside of the surface of the crystals of the solvent.

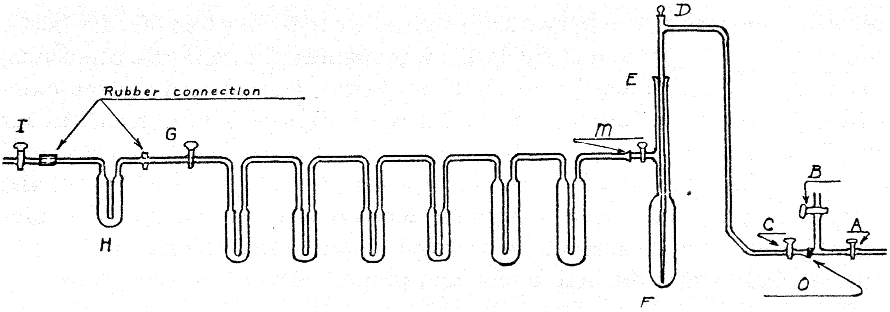

Fig. 1.—Ground-glass joints at O, E and M.

After evacuating the bulb, introducing nitrogen and evacuating again three or four times to remove the air, the liquid air was lowered away from the outer bulb containing liquefied and frozen nitric oxide. By proper adjustment of the cylinder containing the liquid air, the nitric oxide in the outer bulb was allowed to evaporate slowly back into the gasometer. In this manner a constant temperature of approximately −150° could be maintained almost indefinitely.

A measured quantity of nitric oxide was then slowly introduced through A and C (Fig. 1). The reaction, which did not always begin immediately, was apparent from the change in color of the mixture to the red color of nitrosyl chloride. After the desired amount of nitric oxide had been introduced, the mixture was allowed to stand for some time at −150° until the reaction was complete.

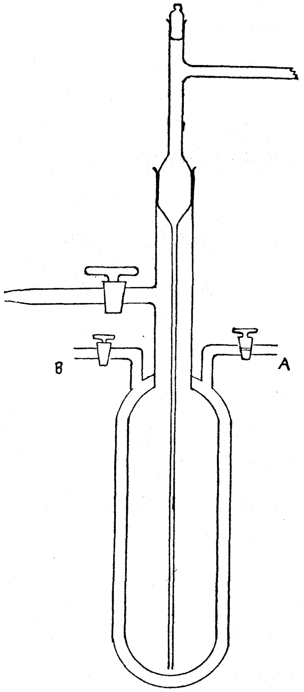

Fig. 2.

A large number of experiments at −150° have been carried through and various changes in the technique of separating the products of the reaction have been tried. The most important change has been measuring the nitrous oxide instead of weighing it. After fractionating the products and condensing the nitrous oxide in the U-tube H (Fig. 1), immersed in liquid air, the tube was connected with a tube leading to the bottom of a dry bottle and a tube from the top of the latter was connected to a bottle containing water in such a manner that as the nitrous oxide was allowed to evaporate, after removing the liquid air in which the U-tube was immersed, the air displaced passed into the second bottle and displaced its own volume of water. The water displaced was measured and thus the volume of the nitrous oxide was determined without allowing the gas to come in contact with water. Small amounts of nitrosyl chloride and chlorine present in the nitrous oxide were determined and proper corrections were made.

Two experiments at −80° were made to test the results given in the first paper by the new technique.

Attempts to carry out the reaction at the temperature of liquid air, −185 to −191°, have not been successful. After 11.9 millimoles of nitric oxide had stood in contact with the mixture containing an excess of nitrogen trichloride, at that temperature, for forty-five hours, 9.4 millimoles were recovered unchanged.

Results and Discussion.—From a large number of experiments, two at −80° and three at −150° have been selected as representing, approximately, the course of the reaction, which is distinctly different at the two temperatures.

TABLE I

RESULTS OF EXPERIMENTS

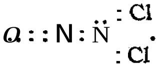
NCl_3 recovered	NCl_3 reacting	Molecular ratios NO				Temp., °C.
		NO	N_2O	NOCl	Cl	
0.04	1	1.96	0.71	1.01	2.20	−80
.23	1	2.42	.85	1.16	1.5	−80
.32	1	2.94	.72	1.70	0.16	−150
.33	1	3.10	.92	2.10	.60	−150
.23	1	3.00	.95	1.70	.90	−150

The results at −80° confirm the equation given in the first paper, $NCl_3 + 2NO = NOCl + N_2O + 2Cl$, as representing, approximately, the reactions which take place at that temperature.

At −150° the results correspond, approximately, to the equation

$$NCl_3 + 3NO = 2NOCl + N_2O + Cl$$

The results at −80° were explained by assuming that nitric oxide, having an odd electron, takes a chlorine atom with an odd electron from the nitrogen trichloride to form nitrosyl chloride. This leaves nitrogen dichloride, NCl_2, having an odd electron, which causes it to combine immediately with a second mole of nitric oxide to give mono-oxygen-dinitrogen-dichloride,



$\mathrm{O}::\mathrm{N}:\overset{\cdot\cdot}{\mathrm{N}}\begin{matrix}:\mathrm{Cl}\\:\mathrm{Cl}\end{matrix}$. Because of the oxygen combined with one of the nitrogen atoms, this compound seems to dissociate to nitrous oxide, ${}^{-}\!:\underset{\cdot\cdot}{\ddot{\mathrm{O}}}:\overset{+}{\mathrm{N}}:::\mathrm{N}:$ and chlorine at −80°.

It seemed difficult, at first, to explain the formation of *two* moles of nitrosyl chloride at −150°, but further consideration has led to the conclusion that the mono-oxygen-dinitrogen-dichloride is sufficiently stable to maintain a brief existence at −150° and that it yields a second atom of chlorine with an odd electron to a second mole of nitric oxide, forming the second mole of nitrosyl chloride. This would leave mono-oxygen-dinitrogen-monochloride, $\underset{\cdot\cdot}{\ddot{\mathrm{O}}}::\ddot{\mathrm{N}}:\underset{\cdot}{\ddot{\mathrm{N}}}:\mathrm{Cl}$. This would dissociate to nitrous oxide and chlorine, either at once or during the subsequent distillation of the products.

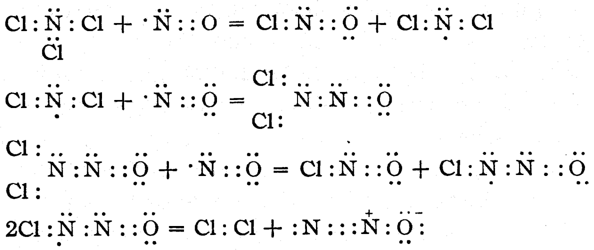
The course of the reaction at –SO° shows that nitric oxide and chlorine combine very slowly to form nitrosyl chloride at that temperature and the second mole of nitrosyl chloride is very unlikely to have come from that combination.

Summary

1. At −150° the interaction of nitrogen trichloride and nitric oxide proceeds, approximately, according to the equation

$$\mathrm{NCl_3 + 3NO = 2NOCl + N_2O + Cl}$$

2. This equation is thought to represent the result of four successive reactions which may be represented by the equations



$$\mathrm{Cl}:\underset{\underset{\displaystyle \mathrm{Cl}}{\cdot\cdot}}{\ddot{\mathrm{N}}}:\mathrm{Cl} + \cdot\ddot{\mathrm{N}}::\mathrm{O} = \mathrm{Cl}:\ddot{\mathrm{N}}::\underset{\cdot\cdot}{\ddot{\mathrm{O}}} + \mathrm{Cl}:\underset{\cdot}{\ddot{\mathrm{N}}}:\mathrm{Cl}$$

$$\mathrm{Cl}:\underset{\cdot}{\ddot{\mathrm{N}}}:\mathrm{Cl} + \cdot\ddot{\mathrm{N}}::\underset{\cdot\cdot}{\ddot{\mathrm{O}}} = \begin{matrix}\mathrm{Cl}:\\ \\ \mathrm{Cl}:\end{matrix}\ddot{\mathrm{N}}:\ddot{\mathrm{N}}::\underset{\cdot\cdot}{\ddot{\mathrm{O}}}$$

$$\begin{matrix}\mathrm{Cl}:\\ \\ \mathrm{Cl}:\end{matrix}\ddot{\mathrm{N}}:\ddot{\mathrm{N}}::\underset{\cdot\cdot}{\ddot{\mathrm{O}}} + \cdot\ddot{\mathrm{N}}::\underset{\cdot\cdot}{\ddot{\mathrm{O}}} = \mathrm{Cl}:\ddot{\mathrm{N}}::\underset{\cdot\cdot}{\ddot{\mathrm{O}}} + \mathrm{Cl}:\underset{\cdot}{\ddot{\mathrm{N}}}:\ddot{\mathrm{N}}::\underset{\cdot\cdot}{\ddot{\mathrm{O}}}$$

$$2\mathrm{Cl}:\underset{\cdot}{\ddot{\mathrm{N}}}:\ddot{\mathrm{N}}::\underset{\cdot\cdot}{\ddot{\mathrm{O}}} = \mathrm{Cl}:\mathrm{Cl} + :\mathrm{N}:::\overset{+}{\mathrm{N}}:\underset{\cdot\cdot}{\ddot{\mathrm{O}}}{}^{-}\!:$$

3. Attempts to isolate the intermediate products, nitrogen dichloride, mono-oxygen-dinitrogen-dichloride and mono-oxygen-dinitrogen-monochloride have not been successful.

THE PREPARATION OF SULFUR HEXAFLUORIDE AND SOME OF ITS PHYSICAL PROPERTIES

BY WALTER C. SCHUMB AND E. LEE GAMBLE

RECEIVED AUGUST 25, 1930 PUBLISHED NOVEMBER 5, 1930

The object of the present research was to investigate in somewhat greater detail than previously has been described the preparation and purification of sulfur hexafluoride, as well as to determine certain of its physical properties which appeared to be in need of revision. Because of the increasing attention which is being given to certain gaseous fluorides as well as the rather unusual intrinsic characteristics of sulfur hexafluoride, it was thought desirable to communicate the results of our study thus far established. Sulfur hexafluoride is a gas at ordinary temperature; it solidifies at low temperature, melting at −50.8°. Its vapor pressure at that temperature is above atmospheric; it must be cooled further, to −63.8°, to lower the pressure to 760 mm.; the determination of these temperatures and pressures was one of the objects of this work.

The Generation of Fluorine.—The only practical method of preparation of sulfur hexafluoride is the combustion of sulfur in fluorine, so that a brief account of our experience with the generation of fluorine would not appear to be out of place here. Since Moissan's[1] first preparation of this gas by the electrolysis of a solution of potassium fluoride in anhydrous hydrogen fluoride, using a U-tube and electrodes of platinum–iridium, much improvement in the design and operation of fluorine generators has been attained. Of various types of generators, such as those of F. Meyer and Sandow,[2] J. Simons,[3] Lebeau and Damiens,[4] and Bancroft and Jones,[5] that described by the last-named investigators is representative of recent practice. Their generator is an improved form of that first described by W. L. Argo,[6] the essential change being in the use of magnesium metal in place of copper for the containing vessel and diaphragm.

In starting the present work, several types of fluorine generators using fused electrolytes were constructed and the unsuitability of copper for the containing vessel and diaphragm was soon established. The generator finally adopted and successfully operated over an extended period of time was a modification of that described by Bancroft and Jones, with one

important difference: welded 3.2 mm. monel metal was used in place of magnesium in the construction of the vessel and diaphragm. After more than one hundred and fifty hours of operation at 220 to 300° there has been no appreciable attack of the monel by the fused electrolyte—KHF_2— and only a slight attack of the graphite anode.

Electrical connection was made to the graphite anode by means of a 3.2-mm. copper wire threaded at the end and screwed tightly into the 2.54-cm. graphite rod, the whole being held at the top of the diaphragm by a "stopper" of Portland cement. A horizontal copper disk attached to the lead wire served as a shield to prevent spray from entering and clogging the outlet tube. The bottom of the diaphragm was closed with a removable monel disk held snugly to the diaphragm by three flat hooks brazed to the latter. Three rows of eight 6.4 mm. holes perforated the lower end of the diaphragm. The current employed varied from 12 to 15 amp.; the potential drop across the cell averaged 3 to 4 volts. The generator held approximately 3.6 kilos of electrolyte, which was melted in a large copper beaker before pouring into the generator, wherein it was kept molten by means of a nichrome heating coil wound about the vessel. When a run was interrupted, the electrolyte was poured out into the copper beaker, in which it solidified. When the electrolysis was resumed the cake was dislodged, broken into large lumps, remelted and again poured into the generator. The fluorine contains some hydrogen fluoride, oxygen and probably a little carbon tetrafluoride. As far as the satisfactory functioning of the generator is concerned, our experience confirms the observations of others in that the water content of the electrolyte has much to do with successful operation. As electrolysis proceeds—at as low a temperature as possible, in order to minimize vaporization of hydrogen fluoride—the water is gradually eliminated.

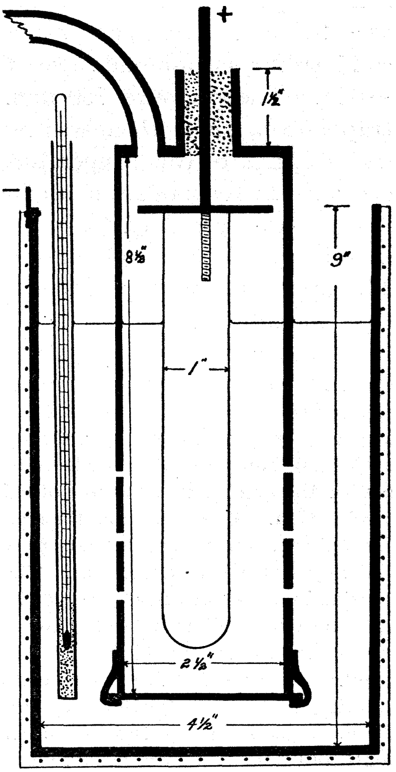

Fig. 1.—Fluorine generator.

The Preparation of Sulfur Hexafluoride and Previous Work.—Moissan and Lebeau[7] discovered that when sulfur burns in fluorine the chief product of the reaction is the gas, sulfur hexafluoride, colorless, odorless and very inert under ordinary conditions. Of this substance they say that "it solidifies at about −55° to a white, crystalline mass, which liquefies and boils at a temperature but little removed from its melting point." In determining the density of the gas, Moissan and Lebeau used a method

---

[7] Moissan and Lebeau, *Compt. rend.*, 130, 865 (1900); *Ann. chim. phys.*, [7] **26**, 147 (1902).

previously described by Moissan and Gautier,[8] which consisted of the comparison of the weights of equal volumes of sulfur hexafluoride and of air taken under the same conditions. Four values were given: 4.95, 4.99, 5.09 and 5.11; average 5.03.

Prideaux[9] later made a comparative study of the physical properties of the hexafluorides of sulfur, selenium and tellurium. The sulfur hexafluoride had been purified by three distillations. He determined the melting point of sulfur hexafluoride as −56 to −55°, the boiling point as −62° at 760 mm., and made a determination of the vapor pressure of solid sulfur hexafluoride over the temperature interval −110° to about −65°. The pressure, 760 mm. at −62°, was calculated by a short extrapolation, since there was not enough sulfur hexafluoride to continue the readings to this temperature. The data were not tabulated but were given in the form of a smooth curve. The temperature of the sulfur hexafluoride was assumed to be the same as that of the ether (cooled with liquid air, and gradually allowed to warm up) that surrounded the bulb. The apparatus was quite small because of the small amount of the substance available.

The method of preparation of sulfur hexafluoride used in the present investigation was as follows. The fluorine from the generator passed through two copper U-tubes coupled thereto and filled with flakes of freshly fused potassium fluoride to remove some of the hydrogen fluoride, then through a 2.5-cm. copper tube about 50 cm. long filled with small lumps of sulfur. The sulfur ignites immediately in the fluorine and the progress of the combustion can be noted by the heating of the copper tube at the zone of combustion. The gases from the reaction tube passed through a long column of freshly fused potassium hydroxide flakes to remove the greater part of lower fluorides of sulfur and any sulfur dioxide present. The gas was now collected over 3 N potassium hydroxide in a 20-liter carboy, the solution being siphoned out as the carboy filled with gas, and the whole allowed to stand for several days with occasional shaking. From the carboy the gas was passed at a rate of about 1.5 liters per hour through a trap cooled to approximately −60° to remove much of the water vapor, through a column of calcium chloride, and then through two absorption bottles containing anhydrous alcohol. Next the gas passed through two absorption bottles containing water and one containing concentrated sulfuric acid to remove alcohol vapor, and finally was solidified by strong cooling in the first of a series of four bulbs. The quantity of solid so obtained was about 80 g. The solid was now repeatedly sublimed, each operation requiring from five to seven hours and approximately one-third (the first and last portions) of each fraction being discarded. Finally the bulb of the vapor pressure apparatus was well evacuated, cooled with liquid air, and the sulfur hexafluoride sublimed directly into it.[10]

Vapor Pressure of Sulfur Hexafluoride.—The apparatus shown in Fig. 2 was employed in the vapor pressure measurements. The purpose of the compressed air, mercury reservoir and stopcocks attached thereto was to make possible the adjustment of

---

[8] Moissan and Lebeau, *Compt. rend.*, 130, 984 (1900); Moissan and Gautier, *Ann. chim. phys.*, [7] 5, 568 (1895).

[9] Prideaux, *J. Chem. Soc.*, 89, 323 (1906).

[10] It was observed that at the temperature of liquid air the vapor pressure of solid sulfur hexafluoride is certainly less than 0.01 mm.

the mercury level in the short arm to the same point when taking readings, so that the work could be carried out at constant volume. The scale was a metal tape, one inch wide, graduated in millimeters. The bulb containing the sulfur hexafluoride was cooled with a mixture of alcohol and solid carbon dioxide in a one-liter Dewar flask. The temperature of this bath was taken as the temperature of the sulfur hexafluoride. This was justifiable for several reasons: (1) the bath in some runs was allowed to warm up very slowly from one point to the next, not less than six hours being taken for a temperature interval of 25°; (2) as will be described presently, the bath could be held at a given temperature for ten or fifteen minutes without further change in pressure; (3) check pressure readings could be obtained with falling temperature. The bath was kept well stirred throughout by means of a motor-driven stirrer. By the gradual addition of cold alcohol–carbon dioxide mixture to the bath it was possible to keep the temperature constant (within approximately 0.1°), or by regulating the rate of addition, to lower the temperature stepwise and thus reach equilibrium from the upper side.

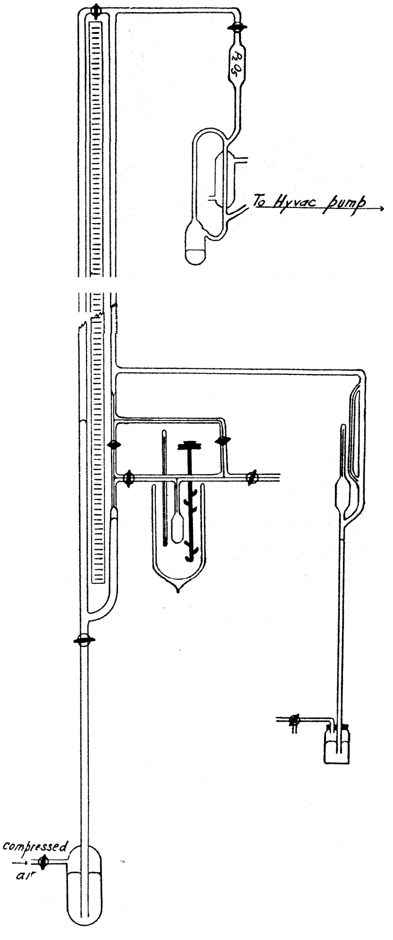

Fig. 2.

Seven runs were made on the vapor pressure, the results of which are shown in the accompanying table and graph. The values designated as "Experimental Data" in the table represent, in general, the mean of several determinations at the given temperatures; from these results the smooth curve was constructed, and from the graph, in turn, the interpolated values given in the table were obtained. By interpolation, likewise, the temperature at which the vapor pressure of solid sulfur hexafluoride becomes 760 mm. was found to be −63.8°. In the individual runs a check upon the purity of the substance was obtained by permitting successive fractions of the same to vaporize, measurements being taken before and after the vaporization. In three runs, beginning with the solid at the lowest temperature (about −72°), the vapor pressure readings were made at intervals with very slowly rising temperature, and were extended well above the melting point (−50.8'); readings were then taken while the substance was cooled slowly, thus passing from the liquid to the solid state. Further evidence of the purity of the substance is afforded by the fact that the measurements recorded were made upon two entirely different samples of sulfur hexafluoride, independently prepared and purified.[11]

TABLE I

VAPOR PRESSURE OF SULFUR HEXAFLUORIDE

Experimental data				Interpolated from graph	
Temp., °C.	Press., mm.	Temp., °C.	Press., mm.	Temp., °C.	Press., mm.
−72.4	433	−58.3	1081	−72.0	445

Melting Point of Sulfur **Hexafluoride.**—The melting point of sulfur hexafluoride as given by Moissan is −55° and by Prideaux −56 to −55°. This value could not be checked by us either from the interpretation of the vapor pressure curves or by direct observation of the melting and solidification of a small quantity of the substance contained in a sealed bulb. The melting point of our purified product thus observed was found to be −50.8 ±0.2°, this value being checked repeatedly. The melting point as indicated by the break in the vapor pressure curve is in fair agreement with this value, but inasmuch as the change of slope at the triple point is so slight, the precise location of the break in the curve is uncertain. Consequently, the value given is based mainly upon the result of direct observation of the melting point. The low values of the earlier observers we feel were due to the presence of impurities. This is also reflected in the case of the gas density determinations which follow.

Density of Gaseous Sulfur **Hexafluoride.**—The density of gaseous sulfur hexafluoride was determined at 20.0°, using the purified material employed in the vapor pressure work. The density globe of known weight and internal volume (495.56 cc.) was connected to the sulfur hexafluoride bulb, the latter immersed in liquid air, and the system evacuated to less

---

[11] It may be worth noting that the pressure of the gas at room temperature becomes too great for ordinary glass apparatus, but there is no reason why liquid sulfur hexafluoride may not conveniently be stored in metal cylinders; the equilibrium pressure under ordinary conditions probably would not exceed greatly that of liquid ammonia.

than 0.001 mm. By allowing the sulfur hexafluoride to warm up the density globe was permitted to fill with the gas at a pressure of a little more than atmospheric. The globe was then removed and placed in a thermostat at 20.0° where it remained for at least fifteen minutes; the stopcock was then opened momentarily to bring the gas to atmospheric pressure and after another short interval again opened and closed, the barometer reading now being taken. The globe and sulfur hexafluoride were weighed by the counterpoise method, employing the usual precautions. The external volumes of counterpoise and globe differed by not more than 0.5 cc. The results given are corrected for the change in volume of the density globe on evacuation, and the pressures refer to mercury at 0°. For the sake of comparison with Moissan's determinations, the relative density referred to air is also given, calculated by assuming the average molal weight of air to be 28.98 and that sulfur hexafluoride behaves as a perfect gas over the interval involved. The theoretical value for sulfur hexafluoride is 5.04.

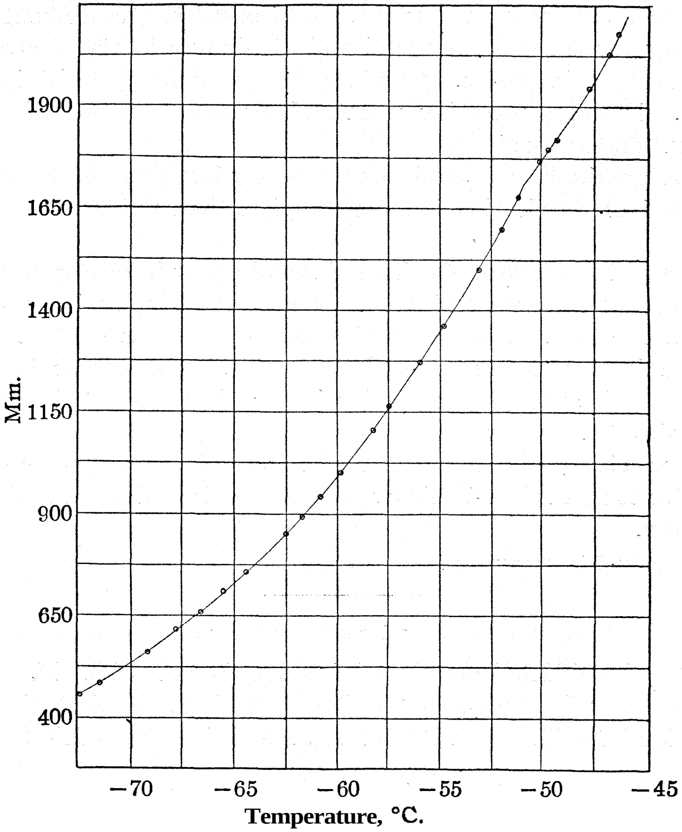

Fig. 3.—Vapor pressure of sulfur hexafluoride.

	Pressure, mm.	Density, g./liter at 20.0°	Relative density (air = 1)
I	753.5	6.091_7	5.101
II	753.5	6.094_9	5.10_3
III	760.5	6.164_6	5.11_4
			5.106 (mean)

Summary

1. In the preparation of fluorine, monel metal has been found entirely satisfactory for the cathode vessel and diaphragm in the electrolysis of fused potassium bifluoride. Graphite as the anode material is slightly attacked. Details concerning structural features and operation of the fluorine generator are given.

2. The synthesis and purification of sulfur hexafluoride are described; the method of purification is more complete than hitherto has been described.

3. The vapor pressure of solid and liquid sulfur hexafluoride has been measured up to three atmospheres, the temperature interval covered being from —72 to —45°. The pressure becomes 760 mm. at —63.8°.

4. The density of the gas at 20°, 753.5 mm., is found to be 6.093 g. per liter. From this the relative density (air = 1) is calculated to be 5.10_6; theoretical, 5.04.

5. The melting point of pure sulfur hexafluoride is found to be —50.8 ± 0.2°. This is more than 4° higher than the earlier values of Moissan and of Prideaux.

DEFORMATION OF ELECTRON SHELLS. II. ABSORPTION SPECTRUM, MOLECULAR VOLUME AND REFRACTION OF CERTAIN RARE EARTH SALTS

BY P. W. SELWOOD

RECEIVED AUGUST 25, 1930 PUBLISHED NOVEMBER 5, 1930

In the first paper of this series[1] it was pointed out that there is a relation between the absorption spectrum and other properties of neodymium perchlorate. The object of the present work was to extend the observations to the nitrate and chloride of neodymium and, so far as possible, to other members of the rare earth group.

Experimental

The experimental procedure involved in the measurements described here will be given only wherein it differs from that already reported.

The quantitative analysis of neodymium nitrate solutions presented a

---

[1] Selwood, THIS JOURNAL, 52,3112 (1930).

much simpler problem than either the perchlorate or the chloride. Weighed samples of the solutions were evaporated to dryness and ignited directly to the oxide. The whole analysis took less than an hour, and the results are believed to be accurate to 0.05%.

In the case of the neodymium chloride it was necessary to use the oxalate–oxide method as described for the perchlorate determination. In every case the filtrate from the neodymium oxalate was tested spectroscopically for neodymium, and the oxide, after being weighed, was dissolved in nitric acid and tested for chloride. The absence of chloride in any of the samples indicates that neodymium oxalo-chloride does not form in noticeable amounts if the rare earth is precipitated slowly from the hot, dilute solution, with fairly dilute oxalic acid. The chloride results are believed to be accurate to 0.1%.

The determinations of density and of refractive index were as described before. All the data on molecular refraction refer to the hydrogen C line. The molecular volumes were calculated as shown by Geffcken[2] from the relation

$$V = \frac{M}{d_0} - \frac{3000\,(d - d_0)}{N}$$

where V is molecular volume, M is molecular weight, d is density of the solution, d_0 is density of water and N is concentration in equivalents per 1000 cc. of solution.

In addition to the absorption bands of neodymium nitrate and chloride, an examination was also made of the spectrum of praseodymium, samarium, europium, gadolinium, holmium and erbium. In all cases the spectrum of a 10 N solution through a 3-mm. layer was compared with that of a 0.2 N solution through the equivalent thickness of 150 mm.

In the case of the gadolinium, which has no absorption bands in the visible region of the spectrum, the procedure was modified in that uranium salts placed in the positive crater of a carbon arc formed the source of ultraviolet illumination. The very large number of emission lines from uranium served in place of a continuous spectrum. It has recently been reported by Freed and Spedding[3] that gadolinium has some faint absorption lines in the visible region. In an effort to verify these results, the writer examined the spectrum of a 150-mm. layer of 10 N gadolinium nitrate, but no trace of selective absorption could be detected. The spectrum was photographed on a Hilger E 1 quartz prism spectrograph.

During the course of the work on neodymium nitrate solutions it seemed desirable to examine the absorption spectrum of a crystal of the same salt. Well-formed crystals were prepared from a saturated solution which was slowly evaporated. They were soft and easily broken, but several pieces

---

[2] Geffcken, *Z. physik. Chem.*, *5B*, 81 (1929).

[3] Freed and Spedding, *Phys. Rev*,, 34, 945 (1929).

with smooth surfaces were obtained by rubbing the crystal down with the moist finger tip. In order to prepare a dilute solution of equivalent thickness with which to compare the spectrum of the crystal it was necessary to determine the concentration of neodymium nitrate in equivalents per 1000 cc. of crystal. This was done by analyzing a crystal for neodymium content by ignition to the oxide, and by finding the density through the loss of weight in benzene, in which neodymium nitrate is insoluble. Two such determinations gave 15.13 and 15.11 as the normality of $Nd(NO_3)_3$ in the crystals. The crystal finally used for the spectroscopic work had a thickness of 1.70 mm. This was equivalent to 100 mm. of 0.257 N solution with which it was compared.

The purity of the neodymium used has already been discussed. All the other rare earths except the praseodymium and the erbium had been prepared by the writer, some expressly for this work and some in connection with other work. The praseodymium contained 1% of lanthanum. The samarium showed no absorption bands of neodymium and no arc lines of europium. The europium, of which only a gram or two was available, was free from all other rare earths. The gadolinium contained only a spectroscopic trace of europium. The holmium and erbium material consisted largely of the colorless rare earth yttria. The first contained 26% holmium, and the second 20% erbium.

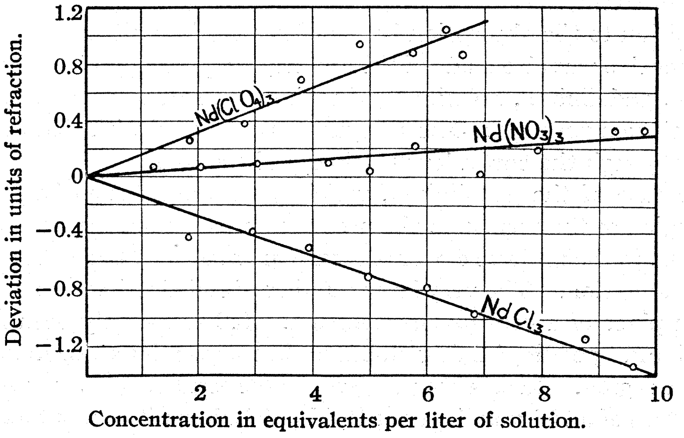

Fig. 1.—Deviations from additivity in the molecular refraction of neodymium perchlorate, nitrate and chloride in aqueous solution.

Results

The values for the molecular volume and refraction of neodymium nitrate and chloride are shown in Tables I and II. Figure 1 shows the deviations from additivity when the molecular refractions of the nitrate and chloride are plotted against concentration. For the sake of complete-

ness the values previously reported for the perchlorate are included. While the perchlorate showed a 2% increase with concentration from 0 to 7 *N*, the nitrate shows a 1% increase from 0 to 10 *N*, and the chloride shows nearly a 3% decrease from 0 to 10 N. Over the same ranges of concentration the molecular volumes of these salts show a marked increase, the perchlorate 12%, the nitrate 27% and the chloride 36%.

In general the absorption bands of the neodymium solutions were shifted toward the red end of the spectrum by increasing concentration. In the case of the perchlorate the shifts were small, in most instances of the order of 1 or 2 Å., while both nitrate and chloride concentrated solutions showed marked shifts toward the red, those of the latter salt sometimes approach-

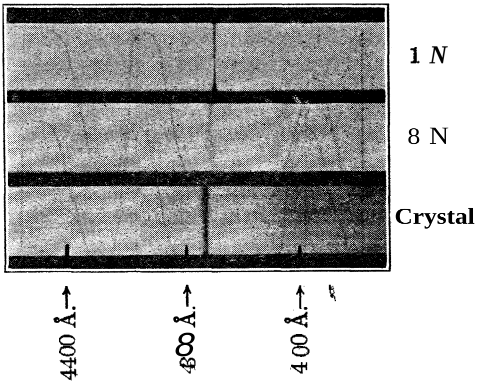

Fig. 2.—The 4272 Å. absorption line of neodymium nitrate.

ing 20 Å. The spectra of the dilute solutions of all the salts were practically identical.

As indicated in Figs. 2 and 3, the spectrum of the neodymium nitrate crystal showed a markedly increased shift in the same sense as did that of

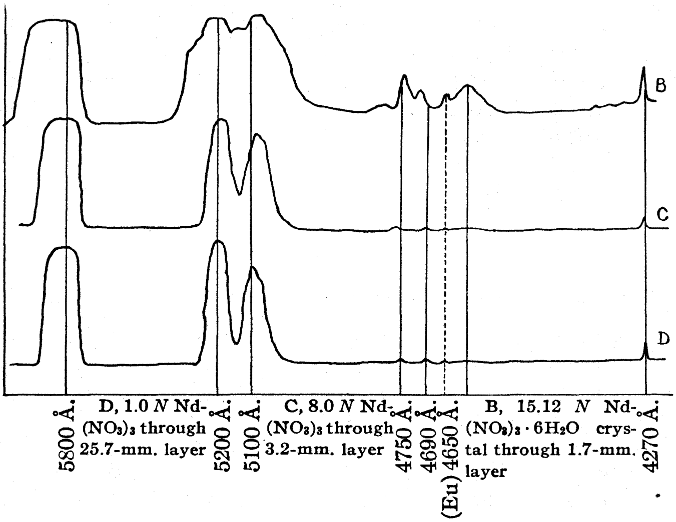

Fig. 3.—Microphotometric curves of the absorption spectrum of neodymium nitrate, showing the effect of concentration on the positions of the various bands.

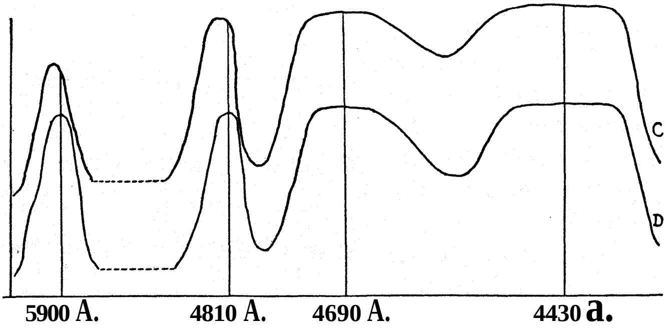
the more concentrated solution. It is evident that whatever forces were causing the shifts in the solution were acting more intensely in the crystal.



D, 0.2 N Pr$(NO_3)_3$ through 150-mm. layer; C, 10.0 *N* Pr$(NO_3)_3$ through 3-mm. layer.

Fig. 4.—Part of the absorption spectrum of praseodymium nitrate.

This observation parallels that of **Brunetti,**[4] who reached the same conclusion in the case of praseodymium salts.

[4] Brunetti, *Nuovo cimento,* [N. S.] **5,** 391 (1928).

The spectral bands of praseodymium, samarium and europium also tended to shift toward the red with increasing concentration. The nitrate was investigated in every case. The bands of praseodymium were all shifted slightly toward the red, those of samarium were very slightly if at all shifted except the broad band at 4020 Å., which was noticeably moved toward the red. All the visible bands of europium seemed to be very slightly shifted toward the red. The relative intensities were also much changed. A few bands in the ultraviolet were too hazy to make any definite statement about their positions.

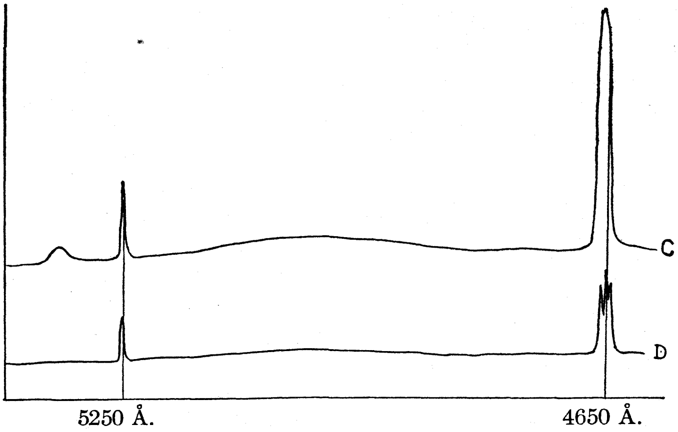
Fig. 5.—Part of the absorption spectrum of samarium nitrate.

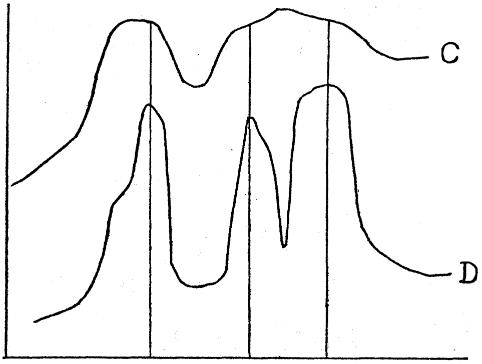


D, 0.2 *N* $Eu(NO_3)_3$ through 150-mm. layer; C, 10.0 N $Eu(NO_3)_3$ through 3-mm. layer.

Fig. 6.—Part of the absorption spectrum of europium nitrate.

At the concentrations employed no bands of gadolinium were observed at

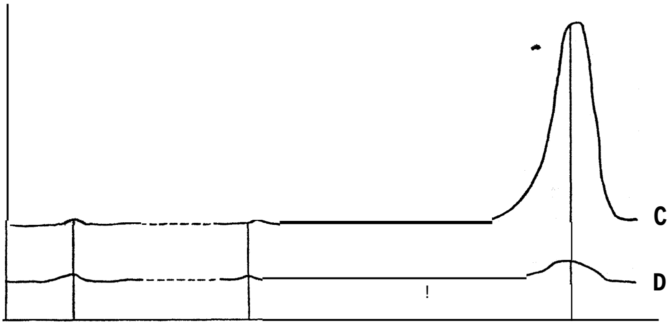
3108, 3059, 3056 or 3052 Å.,[5] where they have previously been reported. Several bands reported by Freed and Spedding, however, were found. Of these, the two at 2730 and 2750 Å. were most intense in the cases of both nitrate and chloride. While the nature of the bands was altered by concentration, it is doubtful whether there was any definite movement one way or another.



D, 0.2 *N* $GdCl_3$ through 150-mm. layer; C, 10.0 N $GdCl_3$ through 3-mm. layer.

Fig. 7.—Absorption bands of gadolinium chloride.

The bands, however, of holmium and erbium were generally shifted toward the blue, the change being most noticeable for those at 4530, 4850 and 5350 Å. for holmium, and 4430, 4490 and 6520 Å. for erbium. This peculiar change is so striking as to suggest some radical difference in the atomic structure of these last rare earth elements. Such a change is, in fact, postulated in the current theories of atomic structure, inasmuch as the 4_4 electron shell is believed to complete its first sextet with europium.[6] But the interpretation of the phenomenon is not entirely clear and it seems at the present time to be impossible to generalize further with respect to the effect of increasing concentration so far as direction of shift is concerned.



D, 0.2 N $Ho(NO_3)_3$ through 150-mm. layer; C, 10.0 N, $Ho(NO_3)_3$ through 3-mm. layer.

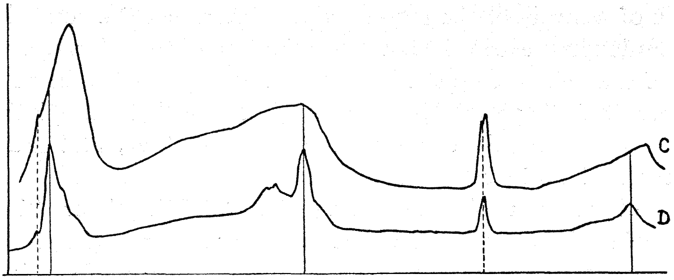
[6] Hevesy, "Die seltenen Erden von Standpunkte des Atombaues," Springer, Berlin, 1927.

As pointed out before, the classical dispersion formula shows that a decrease in characteristic frequency (shift toward the red) should be attended with an increase of molecular refraction. Such is what has been observed for the cases of neodymium perchlorate and nitrate.

Fajans and others have shown that while the perchlorate ion is only slightly influenced by its neighbors, the nitrate ion is somewhat deformed and the chloride ion is very highly deformed. While deformation of *a* cation results in an increase of refraction, deformation of an anion results in a decrease of refraction. It appears then that the increase in refraction of the neodymium ion is partly compensated by the decrease of the nitrate, and it is completely so and more by that of the chloride. The decrease in refraction of neodymium chloride is, therefore, in no way evidence against the conclusion that a shift toward the red of absorption bands is generally attended with an increase of refraction. It appears, then, from both refraction and spectroscopic evidence that the outer electron shell of the neodymium ion must be deformed in concentrated solution, and that this deformation is communicated in part, at least, to the inner electron shells thought to be the source of the characteristic absorption bands,



D, 0.2 N $Er(NO_3)_3$ through 150-mm. layer; *C*, 10.0 *N* $Er(NO_3)_3$ through 3-mm. layer.

Fig. 9.—Part of the absorption spectrum of erbium nitrate.

The writer wishes to thank Professor B. Smith Hopkins, in whose laboratory this work was done, for the invaluable advice and encouragement which he has from time to time supplied.

Summary

The molecular refraction of neodymium nitrate has been found to increase slightly with concentration, while that of the chloride decreases. The molecular volume of both salts is increased. The absorption bands are shifted toward the red. These measurements afford evidence that the neodymium ion is deformed in the more concentrated solutions. The absorption bands of praseodymium and samarium nitrates are also shifted toward the red. The bands of europium and gadolinium are not much

altered in position, while those of holmium and erbium are noticeably shifted toward the blue.

STUDIES ON COMPLEX IONS. III.[1] THE RELATIVE STABILITIES OF THE HALOGENOPLATINATES

BY H. I. SCHLESINGER AND R. E. PALMATEER[2]

RECEIVED AUGUST 30, 1930 PUBLISHED NOVEMBER 5, 1930

As part of a study of the factors which determine the conditions under which complex ions are formed, a determination of the relative stabilities in solution of a series of complex ions of similar types has become desirable. Schlesinger and Tapley[3] have shown that the halogenoplatinates are mutually and reversibly convertible into each other, and are therefore suitable for such an investigation.

The usual method of determining the "stability" or "instability" constants of such ions is inapplicable to this case, for aqueous solutions of the halogenoplatinates contain no detectable quantities of the free platinic ions. Relative values of the stabilities might, however, be obtained if the amount of transformation of one halogenoplatinate into the other could be determined in the presence of given quantities of halide ions. But even such measurements present difficulties, for the reactions involved probably proceed in many steps, leading through all of the theoretically possible mixed halogenoplatinates. No method available allows a determination of each of the seven possible components of such a system.

It nevertheless has become possible to obtain approximate relative values by the following procedure. When, for example, a chloroplatinate is mixed in aqueous solution with a bromide and a chloride in suitable proportions, a reaction occurs which leads to the formation of a mixture intermediate in color between that of the pure chloroplatinate and the pure bromoplatinate. An identical mixture, at least so far as the color is concerned, is obtained if the starting material is the bromoplatinate, a fact which demonstrates that a state of true equilibrium is attained. By comparing photometrically the color of such solutions with mixtures of chloro and bromoplatinates of known concentration, one could estimate the percentage of transformation of the one platinate into the other were no

[1] For the preceding papers of this series see THIS JOURNAL, 51, 3520, 3523 (1929).

[3] Schlesinger and Tapley, THIS JOURNAL, 46, 276 (1924).

intermediate chloro-bromoplatinates formed. From this percentage transformation one could then calculate the ratio of the concentrations of the two complex ions. But, as will be demonstrated in the experimental part of this paper, intermediate complex ions are undoubtedly present, and the color of the solutions is, on that account, not a direct measure of the percentage transformation nor of the ratio of the concentrations of the complex ions. However, as the calculated ratios approach zero or infinity the fictitious values must approach the true ratio. That this assumption is warranted is shown by the fact that under these conditions the colors, as well as the absorption spectra, approach those of the pure complex ions. Hence, by plotting the values of these fictitious ratios[4] against the ratios of the concentrations of the simple halide ions involved in the reaction, and extrapolating the curves to a point representing practically complete transformation, one can determine at what concentrations of the simple ions the transformation of the one complex ion into the other becomes complete. The extrapolation proved to be unexpectedly reliable because the curves proved to be straight lines.

Ratios of the simple ions found in this way to be necessary almost completely to transform one of the halogenoplatinates into the other are very striking. To convert 99% of bromoplatinate[5] into chloroplatinate, the solution must contain approximately 660 times as much sodium chloride as sodium bromide, and to produce the corresponding result in the reaction between iodoplatinate and bromoplatinate, there must be present approximately 25,000 times as much sodium bromide as sodium iodide. From these data we have estimated, by a method to be described below, that to convert iodoplatinate ions almost completely into chloroplatinate ions, the solution must be approximately 16,600,000 times as concentrated

---

[4] These fictitious ratios, calculated from the colorimetric data, will hereafter be called the "apparent ratios" and the corresponding percentage transformation will be called the "apparent % transformation" and will be designated by the letter P.

[5] The choice of 99% for the calculation was based on the following reasons. Theoretically, 100% conversion cannot occur until the concentration of one of the simple halide ions reaches infinity. The data obtained could have been used to calculate the ratio of the simple ions required to produce any degree of transformation below 100%, but such calculations have a concrete meaning only for almost complete transformation, because only under that condition is the color a measure of the amount transformed. Another point of importance should be noted at this time. While it is undoubtedly true that the "apparent ratios" (see footnote 4) approach the true ratios, the two values might still be fairly widely different even at 99% transformation; but that is of no significance. In the transformation of bromoplatinate into chloroplatinate, for example, the color of the solutions is practically identical with that of the latter substance when the "apparent ratio" is 99:1. Hence practically all of the material is in the form of chloroplatinate. The remaining 1% may be largely an intermediate ion instead of bromoplatinate. Consequently the true ratio may be far from 99; but 99% of the material is nevertheless in the form of the chloroplatinate, and this is the quantity in which we are interested.

with respect to sodium chloride as to sodium iodide. An attempt was made to determine the corresponding quantities for the equilibrium between fluoroplatinate[3] and iodoplatinate. The reaction requires months for completion at ordinary temperatures, and the solutions attack glass vessels and undergo decomposition. For these reasons no reliable data have been obtained, but the results indicate that the great difficulty of transforming fluoroplatinate into the other ions is possibly due in part to the sluggishness of reaction rather than entirely to inherent stability.

It is interesting to point out that the results here reported demonstrate how enormously greater is the tendency of iodide ion than of bromide ion, and of bromide ion than of chloride ion, to enter the coordination sphere in the case of the platinates. In the case of some of the solid ammines of chromium and certain other metals, according to the data obtained in this Laboratory and elsewhere,[6] the reverse is true. Whether the difference is to be explained by the influence of changes in lattice energies in reactions between solid compounds as has been suggested,[6] or is to be accounted for by specific influences of the central atoms, can be decided only when further data have been collected. The most likely cause for the difference, however, would seem to be that, in the platinates, the halogen ions are contained in a negative complex ion, while in the other compounds mentioned they are in a positive complex ion.

In the course of this investigation we have had occasion to review the evidence on which rests the idea that all possible intermediate halogenoplatinate complexes exist, and to contribute further data along these lines. We have made some interesting observations on the rates at which equilibria in such mixtures are established, as well as on some other properties of the halogenoplatinates. These observations as well as additional phases of the interpretation of our data will be taken up below.

Experimental

Preparation of Materials.—The platinum from which the salts were prepared was purified by recrystallizing sodium chloroplatinate from alcohol and further by the procedure of Mylius and Mazzucchelli.[7] From the platinum thus purified sodium chloroplatinate was prepared according to the method of Precht.[8]

Potassium bromoplatinate was obtained according to the procedure of Biilmann and Andersen[9] and further purified by two recrystallizations, which yielded a product of constant absorption spectrum. The corresponding sodium salt was obtained by adding a dilute solution of sodium bicarbonate to bromoplatinic acid, an intermediate product in the preparation of the potassium salt. The solution was evaporated to a sirupy consistency on a water-bath and dried in a vacuum desiccator over phosphorus pentox-

ide. The resulting solid was dissolved in absolute alcohol, the solution filtered and treated with ether to precipitate the sodium bromoplatinate.[10] Von Bonsdorff[11] claims to have prepared sodium bromoplatinate bv the addition of sodium bromide to bromoplatinic acid; but sodium bromide is less soluble in water or in alcohol than is sodium bromoplatinate, and his method therefore leads to no results.

Datta's[12] method for the preparation of potassium iodoplatinate was used, and that of Schlesinger and Tapley[a] for the potassium flnoroplatinate. In the latter case it was found preferable to heat the mixture of platinum and the double salt of lead tetrafluoride to just below the melting point of the latter, because under these conditions a better yield was obtained than that described in the earlier paper.

Sodium chloride and sodium iodide were purified by repeated recrystallization from commercial salts of good quality. The iodide was shown by the usual methods to be free from chloride. Sodium bromide was prepared from repeatedly redistilled hydrobromic acid and sodium bicarbonate. The final product contained too small a quantity of sodium chloride to be detected by the ordinary methods of titration. Sodium fluoride was prepared similarly from hydrofluoric acid. The usual drying of these salts by heating them to redness in platinum vessels was omitted, as it was shown spectroscopically that such a procedure introduced traces of the corresponding platinates.[13]

The measurement of the "apparent % transformation" could not be made by a direct comparison of the color of the unknown solutions with that of solutions containing known amounts of the halogenoplatinates in question, because synthetic mixtures cannot be prepared. Both bromo and iodoplatinates undergo moderately rapid decomposition in pure water. To stabilize the former a soluble bromide and for the latter an iodide must be added to the solutions. If these stabilizing salts were added to a mixture of these two platinates or to a mixture of either of them with a chloroplatinate, partial transformation to the more stable complex ion would occur.

It was, therefore, necessary to calculate from the color intensity of the separate halogenoplatinates what must be the color intensity of mixtures of the two salts. To do this we first proved both colorimetrically and spectrophotometrically that each of the salts obeyed Beer's law. Next it was found, for example, that a column of 0.0016 molar sodium chloroplatinate 50 mm. long matched the color of a 3-mm. column of 0.0016 molar sodium bromoplatinate[14] in a Kober colorimeter. Consequently if $P\%$ of the chloroplatinate in the first solution were transformed to bromoplatinate, a column H mm. in length would have to be used to match a 10-mm. column of the 0.0016 molar standard bromoplatinate solution when

[10] This salt is so hygroscopic that we did not weigh it out in making up the standard solutions, but determined the strength of the solution prepared by colorimetric comparison with a standard solution of the potassium salt.

[11] Von Bonsdorff, ***Pogg. Ann.***, 19,344 (1830); 33, 61 (1834).

[12] Datta, THIS JOURNAL, **35**, 1186 (1913).

[13] The amount of platinate was less than 0.00002 molar in the saturated solutions of the simple salts, but was easily discernible in the spectra.

[14] The standard solutions of this salt always contained sufficient sodium bromide to prevent hydrolysis.

$$H = \frac{1000}{P + \frac{3}{50}(100 - P)}$$

The values of P in this equation are what have been called the "apparent % transformation" in the preceding discussion.[4] For the reaction between bromo and iodoplatinates a similar procedure was used, except that the color of the mixtures was compared with that of a 0.0001 molar iodoplatinate solution stabilized by sodium iodide. The equation for calculating the percentage transformation, obtained as described for the preceding case, was

$$H = \frac{1000}{P + \frac{208}{50}(100 - P)}$$

Although this method gives fairly satisfactory results, it suffers from the difficulty that, in spite of the fact that dilute solutions of these various platinum salts are similar in color, the shades are not exactly alike. For this reason colorimetric readings are difficult to duplicate for a given mixture more closely than to 1% in the most favorable case, that is, when the apparent transformation is about 50%, and to 7% in the least favorable cases, that is, when the reaction has gone nearly to completion toward the formation of the less intensely colored compound. Ten to fifteen readings were therefore made of each solution, and all the solutions were made up in several portions. Consequently each of the "apparent % transformations" tabulated below is really the average of from thirty to sixty readings. Since the errors are less marked in dilute than in concentrated solutions, the former were used exclusively. Finally, measurements were restricted to solutions of from three to five different concentrations of the platinum salts, because for each concentration the constants for the equations given above had to be redetermined.

It might be expected that provision would have to be made for keeping the mixtures at constant temperature both while equilibrium is being reached and during the measurement of the color, but this was found to be unnecessary for the degree of precision to which we were limited by the sources of error described. Thus we observed that even though the solutions were kept in the colorimeter for from ten to twenty minutes for measurement, there occurred no change in the reading greater than the reading error itself. Unquestionably this is in part due to the slowness of the transformation of bromoplatinate into chloroplatinate and vice *versa,* but the lack of disturbance caused by temperature changes must be largely due to a very small temperature coefficient for the equilibrium condition. This is shown by two facts. In the first place, the data obtained from solutions kept at 25° in a thermostat did not differ from data on solutions kept in the room. In the second place, the colors of the equilibrium mixtures for the transformation of iodoplatinate into bromoplatinate also remained constant in the colorimeter although in this case equilibrium is attained in a few minutes.

Rate of attainment of equilibrium is greatly affected by light. The reaction between a bromoplatinate and a chloride in a mixture exposed to the light of a north window came to completion in three days; another portion of the same solution was kept in a thermostat in a blackened flask, and did not reach equilibrium before the fiftieth day. Nevertheless, the final equilibrium reading was the same in the two cases. Consequently there is a great advantage in keeping the mixtures exposed to light instead of in a constant temperature bath, and the data presented below, therefore, refer to the reaction at room temperature, *i. e.*, from 20–25°.

In Table I are given the experimental results for the equilibrium between chloroplatinate and bromoplatinate ions. The first column gives the initial concentration of the platinates in moles per liter. The subscript B indicates that equilibrium was reached from the bromoplatinate, the subscript C that the equilibrium was reached from the chloroplatinate side of the reaction. The second and third columns give, respectively, the initial concentrations of the sodium chloride and the sodium bromide in moles per liter. The length of column of the equilibrium mixture required for a color match when read against a 10-mm. column of a solution of potassium bromoplatinate of the same concentration as that of the platinate in the original solution is given in the fourth column.[15] The fifth column is the "apparent % transformation" of chloroplatinate into bromoplatinate, defined and obtained as has already been described. Obviously the transformation of the one halogenoplatinate into the other must be accompanied by decrease in the concentration of one of the simple halide ions and a corresponding increase in the other. Hence the equilibrium ratio of the simple halides differs from the ratio of the initial concentrations. To calculate the former we again proceeded as if no intermediate platinate ions were formed. Consequently these ratios are also fictitious, but they, too, must approach the real values as the "apparent % transformation" approaches 100. In fact, in most of the experiments the change in the ratio of the simple salts resulting from transformation of the platinates is very small, since a large excess of the simple ions was usually present. The calculation of the equilibrium ratios from the "apparent % transformations" is thus made on the basis of the chemical change represented by the equation

$$6\mathrm{NaY} + \mathrm{Na_2PtX_6} \rightleftharpoons 6\mathrm{NaX} + \mathrm{Na_2PtY_6}$$

---

[15] Potassium bromoplatinate was used as a standard because it can be weighed out accurately while the sodium salt is too hygroscopic; but in the equilibrium mixtures the sodium salts had to be used because potassium chloroplatinate would be precipitated from the solution and the equilibrium, therefore, disturbed.

in which X and Y represent halide ions. In Col. 6 are given the equilibrium ratios of the halide ions, and in Col. 7 the corresponding ratios for the platinate ions. As was pointed out above, when these ratios are plotted against each other, a straight line results. Hence, the product of the one set of ratios by the reciprocal of the other is a constant, the value of which is shown in Col. 8.

[a] It must be borne in mind that the equations given above for calculating "P" from "*H*" merely show the principles employed. The solutions actually used as color standards did not always have exactly the same concentration as the experimental solutions, and the values of "P" in the table are corrected for this difference. Furthermore, "P" represents the fraction present as bromoplatinate irrespective of the side from which equilibrium was reached. Similar considerations apply to Table II.

It will be seen from the table that there are considerable deviations from the linear relationship between the "apparent % transformation" and the ratio of the concentrations of the simple halide ions. These deviations, however, show no trend, and can be fully accounted for by the unavoidable reading errors which have already been discussed. To show at a glance that the deviations are symmetrical throughout, we have reproduced the experimental results in Fig. 1. Instead of plotting the two ratios directly, we calculated from the constant what should be the curve for the plot of the "apparent" ratio of the concentration of complex ions against the logarithm of the "apparent' ratio of the concentrations of the simple ions. These curves are shown in solid lines; the circles representing the experimental data show no trend.

The data furthermore show that the equilibrium is determined by the ratio of the concentrations of the substances involved rather than by the values of the concentrations themselves. Thus, for example, there are two mixtures in which the apparent ratio of the concentrations of the sodium bromide to sodium chloride was 0.262 at equilibrium. Although one of these solutions contained 0.1038 mole of sodium bromide and 0.3962 mole of sodium chloride and the other 0.0674 mole of bromide and 0 2576 mole of the chloride. the constant for the first set of data is 0.145 and for the second set 0.151. The difference between the two values is accounted far by a reading error of 1%, which is well within the limit attainable in the experiments. These two solutions illustrate also that the changes in the concentration of the platinate are without effect on the constant, for the first solution was 0.00177 molar with respect to this constituent and the second 0.0020. It should be stated, however, that the platinate concentrations were not varied between wide limits for reasons discussed previously. Numerous other cases showing that the constant is independant of the initial concentrations will be found in the table.

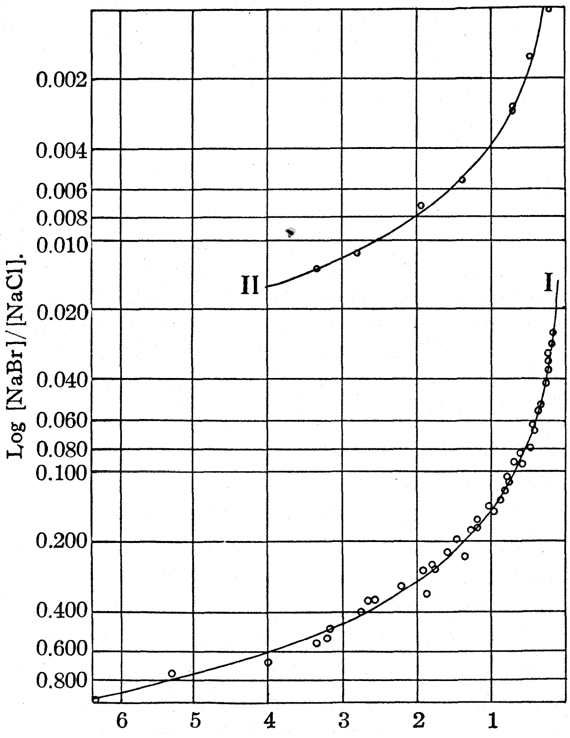

Fig. 1.—Curve I, $[Na_2PtBr_6]/[Na_2PtCl_6]$; Curve II, $[K_2PtI_6]/[K_2PtBr_6]$.

From the average value of this constant we may now calculate the conditions under which bromoplatinate is 99% transformed to chloroplatinate. For, as has already been said, as the "apparent % transformation" approaches 100% it also approaches the value of the real per cent. transformation. The equation by which the constants of Table I were calculated is

$$\frac{[NaBr]}{[NaCl]} \times \frac{[Na_2PtCl_6]}{[Na_2PtBr_6]} = 0.15$$

in which the bracketed symbols denote molar concentrations. If [NaBr] = 1, the ratio $[Na_2PtCl_6]/[Na_2PtBr_6]$ becomes 99 when [NaCl] = 660.

In Table II are given the corresponding data for the equilibrium between iodoplatinate and bromoplatinate ions. In addition to the difficulties of measurement mentioned above, another source of error proved troublesome in this case. Very small traces of alkali, even those dissolved from glass by the solutions, cause decomposition of the iodoplatinate. To prevent this, bromide ion was supplied in part in the form of hydrobromic acid. In these solutions, however, iodine is fairly rapidly liberated, probably on account of reduction of the platinum to the platinous condition since the reaction occurs in solutions free from oxygen. Fortunately the liberation of iodine is much slower than the attainment of the equilibrium under investigation, and causes no serious difficulty if the measurements are made rapidly. The great difference in speed of attainment of equilibrium in the reaction between chloro and bromoplatinate and in that between bromo and iodoplatinate is of considerable interest. For the present we can state, however, only that in the former case equilibrium was reached in about three days in daylight, while in the latter only thirty to eighty minutes are necessary.

TABLE II

EXPERIMENTAL DATA

Halogeno-platinate	Bromide concentration	Sodium iodide	Reading, H	% Transformation, P	Equilibrium ratio		Constant
					NaI/HBr	$PtI_6/PtBr_6$	
0.0001_I	0.8462	0.011	12.93	76.7	0.01318	3.29	0.00400
$.0001_B$	1.6924	.02	13.5	73.5	.01155	2.777	.00416
$.0001_I$	0.8462	.006	15.05	65.5	.00722	1.90	.0038
$.0001_B$	0.8462	.005	16.82	57.6	.0055	1.358	.00405
$.0001_B$	1.6924	.005	22.75	41.0	.00281	0.695	.00405
$.0001_I$	0.8462	.002	24.00	39.0	.00279	.639	.00436
$.0001_I$	.8462	.002	22.84	41.4	.00278	.707	.00393
$.0001_I$	.8462	.002	23.02	41.0	.00278	.695	.0040
$.0001_I$	.8462	.002	23.17	40.7	.00278	.686	.00405
$.0001_B$	.8462	.0025	23.24	40.5	.00266	.68	.00391
$.0001_I$	.8462	.001	29.82	30.6	.001643	.431	.00382
$.0001_B$	1.6924	.001	60.3	12.7	.000545	1.455	.00374

Again the values in Col, 8 are constant to well within the range of experimental error. Hence, when transformation is almost complete

$$\frac{[\mathrm{NaI}]}{[\mathrm{NaBr}]} \times \frac{[\mathrm{Na_2PtBr_6}]}{[\mathrm{Na_2PtI_6}]} = 0.004$$

Substituting 1 for [NaI], 99 for $[Na_2PtBr_6]/[Na_2PtI_6]$, [NaBr] becomes approximately 25,000.

If we multiply the equations $[NaI]/[NaBr]$ X $[Na_2PtBr_6]/[Na_2PtI_6] = 0.004$[16] and $[NaBr]/[NaCl] \times [Na_2PtCl_6]/[Na_0PtBr_6] = 0.15$ by each

---

[16] The actual measurements for this equation were carried out with solutions containing hydrobromic acid and sodium bromide for the reasons given above, but for the very rough calculations now to be discussed, substitution of the salt for the acid will make no difference. As a matter of fact, we showed experimentally that the same value for this constant would have been obtained had sodium bromide alone been used.

other we obtain

$$\frac{[\mathrm{NaI}]}{[\mathrm{NaCl}]} \times \frac{[\mathrm{Na_2PtCl_6}]}{[\mathrm{Na_2PtI_6}]} = 0.0006$$

This is admittedly a mathematical procedure of very uncertain justification. In obtaining the constant values 0.004 and 0.15, we substituted in the first two equations numerical values which in all probability represent concentrations only under the very definite conditions specified above. There was no well-established theoretical basis for expecting that the products of these ratios would be constants, and there is, therefore, no reason for anticipating that a similar relationship would prove true in the case of the equilibrium between iodoplatinate and chloroplatinate, but the last-named equilibrium cannot be studied in the same way as were the others, because the colors obtained, when attempts were made to cause partial transformation, are not intermediate in shade between those of the iodo and chloroplatinate. This is not surprising, for iodoplatinates differ very markedly in color from the chloroplatinates, and if intermediate compounds exist there should be a variety of shades in the equilibrium mixtures. For this reason it was necessary to find a way of estimating mathematically under what conditions almost complete transformation should occur, and then to corroborate this estimate approximately by experiment. The derived equation seemed the most rational approach to the solution of the problem.

According to this equation it would be impossible to transform more than a small fraction of iodoplatinate into chloroplatinate by the addition of chloride ion. A minimum of 0.001 molar potassium or sodium iodide is required to prevent decomposition of iodoplatinates into platinum tetraiodide. If this amount of potassium iodide is present in the solution, the equation requires that the concentration of the chloride ion constituent would have to be 16,000 normal for 99% transformation. In accordance with this prediction, it was found that iodoplatinates, stabiliied with a minimum amount of potassium iodide and treated with a large excess of 6 molar hydrochloric acid, retain a much more intense color than they should, had the iodoplatinate been completely changed to chloroplatinate.[17]

Somewhat more definite information can be obtained by studying qualitatively the reverse reaction. According to the equation it is necessary to make the concentration of the chloride approximately 0.2 molar in order to prevent practically complete transformation of chloroplatinate to iodoplatinate when the former is dissolved in 0.001 molar potassium iodide. A solution thus prepared, using 0.0001 molar sodium chloroplatinate, does

---

but since decomposition tended to occur under these conditions the data were not as reliable as those obtained with the acid.

[17] If concentrated hydrochloric acid is used, the color of the solution gradually fades. The absorption spectrum of this solution shows, however, that the iodoplatinate has been transformed into compounds other than chloroplatinate. Also the addition of potassium iodide to these solutions does not completely reverse the reaction.

not quite attain the color of iodoplatinate of this concentration, but the experiment is only of qualitative character because decomposition to platinum tetraiodide cannot be entirely prevented. On the other hand, a solution molar with respect to hydrochloric acid, 0.001 molar with respect to potassium iodide and 0.0001 molar with respect to sodium chloroplatinate showed, when equilibrium was reached, the brown color characteristic of partial transformation instead of the violet shade of the iodoplatinate. Obviously, then, the data calculated from the derived equation do give results correct at least so far as the order of magnitude is concerned.

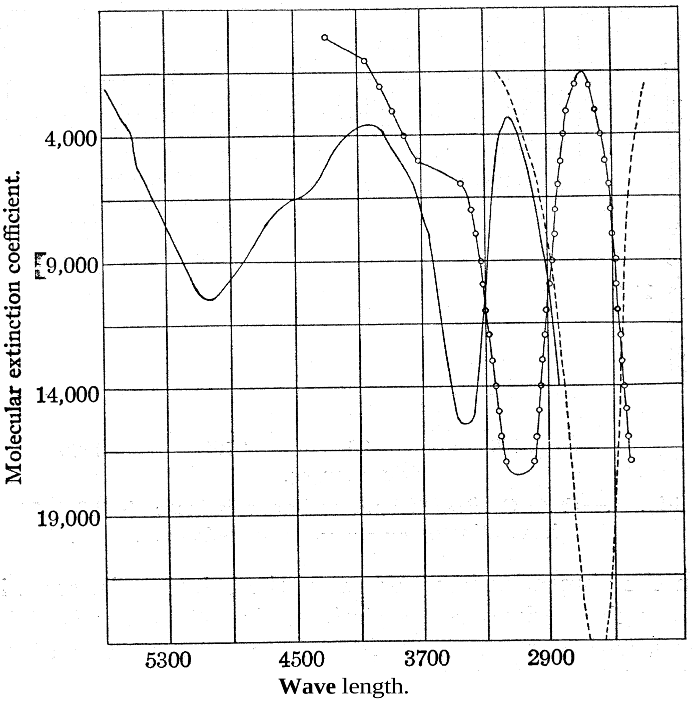

Fig. 2.— - - - -, K_2PtCl_6; O-O-O, K_2PtBr_6; ——, K_2PtI_6.

There are several points of theoretical interest which should be indicated, although our data are as yet too limited to warrant extended discussion. One would expect that equilibrium conditions in the reactions investigated would be expressed by equations of the type $[PtX_6^=][Y^-]^6/[PtY_6^=][X^-]^6 = K$; instead, an equation in which the apparent concentrations of the simple halogenide ions appear as the first power results from the data. The lack of agreement with the mass law is not surprising. We have neglected the activity coefficients; in dilute solutions these might cancel out because of the great similarity of the pairs of ions involved, but in the concentrations used this is hardly to be expected. But the most probable reason for the enormous deviation from the mass law is the possibility that the apparent concentrations are in most instances not the real concentrations because of the formation of intermediate complex ions. Since the existence of such substances has repeatedly been denied, further investigation of this point was undertaken as described below.

While it is thus not difficult to explain the deviation from the mass law, no satisfactory explanation has as yet been found for the fact that the "apparent ratios" happen to vary with the first power of the ratio of the concentrations of the halogenide ions. A possible explanation is that the change in the absorption band, as one of the halogenoplatinates is transformed through a series of mixed platinates into the other, is divided into equal steps, and that the distribution of the concentrations of all of the complex ions is a symmetrical one. Since six such steps are involved in the "apparent % transformation," one might obtain the relationship

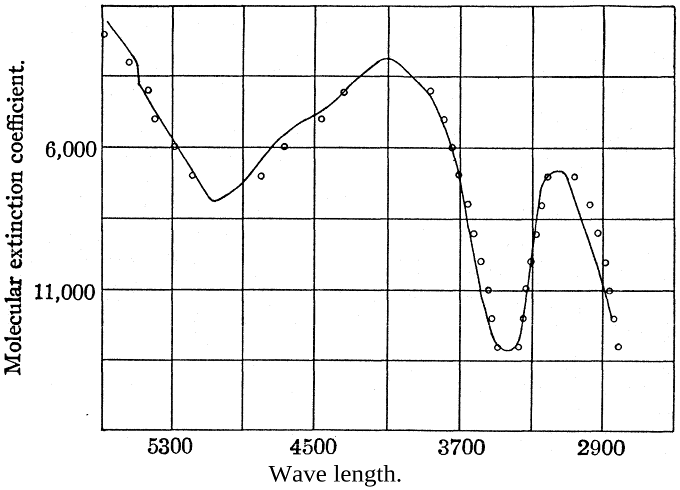

Fig. 3.—○ ○ ○, 0.000025 molar bromoplatinate + 0.000075 iodoplatinate; ———, calculated curve.

(Apparent ratio of complex ions) ▾ ▾ (apparent ratio of simple ions)^6 = constant

This, of course, is what we have found. We believe, however, that too many assumptions are involved in this idea to warrant its acceptance on the basis of the one set of data thus far obtained; the first power relationship may, indeed, be purely accidental.[18]

---

[18] It is also possible that the first power relationship means that the color change is complete in the first step of the series of reactions, for example, that the color of the hypothetical $PtCl_5Br^=$ ion is identical with that of the $PtBr_6^=$ ion. This explanation does not fit with the fact that the values for the constant are independent of the side from which equilibrium is attained nor with facts presented in the following section of this paper.

Existence of Mixed Halogenoplatinates

The existence of the mixed halogenoplatinates has been affirmed and denied. Pitkin[19] and Pigeon,[20] by crystallization of mixtures of chloro- and bromoplatinates, claimed to have obtained mixed chlorobromoplatinates. The former also reported the preparation of the compound $K_2PtCl_4Br_2$ by the action of potassium bromide on platinic chloride. Herty[21] demonstrated that none of these substances was a true compound, and Miolati,[22] by conductivity methods applied to solutions, likewise concluded that there is no evidence for formation of mixed compounds.

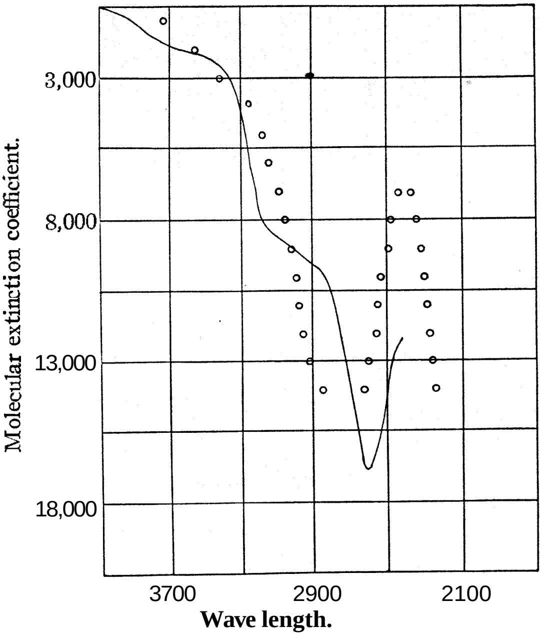

Fig. 4.—O O O, equilibrium mixture—colorimetrically 39.2% $PtBr_6$ and 61.8% $PtCl_6$; ————, calculated curve.

The experimental work herein reported makes possible another method of attacking this problem. If the mixtures prepared by adding, for example, sodium bromide to sodium chloroplatinate contain no intermediate complex ions, the value of the "apparent % transformation" obtained colorimetrically is the real percentage transformation. From the latter we could then calculate the amount of the chloroplatinate and the bromoplatinate in the solutions. With this information and with photometrically determined absorption spectra of each of the platinates, the position of the absorption band of the solution should be calculable.[23] If the calculated and the observed spectra coincide, no intermediate complexes are present. The curves to be presented below show that this is not the case.

Before proceding with these measurements, it seemed desirable to verify the method of calculating the spectra for the mixtures in question. As has

[23] Kayser, "Handbuch der Spektroskopie," S. Hirzel, Leipzig, 1905, Vol. III, p. 92.

already been pointed out, mixtures of known quantities of the two halogenoplatinates cannot be prepared. Consequently we remodeled the Hilger sector photometer to permit us to insert two separate cells into each of the photometer tubes. This allowed **us** to have the'light fall first through a solution of chloroplatinate and then through one of the bromoplatinate before entering the spectrograph.

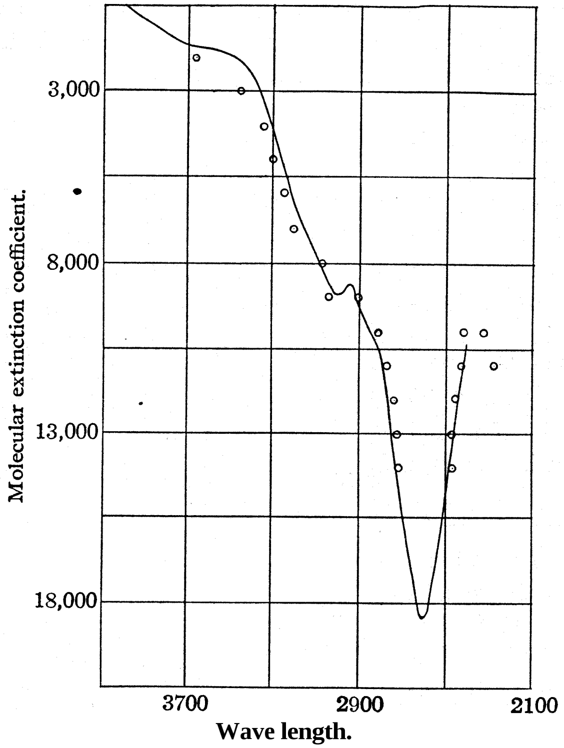

Fig. 5.—0 O 0.0.0001 **molar "$K_2PtCl_4Br_2$;" ———, calculated curve.**

In Fig. **3** the solid line represents the calculated molecular extinction coefficients for a mixture of chloroplatinate and bromoplatinate while the circles are values obtained in the way just described from the absorption spectra of the separate halogenoplatinates reproduced in Fig. 2. Similar curves for bromo and iodoplatinate were obtained but are not reproduced. The agreement is as good as can be expected, and proves that the usual method of calculating the extinction coefficient for solutions of mixtures is applicable to data obtained photographically in the region in which lie the absorption bands of the various halogenoplatinates.

In Fig. 4 the solid line represents the calculated absorption spectrum of a solution containing **39.2%** of sodium bromoplatinate and 61.8% of sodium chloroplatinate. The circles give the observed absorption spectrum of a solution of sodium bromoplatinate to which enough sodium chloride had been added to make the "apparent % transformation" 61.8%. Since the two curves are entirely different, the colorimetric data of such a mixture are not a measure of actual concentrations, and intermediate complex ions must be present. Similar curves have been obtained for solutions of different concentrations, and for mixtures of iodo and bromoplatinates; for them the original thesis[2] must be consulted as they have been omitted to save space.

In this connection Fig. 5 is of interest. In it the solid line represents the absorption spectrum calculated for a mixture of potassium chloroplatinate and potassium bromoplatinate in the proportion corresponding to the formula $K_2PtCl_4Br_2$. The circles represent the absorption spectrum of this "compound prepared according to the method of Pitkin.[19] It will be seen that the spectrum[24] is identical with that calculated for the mixture, and that Pigeon's conclusion that compounds can be prepared in this way is not borne out by the facts. In this we have corroborated the work of Herty.[21]

This research is one of a series of investigations carried out with the aid of a grant from the Bache Fund of the National Academy.

Summary

1. It has been shown that to cause the reaction $PtBr_6^{=} + 6Cl^{-} \longrightarrow PtCl_6^{=} + 6Br^{-}$ to go 99% to completion there must be approximately 660 times as much chloride as bromide ion constituent in the solution. For the reaction between iodoplatinate and bromoplatinate ions there must be 25,000 times as much bromide as iodide ion constituent. From these data we have estimated that roughly 16,000,000 times as much chloride as iodide ion constituent must be present completely to convert $PtI_6^{=}$ to $PtCl_6^{=}$, and have confirmed this order of magnitude experimentally.

2. A study of the absorption spectra of the various equilibrium mixtures indicates that in these reactions intermediate compounds are formed in solution.

3. We have also shown that the solid intermediate compounds which have at various times been reported in the literature are really mixtures. This confirms the conclusions of other workers in this field.

CHICAGO, ILL.

---

[24] The absorption spectrum was measured as soon as possible after dissolving the solid to prevent possible transformation in solution to mixed halogenoplatinates.

THE ATOMIC WEIGHT OF POTASSIUM FROM PLANT ASH

BY H. H. LOWRY

RECEIVED SEPTEMBER 19, 1930 PUBLISHED NOVEMBER 5, 1930

It has been reported by F. H. Loring and J. G. F. Druce[1] that the potassium from the ash of potatoes fertilized from potassium chloride has an atomic weight of 40.5. The accepted atomic weight of potassium is 39.10.[2] It is known that normal potassium consists of two isotopes, 39 and 41, and the small beta radioactivity of potassium has been ascribed to the isotope of atomic weight 41. Loring and Druce cite Zwaardemaker's work[3] on the importance of radioactive material in maintaining life and were led to their experiment from a consideration of the well-known fact that plant cells selectively absorb potassium salts from solutions containing both potassium and sodium. If it is assumed that the reason for this selective absorption is the need of the plant for the radioactive isotope of potassium, it is reasonable to expect that some mechanism may have been developed by the plant cells to absorb selectively the radioactive isotope of potassium from the normal mixture of isotopes. It may be further assumed that the radioactive isotope would be concentrated in those cells which provide the food for the embryo plant, *i.* e., the seeds. To check these hypotheses 25 pounds of cotton—seed hairs—and 75 pounds XXXX Superfine flour—wheat kernels—were ashed, the potassium chloride separated from the ash and purified and the ratio of potassium to chlorine determined.

The ashing was carried out at a low temperature to avoid volatilization of the potassium salts. The ash was extracted with water and excess ammonium carbonate added. The extract was filtered, evaporated to dryness in platinum and the excess ammonium carbonate volatilized. The residue was dissolved in water, acidified with hydrochloric acid, filtered, re-evaporated to dryness, fused, redissolved in a small quantity of water and filtered. The alkali chlorides were then precipitated with hydrogen chloride gas, filtered and then fused. Preliminary analysis of the cotton ash showed a ratio of potassium to sodium of approximately 10 and this ratio for the wheat flour is approximately 40.[4] In the case of the chlorides from cotton ash approximately 20 g. of sodium-free potassium chloride was obtained by fractional crystallization of the aqueous solution at room temperature. It proved much more difficult to secure a pure potassium chloride from the flour ash and the procedure given above for the original purification, including the precipitation of the chlorides with

[4] Bailey, "The Chemistry of Wheat Flour," 1925, p. 148.

hydrogen chloride gas and fusion, was repeated four times. Approximately 3 g. of sodium-free potassium chloride was finally obtained from the wheat flour ash. Analyses of the fused potassium chloride were made for chlorine using silver nitrate, making all precipitations and filtrations in the dark. Microscopic examination of a drop of solution allowed to crystallize on **a** slide showed no impurities. The percentages of chlorine obtained in multiple analyses of the two samples are given below.

Sample	Chlorine in KC1 from cotton ash, %
1	47.63
2	47.50
3	47.52
4	47.56
5	47.54
Av.	47.550 ± 0.016

Sample	Chlorine in KCl from wheat flour ash, %
1	47.57
2	47.52
3	47.60
Av.	47.563 ± 0.020

The ± figures given represent the probable errors calculated according to the method of Shewhart[6] for averages obtained from small samples.

Assuming the atomic weight of chlorine to be 35.457,[2] the atomic weights of the potassium may then be calculated to be 39.111 ± 0.013 from the cotton ash and 39.091 * 0.016 from the wheat flour ash, respectively. Both values are so close to the accepted value of 39.10 that no separation of the potassium into its isotopes is indicated.

The results reported above do not confirm the hypotheses proposed nor the results obtained by Loring and Druce. They cannot be used, however, as *a* direct contradiction of Loring and Druce's findings, since the potassium they obtained was from potatoes, which are morphologically different from the cotton fiber and the wheat flour.

I wish to acknowledge my appreciation of the careful analyses made by Messrs. H. W. Hermance and L. L. Kathan and the assistance of Mr. M. H. Quell in ashing the cotton and in the purification of the chlorides.

NOTES

A Condenser for Low Temperature Evaporation of Water.—In concentrating serums, gland extracts or any water solution containing protein, it is often advisable to evaporate the water at as low a temperature as possible. The ordinary vacuum distillation does not permit a distilling temperature below 35°. Even at 20° there may be denaturing, precipitation or destruction of biological activity due to combined exposure to temperature and mechanical agitation of boiling.

We have two condensers each containing, as inner tube, a glass tube $1^5/_8$ inch in diameter and 12 feet long (standard 2 inch iron pipe jacket), and these may be cooled by ice water; 12-liter pyrex flasks serve as retorts. While this is very effective, the distilling temperature can hardly be below 15°. The cooling water cannot be used below 0°, by adding salt to the ice, because an ice plug will block the condenser. Moreover, the heat absorption of the 40-gallon ice tank, the circulating pump, etc., make the system uneconomical for small quantities.

We find a 12-liter flask filled with crushed ice a very effective condenser. This eliminates necessity for transmitting heat through a glass or metal condenser surface; moreover, salt may be added to the ice, giving an effective condensing temperature below −10°. Theoretically, to condense 1 g. of water vapor at 0° requires melting 7.5 g. of ice, and in practice more is required. The 12-liter condenser may be insulated with rags or shavings, and there is little heat absorption from the atmosphere, because of its compactness. A specially long rubber stopper prevents danger of sucking in. The stopper has a large inlet for water vapor and a small inlet for vacuum; by making the tubes concentric, one reduces the tendency of the stopper to leak. We have used iron pipe for the tubes. A 2-liter flask with not more than 1 liter to be evaporated serves as "retort," but if the liquid foams badly a larger flask may be used. The connection to the "retort" should be 0.5 inch or preferably more inside diameter, and as short as possible.

The distilling rate is slow. Thus with outside water-bath at 20° and 700 cc. of water in the "retort," about 2 cc. per minute distils (temp. inside "retort," 7°). When first connected the distilling rate is faster and a layer of ice quickly freezes over the surface in the "retort," but this ice melts after the dissolved air is removed. If a slow stream of air bubbles into the "retort" through the usual capillary tube made by drawing out a broken thermometer, the retort temperature is lowered with an increase to about 3 cc. of water distilled per minute, and it is easier to keep ice in the "retort." In any case the distillation slows down near the end, due to decrease in heat transmitting surface, so that about ten hours may be required to reduce 700 cc. to 50 cc. (If a bath temperature of 25 or 30° is permissible the time is much reduced.)

A slow stream of tap water suffices for "heating" the bath of the "retort." We use a Nelson two-stage vacuum oil pump of a capacity of 5 cu. ft. of free air per minute for vacuum, for the high capacity saves many minutes in starting and eliminates the necessity for bothering about leaks around rubber stoppers. If the bath is heated by a flame, one must watch for a rise in temperature near the end of the evaporation, when the rate has slowed down.

For a capacity of, say, two 12-liter flasks in parallel as "retorts," each containing, say, 7 liters of serum, a condenser of a capacity of 25 to 30 gallons is required. Such steel tanks are used commercially for hot water storage, and may be insulated with 6 inches or more of shavings. If used only occasionally one may use a commercial insulated hot water storage tank, as the insulation dries out when not in use, but an insulation which does not easily rot should be selected. On this scale a vacuum pump of several cubic feet per minute capacity of free air should be used. Tubing for carrying the water vapor should be 1.25 inch or preferably more in diameter. The vacuum pump must naturally give better than the vapor pressure of water at $-10°$, under *service* conditions. Naturally one will select a condenser giving a large surface above the ice and salt, to increase the condensing rate. The operator should guard against possible serious injury due to collapse of a 12-liter flask under vacuum.

Inorganic Lubricants. III. Mixtures of Aqueous Liquids with Non-Reacting Solids.—When water is mixed with a finely divided insoluble powder in the correct proportions a cream is produced which has the power of forming a thin, continuous film over a surface capable of being wet by water, is "viscous" in proportion to the amount of solid present, and so may act as a lubricant between two moving surfaces.[1] For purely temporary inorganic lubrication such a mixture may operate satisfactorily, but because the water quickly evaporates, leaving a non-lubricating cake of solid, lasting lubrication is not obtained.

When, however, a hygroscopic inorganic liquid, such as a concentrated aqueous solution of a deliquescent salt or acid, is employed instead of water, drying out does not take place, the creamy state persists and lubrication is maintained for an indefinite length of time depending on the relation between the average atmospheric humidity and the relative hygroscopicity of

[1] See, for example, various U. S. Patents, such as Colby, 49,983, Sept. 19, 1865; Farkas, 1,253,362, January 15, 1918, and others.

the liquid. I have prepared many such mixtures, using solutions of calcium, zinc and ferric chlorides, antimony pentachloride,[2] sulfuric and orthophosphoric acids and similar substances as liquids, and kaolin, bentonite, talc, graphite, carbon, precipitated silica, etc. (all sieved to pass a 100-mesh screen), as the non-reacting insoluble solids. Bentonite and talc could not be used with acid liquids because a gas-forming reaction takes place resulting in a frothy mixture. Successful lubricants were obtained in considerable variety. Typical examples are listed in Table I.

TABLE I

LUBRICATING MIXTURES

10 g. of solid used in each experiment

Solid	Kaolin	Kaolin	Kaolin	Bentonite	Graphite	Silica
Soln., 50% concn. of	H_2SO_4	$CaCl_2$	$ZnCl_2$	$CaCl_2$	$CaCl_2$	$ZnCl_2$
Cc. taken	6.0	6–6.5	6.5	8 0	6.5	6.5

MATERIALS.—The kaolin was the N. F. V. product; the silica was an anhydrous, amorphous material (electro-silicon); the bentonite and graphite were fine, commercial powders; and the calcium and zinc chloride solutions were prepared from anhydrous *c.* P. granules.

Of all the mixtures prepared, the best for general use were those of kaolin and of graphite with calcium chloride solution. After three months, although exposed surfaces of these mixtures had fluctuated in liquidity considerably, lubricating films between ground glass surfaces still operated satisfactorily.

Lubricants of this general kind are distinctly limited in usefulness. Their pasty nature permits clogging of small passages; and too great pressure may thin the lubricating film excessively. Nevertheless, they are useful in organic work when protection against leakage of water-insoluble organic liquids and gases is desired; and some of them can be employed with certain inorganic gases (such as those which may attack the common organic lubricants), particularly when it is not important to maintain great purity of these gases. They offer the advantage of being easily and quickly prepared; and the range of possible mixtures is wide enough to permit a considerable degree of choice in both liquid and solid constituents and so enable any specific requirements to be more suitably met.

[2] Mixture of antimony pentachloride solution and kaolin forms a colloidal material, the properties of which will be investigated.

The Constricted Mercury Arc.—The usefulness of the highly intense constricted mercury arc has been seriously limited by its rapid rate of deterioration.[1] The arc described here has been designed to balance the various factors so that it can be burned at a constant high intensity.

A quartz capillary 2 X 8 X 50 mm. was ground on the side away from the slit until a wall of about 0.5 mm. remained. The other side was ground until a face of about 3 mm. width was obtained, thus reducing the apparent size of the capillary. A very satisfactory polish was then obtained on both sides by cleaning with hydrofluoric acid and heating carefully with a sharp flame. A piece of glass tubing was ground open the length of the capillary and fitted to the rear flat side of the lamp in order to cool with running water. The lower electrode was sealed in with de Khotinsky cement. The lamp was wrapped with strips of cloth so that cooling of the cement and electrodes could be efficient and convenient. A stream of air was passed around the front face. By this arrangement the lamp could be run at 4–5.5 amperes and 20–25 volts per sq. cm. for upward of thirty hours with fairly constant intensity. At the expense of rapid devitrification (fifteen to twenty hours) the intensity can be kept constant by no air cooling on the front face, which prevents the formation of silica patches. A fairly constant intensity can be maintained by an intermittent air stream easily arranged by a long lag relay circuit. In case any deposit forms on the front side it can be removed quickly by stopping the air stream and moderately increasing the amperage.

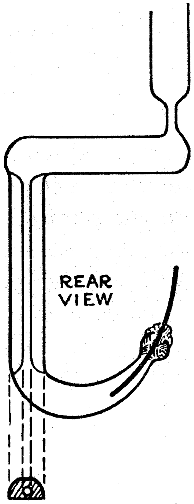

Fig. 1.—Lower electrode is sealed in with de Khotinsky cement. Constriction at upper electrode fits inserted iron wire or is packed with additional pieces to steady the upper meniscus.

THE DECOMPOSITION OF MERCAPTANS IN ALKALI SOLUTIONS[1]

BY E. C. BILLHEIMER[2] AND E. EMMET REID

RECEIVED MARCH 18, 1930 PUBLISHED NOVEMBER 5, 1930

Introduction

It is a well-established fact that the structure of the group attached to a carbon atom in combination with oxygen or a halogen has a great influence upon the strength of that bond. This has been shown by Conant and his associates,[3] who investigated the relation between the structure of organic halides and the speed of their reaction with inorganic iodides, and by Norris and his co-workers,[4] who studied the relative reactivities of the hydroxyl hydrogen atoms in certain alcohols and the effect of various substituted groups on the strength of the carbon–chloride bond.[5] It was thus considered of value to determine the effect of the structure of the alkyl group upon the strength and reactivity of the carbon–sulfur bond, and for this purpose the decomposition reaction of the aliphatic mercaptans in alkali solution was selected. It was desired to determine (1) whether mercaptans decompose in alkaline solution in any definite and reproducible manner, *(2)* the effect of time, temperature and concentration on this reaction, and **(3)** the exact course of the reaction, the products formed, and if possible its velocity constant and temperature coefficient.

Results

The aliphatic mercaptans were found to decompose in sodium hydroxide solution in a definite and reproducible manner. Three simultaneous reactions take place as follows: (1) replacement of the —SH group by hydroxyl to form an alcohol, as

$$RSH + 2NaOH = ROH + Na_2S + H_2O$$

(2) elimination of hydrogen sulfide from two molecules of mercaptan to form the alkyl sulfide, as

$$2RSH + 2NaOH = R_2S + Na_2S + 2H_2O$$

(3) the elimination of hydrogen sulfide from one molecule of mercaptan to form the unsaturated hydrocarbon, as

$$CH_3CH_2SH + 2NaOH = CH_2{=}CH_2 + Na_2S + 2H_2O$$

Two further possible consecutive reactions, in which the alkyl sulfide might decompose with alkali to produce either the alcohol or the unsaturated hydrocarbon, were shown to be unimportant, as they are not given by butyl sulfide heated under the same conditions. The products of the three reactions were identified. The alkyl sulfide was oxidized to the corresponding sulfone with fuming nitric acid, according to the method of Grabowsky,[6] the product purified and identified by its melting point, which was compared with that of pure sulfone prepared in a similar manner from the particular sulfide in question. The alcohol was shown to be present by the formation of the corresponding half-ester of phthalic acid, on refluxing with phthalic anhydride, a dried benzene extraction of a steam distillate of the reaction mixture, from which the unreacted mercaptan had been removed by precipitation as mercaptide with lead acetate solution. The product was subsequently isolated and purified, and its identity proved by melting point determinations. The unsaturated hydrocarbon was easily noticeable in the case of the lower members of the mercaptan series, when it escaped as a gas, especially with ethyl mercaptan, in which case ethylene was evolved upon opening the bomb after a run. The sodium sulfide was easily distinguished by the evolution of hydrogen sulfide upon acidification.

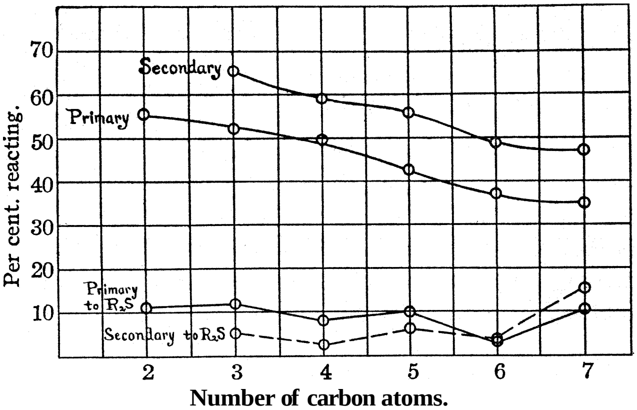

Fig. 1.—Percentage of mercaptans reacting with 3 N NaOH in 2 hours at 260°.

The optimum conditions for comparison of the reactivity of the different members of the mercaptan series were established with n-butyl mercaptan. They were *so* adjusted, by varying concentration, temperature and time of heating, that about half of this mercaptan was decomposed, which is the

---

[6] Grabowsky, Ann., 175, 348 (1875).

case in two hours at 260° with 3*N* caustic soda solution. The runs for comparison of different mercaptans were made under these conditions. Runs with other concentrations of alkali and at other temperatures were made for other comparisons. The straight chain primary and secondary mercaptans from ethyl and isopropyl to heptyl have been studied. It was intended to include the octyl and nonyl mercaptans but their sodium derivatives were found to be insoluble, separating out immediately upon addition of the mercaptan to the alkali. This prevented complete solution of the products of the reaction at the completion of a run, and made it impossible to secure the aliquots necessary for the analytical procedure.

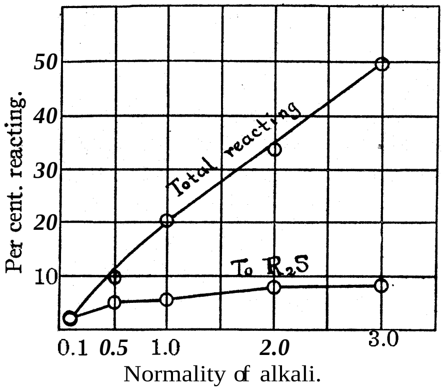

Fig. 2.—Percentage of n-butyl mercaptan reacting with different strengths of alkali.

The results are given in the tables below, the figures being the average percentages of the mercaptans reacting under the conditions stated. The same data are reproduced in the curves, Fig. 1 and Fig. 2.

It appears that the total decomposition decreases, with both normal and secondary mercaptans, as the number of carbon atoms increases. There is a suggestion of alternation. The secondary mercaptans react more rapidly

than the corresponding primary, which is to be expected from the work of Norris and his co-workers, who found that reactions of alcohols in which the hydroxyl is eliminated proceed faster with secondary alcohols than with primary. The amount of sulfide formed is lower with the secondary than with the primary, which agrees with the above. With very dilute alkali the percentage of alkyl sulfide is high when it is compared with the total decomposition. Isobutyl mercaptan reacts much more slowly than *n*-butyl, just as in esterification. At 250° in four hours n-butyl mercaptan gives slightly less decomposition than at 260° in two hours, which shows that the reaction has about the usual temperature coefficient. The proportion of butyl sulfide formed is somewhat higher at the lower temperature.

There is a suggestion of alternation, the values for the mercaptans having an even number of carbon atoms appearing to be below the curve,

Apparatus and Materials

The special apparatus necessary for and used in the preliminary part of this investigation was exactly similar to that employed by Herndon and Reid[7] in work on the decomposition of organic compounds at high pressures and temperatures, which was itself a modification of the type developed by Morey[8] in his studies on hydrated silicates. This consisted of the special steel bomb, the furnace and the automatic temperature control. For the greater part of the present work, however, a smaller type bomb was used, of *25-cc.* capacity, with threads on the outside of the body proper, allowing easier and more complete removal of the reaction products. The plunger rested atop the body proper and carried through its center a steel thermocouple tube silver-soldered to the plunger and extending a half inch into the chamber of the bomb when the latter was closed.

The mercaptans, with the exception of ethyl, n-butyl and isobutyl, were furnished by L. M. Ellis, Jr.9 Normal butyl mercaptan, which was used to standardize the analytical method and establish the proper conditions for comparison, was prepared in large quantities by the method of Grabowsky and Saytzeff.[10] The mercaptan was extracted with dilute caustic soda solution, recovered by steam distillation, dried and fractionated on a tall-column still. The purity was 99.94%. The ethyl and isobutyl mercaptans were Eastman's "Certified" products. The purity of the normal and secondary mercaptans used was in no case less than 99.3%.

Experimental

The purity of the mercaptans was determined volumetrically by the method of Kimball, Kramer and Reid[11] which makes use of their reaction by titration with standard iodine solution. This reaction was also made the basis of the analytical method eventually established. The procedure was essentially as follows. The reaction mixture was washed from the bomb into a separatory funnel, from which the water layer was run into a volumetric flask and diluted to a convenient volume. The insoluble alkyl sulfide was measured and its weight calculated from its density. From the water solution aliquots were taken. First, one aliquot was titrated with 6 N hydrochloric acid, using methyl orange as an indicator, to determine the amount of acid necessary to neutralize the excess alkali and decompose the sodium sulfide formed. Second, an aliquot was run from a pipet with its tip below the surface of excess standard iodine solution containing hydrochloric acid in slight excess of that determined by the first operation and the excess iodine titrated with standard thiosulfate solution. This gave a value for the sum of the sodium sulfide and the unreacted mercaptan. Third, an aliquot was boiled to remove all unreacted mercaptan, diluted with water and boiled several times if necessary, and the hydrogen sulfide formed in the decomposition thus determined by washing into excess iodine solution containing the predetermined amount of hydrochloric acid and back-titrating with thiosulfate solution as before. These three sulfur values, namely, the alkyl sulfide, sodium sulfide and unreacted mercaptan, when calculated to mercaptan, gave a check on the amount originally added, and from them could be determined the percentage decomposition, since all three reactions produce sodium sulfide.

Av.	2.1	2.0	93.8	1.7	97.6

The amount of mercaptan used in each run was always 10 millimoles, which was dissolved in 12 cc. of the sodium hydroxide solution, which for the *3N* was 3.66 equivalents. This was a convenient sized charge since the bomb held 25 cc. The results obtained are given in Table V.

In the runs with pure water, the percentage of mercaptan reacted was found to be practically zero.

Summary

1. Apparatus has been developed and a quantitative method of analysis established for the investigation of the decomposition of mercaptans in alkali solution.
2. Mercaptans have been found to decompose in alkali solution in a definite and reproducible manner.
3. The course of the decomposition has been determined and the products identified.
4. This decomposition reaction has been used as a means of studying the effect of substitution on the reactivity of the C—S bond, and the following mercaptans have been investigated in this way: ethyl, n-propyl, isopropyl, n-butyl, isobutyl, *sec.*-butyl, n-amyl, *sec.*-amyl, n-hexyl, *sec.*-hexyl, n-heptyl, *sec.*-heptyl, n-octyl, *sec.*-octyl, *n*-nonyl, *sec.*-nonyl.
5. The effect of concentration of alkali on the rate of decomposition of the mercaptans has also been determined.

AUTOXIDATION OF THE AMYLENES[1]

BY JULIUS HYMAN AND C. R. WAGNER

RECEIVED MAY 8, 1930 PUBLISHED NOVEMBER 5, 1030

A. Introduction

Although considerable work has already been done on the various phases of autoxidation, the field is of such magnitude that the special divisions of the subject suffer through lack of sufficient definite information concerning details.

One such division has to do with the autoxidation of the cracked gasolines. Much work still remains undone in this field. The chief reason for our lack of scientific knowledge in this especial field lies in the complex nature of the experimental material, namely, cracked gasoline. Such gasoline is doubtless a combination of paraffin, olefin, cyclic and aromatic hydrocarbons, along with hydrocarbons possessing in single molecules the characteristics of two or more of the classes mentioned.

In view of the situation as just presented, the authors of this paper felt that a study of the autoxidation of a comparatively simple series of olefins—the hydrocarbons with which autoxidation in gasolines appears most closely allied—might shed further light on the nature of the autoxidation phenomenon. Chief among the questions which such a study might answer is the one concerning the relation of autoxidation reactivity to the position of the double bond in the molecule, *i. e.*, to the nature and position of the groups attached to the unsaturated carbon atoms.

The simplest of such groups would be the butylenes, which number three. These compounds, however, are gaseous at ordinary temperatures, and in view of the fact that autoxidation in cracked gasolines appears to occur mainly in the liquid phase, it was thought unwise to use these materials in the present work.

The first group of olefins which are liquid at ordinary temperatures is that of the amylenes, five in number. These five are: (1) *n*-propylethylene, (2) isopropylethylene, (3) unsymmetrical methylethylethylene, (4) symmetrical methylethylethylene, (5) trimethylethylene.

The first systematic work on this group appears to have been done by Norris and Joubert.[2] These authors investigated the polymerizing action of sulfuric acid at various concentrations on the individual amylenes and found distinct differences in reactivity. Numbers 5 and 3 were classed as most reactive, Numbers 1 and 4 taking an intermediate position, while Number 2 was found to be comparatively unreactive.

---

[1] Presented before the Petroleum Division of the American Chemical Society at Atlanta, Georgia, April 7–11, 1930.

[2] Norris and Joubert, THIS JOURNAL, 49, 873 (1927).

Work by Kirrmann,[3] however, cast doubt upon the reality of amylene No. 1 used by Norris and Joubert. In the present work, therefore, the authors have prepared amylene No. 1 by the interaction of allyl bromide on the Grignard reagent, ethylmagnesium bromide, using butyl ether as well as the amyl ethers as solvents and diluents. The reaction produced an amylene of boiling point 29–31°, in accord with the results of Kirrmann, as opposed to those of Norris and Joubert, who claimed a boiling point of 39–41°, for the product. It is likely that in the purification of their material, the last-named authors caused their amylene to undergo an intramolecular rearrangement of some type.

B. Experimental

In the present work amylenes 4 and 5 were made according to the methods given by Norris and Joubert. In the preparation of (5) heed was taken of the warning of Norris and Reuter[4] that in the dehydration of *tert.*-amyl alcohol a certain amount of amylene 3 is formed, and only the fraction boiling between 37.5 and 39° was used. Its D-line refractive index at 15° was 1.3898. The preparation of (4) appears to take place without any very great amount of side reaction. The fraction boiling between 35.5 and 37.5° was used in our experiments. The D-line refractive index at 15° for amylene No. 4 was 1.3840.

Amylenes 2 and 3 were made by the action of alcoholic potash on 1-iodo-3-methylbutane[5] and 1-iodo-2-methylbutane,[6] respectively, which had previously been prepared from their respective alcohols. Number 2 showed a boiling range of 21 to 24°, whereas No. 3 boiled almost constantly at 31.1°. Amylene No. 2 was further purified for Run No. 2 (see table) by treatment with 2:1 sulfuric acid at 0°. In this way a product of boiling range 20.5–21.5° was obtained. The D-line refractive index at 15° was 1.3682. The D-line refractive index for amylene No. 3 at 15° was 1.3800.

Amylene No. 1 was prepared as previously described. It was kept in contact with silver acetate in water over a period of weeks, with repeated distillations. Despite this, however, the product still showed a trace of bromine compound. Amylene No. 1 was finally freed from bromides by refluxing for four hours with metallic calcium and redistilling. It showed an almost constant boiling point of 30.0° (corr.). A refractive index determination at 21° gave a value of 1.3718 as compared with Kirrmann's value of 1.3714 for the same temperature. The refractive index reading (D-line) at 20° was 1.3731. An interesting side reaction in the production of amylene No. 1 was the formation of a hydrocarbon possessing a boiling point of around 20°. A fraction boiling between 20 and 24° was isolated.

This fraction decolorized alkaline potassium permanganate very rapidly, and combined with bromine in the cold extremely energetically. While the exact nature of this compound is not known, it would appear probable that one is dealing in this instance with a substituted cyclopropane, probably ethylcyclopropane.

As to the method of determining the degree of oxidation, it was at first held expedient to use a manometric method, the lowering of the pressure in the reaction chambers being an indication of the amount of oxidation. During the course of the work, however, such erratic results were obtained that this method had to be abandoned. In its place was substituted a method based on the liberation of iodine by the bound (peroxide) oxygen.

According to the per-acid theory of autoxidation as suggested by us,[7] such oxidation proceeds in two steps: (1) the formation of a "moloxide"  $\left(\begin{array}{c} -\overset{|}{C}-\overset{|}{C}- \\ |\qquad| \\ O-O \end{array}\right)$ from the breaking down of an oxidized per-ester; (2) the formation of a per-acid  $\left(-\overset{O}{\overset{\|}{C}}-O-OH\right)$ through the oxidation of aldehydes produced by the breaking of a moloxide molecule.

Such per-acids are known to react with double bonds quite energetically, and the per-acid theory postulates a per-ester as the initial reaction product. Unless this cycle is completed, the theory does not allow for progressive autoxidation.

There is considerable evidence to show that peroxides of the type R—O—O—R—to which class moloxides are structurally related—are incapable of liberating iodine from hydriodic acid and, in accordance with this view, not the moloxides but only the per-acids and per-esters would oxidize the hydriodic acid. For comparative purposes in this study, therefore, the authors feel that this method for evaluating the relative extent of autoxidation is permissible.

One cubic centimeter of the amylene to be tested was pipetted from a cold pipet into an iodine flask to which had been added 20 cc. of a 5% alcoholic potassium iodide solution. To this mixture was added 2 cc. of glacial acetic acid, and the flask allowed to stand in the dark for exactly three minutes. The contents of the flask were then rapidly titrated against a 0.01 *N* sodium thiosulfate solution. As is well known, the starch indicator in an alcoholic solution takes on an orange tinge rather than the usual violet. The end-point of the titration is nervertheless very sharp. The iodine color usually reappears shortly after the titration has been completed. This is to be disregarded, however, if one wishes (as in the present case) merely comparative results.

As reaction chambers were used common four-ounce oil bottles, each containing ten pieces of 6-mm. glass tubing, 15 cm. in length (to promote surface oxidation) and being fitted with a good cork stopper. Ten cc. of sample was placed in each bottle, the

oxygen being introduced by a glass tube reaching half-way to the bottom of the bottles. The oxygen was taken from a tank and allowed to run in to each bottle for ten seconds. Thereupon the bottle was corked immediately and the contents thoroughly agitated. Whenever the bottles were opened, they were placed in an ice-bath, in order to maintain approximately constant conditions and to prevent evaporation as much as possible.

As oxidation catalyst cobalt oleate was used. This compound was prepared by dissolving 1 part of C. P. hydrated cobaltous acetate in 10 parts of hot U. S. P. oleic acid, and passing a current of air through the mixture for two hours at a temperature between **125** and 150°. The resulting product is a deep brown liquid which turns deep red upon standing. It is completely soluble in the amylenes. To each 10 cc. of amylene was added two drops (0.0424 g.) of the catalyst. The oxidation was carried out in the dark, at a temperature of 15°.

C. Conclusion

Of the two runs, the second is to be considered as more accurately expressing the reactivities of the amylenes toward autoxidation. The long induction period for amylene No. 2 may be explained by its vigorous purification just prior to use. On the other hand, the lack of an induction period in the autoxidation of amylenes Nos. 4 and 5 may be ascribed to minute quantities of peroxide which may have formed in these olefins during a short period of standing before use. An interesting point to note is the high reactivity of the amylene No. 2, once oxidation had begun, and the lesser but similar orders of reactivity of amylenes Nos. 4 and 5. The disappearance of peroxide at 252 hours is also of considerable interest.

Most noteworthy, however, is the fact that the results here recorded appear to bear little or no relationship to the results of the sulfuric acid polymerization experiments of Norris and Joubert.

A theory has been developed to explain the results herein recorded, and will be published at a later date. From the present data, however, it may be concluded that the *average* internal double bond is much more prone to autoxidation than is the *average* end double bond. It would, therefore, follow that in diolefins the internal double bond would be the first to be attacked. As a matter of record, the authors have previously reported[7] acrolein as being an important constituent among the products resulting from the autoxidation of cracked gasoline, an observation which is in accord with experiments reported herein.

The present paper is intended by the authors as a report of general work on autoxidation now in progress. It is hoped that further details will be ready for publication in the near future.

D. Summary

1. The autoxidation of the amylenes has been investigated.

2. Results indicate that, in general, internal double bonds are more readily oxidized by molecular oxygen than end double bonds.

3. Kirrmann's method of preparation of pentene-1 has been confirmed. A new hydrocarbon obtained as a by-product of this reaction is mentioned.

CHICAGO, ILLINOIS

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

THE USE OF NICKEL AS A CATALYST FOR HYDROGENATION

BY HOMER ADKINS AND HOWARD I. CRAMER

RECEIVED MAY 9, 1930 PUBLISHED NOVEMBER 5, 1930

The hundreds of papers and patents published on the use of nickel as a catalyst for the hydrogenation of organic compounds might well be considered to render unnecessary any extended research in this field. In spite of this profusion of publications and in a sense because of it, a beginning has been made in what is intended to be a systematic investigation of the use of nickel as a catalyst for the hydrogenation and condensation of organic compounds especially with regard to selective reaction, *i. e.*, the modification of the proportion of simultaneous reactions through control of the temperature, pressure, reaction medium and character of the catalyst. For a number of reasons it does not seem that here or now is a suitable place or time for a comprehensive review of the extensive literature on the use of nickel as a catalyst. It must suffice for the present to refer to some of the more prominent investigators such as Sabatier, Senderens, Mailhe, Ipatiev, Schrotter, Brochet, von Braun, Zelinsky, Armstrong and Hilditch, and to the American and German translations of Sabatier's "La Catalyse en Chimie Organique."[1] The German edition contains a valuable review of the literature, prepared by Dr. Hans Hauber for the period 1920 to 1926.

The use of pressures in the range of 50 to 300 atmospheres is usually referred to as the method of Ipatiev and is the one used in the present investigation.[2] It should be pointed out however that Ipatiev, in general, used temperatures of from 200–400°. These high temperatures with their accompaniment of serious side reactions, were necessary, we believe, because he used rather inactive catalysts. Ipatiev believed that the oxide rather than the metal was the real catalyst for hydrogenations. While this is questioned by Sabatier and many others, there can be no doubt that nickel oxide at the temperatures used by Ipatiev is active in promoting reactions other than hydrogenation.

In this paper are described the preparation of a satisfactory catalyst and experimental conditions under which some forty-five representative organic compounds have been hydrogenated to give good yields of various compounds.

The Apparatus.—The material to be reduced was placed in copper or glass bottles or "liners" having an internal volume of from 100 to 600 ml. Each liner bore a pin-hole in the side half-way between its top and bottom. The effective capacity, *i. e.*, the volume below the pin-hole was thus 50 to 300 ml. The glass liners were closed by a ground-glass joint and the copper ones by a cap screwing down against a lead gasket. The caps of both types of bottle were designed with a tube extending downward to accommodate the thermocouple well projecting from the head of the bomb. The bombs were made of chrome vanadium steel by the American Instrument Company of Washington, D. C., using the type of bomb closure described by Ernst.[3] One of the bombs had outside dimensions of 26.7 cm. long by 14 cm. diameter, and the other 42 cm. by 11.4 cm. The inside diameter was 6 cm. for both bombs, one having a depth of 16.5 cm. and the other of 31.5 cm. Each bomb bore in the head a thermocouple so well designed that the end of a thermocouple could be extended beyond the center of the reaction chamber. The thermocouples were of No. 20 iron—onstantan wire encased in 2-holed insulation tubes 4 mm. in outside diameter.

Lead gaskets were used in most instances for the bomb closure. Copper gaskets made of copper wire 3 mm. in diameter were used for pressures above 200 atmospheres. The bomb was placed in a horizontal position in a shaker similar in principle to the one described by Peters and Stanger.[4] The bombs were electrically heated using 110-volt *a.* c. current and nichrome wire 0.1 mm. in diameter. Two heating units for each bomb

[4] Peters and Stanger, *ibid.*, 20, 74 (1928).

were used, each having a resistance of about 27 ohms. The temperature was controlled by a Leeds and Northrup potentiometer controller and recorder.

The valves and connections used were similar in design to those described by Ernst and were supplied by the American Instrument Company. The tubing was $^1/_4$-inch O. D. by $^1/_{16}$-inch I. D. of molybdenum steel. The gages were of the ordinary commercial type having ranges from 0 to 5000 or 0 to 10,000 pounds per square inch and were purchased from the United States Gauge Company, New York.

The Catalyst.—The procedure finally adopted for the preparation of a nickel catalyst was a development from that recommended by Reid and Rather.[5] According to their procedure 100 g. of infusorial earth was treated with a solution of 50 g. of nickel nitrate $[Ni(NO_3)_2 \cdot 6H_2O]$ in about 150 ml. of water, and the resulting moist mass added to a strong water solution of 60 g. of sodium carbonate, $Na_2CO_3 \cdot 10H_2O$, to precipitate the nickel as carbonate. The product was well washed, dried, reduced with hydrogen just below red heat and cooled in carbon dioxide. This method was modified in the following particulars: (1) the infusorial earth was digested with nitric acid before use because otherwise inactive catalysts were obtained; (2) the ratio of nickel to infusorial earth was doubled; (3) the precipitation of nickel carbonate was made at 70–80° in order to avoid loss of nickel salts during washing; (4) the reduction was carried out at 450° for one hour; (5) the catalyst was cooled and transferred in an atmosphere of hydrogen.

The procedure for the preparation of the catalyst was as follows: one-half kilo of infusorial earth, obtained from the Meyer Drug Company, St. Louis, was digested on the steam-bath for sixteen hours with enough nitric acid (d 1.4) to give a suspension of porridge-like consistency. This material, after dilution with an equal volume of water, was filtered on a Buchner funnel and washed repeatedly with distilled water until the wash water gave only a faint acid test. After being thoroughly dried at 110–120° it was pulverized and stored in glass-stoppered bottles.

One hundred grams of acid-washed infusorial earth was treated with a filtered solution of 100 g. of nickel nitrate, $Ni(NO_3)_2 \cdot 6H_2O$, in 150–175 ml. of water, and the whole thoroughly mixed. The resulting paste, warmed to 70–80°, was poured into a filtered solution of 120 g. of sodium carbonate $(Na_2CO_3 \cdot 10H_2O)$ in 100 ml. of water, which had also been warmed to 70–80°. After thorough mixing with a large stirring rod, the material was filtered on a Büchner funnel and washed, first with 300 ml. of water in 75-ml. portions, taken from the filter, dispersed in 300–400 ml. of water and again sucked dry on a filter and washed with 300 ml. of water. The mixture was dried at 110–120° and stored in *dry* glass-stoppered bottles. The yield from such a preparation was 134 g. Considering that no nickel was lost in the preparation, this material contained by calculation 16% nickel. The product was reduced in a stream of dry hydrogen at 450°. The hydrogen was ordinary electrolytic hydrogen with no purification other than drying by passing through a calcium chloride tube. The reduction was carried out in a pyrex tube, 15 mm. by 40 cm. in length, heated in a small electric tube furnace. The hydrogen was passed through the catalyst at the rate of 10 to 15 ml. per minute. The temperature of the furnace was maintained at 450 ± 3°.

The tube containing the catalyst was removed from the furnace after reduction had proceeded for one hour, and allowed to cool to room temperature under a pressure of 1.004 atmospheres of hydrogen. The catalyst was then poured from the tube (through which a stream of hydrogen was rapidly passing) into the liner containing the material to be reduced. The air in the liner had been previously displaced with carbon dioxide. The liner was then closed, placed in the bomb, the latter closed and placed in the shaker, the system evacuated to 15 or 20 mm. and hydrogen introduced to the desired pressure. The shaker was then started at a rate of about 40 cycles per minute. There was a drop

---

[5] Reid and Rather, This Journal, 37, 2116 (1915).

in pressure during the first few minutes but if the connections were all tight the pressure remained constant after ten minutes of shaking. The bomb was then heated to the desired temperature. About an hour was required for reaching 100° and about two hours for 200°. After the reduction was complete the bomb was allowed to cool to room temperature (eight to twelve hours), the liner removed and the catalyst filtered off under suction on a Jena sintered glass filter.

Standardization of the Apparatus.—The course of the reductions was followed by means of the drop in pressure of hydrogen in the system. The volume of hydrogen equivalent to a given drop in pressure on the gage was a function of the volume of the reaction mixture, of the liner and of the temperature of the gas in the bomb. In order to ascertain the amount of hydrogen equivalent to a given drop in pressure on the gage it was necessary to determine the drop in pressure which occurred when a known quantity of material was reduced. Such compounds as acetone, toluene and dimethylacetoacetic ester reduce quantitatively with no side reactions, so that they were used for the purpose of standardization. By means of various fillers, liners and volumes of reactants the drop in pressure per mole of hydrogen absorbed could be varied from 625 to 3000 pounds per square inch measured at 20°. The gages could be read with an accuracy of ten pounds or less. The loss of hydrogen due to diffusion and leaks was less than thirty pounds in the great majority of the experiments. That is to say, if the original pressure was 2000 pounds at 20° and the bomb was then heated to 200°, kept there for perhaps six hours and cooled to 20°, the pressure would be at least 1970 pounds, and in many cases would be 1990 or higher. It is safe to say then that in a successful experiment the drop in pressure of hydrogen was accurate to within considerably less than fifty pounds.

The temperature to be used for the reduction of a compound was usually decided upon as a result of observation of the increase in pressure in the svstem as the temperature of the bomb increased. If no reduction had occurred at a given temperature, the pressure would be within twenty or thirty pounds of that predicted by the gas laws. The beginning of reduction would be evidenced by an increasing divergence between the actual pressure and the calculated pressure for that temperature. There is no doubt that the pressures used are in numerous cases considerably above those necessary for satisfactory results. The relationship of pressure to the rate of reduction varies materially with different types of compounds and this matter will be considered in subsequent papers.

Solvents.—Solvents have been used by workers in this Laboratory to a greater extent than has been done by others using nickel catalysts. It therefore seems worth while to point out the merits of a few of the common solvents. Ether may be used up to 197° if the pressure is above forty atmospheres and methanol to 240° if the pressure is above eighty atmospheres. The other common solvents may be used to even higher temperatures with similar pressures, so that in so far as the boiling point of the solvent is concerned, there is no limitation on the practical use of any of the common solvents up to approximately 200°. The use of a solvent greatly facilitates the handling of the reaction mixture both during the introduction of the catalyst and in filtering it off after the reduction is complete.

The amount of hydrogen absorbed may be readily and accurately calculated from the drop in pressure in the system if the volume of reaction mixture is constant in a series of experiments. This may be most satisfactorily done by using a solvent for making the various mixtures up to constant volume. A solvent is sometimes advantageous for maintaining the homogeneity of the reaction mixture. For example, the reduction of diphenyl carbinol practically stopped with the formation of diphenylmethane because the water formed in the reduction of the alcohol formed an immiscible layer holding the catalyst out of contact with the diphenyl methane. In the presence of alcohol the reduction proceeded smoothly to dicyclohexylmethane. Conversely, it may be desirable to use as a solvent a compound which will give a non-homogeneous mixture with the reaction products and thus prevent its further reduction.

Alcohol was the solvent most commonly used in this investigation, but it apparently cannot be used with amines above perhaps 165° because it reacts with them to form secondary or tertiary amines. Methylcyclohexane has proved itself to be an excellent solvent. It is inert and has a good boiling point (100") for easy separation from the reaction products. Ether proved itself of value in that butyl cyanide reduced more rapidly and gave a higher ratio of primary amines to secondary amine when ether was used than in the absence of a solvent. This was even more marked in the case of isonitrosopropiophenone, which reduced faster at 85° in an ether solution than at 125° in methylcyclohexane. The formation of condensation products was much less in ether, but it is not certain whether this was due to the specific influence of ether or to the lower temperature at which it was possible to carry out the reduction. The effect of alcohol in increasing the yield of β-hydroxyethyl butyrate from acetoacetic ester by 50% will he considered in another paper. Water has not been extensively used as a solvent in this work but it did not materially reduce the rate of reduction when it was used with acetone.

There is recorded in the table a summary of the experimental conditions and results obtained in the reduction of a group of representative organic compounds. The fifty experiments whose results are reported have been selected as representative out of a group of approximately 200 experiments devoted to the study of the reduction of these forty-five compounds. There is given in order the number of the experiment according to our laboratory record, the name of the compound reduced, the amount of material (expressed in moles) placed in the reaction vessel, the moles of hydrogen absorbed, the weight and number of the catalyst according to our laboratory records, the volume and kind of solvent, if any, the temperature at which the reaction was carried out, the range of pressure in atmospheres during the reduction, the approximate time required for the absorption of the hydrogen, the name and yield of product(s) expressed in percentages of the theoretical and the observed physical constants as compared with those given in the literature. The yields were calculated in three ways and the method of calculation used in any particular case is indicated by prefixing the letters A, B or C to the figure giving the percentage yield. "A" shows the yield of the compound actually obtained, "B" gives the percentage of the theoretical yield obtained after making an allowance for the mechanical losses. In calculating "C" allowance was made for mechanical losses and also for that part (if any) of the original compound in the reaction mixture which had not been reduced. In almost every case it would be easy materially to increase the "A" yields by using larger quantities of materials and refinements in working up the products. In our opinion the value for the moles of hydrogen absorbed is a better index, in the great majority of cases, of the quantitativeness of the reduction than is the yield given under "A."

The significance, for the present, of the results obtained in the reduction of the majority of the compounds dealt with in this paper lies in the establishment of experimental conditions under which these reductions may be carried out satisfactorily. For this reason and because of the need of economy in the use of space in THIS JOURNAL nothing will be added in most cases to the simple statement of experimental results given above. It should be pointed out, however, that the low yields in the case of the reduction of salicylaldehyde and isonitrosopropiophenone were due to mechanical losses, and in the case of acetophenone to the fact that it contained chlorine which necessitated a higher temperature for reduction with a resultant increase in side reactions. In the case of toluene and benzene the reduction was so rapid that the temperature of the mixture rose 100° above that at which the reduction was being carried out. Two hundred liters (N. T. P.) of hydrogen was absorbed by three moles of toluene within fifteen minutes, by far the larger part being taken up within five minutes.

Cinnamic aldehyde was reduced both to the corresponding saturated aldehyde and to 3-phenylpropanol at 100° by modifying the time of reaction. Von Braun and Kochendorfer, using an undescribed commercial nickel catalyst, obtained large yields of compounds resulting from the condensation of two moles of the aldehyde.[6]

Phthalimide was reduced in a good yield to phthalimidine, the hydrogen absorption being very close to the theoretical. The benzenoid ring was very resistant to reduction, as only small amounts of hexahydropthalimidine were obtained with the nickel catalyst although Willstatter and Jacquet[7] were able to reduce the ring using platinum as a catalyst. Succinimide and succinamide could not be reduced at 200°.

The hydroxyl group of alcohols is, in general, quite resistant to catalytic reduction but if the hydroxyl group is on a carbon atom to which is attached a benzenoid ring, its replacement by hydrogen takes place at 125° or lower. This is shown by the reduction of benzyl alcohol, diphenylcarbinol, triphenylcarbinol and *sym.*-diphenylethylene glycol to the corresponding hydrocarbons. If the hydroxyl group was in the beta position with respect to the ring, the rate of its reduction was retarded very greatly. This same ease of replacement of oxygen by hydrogen when the oxygen is alpha to an unsaturated ring is also met with in the ready reduction of benzyl acetate to toluene and acetic acid and in the rupture of the ether linkage in diphenyl ether when the latter is reduced at 150°. Benzyl alcohol is reduced almost exclusively to toluene at 175° but at 125° the hydrogen is distributed almost equally between alcohol and ring reduction. However, since three moles of hydrogen are required to reduce the ring and only one to reduce the alcohol, the yield of cyclohexylcarbinol is only about one-third that

---

[7] Willstatter and Jacquet, *ibid.*, 51, 767 (1918).

of toluene under the optimum conditions so far discovered. The hydrogenation of the nucleus of aromatic alcohols without the elimination of the hydroxy group has not previously been accomplished.[8] Diphenyl ether reduced readily but the hydrogen absorption was high, due to rupture of the ether linkage, the ratio of straight reduction to reduction with splitting being approximately 2:3. The dicyclohexyl ether obtained boiled at 238–239° as reported by Schrauth and Wege[9] and not at 275–277° as given by Ipatiev.[10]

Aniline absorbed hydrogen more slowly than did the other benzenoid compounds studied. The absorption of hydrogen was almost, if not quite, the theoretical three-mole equivalents, but small amounts of aniline were always found in the reaction mixture. The rate of reduction was rather rapid at first but quickly decreased. Dicyclohexylamine was formed in the ratio of one part of the secondary amine to nine parts of the primary. The actual yield of cyclohexylamine was considerably lowered due to its being carried over with the methylcyclohexane used as a solvent. When alcohol was used as a solvent an excellent yield of ethylcyclohexylamine was obtained. Trimethylene cyanide and butyl cyanide took up the theoretical quantity of hydrogen but a secondary amine was formed to a considerable amount in each case. In fact piperidine was the only product isolated from the reduction of trimethylene cyanide.

The pyridinoid ring in quinoline was rapidly reduced at temperatures from about 125° upward. The tetrahydroquinoline was obtained in practically quantitative yields. The benzenoid ring requires a considerably higher temperature for its reduction but the absorption of hydrogen was that calculated for complete reduction. The product in all experiments had the correct boiling range of 204–206° but in the earlier experiments the product remained a liquid at 0° but on retreatment with nickel and hydrogen it would absorb no additional hydrogen. Bamberger and Lengfeld assign a melting point of 48.2–48.5° to decahydroquinoline while Skita **and** Meyer give 48° and Ipatiev 45.5°. Ipatiev gives a boiling point of 207–210° while the other authors report 204°. Bamberger and Lengfeld report a melting point of 275.5–276° for the hydrochloride. Later, 77 *g.* of quinoline was reduced and 71 g. of product obtained boiling at 204–206°. On cooling to 0°, 42 g. of crystals melting 48–49° was obtained. This is the *trans* isomer. The hydrochloride melted at 278–279°. The liquid has been identified by Mr. C. F. Bailey as the isomeric cis decahydroquinoline described by Hiickel and Stepf,[11] who give an excellent bibliography on the isomeric decahydroquinolines.

Nickel has been considered to be inferior to platinum as a catalyst for hydrogenation because, in general, nickel is not active as a catalyst at room temperature. This characteristic has its advantages, however, as it permits selective reduction between two reducible groups through control of temperature of hydrogenation, Such selective reduction was achieved at 125° with acetylbenzoylmethane, phenyl ethyl ketone, benzoin, benzil, benzophenone, isonitrosopropiophenone, benzyl cyanide and *o*-methyl phenyl cyanide when the carbonyl, oxime or cyanide group was reduced without affecting the benzenoid ring. At 175 to 200° complete reduction of these compounds occurred. By a similar temperature control it was found possible to reduce the pyridinoid ring in quinoline, α-pyridylphenylethylene, γ-pyridylphenylethylene and a-benzylpyridine without reducing the benzenoid ring.

Summary

The preparation of a reasonably active nickel catalyst has been described and experimental details are given for the satisfactory reduction of forty-five representative organic compounds. The results have been summarized and need not be repeated here. In general, it may be said that an apparatus and technique have been used which have made it possible to determine rather accurately the amount of hydrogen absorbed and the rate of the reduction. This has made it feasible readily to carry on selective reduction of one of two reducible structures through the control of the temperature or time interval of the reduction. The merits of methylcyclohexane, alcohol and ether as solvents during reduction have been discussed.

THE KETO-ENOL EQUILIBRIUM OF ETHYL ALPHA-PHENYL ACETOACETATE

BY HOWARD W. POST AND GLADYS A. MICHALEK[1]

RECEIVED JUNE 6, 1930 PUBLISHED NOVEMBER 5, 1930

The keto-enol equilibrium of ethyl acetoacetate and its derivatives has already received considerable attention, most of the data published being concerned with the unsubstituted ester or its alkyl derivatives. The effect of substituents in the a-position, especially phenyl, has not been extensively investigated as far as the keto-enol equilibrium of the compounds is concerned. It was our purpose to prepare ethyl α-phenyl acetoacetate and to study its keto-enol equilibrium by means of bromine titration as well as its index of refraction.

[1] Presented to the Committee on Graduate Study of the University of Buffalo by the second author in partial fulfilment of the requirements for the degree of Master of Art..

At ordinary temperatures pure ethyl acetoacetate exists in the enol form to the extent of about 7.7% while α-methyl acetoacetic ester contains about 4.1% enol (at 18°). α,γ-diphenyl acetoacetic ester contains about 18.5% enol at 100°.[2]

Ethyl thiolacetoacetate shows 30.8% enol.[3]

The enol form may be titrated against standard bromine solution[4] or we may depend on some physical property such as refractive index.[5]

The n^{20}_{D} of ethyl acetoacetate has been found to be 32.000, corresponding to 59.2% enol at 20°. Obviously this is at wide variance with the value 7.7% obtained by bromine titration and it was our intention to investigate the composition of equilibrium mixtures of ethyl α-phenyl acetoacetate as evidenced by the figures on enol content obtained both by bromine titration and by the determination of the refractive index.

We prepared ethyl α-phenyl acetoacetate by the method of Beckh, modifying the procedure, however, to increase the yield, which was none too great even then, Enol content was determined by bromine titration (indirect method) and by the determination of the molecular refraction.

Preparation of the Ester.—a-Phenyl substitution products of acetoacetic ester may be made by treating the sodium derivative of ethyl acetoacetate with the proper aryl halide providing there are substituents in the ring to give the halogen the necessary negativity. The indirect method of Beckh,[6] however, had to be resorted to in the preparation of the phenyl derivative, modified as follows.

Benzyl cyanide and ethyl acetate were condensed in the presence of sodium ethylate to give the sodium derivative of acetobenzyl cyanide. This nitrile was then hydrolyzed to the ester by means of hydrochloric acid and ethyl alcohol, through the stage of the imide of the ester.

Our procedure differed from that of Beckh in several particulars. In the first place, instead of dissolving the sodium in absolute alcohol, it was suspended in dry ether and the alcohol added. This was merely for the sake of convenience. Second, after condensation of the ethyl acetate and benzyl cyanide, Beckh removed unchanged benzyl cyanide by dissolving the salt in water and extracting with ether. We found it somewhat more effective and considerably more convenient to wash the salt with ether before dissolving in water. After freeing the acetobenzyl cyanide with carbon dioxide, Beckh extracted it with ether. At the comparatively low temperature which was obtained by using a strong stream of carbon dioxide from a tank, the acetobenzyl cyanide came down as crystals which could be removed by filtration. This gave a somewhat purer product than would have been obtained by extraction. Our greatest deviation, however, from the method of Beckh lay in the decomposition of the imido ester. We poured the alcohol solution directly into ice water, extracted with ether, washed the ether solution directly into ice water, and washed the ether solution with sodium carbonate solution, while Beckh allowed the alcoholic solution to stand over potassium hydroxide or soda lime for several days.

[6] Beckh. *ibid.*, 31, 3160 (1898).

Allowing the mixture to stand over soda lime or potassium hydroxide did not remove all the hydrochloric acid even when a considerably longer time than directed was allowed. In one run we attempted to remove it by blowing dry air through the solution held at about 40°. Before all the acid was removed the solution began to precipitate and on completing the hydrolysis we recovered the acetobenzyl cyanide almost quantitatively.

The yields were never high. In the condensation between ethyl acetate and benzyl cyanide the yield was between 25 and 30% of the theoretical. About 25% of the benzyl cyanide could be recovered. In the hydrolysis of the acetobenzyl cyanide the purified ester never represented more than 10% of the theoretical amount and often as low as five.

Acetobenzyl cyanide crystallized in glistening white crystals melting at 90°; insoluble in water, easily soluble in alcohol, ether and ethyl acetate. The alcoholic solution gave a weak green color with ferric chloride. It is also soluble in sodium carbonate solution and other alkaline media, from which it can be precipitated by acidification. It absorbs bromine readily.

Ethyl α-phenyl acetoacetate is a colorless, slightly viscous oil boiling at 145–147° at 11-mm. pressure. Its alcoholic solution gives a strong violet color with ferric chloride solution.

Anal. Calcd.: C, 68.86; H, 6.84. Found: C, 68.66, 68.56; H, 6.66, 6.50.

The phenylhydrazone of ethyl u-phenylacetoacetate was prepared by heating the ester with phenylhydrazine. It crystallizes in white needles turning yellow on exposure to the air; melting point, 103.9 to 104.2°, Beckh reporting 104°.

1,4-Diphenyl-3-methyl-5-pyrazolone was prepared by heating the hydrazone to 170°, whereupon it melted and then solidified, forming crystals which when recrystallized from acetic acid melted at 193–195°. Beckh reported this melting point as 196'.

Bromine Titration

In titrating the enol form of ethyl α-phenyl acetoacetate against standard bromine solution, we first compared what are known as the direct and the indirect methods. By the direct method[7] the alcohol was cooled to −7°, the ester dissolved therein quickly and titrated against freshly prepared bromine ($N/5$). Since the alcoholic bromine solution is not stable for any great length of time, it must be standardized at the time of use. By the indirect method[8] the sample is dissolved in alcohol as before and alcoholic bromine added. The bromine is here approximately of $N/5$ strength and is added until a faint yellow color persists. The excess is then removed by the addition of 2 cc. of alcoholic β-naphthol solution. Potassium iodide solution is then added and the solution heated generally for twenty minutes on the water-bath in the dark, the liberated iodine being titrated against sodium thiosulfate solution. Trying both methods we found the volumes of thiosulfate and bromine to check.

Number	1	2	3
Bromine, cc.	4.60	5.05	5.45
Direct, $Na_2S_2O_3$ equiv., cc.	7.2	8.45	8.45
Indirect, $Na_2S_2O_3$, cc.	7.15	8.3	8.45

---

[7] Auwers and Eisenlohr, Z. *physik. Chem.*, 83, 429 (1913).

[8] Meyer, *Ber.*, 44,2718 (1911).

Using the indirect method of Meyer we obtained the following values for ethyl α-phenyl acetoacetate

Sample, g.	0.4223	0.3317	0.3012	
$Na_2S_2O_3$, cc.	10.8	8.7	7.9	
Enol, %	27.9	28.9	28.9	**Av.,** 28.6

The literature seems to agree that the amount of thiosulfate used is directly proportional to the amount of bromine absorbed. We suggest, as a mechanism, the splitting off of positive bromine, its reaction with potassium iodide to liberate 2I and the reaction of the 21 with sodium thiosulfate. Obviously it would be rather difficult to prove this—isolation of bromo ester undoubtedly would not give us positive bromine united to carbon for very long—a shift to negative bromine would be expected to take place almost immediately when isolated.

Molecular Refraction

Using the additive values found in the literature for the various elements in ethyl acetoacetate and applying these values to the α-phenyl ester, including modifications for various constructions, we calculated the molecular refraction for the equilibrium mixture as follows

$$n_D^{20} = 1.5130 \text{ and } d_4^{20} = 10850$$

Then using the formula

$$\frac{n^2 - 1}{n^2 + 2} \times \frac{M}{d} = 57.10$$

The data for ethyl acetoacetate compared with those for ethyl α-phenylacetoacetate can be plotted as follows

	100% keto calcd.	Found	100% enol
$CH_3COCH_2COOC_2H_5$	31.57	32.00	32.62
$CH_3COCH(C_6H_5)COOC_2H_5$	55.66	57.10	56.71

using Brühl refraction equivalents.[9]

From these figures it will be seen that ethyl acetoacetate shows an enol content of 59.2% by the method of the refractive index and ethyl α-phenyl acetoacetate, 137.13%. These results are nowhere near the values obtained by bromine titration, 7.7 and 28.6%, respectively, and under the circumstances we prefer to place more reliance on the latter pair of figures, as indeed do all those who have preceded us in this sort of work.

We explain our "abnormal" results by assuming an effect due to the presence of the phenyl group in the a-position. We have here at least one pair of conjugate double bonds and if we do not wish to pin ourselves down to any structure of benzene, at least we have the anomalous structure of the phenyl radical, whatever its actual configuration, to use as a reason for this increase in molecular refraction over the value calculated additively. Other investigators have met with the same obstacles.

[9] Brühl, *Ber.*, **27**, 2478 (1894).

Discussion of Results

Ethyl α-phenyl acetoacetate has been found to contain 28.6% of the enol form at room temperatures (20°) in pyrex glass. This is higher than that of the unsubstituted ester and the methyl derivative. These and other values mostly taken from the literature are as follows

$(CH_3CO)_2CHCOOC_2H_5$	100% enol
$CH_3COCH(C_6H_5)COOC_2H_5$	28.6% enol
$CH_3COCH_2COOC_2H_5$	7.7% enol
$CH_3COCH(CH_3)COOC_2H_5$	4.1% enol
$CH_3COCH(CH_2C_6H_5)COOC_2H_5$	3.4% enol
$CH_3COCH(C_2H_5)COOC_2H_5$	Mostly ketonic
$CH_3COCH(CH_2—CHCH_2)COOC_2H_5$	Mostly ketonic

From data at hand, then, it would appear that electropositive substituents repress enolization or at least are accompanied by such repression and electronegative groups facilitate this process.

Conclusions

Lowry and Burgess propose the chelate ring formula for acetoacetic ester.[10] If we modify this conception to admit of oscillation of affinity to account for keto and enol shift, the effect of an electronegative group, substituted in the α-position is more apparent. This group facilitates ionization of the a-hydrogen in much the same manner that chlorine is said to facilitate ionization of the substituted acetic acids.

Materials.—Benzyl cyanide was obtained from the Eastman Kodak Co., and used as received. That recovered from the acetobenzyl cyanide synthesis was washed with water, dried over calcium chloride and distilled under reduced pressure.

Ethyl acetate was washed with dilute alkali, then several times with water and dried over calcium chloride or anhydrous copper sulfate. It was then separated and distilled.

Hydrochloric acid gas was generated by dropping concentrated sulfuric acid on dry sodium chloride.

Summary

1. A method for the preparation of a-phenyl acetoacetic ester is outlined. This method is a modification of one already in the literature.
2. Reliable data from bromine titration of this ester show that it has an enol content at equilibrium, room temperature, in pyrex glass, of 28.6%. A mechanism is suggested for this series of reactions.
3. Data on the enol content obtained from a determination of the molecular refraction show 137.13%, obviously unreliable.
4. The increase in enol content of the a-phenyl ester over that of the unsubstituted ester is ascribed to the greater electronegativity of the phenyl over hydrogen, and the abnormally large value obtained by the refractive index method, to the presence of the anomalous benzene ring.

NOTE ON THE PURIFICATION OF PHENANTHRENE[1]

BY FRANK L. COHEN AND ULYSSE CORMIER

RECEIVED JUNE 12, 1930 PUBLISHED NOVEMBER 5, 1930

Crude phenanthrene from anthracene oil is obtainable as a dark brown oily crystalline substance. It consists largely of phenanthrene, with varying amounts of anthracene, fluorene, carbazole and dark tarry substances. Of these, anthracene is the most persistent, and its complete removal offers considerable difficulty. By fractional crystallization from a number of solvents, a nearly white product can be obtained which, however, melts variously from 102 to 115°, and gives a brilliant red picrate (phenanthrene picrate is pure yellow, with no red tinge).

The toluene method of Wense[2] involves great losses of material, and does not give a sufficiently pure product, nor did Schmidt's procedure[3] give any better results; the method of Anschiitz and Schultz[3,4] is difficult to carry out on large quantities of material. The alkali fusion method[6] is likewise poorly adapted to laboratory use. Purification over the picrate[6] also proved impracticable and too expensive on a large scale. The red picrate from the partially purified phenanthrene, when recrystallized many times and boiled with prepared charcoal, is obtained as yellow hair-like needles of m. p. 145°, but on decomposition with ammonia always gives phenanthrene melting at about 102 to 105°.

As emphasized by Anschütz,[4] phenanthrene is far easier to separate from anthraquinone than from anthracene itself; we therefore turned to a method used by Sandquist,[7] in which the novel feature was a controlled oxidation with concd. nitric acid. Under the conditions employed, anthracene is oxidized to anthraquinone almost completely, while the phenanthrene is nitrated only to a negligible extent. Sandquist made use of the picrate as well, which we have found to be time-consuming and expensive. Over forty kilograms of phenanthrene has been purified in this Laboratory by the method described below; it is rapid, economical, and can be applied to any reasonable quantity of material. The product is obtained in nacreous white flakes of m. p. 99–99.5°, and gives a pure yellow picrate (compare Limpricht, Ref. 6) of m. p. 145°.

[6] Limpricht, *Ber.*, 6, 532 (1873).

[7] Sandquist, "Studien über die Phenanthrensulfosäuren," Dissertation, Upsala, 1912.

Experimental

Five kg. of crude phenanthrene was refluxed with 12 liters of 95% alcohol until solution was complete. This was cooled to about 15° and filtered; the use of a basket centrifuge at this point proved to be of great advantage, both in the amount of solvent recovered and in increased purity of the product. From 4.0 to 4.3 kg. of gray crystalline material of m. p. 105–110° was obtained.[8] This crystallization removed the oily and wax-like impurities and most of the color. A small amount of phenanthrene goes with the mother liquor, but is so impure that its recovery is unprofitable.

The purified product so obtained is now further treated in smaller lots. One kilogram was dissolved in 6 liters of alcohol, 120 g. of concd. nitric acid added and the solution refluxed vigorously for one and a quarter to one and a half hours. If any considerable quantity of red product separates from the hot reaction mixture at this point, it should be filtered out of the nearly boiling solution (centrifuge). When cooled, the solution set to a mass of large red flakes, yield 800 to 900 g., m. p. 93–96°.

The substance was now distilled at atmospheric pressure, using about 500 g. in a liter distilling flask provided with a wide arm about 60 cm. in length to serve as an air condenser. The phenanthrene distilled as a pale yellow oil and dropped from the side arm into a large beaker of water which was stirred mechanically. The distillate solidified in thin yellow flakes or shells. Distillation was continued until the liquid began to come over somewhat darkened. Further heating results in a violent explosion; there is no danger of explosion if the distillation is interrupted at the point where the dark distillate begins to come over. Distillation at reduced pressure is impracticable because of clogging of the delivery tube with crystals.

The dried flakes of the distillate were recrystallized from alcohol (4 to 4.5 kg. in 12 liters), again centrifuging for best results. A second recrystallization may be necessary to obtain a pure white product. Crude phenanthrene varies greatly, and in two cases a second oxidation with nitric acid was found necessary. The yield of pure phenanthrene of m. p. 99–99.5° was from 30–45% of the weight of crude starting material. Over 80% of the solvent can be recovered when the centrifuge is used.

UNIVERSITY, VIRGINIA

MIXED CATALYSTS IN THE FRIEDEL AND CRAFTS REACTION. THE YIELD OF BENZOPHENONE FROM BENZOYL CHLORIDE AND BENZENE USING FERRIC CHLORIDE–ALUMINUM CHLORIDE MIXTURES AS CATALYSTS

BY W. A. RIDDELL AND C. R. NOLLER

RECEIVED JUNE 16, 1930 PUBLISHED NOVEMBER 5, 1030

Those who have used the Friedel and Crafts reaction to any extent are familiar with the fact that the yield of product may vary when different lots of the commercial grades of aluminum chloride are used. The usual explanation is that this variation is caused by exposure of the catalyst to moisture. Another possibility, however, is that the variation is due to a positive or negative acceleration of the main reaction or of side reactions, or the inauguration of side reactions by impurities. Ordinary aluminum is about 98 to 99% pure, the impurities being chiefly iron and silicon,[1] and hence aluminum chloride prepared from it would be expected to contain these same impurities. Aluminum chloride prepared from bauxite[2] would contain a considerably higher percentage of impurities than that made from aluminum.

In view of the well-known effect of impurities on many catalytic reactions, it seemed that an investigation of the effect of impurities in the catalyst on the yield of products from various Friedel and Crafts reactions would be desirable. Since ferric chloride alone is known to have considerable activity[3] and is also known to be an impurity of aluminum chloride, an investigation of the use of mixtures of ferric chloride with aluminum chloride was undertaken. Since we began this work, we have become aware of a publication along similar lines[4] and feel that it is desirable to publish our results in so far as they are complete at the present time.

[3] Nencki and co-workers, ***Ber.,*** 30, 1766, 1768 (1897); 32, 2414, 2419 (1899).

[4] Boswell and McLaughlin, *Can.* J. *Res.,* **1,** 400 (1929); *C.* **A., 24,** 834 **(1930).** These investigators measured the amount of hydrogen chloride evolved in the reaction of benzene with chloroform. The catalysts used were aluminum chloride prepared from ordinary aluminum in various ways, ferric chloride, partially reduced ferric chloride and two mixtures of ferric chloride and aluminum chloride. Evidence is given for a maximum activity when an equimolecular mixture of ferric chloride and aluminum chloride is used.

After several preliminary experiments, it was decided to study first the reaction between benzoyl chloride and benzene. This reaction is not strictly catalytic since the optimum yields are obtained when one mole of aluminum chloride is used per mole of acid chloride. The reasons for studying this reaction, however, were that a comparison of the behavior of the catalysts could be based on the actual yield of the main product of the reaction, and that the results could be duplicated within an experimental error of 2 to 4%. Moreover, in this particular case the catalyst is completely in solution at the end of the reaction so that one is dealing essentially with a single phase system.

Pure aluminum chloride was obtained by the action of chlorine on aluminum having a purity of 99.95%.[5] The material obtained in this way was practically white as contrasted with the gray to deep yellow color encountered in the commercial grades of aluminum chloride. The anhydrous ferric chloride used was a commercial product that was resublimed in a current of nitrogen just before use. In each case where mixtures of aluminum chloride and ferric chloride were used, a homogeneous catalyst was obtained by fusing the mixture in a sealed tube. Actually it appears that the same results are obtained if a simple mixture of the powdered chlorides is used. The exact method of carrying out the reaction is given in the experimental part.

The first series of reactions was carried out to determine the effect of varying the molecular ratio of aluminum chloride to benzoyl chloride. Although it is generally recognized that, in the preparation of ketones, one mole of aluminum chloride is required for each mole of acid chloride,[6] no comprehensive data have been recorded on this point. The results obtained are plotted in Curve I, Fig. 1. According to the procedure used, there was a small amount of material obtained when benzene and benzoyl chloride alone were present, so that the curve does not pass exactly through the origin. As the amount of aluminum chloride is increased, the yield of benzophenone increases in direct proportion[7] until slightly over one mole of aluminum chloride is present. Further increases in the amount of aluminum chloride have no effect.

---

[5] The authors are indebted to the Aluminum Company of America for supplying them with aluminum prepared by the Hoopes process and having this high degree of purity. Aluminum chloride was also prepared by passing carbon tetrachloride vapor over pure alumina heated to redness, but this method is much slower and more difficult. Moreover, the product obtained was not quite as pure as that made from pure aluminum.

[6] Rubidge and Qua, THIS JOURNAL, 36, 732 (1914).

[7] Considerable trouble was experienced in obtaining concordant results when less than 0.5 mole of aluminum chloride was used. This was caused by the difficulty of removing completely the unreacted benzoyl chloride when it was present in considerable quantity, and was overcome by treating the benzene solution with an aqueous alcoholic solution of sodium hydroxide.

The second series was carried out on mixtures of aluminum chloride and ferric chloride. The total amount of mixed chlorides was kept constant at 1.1 moles and the composition varied from 100% ferric chloride to 100% aluminum chloride. The results are plotted in Curve II, Fig. 1, and indicate that in this reaction the use of mixtures gives results that are practically the mean between those obtained with pure aluminum chloride and pure ferric chloride.

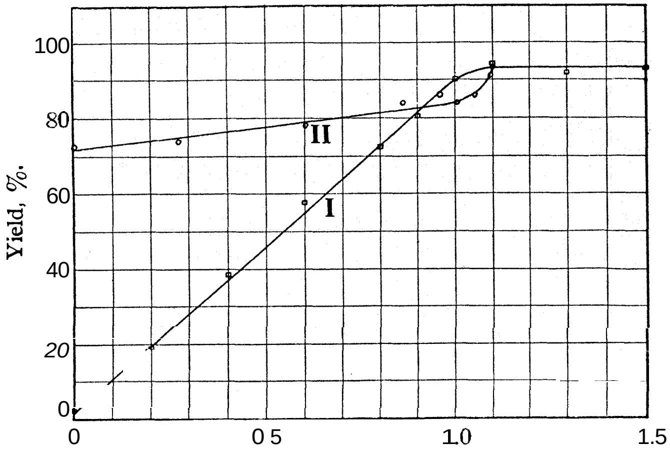

Fig. 1.—Curve I, variation of yield with amount of $AlCl_3$; Curve II, variation of yield using mixtures of $FeCl_3$ and $AlCl_3$, and keeping the total amount of catalyst at 1.1 moles per mole of C_6H_5COCl.

Apparently the lower yields when ferric chloride is present are caused by the acceleration or inauguration of a side reaction. Thus in all cases where ferric chloride is used, a by-product containing iron is formed which is insoluble in the reaction mixture. Further evidence of this detrimental effect is shown by Curve II, Fig. 2. In this series of reactions the amount of aluminum chloride was maintained constant at 1.1 moles, and additional ferric chloride added. In order to compare these results with those obtained when ferric chloride replaces aluminum chloride, the latter have been replotted as Curve I, Fig. 2. Curve II approximates Curve I at first but soon drops below it. A possible explanation of this fact is that when sufficient aluminum chloride is present to take care of all the needs of the main reaction, a greater amount of the ferric chloride is available for producing the side reaction. This explanation would also account for the initial rapid drop of Curve II, Fig. 1, with increasing amounts of ferric chloride. As long as ferric chloride replaces aluminum chloride that is in excess of one mole, the effect is very pronounced, but as the amount of aluminum chloride drops below one mole, the curve flattens out to a straight line whose slope is less because more of the ferric chloride is being used for the main reaction and less is available for producing the side reaction.

The yields of benzophenone are so high that no difference can be detected between the use of pure aluminum chloride and of resublimed commercial products. Some evidence has been obtained in another reaction, however, which indicates that the action of ferric chloride may be different in different types of the Friedel and Crafts reaction.

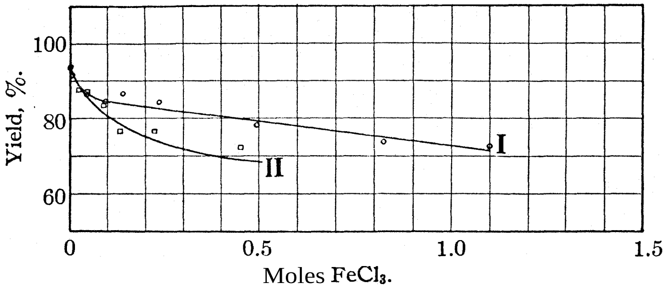

Fig. 2.—Curve I, same as Curve II, Fig. 1, replotted; Curve II, variation of yield using 1.1 moles $AlCl_3$ + varying amounts of $FeCl_3$.

Experimental

Reagents.—Pure anhydrous aluminum chloride was prepared in a suitable apparatus by passing chlorine over heated coils of aluminum sheet having a purity of 99.95%,[5] and was resublimed in an atmosphere of dry nitrogen just before use. The product obtained in this way was almost white, showing only the faintest yellow color in large crystals.

The anhydrous ferric chloride was a commercial C. P. grade and was resublimed in a current of dry nitrogen. Because of the rapid absorption of moisture from the atmosphere, it was necessary to work very rapidly with this material.

A commercial grade of benzoyl chloride was used which boiled at 196–198° and melted at −1 to 0°.

The benzene was dried by distillation and collected over a boiling range of less than 1°.

General Procedure.—Homogeneous mixtures of aluminum chloride and ferric chloride were prepared by placing the two salts in the desired proportions in a pyrex tube, sealing and heating in a bomb furnace until fused. The furnace was tilted at an angle so that the liquid collected in the lower end of the tube.

A 500-cc. three-necked, round-bottomed flask was fitted with a sealed mechanical stirrer, a dropping funnel and a reflux condenser carrying an exit tube for leading off the hydrogen chloride evolved during the reaction. The powdered catalyst was rapidly weighed and transferred to the flask, which contained 70 cc. of dry benzene. After starting the stirrer, 24 g. (0.17 mole) of benzoyl chloride was run in as rapidly as possible. After the reaction had slowed down somewhat, the mixture was refluxed with stirring for three and one-half hours, after which time the evolution of hydrogen chloride had stopped. After cooling, the contents of the flask was decomposed by pouring into 250 cc. of cold water, 10 cc. of concd. hydrochloric acid was added, and the two layers separated. The benzene layer was washed three times with 50-cc. portions of 10% hydrochloric acid and this followed by three washings with 50-cc. portions of 10% sodium hydroxide and a final washing with water. The various aqueous layers were washed successively with a 50-cc. portion of benzene and this was added to the main benzene solution. In the first four runs plotted in Curve I, Fig. 1, where a considerable excess of benzoyl chloride remained at the end of the reaction, it was necessary to modify the method of purifying the benzene solution. It was found that even hot dilute sodium hydroxide would remove the benzoyl chloride only very slowly. This difficulty was overcome by treating the benzene solution, after washing with hydrochloric acid, with 75 cc. of an aqueous alcoholic solution of sodium hydroxide prepared by adding an equal volume of 95% alcohol to a 12N solution of sodium hydroxide. It is essential that a decided excess of sodium hydroxide be present to prevent the formation of ethyl benzoate.

The purified benzene solution was dried over calcium chloride, the benzene distilled, and the residual oil heated in *vacuo* to 160° (thermometer in liquid) at 25-mm. pressure. The resulting crude benzophenone was weighed for yield.[8] The results are plotted in Figs. 1 and 2.

Summary

1. The yield of benzophenone prepared by the reaction of benzoyl chloride with benzene in the presence of mixtures of ferric chloride and aluminum chloride, has been found to be approximately the mean of that obtained using pure ferric chloride and pure aluminum chloride.

2. The ferric chloride has a detrimental action which is apparently due to the acceleration or inauguration of an unknown side reaction.

THE MERCURATION OF BETA-RESORCYLIC ACID

BY REUBEN B. SANDIN AND JACOB M. ZEAVIN

RECEIVED JUNE 18, 1930 PUBLISHED NOVEMBER 5, 1930

During the course of a study of the mercuration of resorcinol and some resorcinol derivatives,[1] it was decided to mercurate a carboxylic acid derivative of resorcinol. β-Resorcylic acid was selected for this work, because of the three carboxylic acid derivatives of resorcinol it is probably the easiest to prepare.

It has been found that β-resorcylic acid very readily forms monomercurated and dimercurated derivatives. The compounds produced are somewhat similar in properties to the corresponding mercurated alkyl resorcinols.[1] The reactions involved are also similar. The β-resorcylic acid derivatives, however, seem to form more stable compounds. For instance, they do not darken appreciably when exposed to sunlight. Also they are

[8] The yields were more readily duplicated using this procedure than by calculating the yield on the distilled product. On distillation practically the entire amount came over between 184 and 186° at 25 mm.

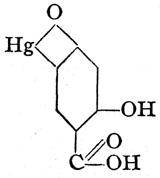
[1] Sandin, THIS JOURNAL, 51, 479 (1929).

more soluble in alkali solutions and these solutions are more stable than the alkali solutions of the mercurated alkyl resorcinols.

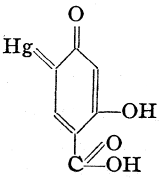
Very recently Fox and Whitmore[2] have found that certain organic compounds can be mercurated in alkaline solution, while other compounds of similar structure cannot. In this work it has been found that β-resorcylic acid is readily mercurated in alkaline solution.

The authors have noticed, as was also the case in the previous work on resorcinol compounds, that a yellow to brown color is associated with the mercurated derivatives which presumably have an anhydro structure. For that reason it is suggested that an alternative structure which involves a quinoid grouping might be used. (Compare formulas I and II. There is no evidence in this work that the substance corresponding to formula II may not be of a para quinoid form instead of the ortho.)

I



II



The mercurated derivatives described cannot be purified by crystallization. They readily lose acetate groups and form anhydro groups, especially on the application of heat. For these reasons, in order to prepare compounds of definite and constant mercury content, the experimental conditions must be constant and rigidly followed. The starting materials must also be quite pure.

Experimental Part

Anhydro-5-hydroxymercuri-β-resorcylic Acid.—The β-resorcylic acid used in this preparation and in subsequent work was obtained from the Eastman Kodak Co. Some β-resorcylic acid was also prepared for this work by the action of potassium bicarbonate on resorcinol.[3] Three and eight-tenths g. (0.02 mole).[4] of β-resorcylic acid dissolved in about 25 cc. of hot glacial acetic acid was added to a hot solution of 3.18 g. (0.01 mole) of mercuric acetate in 25 cc. of glacial acetic acid. The resulting solution was heated for a few minutes and then poured into about one liter of cold water. It was allowed to stand for twelve hours. The white solid (probably the monohydroxymercuri-β-resorcylic acid) was filtered off, washed with water and then dried in the air oven at 100° for twelve to twenty-four hours. It became slightly colored. There was probably the loss of water to form the anhydro-5-hydroxymercuri-β-resorcylic acid. The yield was 95%. It is soluble in a solution of sodium hydroxide.

---

[2] Fox and Whitmore, THIS JOURNAL, 51, 2196 (1929).

[3] Nierenstein and Clibbens, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1930, Vol. X, p. 94.

[4] The above quantity and also the calculation of the percentage yields of mercurated derivatives are based upon the assumption that the β-resorcylic acid is anhydrous.

Anal. Calcd. for $C_7H_4O_4Hg$: Hg, 56.9; acetic acid, 0. Found: Hg, 56.8, 56.7, 57.1, 56.3; acetic acid, 0.[5]

The probable structure of this compound is indicated by formula I or II.

In order to prove the position of the mercury group, one molecular proportion of iodine was added to a suspension of one molecular proportion of the monomercurated compound in glacial acetic acid. This mixture was allowed to stand for about twelve hours, with occasional warming and stirring. The filtrate from this mixture was diluted with water, the precipitate filtered off and extracted with alcoholic alkali. The mono-iodo acid was recovered from the extract by dilution with water and acidification. The product melted at 172° without further purification. Nicolrt and Sampey[6] give 172" as the melting point of 5-iodo-2,4-dihydroxybenzoic acid.

Anhydro-3-hydroxymercuri-5-acetoxymercuri-β-resorcylic Acid. Thrco and eight-tenths g. (0.02 mole) of @-resorcylicacid dissolved in 50 cc. of hot alcohol was added to a boiling solution of 12.72 g. (0.04 mole) of mercuric acetate in 300 cc. of alcohol and 5 cc. of glacial acetic acid. Almost instantly a pale yellow solid separated. It was immediately filtered off by suction and washed with hot alcohol. It was air dried for three days. The yield was 11.6 g. or 95%. It is soluble in a solution of sodium hydroxide, but otherwise insoluble in the ordinary organic solvents.

Anal. Calcd. for $C_9H_6O_6Hg_2$: Hg, 65.6; acetic acid, 9.8. Found: Hg, 64.8, 64.8; acetic acid, 9.1. Other preparations of this compound gave the following percentages for mercury: 66.4, 66.1, 65.6, 65.5.

Of the several attempts to replace the mercury groups by iodine, according to the procedure outlined above, only one was apparently successful. The di-iodo acid obtained decomposed at 191–195°.

Nicolet and Sampey[6] give the decomposition range of 3,5-di-iodo-2,4-dihydroxybenzoic acid as 193–196°.

In the preparation of the above dimercurated derivative, if a large amount of glacial acetic acid was used and practically no alcohol, or if the experiment as already described was carried out and then followed by a heating on the water-bath, a precipitate which was white and not yellow was obtained. This compound was probably the **di-acetoxymercuri-β-resorcylic** acid. However, attempts to obtain it pure by using glacial acetic acid as the medium were unsuccessful. The material on drying gradually lost acetic acid and became colored. The mercury content at the same time gradually approached that required for the **anhydro-3-hydroxymercuri-5-acetoxymercuri-β-resorcylic** acid.

Mercuration of **β-Resorcylic** Acid in Alkaline **Solution.**—β Resorcylic acid was converted into a dimercurated derivative, in alkaline solution according to the procedure of Fox and Whitmore.[2] The mercurated compound was precipitated by bubbling carbon dioxide through the alkaline solution or by nearly neutralizing the solution with dilute hydrochloric acid. The compound, which was brown in color, was probably anhydro-3,5-dihydroxymercuri-β-resorcylic acid. The yield was 80%.

Anal. Calcd. for $C_7H_4O_5Hg_2$: Hg, 70.4. Found: Hg, 69.9, 69.4, 69.3, 71.4.

Summary

1. The mercuration of β-resorcylic acid gives mono and dimercurated products.

---

[5] It was evident that the carbon dioxide formed by the decomposition of the β-resorcylic acid [Hemmelmayr and Meyer, *Monatsh.*, 46, 143 (1916)] would interfere with the titration of acetic acid by the regular method [White, THIS JOURNAL, 42, **2355** (1920)]. For this reason a blank determination was carried out on β-resorcylic acid and phosphoric acid, making conditions as similar to the actual determinations as possible.

[6] Nicolet and Sampey, THIS JOURNAL, 49. 1796 (1927).

2. The anhydro compounds obtained are colored in such a way as to indicate the possibility of quinoid structure.
3. β-Resorcylic acid can be mercurated in alkaline solution to give a dimercurated product.

THE THERMAL DECOMPOSITION OF GASEOUS GERMANIUM TETRAETHYL

BY RAY L. GEDDES[1] AND EDWARD MACK, JR.

RECEIVED JUNE 24, 1930 PUBLISHED NOVEMBER 5, 1930

In connection with the modern theory of the mechanism of gaseous reactions it probably would be very helpful to study the kinetics of decomposition of a series of molecules which present a stepwise gradation of structure and stability. With this in mind we have begun an investigation of the thermal decompositions of the tetra-alkyls (such as the tetramethyls and tetraethyls) of carbon, silicon, germanium, tin and lead. This family of compounds presents a considerable variety of sizes of the central atom, a great difference of bonding forces with which the outlying groups are bound to the central atom, and affords the possibility of examining related molecules of various degrees of complexity. Preliminary study shows that the temperatures of appreciable decomposition extend over a wide range, from about 220° for lead tetraethyl to about 650" for silicon tetramethyl, and that in at least two cases, germanium tetraethyl and lead tetraethyl, and probably in all of the other cases, the decomposition is predominantly homogeneous and unimolecular. The present paper is an account of the behavior of germanium tetraethyl. Data for the other compounds will be presented in later papers.

The thermal decomposition of gaseous germanium tetraethyl in the range 420–450° is a reaction about 98% homogeneous, and unimolecular down to pressures of about 8 cm. During the course of the decomposition, metallic germanium is deposited as a semi-mirror, or as what amounts to a sputtered film, on the walls of the reaction vessel, and it seems natural to represent the primary reaction as

$$Ge(C_2H_5)_4 \longrightarrow Ge + 4C_2H_5$$

(It must be admitted that this is only a suggested manner of decomposition, and that there is not enough evidence to justify setting up a detailed reaction mechanism. A similar formation of free methyl[2] groups seems to be well established in the decomposition of lead tetramethyl.) The free ethyl groups might then be supposed virtually to unite to form normal bu-

tane, and indeed in a preliminary study of the decomposition of lead tetraethyl (250°), this seems to be essentially what occurs; but in the case of germanium tetraethyl, which decomposes at a temperature almost 200° higher than lead tetraethyl, it is not likely that much actual butane would be formed. Hague and Wheeler[3] noticed slow decomposition of butane at about 435°, and Hurd and Spence[4a] found some decomposition even at 400°. The ethyl groups sloughed off from the germanium may react to give gaseous products very much like the products which Hurd and Spence found for the pyrolysis of n-butane. Our ethyl groups yield 60–70% ethane and ethylene, a proportion which would be obtained if the butane molecules split in the middle, and followed predominantly Equation 2 of Nurd and Spence.[4b] A more detailed account of the decomposition products will be presented in Table V.

Experimental

The course of the decomposition of germanium tetraethyl was followed by measurement of the change of pressure in a reaction vessel. Because of the low vapor pressure of germanium tetraethyl at room temperature, glass membrane manometers of the null type described by Jackson[5] and Gibson[6] were employed. A combination mercury-piston mercury manometer was used for adjusting and measuring the higher air pressures outside the glass membrane, and an ethyl phthalate manometer for measuring the lower pressures (1–2 cm.).

Both pyrex and quartz membranes and reaction chambers (of about 10–15 cc. capacity) were constructed. At 440° even the stiffer pyrex membranes had a slight tendency to soften, although the subsequent change in zero point was not enough to affect the calculations to any great extent. However, to eliminate possible error from this source, clear fused quartz reaction chambers were used in practically all cases. The quartz membrane manometers were made of various degrees of sensitivity, depending on the pressures at which they were intended to serve. A few were estimated to have an extreme sensitivity of about 0.002 mm.

Constant temperature was maintained, within 0.1–0.2°, with a sulfur-bath boiling under the required pressure, generally for convenience at atmospheric pressure. The temperature was measured with a carefully calibrated chromel–alumel thermocouple placed alongside the reaction chamber at its mid-portion.

Samples of germanium tetraethyl were very kindly donated by Professor L. M. Dennis of Cornell University, Professor C. A. Kraus of Brown University, and Mr. Thomas Midgley, Jr.

[6] Gibson, *Proc. Roy. Soc. Edinburgh*, 33, 1 (1912).

Briefly the procedure in making a run was as follows. A small amount of liquid germanium tetraethyl was sealed up in a small glass bulb with minute capillary ends in such a way that the bulb was filled and only an extremely small quantity of air was left in the capillary ends. This was an important precaution since small amounts of oxygen were found to increase the rate of decomposition quite appreciably. The reaction chamber was connected to a diffusion pump system by a short length of suction tubing, after a bulb of germanium tetraethyl had been placed in the tube a short distance from the chamber. The air pressure was reduced to about 0.001 mm., and during this evacuation the chamber was heated for about fifteen minutes with *a* blast lamp to remove adsorbed gases. The chamber, was then allowed to cool, the bulb rolled down into the chamber and the latter sealed off. The chamber was preheated in an electric furnace to a temperature about 100" below the temperature of appreciable decomposition, and from the pressure of the germanium tetraethyl at this temperature the initial pressure at the temperature of the decomposition run was calculated by means of Charles' law. The reaction chamber was quickly withdrawn from the furnace, thrust into the sulfur bath, clamped fast in a vertical position and a microscope focused on the edge of the membrane manometer pointer when it was in its zero position. Simultaneous readings of pressure and time were taken at one- to two-minute intervals during the first three-quarters of the decomposition, and at longer intervals during the remainder. The data for a typical run at 440.9° are given in Table I.

TABLE I

DATA AND VELOCITY CONSTANT AT 440.9°

Time, minutes	Pressure, cm.	$p_\infty - p$	Velocity constant, k	Time, minutes	Pressure, cm.	$p_\infty - p$	Velocity constant, k
0	30.74	77.16	.....	15.60	68.66	39.24	0.0492
2.45	33.97	73.93	.....	17.25	71.56	36.34	.0465
3.85	37.87	70.03	0.0389	19.12	74.50	33.40	.0432
5.35	42.27	65.63	.0432	26.30	82.80	25.10	....
6.40	45.58	62.32	.0493	29.97	85.62	22.28	.0325
7.75	49.75	58.15	.0512	49.10	94.40	13.50	....
9.44	54.65	53.25	.0521	64.75	97.90	10.00	.0192
10.73	57.98	49.92	.0501	187	106.20	1.70	....
12.65	62.62	45.28	.0509	225	107.10	0.80	....
14.17	65.80	42.10	.0479	267	107.90	.00	....

Column 3 gives the differences between the final pressure and the pressures at the various time intervals. After the first five minutes the velocity constant, k, calculated between successive time intervals by the usual unimolecular equation, assumes a fairly constant value and remains fairly constant until the reaction is about 50% completed, and then falls off considerably.

The fact that the decomposition is almost wholly homogeneous is demonstrated by the data presented in Table II,

TABLE II

HOMOGENEITY OF THE REACTION IN QUARTZ

Run	Temp., °C.	p_{initial} (cm.)	k	k (442°)	Surface ratio
Average	...	..	....	0.0505	1
75	442.3	12.7	0.0550	.0544	10
115	442.2	24 2	.095	.094	40–50
204	441.1	29.5	.095	.099	40–50
206	441.8	35 9	.090	.091	40–50

In Column 5 the velocity constants are corrected to 442°. Since an increase in the surface to volume ratio of 40–50 times does not quite double the velocity constant, it follows that the reaction cannot be more than about 2% heterogeneous. The reproducibility of results from run to run argues for a largely homogeneous reaction. The reaction was also homogeneous in pyrex.

That the decomposition is kinetically unimolecular is shown by the very constant values for the time of half change, $t_{1/2}$, in Col. 6, and by the good

agreement among the velocity constants of the various runs, indicated in Col. 8 of Table III.

Column 3 indicates the nature of the reaction chamber, pyrex or quartz, Col. 4 the initial pressure, and Col. 5 the ratio of final to initial pressure.

The variation of the velocity constant with temperature is shown in Table IV.

TABLE IV

TEMPERATURE COEFFICIENT DATA

Init. press., cm.	Temp., °C.	Velocity constant, k
Average	442	0.0505
22.7	431	.031
22.2	431.1	.030
26.9	430.6	.031
33.8	419.5	.0153
16.4	419.1	.0142

The velocity constant as a function of temperature may be expressed approximately by the equation

$$\ln k = 32.88 - 51{,}000/RT$$

The energy of activation of this reaction is about 51,000 with a possible error of several thousand calories.

Discussion of Results

Reference to the last three runs of Table III shows that the velocity constant begins to drop off appreciably at low pressures. At a partial pressure of germanium tetraethyl of about 7 cm. the velocity constant is about 0.040. We have estimated the effective diameter of a germanium tetraethyl molecule to be about 7 Å. from the critical density, by using Herzog's[7] empirical equation; and also roughly from the average shadow area[8] of a model of the molecule. From these data we have calculated that z, the total number of collisions per cc. per second, is 6 X 10^{26} and that the number of molecules reacting per cc. per second is **6.3** X 10^{14}. Then from the usual equation

$$k\left(\begin{matrix}\text{molecules}\\ \text{reacting}\end{matrix}/\text{cc./sec.}\right) = 2.5\,ze^{-\left[\frac{E+(\frac{1}{2}n-1)RT}{RT}\right]}\cdot\left[\frac{E+\left(\frac{1}{2}n-1\right)RT}{RT}\right]^{\frac{1}{2}n-1} \qquad \frac{}{2}n-1$$

we obtain a value between 8 and 10, for n the number of so-called active degrees of freedom, or the number of "square terms."

Although the velocity constant falls off at low pressures, the introduction of hydrogen at a pressure of 20 cm. into germanium tetraethyl at a pressure

of 4.6 cm. failed to raise the value of the constant appreciably. Helium, argon and nitrogen at pressures of about 60 cm. were added to the germanium tetraethyl at about 25 cm. and at first the results seemed to indicate that these inert gases were raising the value of the velocity constant. However, careful analysis of the helium, argon and nitrogen showed the presence of oxygen to the extent of 0.1–0.2%, and since the presence of oxygen in concentrations as large as this in the germanium tetraethyl system increased the velocity constant (in blank determinations) to about the same extent as that found in the case of the inert gases, we concluded that the helium, argon and nitrogen themselves had in reality little, if any, effect on the velocity of the reaction. Our experience with the effect of oxygen in this system leads us to suggest that the increase in the velocity constant observed by Pease[10] and Durgan for the pyrolysis of butane and propane, in the presence of added nitrogen, may be explained by the presence of small quantities of oxygen.

Carbon dioxide, at pressures of 42.4 and 86.5 cm., in germanium tetraethyl at pressures of 21.7 and 8.2 cm., respectively, caused the velocity constant to fall off to 0.034 and 0.024. The lowering was approximately proportional to the partial pressure of the carbon dioxide. This behavior suggests that the activated germanium tetraethyl molecules are being robbed of energy of activation by collision with the carbon dioxide molecules, and indeed the observed falling value of the velocity constant with gradual accumulation of reaction products toward the latter part of the reaction is in line with the same idea.

When hydrogen was introduced into the system with germanium tetraethyl at ordinary pressures (15–25 cm.), the ratios of the final to initial pressures indicated that some of the hydrogen was disappearing in the reaction, and the amounts disappearing were roughly proportional to the pressure of the added hydrogen. Since hydrogen at pressures above about 25 cm. was lost in appreciable amounts by diffusion through quartz membranes of the type we were using, it was necessary to conduct these experiments in pyrex. Analysis of the products of the reaction showed undoubtedly that the disappearance of hydrogen in the reaction was due to the hydrogenation of unsaturated hydrocarbons, as Pease found in the case of ethylene–hydrogen mixtures,[11] although, in the present instance, as suggested below, it seems likely that the hydrogenation reaction occurs at the instant of germanium tetraethyl decomposition.

Analyses of the gaseous products of decomposition were carried out in a modified Bone–Wheeler apparatus. Special reaction vessels were constructed in order to facilitate the handling of the small volumes of gas, amounting to about 10 cc., available for analysis. When the decomposi-

[11] Pease, *ibid.*, 52, 1185 (1930).

tion was completed, the chamber was cooled to room temperature and the pressure measured. This pressure, when calculated by Charles' law to the temperature of the decomposition, in nearly all cases checked fairly well with the final pressures actually measured, thus affording evidence that the amounts of high-boiling compounds were very small or zero. The chamber was then cooled to liquid-air temperatures and the vapor phase, consisting of hydrogen and methane, pumped off by means of a Topler pump. The residue was warmed to room temperature, cooled in liquid air and the vapor phase pumped off again. As a rule very small amounts of gas were obtained from this second fractionation. By slow combustion analysis the amounts of hydrogen and methane in the original sample were obtained. The residual gas in the reaction chamber was pumped out and analyzed for saturated and unsaturated hydrocarbons. At first the unsaturation was estimated only as ethylene and higher olefins, according to Hague and Wheeler. In later analyses the higher olefins were separated into groups according to Hurd and Spence. Combustion of the saturated hydrocarbons gave the average carbon content per molecule, and showed the presence of practically nothing except ethane and propane. No great accuracy is claimed for the analysis, but on any given sample it is probably correct to within a few per cent. Typical analyses are given in Table V. It will be noted from the table that the total percentage of unsaturation is practically independent of the two methods, (a) and (b), employed, although the separation of the different groups of the unsaturated fraction according to the Hurd and Spence method (b), is undoubtedly more reliable.

[a] Hague and Wheeler method of analysis of unsaturation. [b] Hurd and Spence method.

Among the experiments in which hydrogen was added to the reaction system were three, namely, Runs 170, 174, 182, with the added hydrogen at a pressure of about 50 cm., which are tabulated above. In order to obtain a comparison between the composition of the product gases in these cases and the normal decompositions in the absence of added hydrogen, it was assumed as an approximation that about 11% of hydrogen would be formed in all of the decompositions, and the added hydrogen was not included in the listed percentage composition.

The data show clearly that in the presence of added hydrogen the decomposition yields a higher proportion of saturated hydrocarbons. Still, a large part of the unsaturation always remains. In addition, the times of half change, $t_{1/2}$, had about the same value as in the absence of added hydrogen. This indicates that the hydrogenation takes place simultaneously with the decomposition of the germanium tetraethyl molecule, and not in a later independent reaction, It seems probable that during the instant immediately following decomposition, while an unsaturated molecule (C_2H_5, C_2H_4, etc.), still has its share of the energy of activation from the decomposition, it is much more easily hydrogenated by collision with hydrogen than after the loss of this energy by collision with other molecules.

When the decomposition was carried out in the presence of *added* ethylene, part of the ethylene was found to disappear during the reaction. Probably there were two factors involved, hydrogenation and polymerization to the more stable butylene, as Pease found in the case of ethylene–hydrogen mixtures at this temperature. This polymerization, with large amounts of added ethylene, had the effect of raising the velocity constant during the first part, and of lowering it during the last part, of the reaction. This effect is to be expected since the calculation of the velocity constant involves the final pressure and since the polymerization lowers the ratio of final to initial pressure markedly. The polymerization of ethylene comes practically to a stop toward the later stages of a run, not only because of the decreasing partial pressure of the ethylene, but probably also because of the decreasing effect of the falling concentration of germanium tetraethyl on the polymerization. Taylor[12] and Jones have recently claimed that decomposition of metal alkyls induces ethylene polymerization.

In a *normal* run, in the absence of *added ethylene,* it seems that the velocity constant and the time of half change of the primary decompositions of germanium tetraethyl are unaffected by any reactions occurring among the product gases, if such reactions occur at all, or at least that these latter consecutive reactions must be rapid compared with the slower primary decomposition. Other considerations, as well, seem to justify the validity of using pressure measurements as a means of following the course of the primary decomposition.

The above analyses also show that the products vary slightly in proportion from run to run. This is also indicated by the variation in the values of the ratios of final to initial pressure in Table III. It is to be noted, though, that the absolute variations in the ratios of final to initial pressures

---

[12] **Taylor** and Jones, Tars JOURNAL, 52,1111 (1930).

are not to be taken too seriously, since there is one important source of error in the determination of these values. The final pressure was measured in the sulfur-bath; the initial pressure in an electric furnace. It was not always expedient to see that the chamber took exactly a vertical position in both cases. Hence the weight of the manometer pointer would cause error in each measurement which would be magnified in the ratio. Since the velocity constants were calculated from differences in pressure in the sulfur-bath, they are reliable in spite of the possible error in the absolute pressures.

Summary

The thermal decomposition of gaseous germanium tetraethyl in the temperature range 420–450° has been studied and has been found to be about 98% homogeneous, and unimolecular down to a pressure of about 8 cm.

At about 7 cm. the value of the velocity constant begins to fall off, but the addition of hydrogen gas to the reaction system does not raise the constant appreciably.

The energy of activation is about 51,000, with a possbile error of several thousand calories, and the velocity constant is given by the equation, $\ln k = 32.88 - 51{,}000/RT$. The number of active degrees of freedom calculated at the pressure where the velocity constant begins to fall off is between 8 and 10.

The reaction yields metallic germanium, and analysis of the gases from the decomposition shows essentially the products obtained by pyrolysis of butane. Added hydrogen and ethylene enter into hydrogenation and polymerization reactions in the gaseous system. Added carbon dioxide cuts down the velocity constant, but nitrogen, helium and argon have little, if any, effect.

It seems justifiable to measure the course of this decomposition by pressure changes, and the pressures have been measured with quartz and pyrex membrane manometers.

THERMAL DATA ON ORGANIC COMPOUNDS. IX. A STUDY OF THE EFFECT OF UNSATURATION ON THE HEAT CAPACITIES, ENTROPIES AND FREE ENERGIES OF SOME HYDROCARBONS AND OTHER COMPOUNDS[1]

BY GEORGE S PARKS[2] AND HUGH M. HUFFMAN[3]

RECEIVED JUNE 27, 1930 PUBLISHED NOVEMBER 5, 1930

In the three papers[4] of this series immediately preceding the present one, we presented data for the heat capacities, entropies and free energies of more than thirty hydrocarbons. These results were utilized in determining the effect (1) of increasing the length of the chain in an aliphatic hydrocarbon, (2) of inserting side branches on the main chain and (3) of introducing one or more phenyl groups. The present investigation is essentially similar in character to those which have gone before it but deals particularly with the problem of unsaturation, *i. e.*, the effect of the C=C bond on the heat capacities, entropies and free energies of hydrocarbons and other compounds. In this study we have used many of the data previously obtained and also have made new heat capacity measurements on the following twelve compounds fumaric acid, maleic acid, succinic acid, pentene-2, trimethylethylene, n-pentane, cyclohexene, methylcyclohexane, di-isobutylene, stilbene, dibenzoylethylene and dibenzoylethane.

Materials

Fumaric Acid, Maleic Acid, Succinic Acid, Dibenzoylethylene and Dibenzoylethane.—These substances were supplied to us in pure form by Professor James B. Conant of Harvard University. Concerning them he writes as follows.

"The fumaric acid was a commercial material (presumably prepared by the catalytic oxidation of benzene) which I recrystallized three or four times from water. The succinic acid was a high-grade commercial product which I personally recrystallized twice.

"The maleic acid was prepared by redistilling in glass maleic anhydride. This anhydride was then dissolved in distilled water and crystallized by concentration in *vacuo*. This is the only method which gives a really pure maleic acid free from fumaric. The melting point given in the literature is 130–131°. If slowly heated in the ordinary melting point apparatus. the acid I am sending you melts at this temperature. It shows a somewhat higher melting point if rapidly heated. Personally I am inclined to

[4] Parks, Huffman and Thomas, THIS JOURNAL, 52,1032 (1930); Huffman, Parks and Daniels, *ibid.*, 52, 1547 (1930); Huffman, Parks and Thomas, *ibid.*, 52,3241 (1930).

think that this higher value may be nearer the truth, in spite of the statements in the literature.

"The dibenzoylethane ($C_6H_5CO(CH_2)_2COC_6H_5$) and ethylene (*trans*-$C_6H_5COCH{=}CHCOC_6H_5$) were prepared according to the methods described by Lutz and myself.[6] They were purified by repeated recrystallization from alcohol. In this connection it should be noted that the ethane sample was very kindly donated by Professor Lutz of the University of Virginia."

Pentene-2, Trimethylethylene, *n*-Pentane and **Di-isobutylene.**—These four hydrocarbons were very carefully prepared for us by Dr. H. E. Buc of the Standard Oil Development Company. Their preparation is difficult, and none of them could be obtained in the open market in a state of purity sufficient for our work.

The pentene-2, $CH_3CH{=}CHC_2H_5$, was prepared by dehydration of secondary amyl alcohol. The product was dried with alkali and then refractionated over anhydrous copper sulfate. Two additional fractionations in a special still gave a final product which boiled between 36.27 and 36.31" at 765 mm. In spite of the very small boiling range of this material, we were never able to crystallize it completely in the course of our specific heat measurements. The explanation of this fact is probably to be found in geometrical isomerism, since pentene-2 may exist in cis and trans forms similar to maleic and fumaric acids. Undoubtedly one of these forms of pentene-2, probably the trans, is somewhat more stable thermodynamically than the other; but it is quite possible that some of each was produced in the present synthesis and was carried through the fractional distillations into the final product. In this event we were really working upon a solution rather than on a pure compound. However, the specific heats of the two forms should not differ greatly, and therefore we believe that our data for this substance in the liquid state are fairly reliable. The incomplete crystallization prevented us from obtaining accurate values for the crystals or for the heat of fusion.

The trimethylethylene, $(CH_3)_2C{=}CHCH_3$, was prepared from a cruder sample of this material by fractional distillation. Fifteen successive fractionations, starting with about 1800 cc. and ending with 200 cc., gave a final product which boiled at 38.5–38.6°, 765 mm. This material crystallized in satisfactory fashion and was evidently fairly pure. It is interesting to note that the compound does not admit of geometrical isomerism.

The *n*-pentane was similarly prepared from a sample of crude "normal pentane" (a petroleum product) by an elaborate series of fractional distillations It boiled at 35.75–35.80" (746 mm.) and, when cooled by liquid air, produced crystals which exhibited a very sharp melting point at 143.4°K. Without doubt this was one of the purest hydrocarbon samples that we have ever studied.

The di-isobutylene was prepared by polymerization of isobutylene and subsequent fractionation. It presumably has the formula $(CH_3)_3CCH{=}C(CH_3)_2$. On being cooled with liquid air, it first formed a glass, which crystallized completely as it warmed up. While the melting point of the crystals was not sharp, we believe that our thermal data for this substance are fairly reliable, although probably not of the same order of accuracy as for the other compounds.

Cyclohexene and **Methylcyclohexane.**—High grade Eastman products were subjected to a series of fractional distillations and to successive dryings with anhydrous copper sulfate. The final sample of cyclohexene boiled at 83.0°, 765 mm.; that of the methylcyclohexane boiled at 100.95–101.00°, 763 mm. Both substances exhibited sharp melting points after crystallization with liquid air. .

Stilbene.—Eastman's stilbene (m. p. 120°) was subjected to four crystallizations from ethyl alcohol. The final product melted at 124.2°. It is considered to be the trans form.

---

Experimental Results

In principle, the method of Nernst was employed with an aneroid calorimeter in determining the "true" specific heats and the fusion data. The apparatus and details of experimental procedure have been fully described in other places.[6] In view of the accuracy of the various measurements involved, the error in the experimental values thereby obtained is probably less than 1%, except in so far as impurities in a hydrocarbon sample, such as that of di-isobutylene, may cause premelting or otherwise influence the results.

The specific heats and the fusion data, expressed in terms of the 15° calorie[7] and with all weights reduced to a vacuum basis, appear in Tables I and II.

[a] In this connection we wish to acknowledge our indebtedness to Mr. A. C. Daniels of this Laboratory, who very kindly made the measurements on stilbene for us.

TABLE II

FUSION DATA[a]

Substance	M. p., °K.	Heat of fusion (cal. per g.) 1st result	2d result	Mean
Trimethylethylene	138.9	25.82	25.66	25.74
n-Pentane	143.4	27.75	27.75	27.75
Cyclohexene	169 0	9.56	9.58	9.57
Methylcyclohexane	146.2	16.25	16.24	16.24
Di-isobutylene	172	16.83	...	16.83

[a] In the calculation of these fusion values, the marked rise in the specific heat of the crystals as the melting point is approached was attributed to premelting; and the heat absorbed in this region in excess of that obtained by extrapolation of the specific heat data at lower temperatures was added to the heat absorbed at the melting point.

TABLE III

TRANSITION DATA

Substance	Transition temperature, °K.	Heat of transition (cal. per g.) 1st result	2nd result	Mean
Cyclohexene	138.7	12.19	11.53	11.86

For comparison with these values the literature[8] contains only very meager data. Our extrapolated specific heat curve for succinic acid is about 6% above the value obtained by Hess at a mean temperature of 25° and 3.5% above that of deHeen at 35°. For n-pentane Schlesinger has made determinations on the liquid at −78 and 0°. His results are below our curve by 0.2 and 2.3%, respectively. The specific heat value of Nadejdin for "isoamylene," presumably trimethylethylene, at *a* mean temperature of −3.5° is only 0.4% above our curve for this substance.

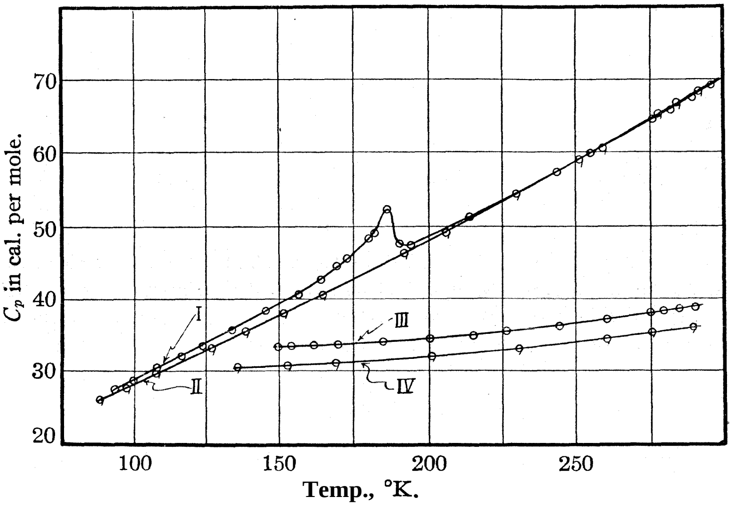
Cyclohexene was found to exist in two crystalline forms with a fairly definite transition temperature at 138.7°K., and the heat of transition was measured by the same procedure used in the fusion determinations. The data thus obtained are recorded in Table III. In this connection it is noteworthy that the heat of transition is about 25% greater than the heat of fusion.

In the cases of succinic acid and dibenzoylethane the specific heat curve for the crystals show a small maximum or "hump." Such a phenomenon

---

[8] Landolt–Börnstein–Roth–Scheel, "Tabellen," Julius Springer. Berlin. 1923, pp. 1267 and 1271.

has been observed for several other compounds which have been studied in this Laboratory and is undoubtedly real, although its explanation is not apparent. For dibenzoylethane the hump comes at about 187°K. (see Fig. 1) and the heat effect in excess of the normal specific heat amounts to **0.22** cal. per g. or **52** cal. per mole. The two parts of the heat capacity curve below and above this transition region fit together quite smoothly, indicating that the same crystalline form probably exists over the entire temperature range. A similar hump was found for succinic acid at about 272°K. with a heat effect of 41 cal. per mole.



Pig. 1.—Curve I refers to dibenzoylethane; II to dibenzoylethylene; III to n-pentane; IV to pentene-2.

A careful study of the thermal data indicates that the withdrawal of a mole of hydrogen, with the resulting production of an ethylenic double bond in the parent compound, ordinarily lowers somewhat the molal heat capacity at a given temperature. Outside of the hump region the effect is hardly noticeable in the case of crystalline dibenzoylethane and dibenzoylethylene, where the change in the molecular weight is less than 1%, while it is quite appreciable with liquid n-pentane and pentene-2, where the change in molecular weight is about **3%.** These examples are, perhaps, rather extreme cases, and, accordingly, we have represented them graphically in Fig. 1.

The lowering in molal heat capacity on formation of an olefin is undoubtedly due to the decreased vibrations (as a result of the increased constraints) of the carbon atoms adjacent to the double bond rather than to a loss of the thermal energy associated with the vibrations of the two hydrogen atoms. This last is probably negligible at all temperatures up to that of the room.

Discussion

Entropies **of the** Compounds.—Using the data contained in Tables I, II and III in conjunction with the third law of thermodynamics, we have calculated the molal entropies at 298.1°K. for all the compounds except pentene-2. In these calculations we have employed the extrapolation method of Kelley, Parks and Huffman[9] for estimating the entropy increase for the crystals, Col. 2 of Table IV, from 0 to 90°K. The various entropy increments from 90 to 298.1°K., which appear in Cols. 3, 4 and 5 of the table, were obtained by the usual methods directly from the experimental data. The results for the total entropy in calories per degree appear under the heading S_{298} in the last column. In the case of stilbene, which is normally crystalline, we have roughly calculated the entropy of fusion[10] at 298° so as to obtain a value for its entropy as a liquid, even though the liquid state is unstable at this temperature.

TABLE IV

ENTROPIES OF THE SUBSTANCES PER MOLE

Substance	Crystals 0–90°K.	Crystals Above 90°K.	Fusion	Liquid	S_{298}
Fumaric acid	12.31	27 34	...	...	39.7
Maleic acid	12.10	25.97		...	38.1
Succinic acid	13.17	28.86[a]	...	. .	42.0
Trimethylethylene	13.12	8.37	12.99	25.00	59.5
n-Pentane	13.53	9.09	13.95	25.42	62.0
Cyclohexene	11 76	18.13[b]	4.65	17.28	51.8
Methylcyclohexane	13.08	8.77	10.90	26.59	59.3
Di-isobutylene	15.24	18 03	10.96	27.12	71.4
Stilbene (solid)	19.81	40.16	...	...	60.0
Stilbene (liquid)	...	...	15.7	...	75.7
Dibenzoylethylene	24.88	51.42	...	...	76.3
Dibenzoylethane	24 79	52.81"	...	...	77.6

[a] This value includes 0.15 E. U. for the entropy of the hump at 272°K.

[b] This value includes the entropy increase for both crystalline forms as well as the entropy effect (7.11 E. U.) for the transition between them.

[c] This value includes 0.28 E. U. for the entropy of a hump at 187°K.

We now possess entropy values for a number of unsaturated compounds and are in a position to compare these with the entropies of the corresponding saturated substances. We have made such a comparison in Table V.

In eight cases out of the nine cited the entropy of the unsaturated compound is appreciably less than that of the corresponding saturated one.

---

[9] Kelley, Parks and Huffman, J. *Phys. Chem.*, 33,1802 (1929).

[10] This approximate calculation of the entropy of fusion was made by the equation $\Delta S_{298} = (\Delta H \text{ fusion})/T_{\mathrm{M}} - AC, \ln (T_{\mathrm{M}}/298)$, where A H and T_{M} are, respectively, the molal heat of fusion and the melting point. In this case ΔC_p, the difference between the molal heat capacity of the liquid and crystals, was assumed to be approximately 9 cal. For AH, we have used 7200 cal. per mole ("International Critical Tables," Vol. V, p. 134).

TABLE V

A COMPARISON OF THE ENTROPIES OF SOME SATURATED AND UNSATURATED ORGANIC COMPOUNDS

Entropy of the saturated compound		Entropy of the unsaturated compound		Entropy decrease with unsaturation, E. U.
Succinic acid	42.0	Fumaric acid	39.7	2.3
Succinic acid	42.0	Maleic acid	38.1	3.9
Dibenzoylethane	77.6	Dibenzoylethylene	76.3	1.3
2-Methylbutane	60.8	Trimethylethylene	59.5	1.3
2,2,4-Trimethylpentane	75.2	Di-isobutylene	71.4	3.8
Dibenzyl	64.6	Stilbene	60.0	4.6
Cyclohexane	49.2	Cyclohexene	51.8	−2.6
Cyclohexane	49.2	Benzene	41.9	2.4 X 3
Methylcyclohexane	59.3	Toluene	52.4	2.3 X 3

In these eight comparisons the differences, while by no means constant, average 2.7 E. U. per double bond, or mole of hydrogen withdrawn. In the cyclohexane–cyclohexene comparison, however, the entropy of the latter is actually greater by 2.6 E. U. In our opinion this anomaly is to be attributed to an abnormally low entropy value for cyclohexane, which (like benzene) possesses great molecular symmetry and is somewhat unique in character.

In a preceding paper[11] it was shown that the entropy of a liquid paraffin or benzenoid hydrocarbon could be calculated quite accurately by the empirical equation, $S_{298} = 25.0 + 7.7n - 4.5r + 19.5p$. Here n and p represent, respectively, the number of aliphatic carbon atoms and phenyl groups in the molecule, and r ordinarily refers to the number of methyl branches attached on the main aliphatic chain. In order to apply the equation to olefin hydrocarbons we might now add the term $-2.7e$, where e represents the number of ethylenic double bonds within the acyclic portion of the compound. The equation for liquid olefins then becomes, $S_{298} = 25.0 + 7.7n - 4.5r - 2.7e + 19.5p$. Using it, we calculate the following entropies: trimethylethylene, 56.3 E. U.; di-isobutylene, 70.4 E. U.; and stilbene, 76.7 E. U. These values differ from the experimental results of Table IV by -3.2, -1.0 and $+1.0$ E. U., respectively. Thus the above formula, though not precise, may be useful in roughly estimating the entropies of olefin hydrocarbons.

The Free Energies of the Compounds

We have also calculated the free energies of these eleven compounds by means of the third law of thermodynamics and the fundamental thermodynamic equation, $AF = AH - TAS$.

The essential data are given in Table VI. For obtaining the AH of formation for succinic acid we have used the heat of combustion reported by Verkade, Hartman and Coops,[12] and for dibenzoylethylene and dibenzoyl-

---

[11] Huffman, Parks and Daniels, THIS JOURNAL, 52, 1553 (1930).

[12] Verkade, Hartman and Coops, *Rec. trav. chim.*, 47,608 (1928).

ethane we have employed some unpublished values, recently obtained in our Laboratory by Mr. T. R. Lumb. In the cases of the remaining eight compounds we have taken the heats of combustion as given in the "International Critical Tables."[13] For our present purpose we have converted all these combustion data to 298.1°K. The ΔH_{298} values were then calculated by use of 68,330 and 94,270 cal.[4] for the heats of combustion of hydrogen and graphitic carbon, respectively. Column 4 contains the entropy of formation of each compound, which is simply the difference between its S_{298} and the corresponding values for the entropies of the elements contained therein. For this purpose the respective entropies of carbon and hydrogen were taken as **1.3** and 14.8 E. U.[4] per gram atom.

TABLE VI

THERMAL DATA AT 298.1°K.

The 15° cal. is used throughout and all weights have been reduced to a vacuum basis

Substance	Heat of combustion at constant pressure	ΔH_{298} Cal.	ΔS_{298} E U.	ΔF°_{298} Cal.
Fumaric acid (S)	319.900	−193,800	−122.7	−157,200
Maleic acid (S)	326.000	−187,700	−124.3	−160,600
Succinic acid (S)	356,900	−225,100	−150.0	−180,400
Trimethylethylene	795,700	− 17,300	− 95.0	+ 11,000
n-Pentane	833,100	− 48,300	−122.1	− 11,900
Cyclohexene	891,700	− 15,600	−104.0	+ 15,400
Methylcyclohexane	1,091,400	− 46,800	−157.0	0,000
Di-isobutylene	1,252,000	− 48,800	−175.8	+ 3,600
Stilbene (S)	1,764,600	+ 34,800	−135.8	+ 75,300
Dibenzoylethylene (S)	1,885,300	− 33,000	−171.1	+ 18,000
Dibenzoylethane (S)	1,920,700	− 65,900	−199.4	− 6,500

The molal free energies appear in the last column of the table. For comparative purposes the accuracy of these values is largely limited by the accuracy of the combustion data employed. In the cases of di-isobutylene and stilbene the present combustion values may be in error by as much as five thousand calories; and therefore the free energies are uncertain to this extent. On the other hand, in the cases of the three dibasic acids the combustion results are accurate to about three hundred calories. For the remaining compounds the values are probably reliable to one or two thousand calories.

The results for maleic and fumaric acids provide quantitative thermodynamic evidence on the interesting problem of geometrical isomerism. It is well known that the cis form, maleic acid, tends to change over into the *trans* isomer. fumaric acid, and the present data show that for the transformation $\Delta F_{298} = -6600$ cal. Hence, the reaction should ***go*** virtually to completion. Furthermore, such a marked difference in the values for two geometrical isomers serves to emphasize the specific influence of structure in determining the free energies of unsaturated compounds.

---

[13] **"International Critical Tables," Vol. V, p.** 163.

To develop further this last thesis, we have calculated from the data of this and the immediately preceding papers the free energy changes accompanying a number of reactions in which a saturated compound loses hydrogen and yields an olefinic or benzenoid compound. The results appear in Table VII. For completeness we have also included a value for the conversion of ethane into ethylene derived by Pease and Durgan.[14] It is evident that ΔF_{298} for the process of forming an olefin varies greatly, and no generalization concerning this quantity can be made with any certainty. However, the respective values for the production of ethylene, trimethylethylene and di-isobutylene indicate that ΔF for the dehydrogenation process probably decreases rapidly as we proceed up the series of olefin hydrocarbons.

In the two parallel cases involving the production of benzene and toluene from cyclohexane and methylcyclohexane, respectively, it is noteworthy that the ΔF values are practically identical, *i. e.*, about 24,000 cal. for the loss of three moles of hydrogen. Here the average ΔF_{298} per mole of hydrogen withdrawn (8000 cal.) is considerably less than in the case of any olefin compound except di-isobutylene.

TABLE VII

FREE ENERGY CHANGES ACCOMPANYING SOME DEHYDROGENATION REACTIONS

Saturated compound		Unsaturated compound	ΔF°_{298}, cal.
Succinic acid	=	H_2 + Maleic acid	+29,800
Succinic acid	=	H_2 + Fumaric acid	23,200

Before concluding, the authors wish to thank the Research Laboratory of the Standard Oil Development Company and Professor James B. Conant of Harvard University for the valuable compounds which made this research possible.

Summary

1. The specific heats of twelve organic compounds, including seven hydrocarbons, have been measured over a wide range of temperatures. The heats of fusion of five of the hydrocarbons and the heat of transition of cyclohexene have also been determined.

2. The entropies of eleven of the compounds have been calculated from these heat capacity data. In general the entropy of an unsaturated sub-

---

[14] Pease and Durgan, THIS JOURNAL, 50, 2715 (1928).

stance was found to be slightly less than that of the corresponding saturated compound.

3. The corresponding free energies have also been calculated. The free energy change in dehydrogenation reactions was found to vary greatly, and it is apparent that the effect of unsaturation in determining the free energy value of an organic compound is very specific.

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

THE ALCOHOLYSIS OF CERTAIN 1,3-DIKETONES AND BETA-KETONIC ESTERS

BY WALTER M. KUTZ AND HOMER ADKINS

RECEIVED JULY 3, 1930 PUBLISHED NOVEMBER 5, 1930

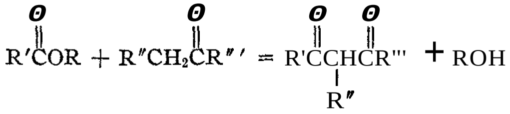
This investigation was undertaken originally for the purpose of studying the influence of structure on the extent of formation and cleavage of carbon to carbon linkages in organic compounds. The ideal condition for a study of this nature would be a perfectly reversible reaction in which the concentration of various sets of reactants at the equilibrium point could be measured accurately. The quantitative work which has been done previously in connection with this problem has been concerned chiefly with the extent of dissociation of hexa-substituted ethanes. The interpretation of the experimental data in terms of the relation of structure to the strength of the carbon to carbon linkage between the substituted methyl groups is complicated by the fact that the dissociated radical is apparently in equilibrium with compounds having a quinoid structure. In addition to the rather large volume of literature upon the hexa-substituted ethanes there has been, also, a paper by Miss Edith Usherwood[1] upon the position of the equilibrium point in the aldolization of isobutyric aldehyde.

The Claisen or acetoacetic ester condensation since the publication of Dieckmann's work[2] has been considered to be a reversible reaction, and it seemed upon preliminary consideration to be better suited than any other reaction for an investigation of the relationship of the structure of a compound to the strength of carbon to carbon linkages. In general terms the Claisen synthesis may be considered to involve the elimination of a molecule of alcohol through the reaction of the alkoxy group of an ester with a hydrogen on a carbon atom alpha to a carbonyl or other activating group in the presence of such reagents as sodium, sodium ethoxide or sodamide. The type reaction may be represented as

---

[1] **Usherwood,** *J. Chem. Soc.*, 123, 1917 (1923).

[2] Dieckmann, *Ber.*, **33,** 2670 (1900).



$$R'\overset{O}{\overset{\|}{C}}OR + R''CH_2\overset{O}{\overset{\|}{C}}R''' = R'\overset{O}{\overset{\|}{C}}\underset{R''}{\underset{|}{CH}}\overset{O}{\overset{\|}{C}}R''' + ROH$$

It is obvious that this simple formulation is very far from giving an adequate picture of this reaction. Sodium ethoxide for example forms addition compounds with the ester and the ketones. The ketones also compete through their enol forms for the metal of the alkoxide. However, these complications do not make it impossible profitably to utilize this action for the study of the relation of structure to the extent of the cleavage of the carbon linkage, although they may make very difficult an interpretation of the results. An attempt was therefore made to determine the concentration at equilibrium of the reactants in the synthesis and alcoholysis of acetoacetic ester.

Higley[3] found that he could obtain acetoacetic ester in a 36% yield (based on the sodium ethoxide) through the reaction of **0.4** mole of ethyl acetate and **0.14** mole of sodium ethoxide. He believed that this represented the concentration of acetoacetic ester at equilibrium. McElvain[4] showed that a **68%** yield of the keto ester (based on the sodium ethoxide) could be obtained if the alcohol formed in the condensation were distilled out of the reaction mixture before the ester was isolated. He used 6 moles of ethyl acetate and *0.5* mole of sodium ethoxide. The reaction mixture was not homogeneous after the removal of the alcohol, so that both of these factors tended to drive the condensation toward completion. McElvain's results have been duplicated and the extent of condensation of ethyl acetate in a homogeneous reaction mixture determined both by synthesis and alcoholysis to be from **44** to 50% in so far as this may be judged through the isolation of acetoacetic ester. This last statement is based upon the results of the following experiments in which the homogeneity of the reaction mixture was maintained through the use of a large excess of ethyl acetate.

1. One-half mole of sodium ethoxide and 6 moles of ethyl acetate were refluxed for periods of from ten to ninety-six hours. The reaction mixture was then acidified with 35 ml. of acetic acid in 70 ml. of water and the aqueous layer extracted twice with 50-ml. quantities of ether after the removal of the layer of acetoacetic ester. The fractionation of the products gave from 32 to 33 g. of ester boiling at 84–87° (25 mm.). This represents a yield of 50 to 51%.

2. One-half mole each of acetoacetic ester, of sodium ethoxide and of ethanol were refluxed for twenty-four hours in six moles of ethyl acetate. The reaction mixture was worked up as described above and from 29 to 30 g. of acetoacetic ester obtained.

3. One-half mole of sodium ethoxide and six moles of ethyl acetate were allowed to react and the alcohol and excess simple ester distilled off as described by McElvain. One mole of ethanol and six moles of ethyl acetate were then added to the solid reaction products and the whole refluxed for twenty-four or forty-eight hours. Upon working up

[4] McElvain, THIS JOURNAL, 51, 3124 (1929).

the reaction mixture 28.5 to 29 g. of acetoacetic ester was obtained. This is to be contrasted with the yields of from 43 to 44 g. of keto ester obtained if it were isolated before the addition of the ethanol and ethyl acetate or before the second refluxing of the mixture but after the addition of ethanol and ethyl acetate. The last experiment was performed in order to make sure that the higher yields obtained where the alcohol was distilled off were not due at least in part to the greater ease of isolation of the ester.

The condensation of esters other than ethyl acetate with the formation of beta ketonic esters does not lend itself to a study of the relationship of structure to extent of reaction. It is possible to vary one group at a time only through the condensation of dissimilar molecules of ester and this makes possible the formation of two or three different beta ketonic esters in the reaction mixture, thus greatly increasing the difficulties of analysis. In the case of the 1,3-diketones a simple synthesis and alcoholysis is possible only when the ester concerned is incapable of condensation with itself, and the monoketone is of such a structure that it can condense with the ester to form only a single compound. The structures of dibenzoylmethane and its derivatives are such that only simple alcoholysis and synthesis are possible and so these diketones were selected as the basis of study. Broderick in 1927[5] showed that the percentage of diketone present in the reaction mixtures was the same irrespective of whether he started with dibenzoylmethane and alcohol or ethyl benzoate and acetophenone. However, this did not represent a true equilibrium point because of the separation of the solid salt of the diketone. An extensive search has been carried on since that time in order to discover an inert solvent in which homogeneity could be maintained during the synthesis or alcoholysis of a diketone. There has been found no inert solvent in which the sodium, potassium or lithium salt of a diketone was sufficiently soluble to permit determinations of the extent of alcoholysis or synthesis in the presence of a catalyst for the latter reaction. Attention was therefore directed toward the study of the relationship of structure to the rate of alcoholysis in the presence of hydrogen chloride,[6] and of sodium ethoxide.

There are several reasons why the relative rates of alcoholysis of 1,3-diketones cannot be determined and compared as accurately in the presence of sodium ethoxide as when hydrogen chloride is the catalyst. For example, the former reagent catalyzes "side reactions" such as the acetoacetic ester condensation. This may be minimized and it is believed practically eliminated through the use of a large molecular excess of alcohol. However, as may be seen from an inspection of the data shown in the figures, the ultimate percentage of alcoholysis, calculated on the amount of diketone used, is in many cases considerably less than 100%, this despite the fact that with the ratio of one mole of sodium ethoxide to two moles of acetylbenzoylmethane all of the diketone had disappeared after one hun-

[6] Adkins, Kutz and Coffman, THIS JOURNAL, 52, 3212 (1930).

dred hours. This failure to obtain a 100% recovery of ester is no doubt connected with the fact that it is impractical to determine how much ester is lost during the analysis, due to saponification or other reactions, as was done in the study of alcoholysis involving the use of hydrogen chloride. Perhaps the most serious obstacle to a precise comparison of the rates of alcoholysis of various diketones is the fact that they differ so greatly with respect to their sensitivity toward the catalyst. This makes it impossible to compare any considerable group of diketones or keto esters under identical experimental conditions.

The rates of alcoholysis at 60° of diacetylmethane, acetylbenzoylmethane, benzyldiacetylmethane, dibenzyldiacetylmethane, ethyldiacetylmethane, benzylacetylbenzoylmethane, ethyl acetoacetate, ethyl ethylacetoacetate, ethyl benzylacetoacetate, ethyl diethylacetoacetate and ethyl dibenzylacetoacetate were measured in ethanol in the presence of various amounts of sodium ethoxide. Approximately 0.01 mole of the diketone or keto ester with the desired amount of sodium ethoxide was dissolved in enough ethanol to make the volume of the reaction mixture 40 ml. The reaction was stopped after the alcoholysis had proceeded for the desired length of time by adding an excess of a normal solution of hydrogen chloride in ethanol. After shaking the mixture, 2 ml. of phenylhydrazine was added to combine with the excess hydrogen chloride and ketones. After standing for two or three hours the ester was distilled out and determined as described in our previous paper. In only one case was any modification of this procedure necessary. Ethyl ethylacetoacetate gave ethyl butyrate as well as ethyl acetate upon alcoholysis so that two 20-ml. portions of propanol were added and distilled out after the normal distillation procedure had been followed.

Diacetylmethane, acetylbenzoylmethane, ethyldiacetylmethane, benzyldiacetylmethane, dibenzyldiacetylmethane and benzylacetylbenzoylmethane were prepared and had the physical constants described in a previous paper. Acetoacetic ester was dried over calcium chloride and fractionated from the commercial products, b. p. 85–87° (25 mm.), d_{25}^{25} 1.012. Ethyl ethylacetoacetate was prepared from acetoacetic ester, using toluene as a medium; the yield was 60% of product boiling at 100–102° (25 mm.), d_{25}^{25} 0.9690. Ethyl diethylacetoacetate was prepared from the monoethyl compound, the yield being 40 to 50%; b. p. 115–117° (25 mm.), d_{25}^{25} 0.9435.[7] Ethyl benzylacetoacetate was obtained in a 58% yield, b. p. 165–170° (25 mm.), d_{25}^{25} 1.050.[8] The ethyl dibenzylacetoacetate after crystallization from ethanol had a melting point of 56–57°.[9] Diethyldibenzoylmethane was prepared in a yield of 35% through the re-

action of diethyl malonyl dichloride with benzene in the presence of aluminum chloride. The diketone melted at 102–103°.[10]

The rate of alcoholysis of five beta ketonic esters and six 1,3-diketones for various concentrations of sodium ethoxide is shown in Figs. 1, 2 and 3. The molar ratio of sodium ethoxide to diketone or keto ester is shown in parentheses for each curve. The rate of alcoholysis of diacetylmethane and acetylbenzoylmethane was increased by almost 100% when the ratio of sodium ethoxide to diketone was increased from 1:5 to 1:2. A further increase to a ratio of 1:1 brought about what was apparently a small decrease in the rate of alcoholysis but it is believed that this was due to the greater loss in ethyl acetate prior to analysis rather than to a real decrease in the rate of alcoholysis.

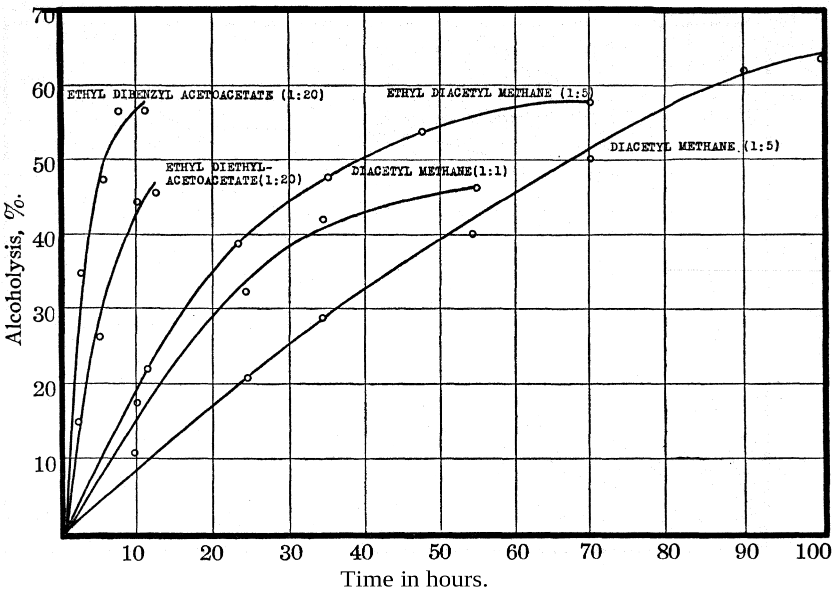

Fig. 1.—Rates of alcoholysis of various 1,3-diketones and β-keto esters. The molecular ratio of sodium ethoxide to dicarbonyl compound is shown in parentheses for each curve.

There was very little difference between the rates of alcoholysis of diacetylmethane and acetylbenzoylmethane irrespective of whether the comparison was made at a ratio of sodium ethoxide to diketone of 1:5 or 1:2.

The keto esters undergo alcoholysis more slowly, for a given ratio of keto compound to sodium ethoxide, than do the 1,3-diketones. This is true irrespective of whether the comparison is made between the unsubstituted compounds or between those in which one or more substitutions have been made on the carbon atom between the carbonyl groups.

---

[10] Freund and Fleischer, *Ann.*, 373,296 (1910).

Substitution of ethyl or benzyl groups on the carbon atom between the carbonyl groups greatly increases the rate of alcoholysis of both keto esters and diketones for a given ratio of keto compound to sodium ethoxide. This may be expressed in another way by saying that it is feasible to cleave a monosubstituted compound, within a given period, with a very much lower ratio of sodium ethoxide to keto compound than is possible in the case of the parent substance. In the case of the disubstituted compounds the rate of alcoholysis is relatively very rapid even where there is only one mole of sodium ethoxide for twenty moles of dicarbonyl compound. However, even a qualitative comparison is perhaps not justifiable, for in the case of the unsubstituted and of the monosubstituted compounds there is the probability that a very considerable portion of the sodium ethoxide reacts with the enol and is thus eliminated as a catalyst. There is no possibility of this in the case of the disubstituted dicarbonyl compounds unless enolization occurs by the migration of a hydrogen from the methyl group at the end of the molecule. Even this is not possible for diethyldibenzoylmethane, which readily undergoes alkaline alcoholysis and hydrolysis.

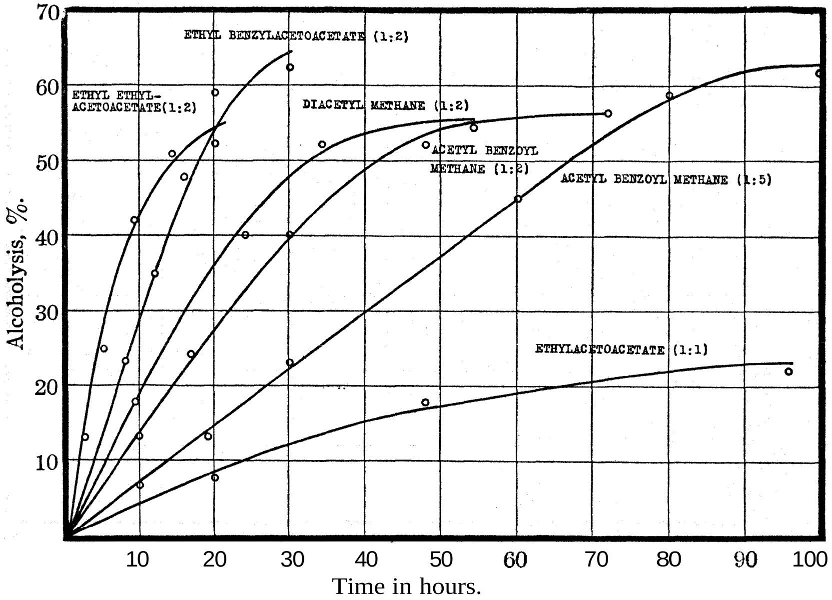

Fig. 2.—Rates of alcoholysis of various 1.3-diketones and β-keto esters. The molecular ratio of sodium ethoxide to dicarbonyl compound is shown in parentheses for each curve.

Two grams of this diketone dissolved in 50 ml. of ethanol was allowed to undergo alcoholysis at 60° for twelve hours in the presence of an equimolecular amount of sodium ethoxide. Acidification with 50 ml. of dilute aqueous hydrochloric acid did not give a crystalline precipitate and it was considered that the diketone had been completely split into ethyl benzoate and the corresponding monoketone. The reaction mixture was then made alkaline with solid sodium hydroxide and the ester saponified. After evaporation to dryness, the residue was dissolved in 200 ml. of water and washed with ether. Evaporation of the water solution to a small volume, acidification with hydrochloric acid and cooling precipitated out 0.819 or 94% of the theoretical amount of benzoic acid. One and four-tenths grams of diethyldibenzoylmethane was hydrolyzed at 60° for ten hours in 75 ml. of a 1% solution of sodium hydroxide in 80% ethanol. After evaporation to dryness, the residue was dissolved in 200 ml. of water, washed with ether and 0.5960 g. of benzoic acid precipitated with sulfuric acid. The yield was thus 98% of the theoretical.

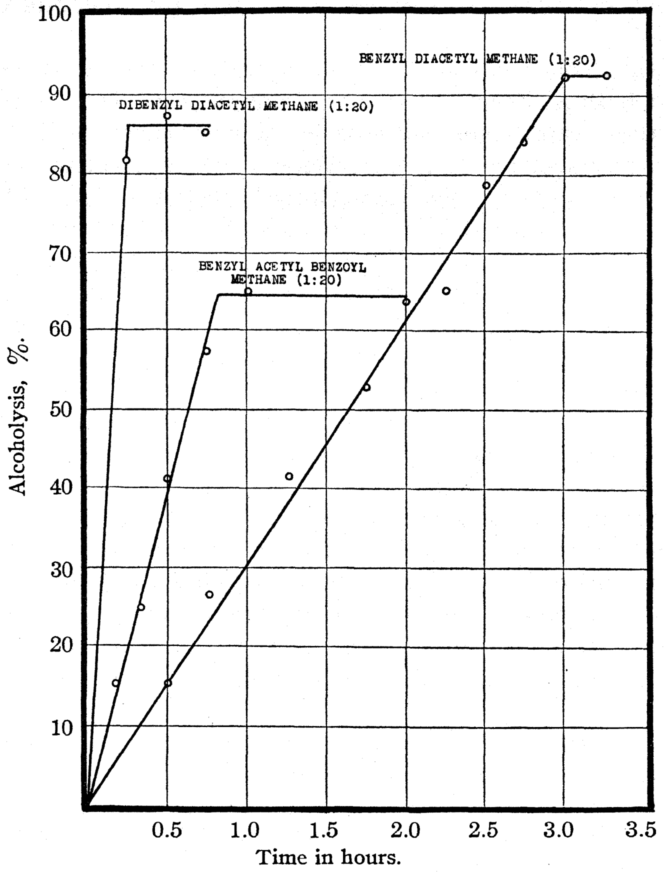

Fig. 3.—Rates of alcoholysis of three 1,3-diketones.

The high reactivity of the substituted keto esters in alkaline alcoholysis as compared with the unsubstituted esters is in accord with the qualitative experiments of Dieckmann[11] on the cleavage of substituted acetoacetic esters. However, his inference from these experiments with regard to the concentration at equilibrium of acetoacetic ester and its derivatives is unjustified by any experimental work, and in so far as it applies to the non-condensation of isobutyric ester has been shown by McElvain to be incorrect.

The rate of alcoholysis of six of the diketones has been determined in the presence of both hydrogen chloride and sodium ethoxide. As previously reported, these compounds in the order of decreasing reactivity are as follows: diacetylmethane, ethyldiacetylmethane, acetylbenzoylmethane, benzoyldiacetylmethane, benzylacetylbenzoylmethane and dibenzyldiacetylmethane. This is also the order of reactivity (with one exception) of the diketones with respect to sodium ethoxide except that it is one of increasing reactivity. The exception to this statement is acetylbenzoylmethane, which is slightly less reactive in the presence of sodium ethoxide than would be expected on the basis of its reactivity in the presence of hydrogen chloride. There can be no doubt that in general this reversal of reactivity with respect to the two conditions of alcoholysis holds true and that the differences in reactivity are quite large. For example, taking the end members of the series referred to above, it was found that in the presence of hydrogen chloride, diacetylmethane was in the vicinity of ten times as reactive as its dibenzyl derivative, while in the presence of sodium ethoxide the dibenzyl derivative was one or two hundred times as reactive as the parent substance. A similar comparison cannot be made for the keto esters because experimental conditions have not as yet been found in which these compounds undergo alcoholysis in the presence of hydrogen chloride.

It was previously pointed out that there seemed to be a parallelism between the extent of enolization of a 1,3-diketone and its reactivity toward alcoholysis in the presence of hydrogen chloride. Since the order of reactivity of the 1,3-diketones is the opposite in alkaline alcoholysis to that in acid alcoholysis, it seems reasonable to consider this as evidence in support of the hypothesis of Bradley and Robinson that the cleavage of diketones in alkaline medium takes place through the keto rather than the enol compound. This view is also in accord with the very high reactivity in alkaline alcoholysis of the disubstituted 1,3-diketones and keto esters which are incapable of enolization. It is quite possible that cleavage also occurs through the enol compound since Fieser[12] has shown that a fixed enol of a 1,3-diketone readily undergoes cleavage.

---

Summary

It has been shown that the amount of acetoacetic ester to be obtained from the reaction mixture is the same irrespective of whether it is synthesized from ethyl acetate and sodium ethoxide or remains from the alcoholysis of an amount of acetoacetic ester molecularly equivalent to the amount of sodium ethoxide used in the synthetic reaction. All attempts to make similar determinations on the synthesis and alcoholysis of 1,3-diketones have failed because no conditions have been found under which homogeneity would be maintained during the synthesis and alcoholysis.

The rates of alcoholysis of six 1,3-diketones and five beta keto esters have been determined at 60° in the presence of various ratios of sodium ethoxide. The keto esters were found to be more stable than the diketones toward alcoholysis for a given ratio of sodium ethoxide. Substitution on the carbon atom between the two carbonyl groups very considerably increased the rate of alcoholysis in the presence of sodium ethoxide. This effect reached its maximum in the case of the diacyl dialkyl methanes, which underwent alcoholysis hundreds of times as rapidly as the diacyl methanes.

When the six diketones whose reactivity was measured in the presence of both hydrogen chloride and sodium ethoxide were arranged in the order of decreasing reactivity with respect to alcoholysis in the presence of hydrogen chloride, they were found to be arranged (with one exception) in the order of increasing reactivity toward alcoholysis in the presence of sodium ethoxide. Diethyldibenzoylmethane, which is incapable of enolization, readily underwent alkaline alcoholysis and hydrolysis. These facts taken in conjunction with the parallelism between extent of enolization and rate of acid alcoholysis offer support to the hypothesis of Bradley and Robinson that alkaline cleavage of 1,3-diketones takes place through the reaction of the carbonyl rather than of the enol form of the diketone.

THE MOLECULAR WEIGHT OF COCOSIN

BY BERTIL SJÖGREN AND ROMUALD SPYCHALSKI

RECEIVED JULY 5, 1930 PUBLISHED NOVEMBER 5, 1930

The oil-seed globulins, edestin,[1] amandin[2] and excelsin,[2] as well as the other vegetable proteins, legumin,[3] *r*-phycocyan,[4,5] *r*-phycoerythrin[4,5] and *c*-phycocyan,[5] so far studied in this Laboratory by means of ultracentrifugal analysis, have all proved to be monodisperse and to belong to the fourth group of proteins, having a molecular weight of about 208,000, that is, approximately six times the weight of ovalbumin.6 They were found to be very stable, but with a tendency to dissociate into lower multiples of 34,500 at higher PH values.[6]

In order to get more information concerning this large class of proteins, we took up the coconut globulin, in the following called cocosin,[7] for an ultracentrifugal examination. In chemical composition cocosin resembles excelsin very much, both having a high sulfur content, slightly exceeding 1%. With respect to solubility cocosin and edestin are almost identical, in so far as high salt concentrations are necessary to hold them in solution. Cocosin is obtained in a definite crystalline state, which may be taken as an indication of its homogeneity. Therefore the result arrived at was quite surprising: the protein was easily decomposed during the preparation and gave an unstable and polydisperse product.

Preparation of Material.—The nuts were freed from shells and skins, then ground in a mill to a fine paste (340 g.) and suspended in 10% sodium chloride solution (3000 cc.). Enough toluene was added to serve both as a preservative and as a solvent for the fat. The mixture was digested with stirring at room temperature for twenty-four hours. A test showed that no more protein could be extracted after this treatment. The bulk of the insoluble part was removed by means of a cloth filter. The solution was further freed from suspended particles and from oil and fat partly dissolved in the toluene by filtering and centrifuging. Saturated ammonium sulfate solution was then added to 60% saturation. After standing for one day at 5° the precipitate was filtered off and washed with half-saturated ammonium sulfate solution. The protein precipitate was dissolved in phosphate buffer of *PH* 6.7 (0.033 *M* in KH_2PO_4 and 0.033 M in Na_2HPO_4), containing 7% of sodium chloride. This high *PH* and salt content was used in order to increase the solubility. The solution was then dialyzed in the ice box for six days against the same buffer; volume of solution, 20 cc.; concentration, 3.05% (Ma-

terial I). The substance was comparatively homogeneous, consisting principally of one component.

It may be mentioned that the above method of preparation was used for preparing another batch of cocosin, the final product, however, being dissolved in 10% sodium chloride solution. This material was very non-homogeneous, breaking up more and more with time. The same result was obtained when coconut meal was used instead of the fresh nuts.

Before carrying out these preparations we also made an attempt to get the protein in a pure state by dialyzing the solution against water after precipitation with ammonium sulfate and dissolving in 10% sodium chloride. When working with proteins we have often had the opportunity to observe that some of them, and especially the oil-seed globulin, are very sensitive to long water dialysis. Hydrolysis and denaturation then occur. Cocosin showed this phenomenon in a pronounced way, the crystallized cocosin material prepared by dialysis against water proving to be very difficult to bring into solution. By centrifugal analysis this material was found to be quite decomposed.

To avoid these difficulties, especially the using of high salt contents, which complicates the centrifugal analysis, we modified the method in the following way. After precipitation with crystallized ammonium sulfate to 60% saturation, the globulin was dissolved in 5% sodium chloride solution. Hereafter, in order to increase the solubility, Na_2HPO_4 was added to a concentration of 0.017 M. Then, before a second precipitation, the P_H of the solution was decreased to 5.5 by means of KH_2PO_4. This brought about no change in the precipitation limits. After treatment as before, cocosin was completely dissolved in Na_2HPO_4 (0.2 M) and dialyzed against the same solvent for six days. From 700 g. of coconut paste we derived 30 cc. of solution containing 0.99% cocosin (Material II). The protein was found to be a mixture of two components.

In our last attempt to prepare cocosin we worked as quickly as possible, also using the simplest method of purification. After digesting the paste (340 g.) and precipitating once as in the case of Material I, the product was dissolved in phosphate buffer of P_H 6.7 (0.033 M in KH_2PO_4 and 0.033 M in Na_2HPO_4), containing also 4% of sodium chloride, and dialyzed against the same buffer in the ice box for five days; volume of solution, 50 cc.; concentration, 0.74% (Material III). This substance was also a mixture of two molecular species.

Specific Volume and Light Absorption.—For both these measurements Material III was used at a P_H of 6.7 with solvent as above.

The partial specific volume was determined pycnometrically at 20.2°. Two determinations at different concentrations gave the mean value 0.746 in agreement with the values obtained for the other proteins which follow the law of simple multiples.

The light absorption was studied by means of the Judd-Lewis spectrophotometer as described in earlier communications. The protein concentrations were 0.15 and 0.074% with a thickness of layer 2.0 cm. The absorption maximum $\epsilon/c = 7.0$ was situated at 280 $m\mu$, and the minimum $\epsilon/c = 2.7$ at 255 $m\mu$. The absorption curve is given in Fig. 1.

Determination of Sedimentation Constant and Different Molecular Components.—The runs were carried out with the high-speed oil-turbine ultracentrifuge. In the case of Material I the speed was 23,000, in the other runs about 43,000, r. p. m. The time varied from two to three and one-half hours, the temperature during each run from 20 to 23°, other experimental conditions being as usual.

The sedimentation constant is given by $s = (dx/dt) \times 1/(0^2x)$, where x is the distance from axis of rotation, ω the angular velocity and t the time. In cases of non-homogeneous material the amounts of the different molecular species may be calculated from their sedimentation and diffusion constants, reducing the galvanometer deflections of the microphotometer curves to represent relative concentrations.[1,2,4] The centrifugal force must be large enough to give a marked separation of the components. Thus, at the highest possible speed, *viz.*, 45,000 r. p. m., giving a centrifugal force of about 120,000 times that of gravity, it is easy to observe a component of weight 6 × 34,500 in mixture with a substance of molecular weight 3, 2 or 1 X 34,500. It is also possible to distinguish a component of 104,000 from one of 34,500 but not from one of 68,000, without using a very long time of centrifuging. Owing to the difficulties of taking into account the difference in light absorption between the normal and the decomposed product, the calculations of the relative amounts of the components should only be regarded as an approximation.

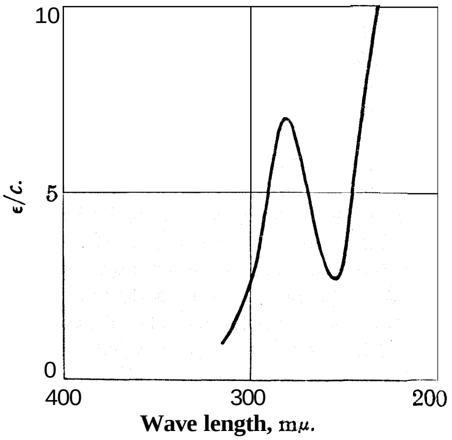

Fig. 1.—Light absorption of cocosin.

In Table I the determinations with the Materials I, II and III are summarized. The other preparations gave such unstable products that we refrain from mentioning the values obtained.

[a] 0.033 M in NaOH. [b] 0.067 M in NaOH. [c] Mixture of approximately 65% molecules of weight 208,000 and 35% of weight 104,000. [d] Mixture of approx. 75% 208,000, 25% 104,000. [e] Mixture of approximately 50% 208,000, 50% 104,000. [f] Decomposed; 15% non-centrifugible products.

As may be seen from the table, Material I was almost homogeneous, giving a value of s quite in agreement with the values obtained for the other proteins possessing a molecular weight of 208,000. A small amount of a lighter component was present.

There were at least two molecular species present in Material II. The stock solution was a mixture of about 65% molecules of weight 208,000 and 35% of weight 104,000. Assuming the cocosin molecule to be of weight 208,000, then the presence of the smaller component can be considered as the first stage of the protein cleavage, caused by the high PH. This splitting-up of the molecule with increasing PH has in earlier cases, as a rule, been found to be reversible. Thus if the PH of the solution is brought back to a value lying in the stability region, one would expect a monodisperse product. The stock solution of Material II was dialyzed against a phosphate buffer of PH 6.0 (0.17 *M* in KH_2PO_4 and 0.03 *M* in Na_2HPO_4, containing 4% of sodium chloride) for five days. By a second analysis we found that the amount of the smaller component had decreased. In order to complete the reaction in this direction the dialysis was continued for six days more. During this treatment the cocosin was, however, totally decomposed which behavior is in line with the former experience on the high sensitivity of the oil-seed globulins to prolonged dialysis.

Material III proved to be somewhat more homogeneous in so far as the stock solution had approximately a composition of 75% molecules of weight 208,000 and 25% of weight 104,000. In more alkaline solutions the protein was broken up into units of one-half the normal molecular weight and at still higher PH values into particles of unequal size. A run was also made at a PH of 5.5, using phosphate buffer and 9% sodium chloride, which confirmed the result obtained at PH 6.7. Because of the very high salt content, involving great corrections, the values are not reproduced here.

Determination of Molecular Weight.—For the sedimentation–equilibrium method, the molecular weight is given by the relation

$$M = \frac{2RT \ln (c_2/c_1)}{(1 - V\rho)\omega^2(x_2^2 - x_1^2)}$$

where c_1 and c_2 are the concentrations at the distances x_1 and x_2 from the center of rotation, R the gas constant, T the absolute temperature, V the partial specific volume of the solute, p the density of the solvent and w the angular velocity.

Two runs were made with Material III at PH 6.7 using the same buffer as before and the concentration 0.15%. In Fig. 2 the values of the molecular weight are plotted against the distance from the center of rotation. As may be seen from the diagram the material was non-homogeneous with regard to molecular weight, giving values from approximately 215,000 down to 110,000 with the higher values all lying around 208,000. As the time between the two runs was nearly a week, the slight difference observed may be interpreted as a further splitting-up of the cocosin.

The results of our measurements make it extremely probable that normal native cocosin has a molecular weight of the same magnitude as the other oil-seed globulins so far analyzed, *viz.*, six times the weight of ovalbumin or 208,000. Their molecules are all spherical with a molecular radius of about $3.95\ m\mu$. The component with a molecular weight half that of the normal present in the cocosin samples studied may be considered as the first decomposition product of the protein cleavage.

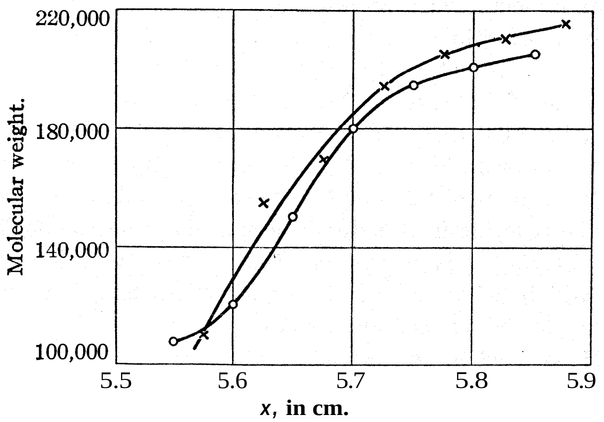

Fig. 2.—Variation of molecular weight with distance from axis of rotation: —X—. Run 1; —O— Run 2, one week later.

The expenses connected with this work have been defrayed by a grant from the foundation "Therese och Johan Anderssons Minne."

Summary

1. By means of ultracentrifugal methods an attempt was made to determine the molecular weight of the coconut globulin, called cocosin.

2. This protein was found to be rather unstable, being easily decomposed during the process of preparation.

3. The centrifugal analysis proved cocosin to be a mixture of two main components of weight about 208,000 and 104,000 with the larger molecules present in much greater amounts than the smaller ones.

4. It was considered as extremely probable that native cocosin has a molecular weight within experimental limits identical with the other oil-seed globulins earlier studied, *viz.*, 208,000, and that the small fraction present of weight half of this normal molecule represents the first stage of the protein cleavage.

UNSATURATION PHENOMENA OF ACETYLENIC ACIDS AND ESTERS.
III. THE CONSTITUTION OF SOME MERCURY DERIVATIVES

By William Whalley Myddleton, Arthur W. Barrett and John H. Seager

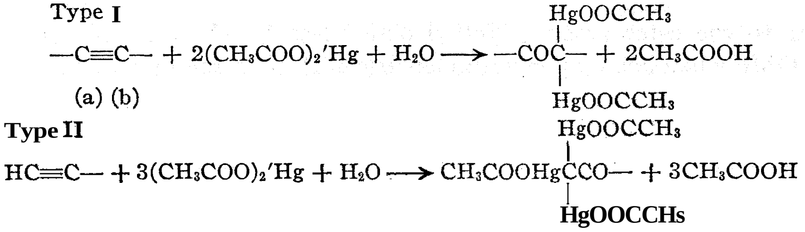
Received July 7,1930 Published November 5.1930

Earlier communications published from these Laboratories[1] described the isolation of mercury derivatives formed by the action of mercuric acetate upon various acetylenic acids and esters in acetic acid solution. The acetylenic compounds employed were of two types: I, $CH_3(CH_2)'_mC\equiv C(CH_2)'_nCOOR$, where R is alkyl or hydrogen and where the values of m and n were

$m = 0, n = 7$ in 9–10 undecinoic acid
$m = 7, n = 7$ in stearolic acid
$m = 7, n = 11$ in behenolic acid

and II, $HC\equiv C(CH_2)'_nCOOR$, where $n = 8$ in 10,11-undecinoic acid.

The mode of formation and the composition of the mercury compounds as well as the nature of the products derived from them by decomposition with hydrochloric acid were in accord with the following interpretation of the action of mercuric acetate upon the acetylenic linkage.



Type I

$$-C\equiv C- + 2(CH_3COO)_2'Hg + H_2O \longrightarrow -CO\overset{HgOOCCH_3}{\underset{HgOOCCH_3}{C}}- + 2CH_3COOH$$

(a) (b)

Type II

$$HC\equiv C- + 3(CH_3COO)_2'Hg + H_2O \longrightarrow CH_3COOHg\overset{HgOOCCH_3}{\underset{HgOOCCHs}{C}}CO- + 3CH_3COOH$$

In Type II the acetylenic hydrogen atom is substituted while the usual addition takes place at the triple bond.

During decomposition of the mercury compounds with hydrochloric acid, each acetoxymercuri group was assumed to be replaced by hydrogen with formation of a ketonic compound free from mercury. In the case of 9,10-undecinoic acid (Type I) and its ethyl ester, two isomeric ketonic derivatives were isolated, thus establishing an alternative reaction in which the acetoxymercuri groups were added to the carbon atom (a) and the oxygen atom to (b) in the equation given above.

The present communication describes further investigations upon the constitution of the mercury compounds.

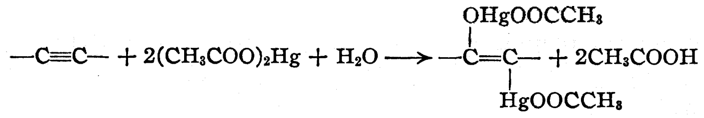
Mercuration of Acetylenic Compounds of Type I

In the mercury derivatives from esters of Type I there appeared to be a difference in reactivity of the two mercury atoms toward caustic alkalies and hydrogen sulfide but this could not be established by the isolation of pure products from these reactions. An alternative constitution was therefore tentatively assigned to the mercury derivatives to account for a difference in reactivity of the mercury groups and evidence of this constitution was sought and discovered in other directions. The alternative constitution was derived from the following interpretation of the action of mercuric acetate upon the acetylenic bond.



$$-C\equiv C- + 2(CH_3COO)_2Hg + H_2O \longrightarrow -\overset{\overset{\displaystyle OHgOOCCH_3}{|}}{C}=\underset{\underset{\displaystyle HgOOCCH_3}{|}}{C}- + 2CH_3COOH$$

The resulting mercury derivative is unsaturated and the first action of hydrochloric acid in causing the replacement of acetoxymercuri groups by hydrogen would be to yield an enolic product containing the group $-C(OH)=CH-$. Rapid transformation to the ketonic form might be anticipated under the influence of the mineral acid. Indeed no signs of an enolic form were discovered during the decomposition of the mercury derivatives already described. The most favorable conditions for observing the intermediate formation of an enolic derivative were sought by choosing an acetylenic ester with a shorter carbon chain and with the acetylenic bond near to the ester group. Methyl octine-1-carboxylate $CH_3(CH_2)_5C\equiv C-COOMe$ when acted upon with mercuric acetate in the manner previously described gave a mercury derivative analyzing in accordance with the composition $CH_3(CH_2)_5C(OHgOOCCH_3)=C(HgOOCCH_3)COOMe$.

The decomposition of this compound with concentrated hydrochloric acid gave an ester which, as soon as liberated, gave a deep violet coloration with ferric chloride in alcoholic solution, indicating the presence of an enolic form. Analysis of the ester by the method of Kurt Meyer[2] indicated the presence of 13.5% of the enolic form.

The mercury derivative was very slightly soluble in hot alcohol and when the cooled solution was mixed with two drops of a neutral aqueous solution of ferric chloride it gave in about one minute a faint reddish-violet coloration indicating an enolic structure. In this reaction there is a direct replacement of an acetoxymercuri group by iron to give the colored ferric salt of an enolic compound. To facilitate this reaction a mercury derivative more soluble in alcohol was sought by introducing a phenyl group into the acetylene. Ethyl phenylpropiolate $C_6H_5C\equiv CCOOEt$ gave a mercury derivative melting with decomposition at 192° and analyzing in agreement with the composition $C_6H_5C(OHgOOCCH_3)=C(HgOOCCH_3)COOEt$. It was

---

[2] K. Meyer, Ber., 44, 2718 (1911).

readily soluble in hot alcohol and moderately soluble in cold. The cold alcoholic solution gave in a few seconds a deep reddish-violet coloration with two drops of aqueous ferric chloride. The ester liberated from the mercury derivative by the action of hydrochloric acid gave a similar coloration and was shown by Kurt Meyer's method to contain 20% of the enolic form an hour after isolation.

The Action of Halogens on the Mercury Derivatives.—As a means of further distinguishing between the two structures $—COC(HgOOCCH_3)_2—$ and $—C(OHgOOCCH_3)=C(HgOOCCH_3)—$ the action of halogens was investigated. In the first case chlorine would be expected to produce a dichloro ketone by causing the replacement of each acetoxymercuri group by a chlorine atom; in the second case a monochloro ketone would result through the intermediate formation of $—C(OCl)=CCl—$ which after hydrolysis in the aqueous acid used in the isolation would lead to $—C(OH)=CCl—$ and finally the ketonic form $—COCHCl—$.

The mercury derivatives prepared from stearolic acid and behenolic acid were made to react with chlorine and with bromine in refined petroleum ether, in chloroform and in glacial acetic acid. Mono-halogen ketonic acids were formed quantitatively. The mercury derivatives from methyl octine-1-carboxylate and from ethyl phenylpropiolate gave dibromo ketonic esters when decomposed with bromine. As in the last two instances the mercury derivatives developed a violet coloration in contact with alcoholic ferric chloride, it cannot be assumed that the formation of a dibromo ketonic ester is evidence that two mercury atoms are attached to one carbon atom. To reconcile the two reactions it is necessary to assume that during treatment with bromine the following changes take place.

$$—C(OHgOOCCH_3)=C(HgOOCCH_3)— \xrightarrow{+Br_2} —C(OBr)=CBr— \xrightarrow{+Br_2}$$
$$—C(OBr)BrCBr_2— \xrightarrow{-Br_2} —COCBr_2—$$

The dibromo ketonic ester prepared in this way from ethyl phenylpropiolate gives the theoretical yield of benzoic acid after hydrolysis with a semi-normal alcoholic solution of potassium hydroxide, thus proving that when mercuric acetate acts upon ethyl phenylpropiolate under the stated conditions the mercury groups enter the side chain exclusively. Phenylpropiolic acid is also mercurated exclusively in the side chain and the derivative formed yields with bromine benzoyl dibromo-acetic acid, which is recovered as w-dibromo-acetophenone after loss of carbon dioxide.

Mercuration of Acetylenic Compounds of Type II

The following acetylenic compounds containing the group $HC\equiv C—$ were converted into mercury derivatives by the action of mercuric acetate in acetic acid solution.

$HC\equiv C(CH_2)_2COOH$	10.11-undecinoic acid
$CH_3(CH_2)_4C\equiv CH$	Heptine-1
$CH_3(CH_2)_5C\equiv CH$	Octine-1
$C_6H_5C\equiv CH$	Phenylacetylene

The analysis of the products indicates the presence of three acetoxymercuri groups, and methyl ketones are formed by decomposition with hydrochloric acid.

The mercury derivative from phenylacetylene cannot be decomposed with bromine at a temperature sufficiently low to yield a simple product, but the other derivatives examined gave tribromo ketones with bromine in the form of non-crystallizable oils. Since they give bromoform when they are decomposed with caustic alkalies, it is necessary to assume that during mercuration the acetylenic hydrogen is replaced by an acetoxymercuri group.

It is possible to formulate the behavior of these mercury derivatives on the assumption that they possess a constitution similar to those derived from acetylenic compounds of Type I, namely, $—C(OHgOOCCH_3)=C(HgOOCCH_3)_2$, although no evidence has been obtained of unsaturation or of the formation of enolic compounds during decomposition with acids. They do not for example develop any coloration with ferric chloride in alcohol, but this of course may be due to their insolubility.

The decompositions of these derivatives with hydrochloric acid and with bromine may be accounted for as follows

$$—C(OHgOOCCH_3)=C(HgOOCCH_3)_2 \xrightarrow{HCl} —C(OH)=CH_2 \longrightarrow —COCH_3$$

$$—C(OHgOOCCH_3)=C(HgOOCCH_3)_2 \xrightarrow{Br_2} —C(OBr)=CBr_2 \xrightarrow{Br_2}$$

$$—C(OBr)BrCBr_3 \xrightarrow{-Br_2} —COCBr_3$$

Experimental Part

The Action of Mercuric Acetate on Acetylenic Compounds.—The preparation of mercury derivatives of acetylenic compounds by the action of mercuric acetate was carried out under the conditions described in a previous communication.[1b]

When the acetylenic compound contains the group $HC\equiv C—$, it was found desirable to moderate the reaction by dissolving the mercuric oxide in hot acetic acid and then cooling to crystallize some mercuric acetate before adding the acetylene slowly. Under other conditions the heat evolved was sufficient to cause the formation of much mercurous acetate and even free mercury by reduction. Further experience in the preparation of these mercury derivatives has shown that they sometimes separate as viscous oils when the acetic acid solution is diluted with water. Such oily products may be converted into a microcrystalline powder by triturating with alcohol and then with ether.

Analysis of the Mercury Derivatives.—Mercury was determined by the destructive hydrogenation method of H. ter Meulen.[3] Other analyses were carried out as described in the earlier communication.[1a] The following results were obtained.

---

[3] H. ter Meulen, Rec. *trav. chim.*, 45, 368 (1926).

	Analysis of Hg derivative		
Acetylenic compd.	Hg, %	CH_3COO, %	Yield of ketonic compd. after dromp, with HCl, %
Methyloctine carboxylate	56.1	16.75	24.0
Calcd. for $C_{14}H_{22}O_7Hg_2$	57.0	16.78	26.45
Ethyl phenylpropiolate	56.46		26.6
Calcd. for $C_{15}H_{16}O_7Hg_2$	56.56		27.07
Heptine-1	67.8	20.1	13.0
Calcd. for $C_{13}H_{20}H_7Hg_3$	67.6	19.93	12.84
Octine-1	66.5	19.5	14.0
Calcd. for $C_{14}H_{22}O_7Hg_3$	66.6	19.6	14.13
Phenylacetylene	66.9	19.1	
Calcd. for $C_{14}H_{14}O_7Hg_3$	67.17	19.8	
Phenylpropiolic acid	64.5	15.0	
Calcd. for $C_{13}H_{11}O_7Hg_{2.5}$	64.24	15.12	

Decomposition of the Mercury Derivatives with Hydrochloric Acid.—The mercury derivative of methyl octine carboxylate was suspended in water and decomposed by adding concd. hydrochloric acid. The oily ester liberated was extracted with light petroleum, the extract washed, dried and evaporated. From 50 g. of material was obtained 12 g. of methyl β-keto-nonoate, b. p. 137.5° (28 mm.). By dissolving in alcohol and adding cupric acetate, the green copper salt was obtained, melting after recrystallization from benzene at 99°. The ester gave a deep violet coloration with ferric chloride in alcohol and a determination by the method of Kurt Meyer[2] showed the presence of 13.5% of the enolic form one hour after isolation.

A quantity of the ester was allowed to stand in contact with concd. hydrochloric acid for two days at room temperature. A mass of crystalline lamellae formed. After washing with water and recrystallization from light petroleum, these crystals of β-keto-nonoic acid melted at 70.5' and decomposed just above this temperature, losing carbon dioxide and forming methyl hexyl ketone, b. p. 171° (760 mm.); semicarbazone, m. p. 123". The semicarbazone mixed with the semicarbazone of authentic methyl hexyl ketone melted at 123°. The mercury derivative of heptine-1 gave with hydrochloric acid almost theoretical yields of methyl n-amyl ketone, b. p. 150° (760 mm.); semicarbazone, m. p. 123°, unchanged by admixture with semicarbazone of authentic methyl n-amyl ketone. It will be noted that this semicarbazone melts at the same temperature as that of methyl n-hexyl ketone.

The mercury derivative of octine gave methyl n-hexyl ketone, identified by the characteristics described above.

The mercury derivatives from phenylacetylene and phenylpropiolic acid gave with hydrochloric acid acetophenone, b. p. 200" (760 mm.). The semicarbazone melted when slowly heated between 188–190°, and when heated rapidly at 201°. The semicarbazone of authentic acetophenone behaved similarly. The oxime melted at 59°.

Decomposition of the Mercury Derivatives with Halogens.—The reaction between the mercury derivatives and halogens was found to proceed best in chloroform. In carbon tetrachloride the reaction was slower and in acetic acid was complicated by contamination of the halogen derivative with halogen-free ketonic compounds. By varying the water content of the acetic acid this complication was found to be due to the hydrolysis of the halogen followed by the action of the halogen hydracid thus formed on the mercury compound. Refined light petroleum was also an effective medium.

The mercury derivatives were suspended in the solvent and the halogen added slowly. In most cases it was necessary to warm the mixture in a water-bath at 40° during addition of the halogen. When excess was present the mixture was allowed to stand for several hours. The precipitate was filtered off and the solution washed repeatedly with water acidified with hydrochloric acid, and finally with distilled water. It was then dried over anhydrous sodium sulfate and evaporated. In some cases it was found possible to distil the halogen derivative under diminished pressure without decomposition and in these cases the boiling point is recorded in the table below.

Mercury derivative from	Halogen derivative analyzed	B. p., °C.	Halogen, % Calcd.	Found
Stearolic acid	Chloroketostearic acid	Dec.	Cl 10.66	10.68
	Bromoketostearic acid	Dec.	Br 21.20	21.07
Behenolic acid	Chloroketobehenic acid	Dec.	Cl 9.12	9.02
	Bromoketobehenic acid	Dec.	Br 18.46	18.36
Methyl octine carboxylate	Methyl dibromoketononoate	169 (14 mm.)	Br 46.49	46.31
Ethyl phenylpropiolate	Ethyl benzoyldibromoacetate	194 (15 mm.)	Br 45.72	45.92
Heptine-1	Tribromomethyl n-amyl ketone	120 (0.5 mm.)	Br 68.36	68.4
Octine-1	Tribromomethyl n-hexyl ketone	137 (0.5 mm.)	Br 65.74	65.8
Phenylacetylene	Very slight action at low temperatures			
Phenylpropiolic acid	ω-Tribromo-acetophenone	174 (14 mm.)	Br 67.22	67.0
10,11-Undecinoic acid	Trichloroketo-undecoic acid	Dec.	Cl 35.06	34.8

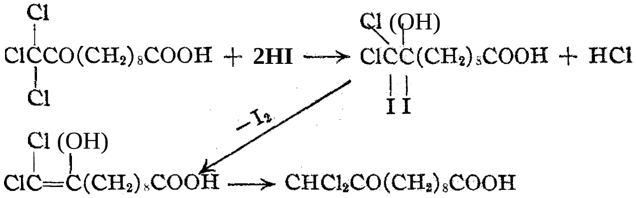
Characteristics of the Halogen Derivatives.—9-Chloro-10-ketostearic acid and the corresponding bromo acid were obtained as viscous oils which were converted into non-crystalline resinous masses by cooling with a mixture of solid carbon dioxide and ether. The sodium, potassium and lithium salts were soft and soapy. The calcium, barium and lead salts were cheese-like solids. The ethyl and methyl esters were oils which could not be distilled under a pressure of 2 mm. Both the chloro and the bromo acids were reduced to 10-ketostearic acid melting at 76° by refluxing on a water-bath with aqueous alcoholic hydriodic acid under the following conditions. 2 g. of the halogen acid was dissolved in 50 cc. of absolute alcohol and to the solution were added 5 g. of potassium iodide in 50 cc. of water and 5 cc. of concd. hydrochloric acid. The mixture was heated on a boiling water-bath under reflux for fifteen minutes and a titration made with *N*/10 thiosulfate until only a faint yellow coloration remained. The flask was again heated, thiosulfate being added at intervals of five minutes to remove free iodine. The heating was continued until only a faint coloration appeared during ten minutes. Water was added and the precipitate filtered off and recrystallized from light petroleum. The ketonic acid thus obtained was identified after establishing absence of halogen by its melting point and its unchanged melting point when mixed with the ketonic acid derived from the corresponding mercury compound by decomposition with hydrochloric acid.

13-Chloro-14-ketobehenic acid and the corresponding bromo acid were also obtained as viscous oils showing the same general characteristics as the stearic derivatives. Reduction with hydriodic acid gave 14-ketobehenic acid melting at 83–84°.

The mercury derivative of 10,11-undecinoic acid gave with chlorine the trichloro ketonic acid $Cl_3CCO(CH_2)_8COOH$ in quantitative yield. The acid and its methyl and ethyl esters were viscous oils which could not be distilled under a pressure of 2 mm.

They showed no tendency to hydrate. The acid decomposed when warmed with a 20% solution of caustic soda to yield chloroform and sodium sebacate. After one hour's reduction with aqueous alcoholic hydriodic acid under the conditions already described the acid gave an iodine-free oil containing 30.8% of chlorine. After twenty-two hours, during which liberated iodine was removed by addition of thiosulfate at intervals, an oil containing 24.2% of chlorine was obtained. Iodine was absent. Dichloro-keto-undecoic acid contains 26.26% of chlorine.

The removal of chlorine during this reaction can be accounted for by the simultaneous replacement of chlorine by iodine and the addition of hydrogen iodide to the carbonyl group.



$$\mathrm{Cl\overset{Cl}{\underset{Cl}{C}}CO(CH_2)_8COOH + 2HI \longrightarrow Cl\overset{Cl}{\underset{I}{C}}\overset{(OH)}{\underset{I}{C}}(CH_2)_8COOH + HCl}$$

$$\mathrm{Cl\overset{Cl}{C}{=}\overset{(OH)}{C}(CH_2)_8COOH \longrightarrow CHCl_2CO(CH_2)_8COOH}$$

$$\xrightarrow{-I_2}$$

The analyses recorded in this communication were effected by the methods of H. ter Meulen.

Summary

1. Mercury derivatives prepared by the action of mercuric acetate upon acetylenic compounds have been utilized for the synthesis of halogenated ketones, ketonic acids and esters.
2. Where the acetylenic compounds contain no labile acetylenic hydrogen atom, the mercury derivatives have been shown to be unsaturated and to contain the grouping $—C(OHgOOCCH_3)=C(HgOOCCH_3)—$.
3. Where the acetylenic compound contains labile acetylenic hydrogen, substitution of this hydrogen atom takes place and, while no evidence of unsaturation has been obtained, the properties of the mercury compounds can be accounted for by assuming the presence of the unsaturated grouping $—C(OHgOOCCH_3)=C(HgOOCCH_3)_2$.

THE REACTION BETWEEN TRIPHENYLMETHYL, MAGNESIUM AND A SMALL AMOUNT OF MAGNESIUM HALIDE. THE COMPOSITION OF THE GRIGNARD REAGENT

BY W. E. BACHMANN

RECEIVED JULY 7, 1930 PUBLISHED NOVEMBER 5, 1930

In studying the action of a mixture of magnesium and magnesium halide on ketones, 1,2-diketones and on aromatic acids,[1] it was observed that a molecule of magnesium halide was split off from the halogen-magnesium compounds initially formed in the reaction. In virtue of this regeneration of magnesium halide, a small amount of halide in the mixture could suffice for complete reaction of a large amount of the ketones or acids, provided the mixture was heated.

It has now been found that a Grignard reagent may be made to undergo a similar loss of magnesium halide

$$2(C_6H_5)_3CMgX \rightleftarrows (C_6H_5)_3CMgC(C_6H_5)_3 + MgX_2 \qquad (1)$$

Recently[2] it was shown that triphenylmethylmagnesium bromide, and the iodide, can be prepared in excellent yields from triphenylmethyl and a mixture of magnesium and magnesium halide, according to the following formulation

$$2(C_6H_5)_3C + Mg + MgX_2 \longrightarrow 2(C_6H_5)_3CMgX \qquad (2)$$

It is now found that a small amount of magnesium halide suffices for complete conversion of triphenylmethyl to its magnesium derivatives. To be sure, the reaction is slower than is the case when a large amount of halide is present, but nevertheless it is complete. Either magnesium halide, as such, or a small amount of triphenylbromomethane may be added to the triphenylmethyl and magnesium; in the latter case, the carbinol bromide is first of all changed to the radical and magnesium bromide.[2] Since the radical does not react with metallic magnesium without halide present, the magnesium halide must be continuously reproduced according to Equation 1, being made available for further reaction. At the end of the reaction there exists an equilibrium mixture of triphenylmethylmagnesium halide, magnesium triphenylmethyl and magnesium halide.

It is considered that a similar equilibrium mixture may exist in the case of this and all other Grignard reagents even when the amount of metal halide is equivalent to a full mole, as is the case with such reagents prepared from the alkyl halides. Schlenk and Schlenk, Jr.,[3] employing a different method, came to a similar conclusion. Gilman and co-workers[4] consider

[2] Gomberg and Bachmann, *ibid.*, 52, 2455 (1930).

[3] Schlenk and Schlenk, Jr., Ber., 62, 920 (1929).

[4] Gilman and Fothergill, THIS JOURNAL, 51, 3149 (1929); Gilman and Brown, *Rec. trav. chim.*, 48, 1133 (1929).

that there is little or no $R_2Mg{\cdot}MgI_2$ in the Grignard reagent under ordinary conditions in ether solution but that the amount varies markedly with the nature of the solvent, reactant and temperature.

Experimental

Triphenylmethyl + Mg.—A mixture of 9.8 g. of triphenylmethyl and 0.62 g. of magnesium ribbon in 120 cc. of ether–benzene (1:2) was heated for forty-eight hours in an atmosphere of nitrogen. At the end of this time no weighable amount of magnesium had reacted. In another experiment no magnesium was dissolved after one hundred hours, and the triphenylmethyl used was recovered unchanged.

Triphenylmethyl + Mg + MgI_2 (42%).—Twelve grams of triphenylmethyl, 3 g. of magnesium iodide and 0.77 g. of magnesium ribbon were heated in an atmosphere of nitrogen in a mixture of 40 cc. of ether and 70 cc. of benzene. After twenty hours, the clear solution was filtered from excess of magnesium and hydrolyzed. The magnesium loss was 0.59 g.; this represents 97% of the calculated value. The magnesium hydroxide produced on hydrolysis required 46.05 cc. of N acid for neutralization; theoretical value on basis of triphenylmethyl, 50.0 cc. From the ether–benzene solution there was obtained 11 g. (92%) of triphenylmethane.

Similar results were obtained when magnesium bromide was used in place of the iodide, even when the amount of halide corresponded to only 0.05 mole for a mole of triphenylmethyl.

Triphenylmethyl (0.9 mole) + Triphenylbromomethane (0.1 mole) + Mg.—A mixture of 13.4 g. of triphenylmethyl and 1.98 g. of triphenylbromomethane was heated with 1.19 g. of magnesium ribbon in 200 cc. of ether–benzene (2:3). The reaction started immediately. After three days the solution was filtered; loss in magnesium, 0.83 g.; theoretical value, 0.82. Dry carbon dioxide was passed into the solution for six hours. Hydrolysis yielded 8.5 g. of triphenylacetic acid or 50% of the calculated amount. From this single experiment, it would appear that the reaction between magnesium triphenylmethyl and carbon dioxide is considerably slower than carbonation of triphenylmethylmagnesium bromide. Gilman and Brown[6] report that phenylmagnesium bromide reacts with n-valeronitrile more readily than does an equivalent solution of magnesium diphenyl.

In another experiment in which 13.4 g. of triphenylmethyl and 1.80 g. of triphenylbromomethane were allowed to react with magnesium, 0.80 g. of metal was dissolved; calculated, 0.80. Hydrolysis gave 11.3 g. of triphenylmethane; calculated, 14.8.

Summary

A small amount of magnesium iodide (or bromide) can suffice to convert triphenylmethyl and magnesium to the magnesium derivatives of triphenylmethyl. The reaction takes place in two steps: (a) $2(C_6H_5)_3C + Mg + MgX_2 = 2(C_6H_5)_3CMgX$; (b) $2(C_6H_5)_3CMgX \rightleftarrows MgX_2 + (C_6H_5)_3CMgC(C_6H_5)_3$. The latter step makes the MgX_2 available for continuous reaction.

STUDIES RELATING TO BORON. II. ACTION OF LITHIUM ON ETHYLAMMINO BORON TRIFLUORIDE

BY CHARLES A. KRAUS AND EARL H. BROWN

RECEIVED JULY 10, 1930 PUBLISHED NOVEMBER 5, 1930

As was stated in a preceding paper,[1] ammino boron trifluoride is appreciably ammonolyzed when dissolved in liquid ammonia. This is conclusively shown by the fact that when sodium is added to a solution of the trifluoride in liquid ammonia, hydrogen is evolved. It was at first thought that ethylammino boron trifluoride might dissolve in ethylamine without aminolysis. However, on adding lithium to a solution of this compound in ethylamine, three atoms of hydrogen were evolved per mole of boron trifluoride, thus showing that aminolysis went to completion.

The reaction between lithium and boron trifluoride in ethylamine may be expressed by the equation

$$BF_3 + 3C_2H_5NH_2 + 3Li = B(C_2H_5NH)_3 + 3LiF + 3/2H_2$$

Experiment has shown that the reaction proceeds practically quantitatively. The various products of the reaction have been isolated and identified.

Preparation of Tertiary Boron Ethylimine.—On adding lithium to an ethylamine solution of ethylammino boron trifluoride, hydrogen is evolved and a precipitate, consisting of lithium fluoride, is formed. This reaction is due to aminolysis of the boron trifluoride, the resulting ethyl ammonium fluoride reacting with lithium to form lithium fluoride and hydrogen. The reaction proceeds until all the fluorine atoms have been aminolyzed.

Four reactions were carried out for the purpose of determining the nature of the various reaction products. The apparatus employed was substantially as is shown in Fig. 1. The reactions were carried out in a weighed tube A. A known quantity of ethylammino boron fluoride was introduced into the bottom of the reaction tube and a weighed quantity of lithium into the introduction tube B. The reaction tube was attached to the system at T by means of de Khotinsky cement. After exhausting the apparatus, a bath of ammonia was placed around the auxiliary chamber M, into which a quantity of lithium had previously been introduced, and, by opening the valve O of the cylinder L, containing ethylamine, the desired quantity of solvent was condensed in M. After closing stopcock K, the bath surrounding M was removed and placed around the reaction tube A. Stopcocks C, D and H were opened, allowing the solvent evaporating in M to condense in the reaction tube. When condensation was completed, any hydrogen present was removed with a pump and the lithium in the addition tube B was introduced as needed by turning this tube through a suitable angle about its axis. In the meantime, the stirrer Z, suspended from a spring Y, was set in motion by an intermittent current passing through the solenoid X. Lithium was added slowly, piece by piece, the evolved hydrogen passing through stopcocks C, D and F and through a sul-

[1] Kraus and Brown, THIS JOURNAL, 51, 2690 (1929).

furic acid trap W into the chambers V and U containing sulfuric acid and phosphorus pentoxide, respectively. The acid and oxide served to remove ethylamine carried over with the hydrogen.

The addition of lithium was continued until the solution remained permanently blue. All the hydrogen was carried over into the drying tubes by the amine vapor.

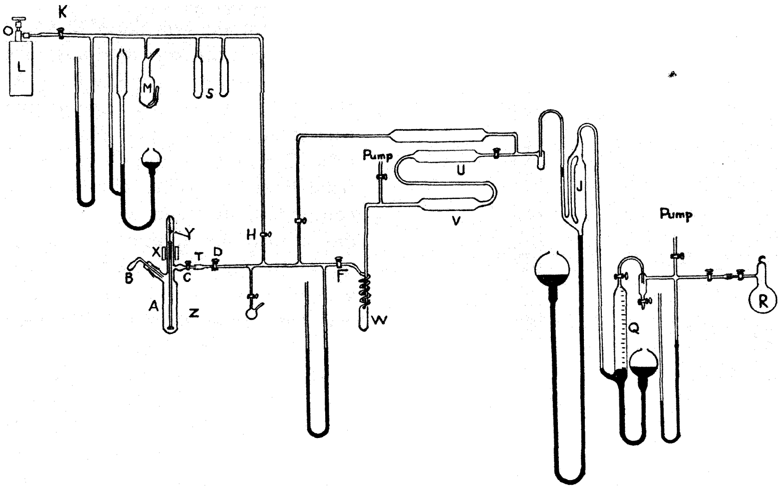

Fig. 1.—Apparatus used in aminolysis of boron trifluoride.

After standing, it was removed by means of a Topler pump, J, and transferred into a graduated buret Q. After determining the volume of the hydrogen, it was introduced into a bulb R of known volume and its density determined from the weight and pressure of the gas.

The excess solvent was distilled from the reaction tube into the recovery tubes, S, which were then sealed off from the system. Dry nitrogen was introduced into the reaction tube, the addition tube B was removed and the amount of lithium remaining, determined. The reaction tube A was then pumped to constant weight.

On weighing, it was found that the weight of the contents was less than that of the materials used. This led to the inference that one of the products of the reaction was a more or less volatile liquid or solid.

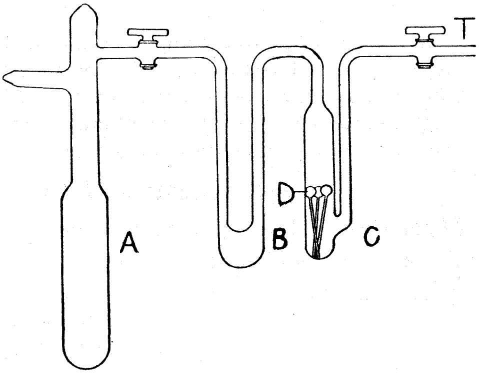

Fig. 2.—Apparatus used in preparing boron triethylimine.

Accordingly, in a third experiment, a two-legged reaction tube was used in place of that illustrated in Fig. 1. Before distilling off the amine at the end of the reaction, the tube was detached from the system, the precipitate was allowed to settle and the clear liquid decanted into the second limb of the tube. The solvent was then distilled back into the first leg for the purpose of washing the solid residue. This process was repeated nine times. The tube was then again attached to the system and the excess amine recovered. It was found that a quantity of liquid remained in the second limb of the reaction tube which was much less volatile than ethylamine. The two limbs of the reaction tube were sealed and separated from each other, and the limb A containing the liquid product was attached to two U-tubes, B and C, as shown in Fig. 2. The tube T was attached to T of the apparatus as shown in Fig. 1. The apparatus was exhausted through T while a bath of liquid ammonia was placed around tube B. Under a pressure of about 0.1 mm.. the liquid distilled rapidly from A into the cooled tube The ammonia bath was then removed and placed around tube C and the liquid was redistilled from B to C. When this process was completed, nitrogen was slowly introduced into the apparatus. forcing the liquid through the capillaries into the previously weighed bulbs D. Tube C was then opened, the bulbs were removed and the capillaries sealed and weighed The solid residue left in the first limb of the original two-legged reaction tube was treated with sulfuric acid in a platinum crucible and the weight of lithium determined as lithium sulfate.

A fourth reaction was carried out with a tube of the form shown in Fig. 3. Tube A' was attached, by means of T to tube T of Fig. 1 in place of the reaction tube A. The reaction was carried out as already described and. when completed. stopcock D was closed and tube X was attached to a pump. On placing a liquid ammonia bath around tube B (containing the weighed bulbs) and exhausting the system through *C*, the volatile product distilled rapidly from the reaction tube A' into B. This liquid was then forced through the capillaries into the bulbs under a pressure of nitrogen. The known samples in the bulbs were employed for analyses and molecular weight determinations.

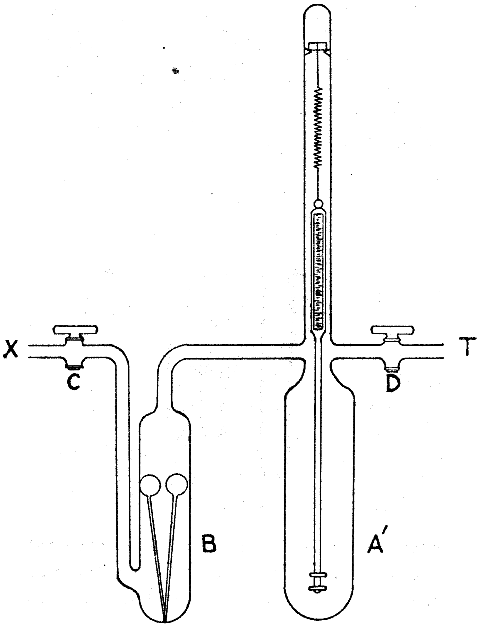

Fig. 3.—Improved apparatus for Preparing boron triethylimine.

Determination of Products of Reaction

Hydrogen.—The relation between the volume of hydrogen collected and the weights of material used is summarized in the following table for Expts. 1, 2 and 3.

TABLE I

DATA RELATING TO HYDROGEN EVOLVED

Expt. no.	Mole of BF_3	Mole Li	H_2, cc.	Atoms H_2
1	0.0095	0.037	266	0.0238
2	.00681	.0217	240	.0214
3	.00626	.0187	197.2	.0176

The density of the gas evolved in Reaction 1, was 3.36, which clearly indicates that it consisted essentially of hydrogen. As is shown by the figures in the last column, the volume of hydrogen collected in Expts. 2 and **3** was approximately three atoms per mole of boron trifluoride,

The Insoluble Solid Product of Aminolysis.—The solid product of the reaction, which was insoluble in ethylamine, was assumed to be lithium fluoride. After washing with ethylamine, various samples were analyzed for lithium and fluorine without further purification.

Anal. Lithium subs., 0.0621, 0.1898, 0.2413: Li_2SO_4, 0.1206, 0.3882, 0.4965. Calcd. for LiF: Li, 26.75. Found: Li, 24.51, 25.82, 25.87.

The solid was also analyzed for fluorine by the lead chlorofluoride method.

Anal. Subs., 0.0322: PbClF, 0.3119. Calcd. for LiF: F, 73.4. Found: F, 70.32.

The results show that the insoluble product of reduction was slightly impure lithium fluoride.

Analysis of Liquid Product $B(C_2H_5NH)_3$.—Samples of the liquid product, prepared as described above, were analyzed for nitrogen by hydrolyzing the material, distilling the ethylamine with water vapor and titrating the distillate with hydrochloric acid of known concentration.

Anal. $B(C_2H_5NH)_3$ subs., 0.0777, 0.0712: cc. of 0.1083 *N* HCl, 15.11, 13.78. Calcd. for $B(C_2H_5NH)_3$: N, 29.30. Found: N, 29.20, 29.36.

A quantity of the material was hydrolyzed by means of a small quantity of water vapor and the amine resulting was collected and its vapor density determined. The vapor density corresponded to a molecular weight of 44.8, as against 45.1 for ethylamine.

Analyses for boron were carried out by the titration method, as described in the preceding paper. In a number of instances the ethylamine was boiled off from an alkaline solution, while in others, the amine was first titrated with 0.1 *N* HCl. Samples of material from which the amine had been removed by the boiling of an alkaline solution yielded, in three determinations, 8.11, 8.27 and 8.16% of boron. In another series of determinations, in which the amine was neutralized with 0.1 N HCl, there were obtained the following values: 8.00, 7.96, 8.02 and 7.96% of boron. The boron content of $B(C_2H_5NH)_3$ is 7.67%. The value found for boron was slightly high. This discrepancy was due to inadequacy of the analytical method rather than to lack of purity of the compound.

Properties.—The properties of tertiary boron ethylimine, which is an ammono boron ethyl ester, were not extensively studied. It is fairly volatile at ordinary temperatures and, except for its sensitiveness to moisture, it is quite stable. It is readily soluble in ethylamine.

Summary

Ethylammino boron trifluoride is aminolyzed when dissolved in ethylamine. When a solution of this compound is treated with three atoms of metallic lithium, boron triethylimine, $B(C_2H_5NH)_3$, is formed. This ammono boron ethyl ester is a liquid readily soluble in ethylamine, ap-

preciably volatile at ordinary temperatures and readily hydrolyzable by water vapor.

COBALT COMPLEXES OF THIOGLYCOLIC ACID

BY LEONOR MICHAELIS AND MAXWELL P. SCHUBERT

RECEIVED JULY 10, 1930 PUBLISHED NOVEMBER 5, 1930

For reasons understandable from some preceding papers,[1] it seemed important to enhance our knowledge of metal complexes of sulfhydril compounds which also contain a carboxyl group. Though the behavior of various representatives of this group toward cobalt has some common aspects, there are individual differences. This paper is restricted to the simplest of these compounds, thioglycolic acid.

Compounds of cobalt and thioglycolic acid have been described by Rosenheim and Davidsohn.[2] Attempts to repeat their work did not yield readily crystallizable compounds and furthermore these authors were not aware of the fact that the formation of their brown compounds requires free oxygen and does not take place in the absence of air.

Another brief notice is given by Myers[3] but he evidently did not obtain a pure compound and was also unaware of the oxidation which takes place in its formation. Much more nearly related to the compounds described in this paper is Cremer's[4] observation of a complex established with cysteine and cobalt in the absence of air and in the presence of carbon monoxide. This complex, according to Cremer, contains two molecules of cysteine and one molecule of carbon monoxide for each atom of cobalt. The color of this complex is olive-green, more intense than the color of the cobaltous complex of cysteine without carbon monoxide. This author does not mention the fact that this cobalto complex in contact with air undergoes a considerable change and intensification of color, a fact which will be the starting point for our investigation. Cremer also describes an analogous complex of ferrous iron. One atom of iron combines with two molecules of cysteine and two molecules of carbon monoxide, so differing from the cobalt complex. This ferrous complex is highly optically active, is orange-yellow in color, and reversibly dissociates the carbon monoxide on being illuminated.

Closely related to the present work is the attempt of Cannan and Rich-

ardson[5] to establish by indirect physico-chemical analysis the composition of iron thiogylcolic acid complexes. Their conclusions, however, are quite different from what will be suggested here.

Yet among the innumerable papers on cobalt complexes by such authors as Werner, Pfeiffer, Jörgensen, Weinland, Tchugaeff, Ley and others, there is not a single one concerned with compounds such as cysteine or thioglycolic acid which has in addition to an SH group some other group capable either of direct salt or complex formation so that the whole molecule would give an inner complex in the sense of Ley.[6] This is the more remarkable as many other sulfur compounds have turned out to form quite stable complexes with cobalt; even in compounds in which the sulfur seems quite saturated, such as the thioethers and disulfides, there seems to be a strong affinity between sulfur and cobalt.

When a cobalt salt is mixed with a buffer around *P*H 6–10 (phosphate, carbonate, veronal) a pink precipitate arises which is perfectly stable in air and shows no trace of any oxygen consumption when observed in a microrespiration apparatus. In the same way, the soluble slightly pink cobalt complex of pyrophosphate is not oxidized by air, in contrast to the analogous ferro complex.

When the mixture of cobalt salt and phosphate buffer, containing the slightly pink precipitate, is mixed with thioglycolic acid under such conditions that the reaction never becomes acid, the precipitate is dissolved and the color rapidly becomes brown. Under favorable conditions one may see an intermediate state of deep blue-green color. This intermediate state, difficult to observe in air, is the permanent state in absence of air. On mixing the components under completely deaerated condition in a stream of nitrogen, the green color arises and is stable. The green color may be intense at high concentration but is by no means comparable in color intensity to the brown color established in air. Instead of oxygen, ferricyanide, or a dyestuff such as indophenol, methylene blue, or even indigo disulfonate can be used as oxidant with equal effect, the dye being reduced instantaneously. The green cobalt complex is so sensitive to air that we have not attempted as yet to prepare it in pure condition. The only statement one may make is that in absence of air approximately two molecules of thioglycolic acid are necessary to dissolve one molecule of cobalt present in the form of the phosphate precipitate.

When this mixture is exposed to the air it rapidly consumes oxygen, simultaneously turning brown. To get an idea of the oxidation level of this brown complex a study was made of the amount of oxygen taken up in its formation. This study has shown that there is more than one step to the oxidation process and that by adjusting the conditions these steps

[6] H. Ley, *Z. Electrochem.*, 10, 954 (1904).

can be quite sharply distinguished. It is particularly necessary to avoid too alkaline a reaction.

The oxygen uptake was measured in a 500-cc. Erlenmeyer flask with a one-holed rubber stopper leading to a calibrated air reservoir with a manometer attachment so that the whole system could be held at atmospheric pressure. In the flask two test-tubes were placed, one with thioglycolic acid and one with alkali, while in the bottom of the flask itself was placed the cobalt salt with some primary phosphate. The whole was sealed with paraffin and after standing for at least an hour in a constant temperature room at 30° and under slight pressure to make sure there were no leaks, the flask was tipped to allow the contents of the test-tubes to mix with those of the flask and then the decrease in volume of the gas in the system was read off at successive time intervals, the flask being shaken all the time.

Under these conditions and with the amounts of material noted in the table there was observed for the first thirty minutes a rapid oxygen uptake which then dropped off quite suddenly, falling to a rate which was about one-twentieth to one-hundredth of the average rate during the first thirty minutes. After an hour the oxygen uptake had dropped to a rate of the order of 1% or less of the rate during the first thirty minutes and continued for days without reaching a definite end. The amount of oxygen taken up during this first thirty-minute interval, which quite evidently corresponds to a distinct step of oxidation, is one-eighth mole of oxygen per mole of thioglycolic acid used, provided the molecular ratio of thioglycolic acid to cobalt is not greater than two to one and provided the mixture is not too alkaline. These are the conditions under which the crystalline complexes were made and frequently isolated within an hour with yields of over 70%. If the thioglycolic acid be in excess with respect to cobalt beyond the ratio noted above, then the oxygen uptake also increases somewhat, the rate depending on the alkalinity of the solution, for the excess thioglycolic acid is oxidized by oxygen to dithiodiglycolic acid. Under these conditions it is sometimes difficult to isolate the crystalline products which are our present concern, but even under these conditions there is an approximate step in the oxidation which calculated now to the cobalt amounts to one-fourth mole of oxygen per atom of cobalt. Also, if the mixture is made too alkaline

TABLE I

OXYGEN CONSUMPTION IN MIXTURES OF COBALT CHLORIDE AND THIOGLYCOLIC ACID

The column headed "calcd. O_2 consump." is the theoretical oxygen consumption calculated as one-fourth mole of oxygen per atom of cobalt if thioglycolic is in excess to cobalt over 2 to 1. If the ratio of thioglycolic acid to cobalt is less, then one-eighth mole of oxygen per mole of thioglycolic acid is taken as the theoretical value.

Expts. 2 and 7, oxygen consumption under conditions for making complexes described; Expts. 1 and 9, oxygen consumption with excess cobalt; Expts. 3, 6 and 8 increased oxygen consumption with excess alkali; Expts. 4 and 5, increased oxygen consumption with excess thioglycolic acid.

	Composition of mixture, millimoles Volume of the whole 30–40 cc.					Observed O_2 consump., mmols.			
Expt.	Thiogly. acid	Co	KOH	KH_2PO_4	Calcd. O_2 consump., mmols.	30 min.	3 hrs.	20 hrs.	% Excess of O_2 consumed in first hour over calcd.
1	6.5	6.5	21	4.5	0.81	0.93	1.11	1.54	26
2	14.4	6.5	23	4.5	1.62	1.47	2.01	2.37	7
3	14.4	6.5	52	4.5	1.62	1.98	2.98	3.99	53
4	10.3	2.5	15	9	0.63	0.67	0.90	1.23	24
5	10.3	3.4	19	9	.85	.98	1.13	1.44	23
6	10.3	3.4	37	9	.85	1.42	1.59	2.11	76
7	10.3	5.0	22	9	1.25	1.21	1.44	1.62	6
8	10.3	5.0	45	9	1.25	1.65	1.80	3.32	38
9	10.3	10.0	37	9	1.29	1.26	1.52	1.80	8

the second slow step of oxidation seems to be speeded up so that the two steps are not as sharply separated and the total oxygen uptake is increased This is probably due to a slow oxidation of the sulfur in the complex.

We were interested in the problem whether the consumed oxygen might be completely reduced or in part stay in the form of hydrogen peroxide. The only test for hydrogen peroxide in a solution of such a deep color is the test with chromic acid and extraction of the blue chrom-peroxide by ether (or better still ethyl acetate). When there is an excess of thioglycolic acid, with respect to cobalt (referred to the normal ratio 2 : 1), there is no hope of detecting hydrogen peroxide because thioglycolic acid, when not combined to form the metal complex, is rapidly oxidized by hydrogen peroxide; but on working with the ratio 2 : 1, traces of peroxide could be detected in some of the experiments. It is very likely that the formation of hydrogen peroxide depends on the partial pressure of free oxygen and on the rate of stirring, as Wieland and Franke[7] have shown for the oxidation of cobalto-hexacyanide by oxygen. At any rate, even in the best case we found only a minute trace of peroxide under such conditions where in the analogous case of cobalt cyanide a very conspicuous amount of peroxide could be found, as has been shown already by Manchot and Herzog[8] and also by Wieland.

So we may state with a fair degree of accuracy that in a mixture of one atom of cobalt and two molecules of thioglycolic acid, one-fourth of a molecule of oxygen is used up with no, or no appreciable, residue of hydrogen peroxide, during the first, rapid stage of the oxidation, with which this paper is concerned, and that the compounds to be described here represent such a state of oxidation that the cobalto-thioglycolic acid complex has consumed one-fourth of a molecule of oxygen for each atom of cobalt. This is no more oxygen than would be necessary to oxidize the cobaltous state to the cobaltic, without further oxidation of the sulfur groups. It should be emphasized that this stage of oxidation is not the highest obtainable but it is the first product of oxidation which is stable enough to isolate in pure condition. Only with this stage of oxidation is the present paper concerned.

The Preparation of the Complexes.—The simplest of these cobalt-thioglycolic acid complexes to prepare is the potassium salt. 10 cc. of thioglycolic acid (140 millimoles) is dissolved in 15 cc. of water and then 20 cc. of 7.5 *M* potassium hydroxide is added. This potassium thioglycolate solution is then poured into a mixture of 130 cc. of cobalt chloride (0.5 M), 50 cc. of potassium dihydrogen phosphate (0.9 M) and 19 cc. of potassium hydroxide (7.5 M) with rapid stirring. The mixture immediately turns a deep red-brown. On examination under a microscope the solution now appears practically clear. The mixture should be shaken or stirred in contact with the air or have air bubbled through it for an hour. If necessary it is filtered. The solution is

---

[7] H. Wieland and W. Franke, Ann., 473, 289 (1929).

[8] W. Manchot and J. Herzog, Ber., 33, 1742 (1900).

evaporated either *in vacuo* or over steam to about one-third its volume. After cooling in the ice box for an hour or two, the crop of crystals is filtered off on a Büchner funnel and sucked as dry as possible. This product dissolves readily and completely in water, giving an intensely colored red-brown solution. It is dissolved in about 125 cc. of water and 95% alcohol is added slowly and with stirring until about 125 cc. has been added. An amorphous precipitate immediately appears which rapidly becomes crystalline. The crystals observed under low magnification are thin rectangular plates pointed at the ends. After standing for a few hours they can be filtered on a Büchner and washed first with 50% alcohol, then with 95% alcohol. The yield after drying for a day or two in the air is over 16.5 g. or over 75% calculated on the basis of the composition found by analysis. After drying by exposure to the air for a few days the following analytical results were obtained.

Anal. Calcd. for $[Co(SCH_2COO)_2KH]_2O{\cdot}5H_2O$: K, 11.76; S, 19.28; Co, 17.74; H_2O, 13.55. Found: K, 11.55; S, 19.31; Co, 17.83; H_2O, 13.07.

The potassium salt which has just been described is the best starting point for the preparation of the rest of the compounds studied here. To prepare the barium salt 3 g. of the recrystallized potassium salt is dissolved in 150 cc. of water and an aqueous barium chloride solution is added. An amorphous precipitate forms immediately, which begins to crystallize only after standing for about an hour. The crystallization is watched under a microscope and may take from one to four or five days for completion. Then the crystals are filtered off and washed several times with water and finally with 95% alcohol. The yield of the air-dried product is 3.2 g. This salt is quite insoluble in cold or hot water and dissolves only partially on addition of concentrated hydrochloric acid. The following analytical results are on the air-dried product.

Anal. Calcd. for $Ba[Co(SCH_2COO)_2H]_2O{\cdot}5H_2O$: Ba, 18.96; S, 17.72; Co, 16.30; H_2O, 12.45. Found: Ba, 18.87; S, 17.41; Co, 16.41; H_2O, 12.02.

Another crystalline product which appears to bc an acid potassium salt may also be obtained from the potassium salt already described. About 15 g. of the potassium salt is dissolved in 75 cc. of water, then drop by drop and with constant stirring 3.5 cc. of concentrated hydrochloric acid is added. The mixture is set on ice for about twelve hours. The solution then turns almost solid with a light brown precipitate which under the microscope appears as exceedingly fine hair-like crystals. They are difficult to filter and are best separated by centrifuging. Then they are dissolved in about 250 cc. of water. In contrast to the former potassium salt these crystals dissolve only very slowly. After solution is complete alcohol is stirred in slowly and in small portions until about 150 to 200 cc. has been added. An amorphous precipitate appears which sometimes crystallizes in an hour or two and at other times does so only after standing for a week. The crystals are filtered off, washed with 50% alcohol, then with 95% alcohol and dried by exposure to air. This air-dried product amounts to 7 g.

Anal. Calcd. for $KH[Co(SCH_2COO)_2H]_2O{\cdot}4H_2O$: K, 6.42: S, 21.07; Co, 19.37; H_2O, 11.84. Found: K, 7.17; S, 20.39; Co, 19.72; H_2O, 12.66.

The free complex acid corresponding to the compounds which have been described can be prepared from the acid potassium salt by dissolving the latter in water and adding concentrated hydrochloric acid drop by drop with steady stirring until a permanent precipitate is formed. Under the microscope the precipitate appears as very short narrow bars. These are filtered off after several hours, washed with 30% alcohol and finally with 95% alcohol. After drying in the air, these crystals were analyzed.

Anal. Calcd. for $[Co(SCH_2COOH)_2]_2O{\cdot}3.5H_2O$: S, 22.87; Co, 21.01; C, 17.10; H, 3.42; H_2O, 11.24. Found: S, 23.04; Co, 21.45; C, 16.88; H, 3.21; H_2O, 11.26.

All of these complexes are quite stable and hydrogen sulfide, potassium hydroxide and potassium ferrocyanide all fail to precipitate the cobalt. The dry crystalline compounds are quite stable and can be heated to 140° without decomposition provided they are not heated for too long a time. The aqueous solutions of these compounds are intensely reddish-brown, with no band in the visible part of the spectrum but with increasing absorption toward the violet end.

The analytical results given are in all cases the mean results of duplicate analyses run on two or three entirely independent preparations.

For the C and H determinations we are indebted to Dr. Elek.

In the case of the potassium salt and the barium salt, water was determined by heating to constant weight at 110 to 120°. In the case of the potassium salt subsequent exposure to the air brought about, in a week, a recovery of most of the lost weight. The acid potassium salt and the free acid seem to begin to decompose slowly after heating for a few days at 120°, so in these cases water was determined in a vacuum desiccator over sulfuric acid.

Discussion of the Constitution.—In setting up formulas for the compounds which have been described, the oxygen consumption studies must be considered as well as the analytical figures. All the compounds show a sulfur to cobalt ratio of 2:1 and where carbon and hydrogen have also been determined the results show that the thioglycolic acid molecule behaves as a unit in coordinating with the cobalt. Furthermore, in none of these compounds has there ever been found any negative radical other than the thioglycolate although made in the presence of chloride, phosphate or pyrophosphate. The complex nucleus of the compounds considered here, therefore, consists of two molecules of thioglycolic acid distributed around the cobalt atom. This nucleus forms the negative ion of the compounds.

The oxidation level for a unit consisting of a cobalt atom and two thioglycolate radicals is such that one electron is lost for each such unit. This could mean either that the cobalt is oxidized from a cobaltous to a cobaltic condition or that half the thioglycolic acid is oxidized to a disulfide form.

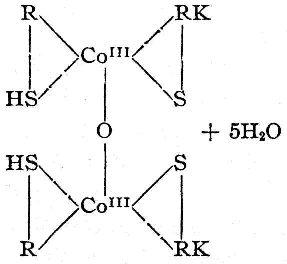
Finally, the existence of the acid potassium salt with one potassium atom to two cobalt atoms and four thioglycolate radicals suggests the possibility that these complexes may be dinuclear in structure.

To get some further evidence to show whether the compounds were mono- or dinuclear, the freezing point depressions of aqueous solutions of the potassium salt were determined. The results were: (a) 0.091° lowering of freezing point of water in a solution of 0.3884 g. of the potassium salt in 20.10 g. of water; (b) 0.147° lowering for 0.6389 g. of the potassium salt in 17.65 g. of water. This is, on the average, a freezing point depression of 0.0044' for each gram of substance dissolved in 1000 g. of water. The expected depression for a solution 1:1000 would be, assuming total dissociation of all potassium ions

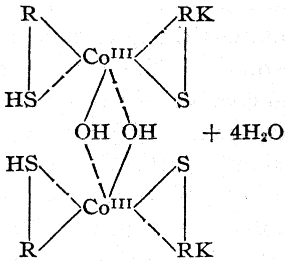
For the monomolecular formula	0.0112°
For the dimolecular formula	0.0084°

It can be seen that the monomolecular formula is not in accordance with the observed freezing point at all. The dimolecular formula is more compatible, taking into consideration that in electrolytes with polyvalent anions the assumption of 100% dissociation and the neglecting of osmotic coefficients (in the sense of Debye) are not justifiable and necessarily render the calculated depression greater than it can really be. Even a higher polymerization might be in agreement with the observed freezing point. Anyhow, this method is not very conclusive for polyvalent electrolytes and may be only utilized here to discredit a monomolecular formula.

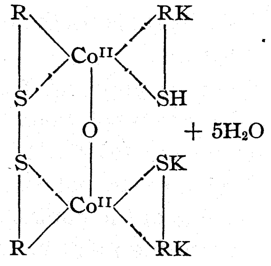
Putting all these facts together leads to the following tentative formulas in which Ia and Ib represent a cobaltic compound, IIa and IIb a cobalto-disulfide compound, both in the form of the potassium salt. The two b-formulas are analogous to what Werner designated as 01-complexes. They have the advantage that the six coordination places around the central cobalt are occupied and at the same time account for the fact that the crystals of both the free acid and the potassium salt, as well as the barium salt contain an odd number of water molecules (as reckoned for the bi-molecular formula). The odd water molecule may be the one which the two b-formulas have in the inner spheres of the cobalt atoms, and which the a-formulas do not have.



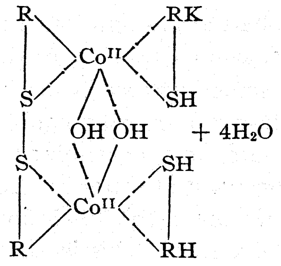
Ia



Ib



IIa



IIb

$R = SCH_2COO$

A similar formulation of some cobalt complexes which are somewhat analogous to the ones here described is given by Durrant,[9] who also at-

---

[9] R. G. Durrant, *J. Chem. Soc.*, 87, 1781 (1905).

tempted to determine the oxidation level as well as the molecular weight of the compounds he describes, particularly of the oxalate compounds.

So far no isomers have been found. It may be that the residual valences between pairs of sulfur atoms, even in the saturated form as SH groups, prevent them from taking a tmns-position instead of cis, and so prevent the formation of isomers.

As we attempt to bring up various arguments for the preference of one or the other of the two possibilities I or II, the following ideas may be set forth.

Nickel sulfate (or chloride) reacts, under the same conditions as cobalt, with thioglycolic acid, giving a red color, but is the same in the absence or in the presence of oxygen. Oxygen consumption is, therefore, not involved in the establishment of this compound. This complex is, therefore, most likely analogous to the slightly green cobaltous complex which arises in the absence of oxygen. Ferrous salts, under similar conditions, and in the absence of oxygen, form a practically colorless soluble complex with thioglycolic acid, which combines avidly with oxygen and forms the red complex differing from the oxidized cobalt complex by its lability so that iron is a catalyst for the oxidation of thioglycolic acid to dithiodiglycolic acid. The behavior of the three complexes: ferrous, nickelous and cobaltous cysteine, toward oxygen is, therefore, what may be anticipated from the general properties of the metals, but scarcely from the general property of thioglycolic acid. Nickel compounds are under any conditions stable only in the nickelous state. Cobalt compounds are in certain compounds stable only in the cobaltous state (cobalt sulfate, chloride, etc.), in others they are, when produced in the cobaltous state, spontaneously and completely oxidized even by moleular oxygen to the cobaltic state and then cannot be reduced to the cobaltous state even by powerful reductants. Iron compounds can always be shifted easily from the ferric state to the ferrous and *vice* versa. From this point of view, the cobaltic formula No. 1 is preferable.

On the other hand, the high affinity of the two sulfur atoms, deprived of the H-atoms, in such a vicinity as indicated in the formula should be taken into account. This might involve a secondary change of formula I to II.

Many attempts have been made to decide between the two possible formulations, but with no decisive result as yet. One may think of a desmotropic relationship between the two formulas. This idea might account for the intense color of the complexes. Anyhow, the very fact that such a doubt is possible at all hints at the close relationship between a cobaltihydrosulfide form and a cobalto-disulfide form, and seems to be an approach toward an understanding of the metal catalysis in the oxidation of hydro: sulfides to disulfides.

Summary

Some crystalline complex compounds of cobalt and thioglycolic acid have been prepared and on the basis of chemical analysis and oxygen consumption their possible constitutions have been discussed. The bearing of these constitutions on the heavy metal catalysis of the oxidation of thiol acids has been pointed out.

STUDIES RELATING TO METHYL TIN DERIVATIVES. VI. THE REACTION BETWEEN CHLOROFORM AND SODIUM TRIMETHYL STANNIDE IN LIQUID AMMONIA

BY CHARLES A. KRAUS AND ARTHUR M. NEAL

RECEIVED JULY 11, 1930 PUBLISHED NOVEMBER 5, 1930

As was shown in an earlier paper[1] sodium trimethyl stannide reacts with methylene chloride in liquid ammonia with the formation of di-trimethyl stannyl methane. It might, therefore, be expected that a corresponding reaction would take place between chloroform and sodium trimethyl stannide according to the equation

$$3(CH_3)_3SnNa + CHCl_3 = [(CH_3)Sn]_3CH + 3NaCl \qquad (I)$$

Indeed, when chloroform is added to a solution of sodium trimethyl stannide in liquid ammonia, reaction takes place immediately with the formation of a white precipitate which, in part at least, is solid. On evaporation of the ammonia, an oily liquid is left behind, which might be expected to be tri-trimethyl stannyl methane. A closer investigation of this liquid, however, showed that it consisted of at least two substances and it was found necessary to examine the product at length in order to establish the nature of the substances in question. The various experiments relating to this study are described below.

Preliminary Experiments.—A quantity of sodium trimethyl stannide was treated with chloroform in liquid ammonia. When the reaction was completed, the ammonia was allowed to evaporate and the oily liquid left behind was washed several times, first with ammonia water and, finally, with distilled water. The liquid was separated from the water layer and dried by filtering through anhydrous sodium sulfate in an atmosphere of nitrogen. Samples were sealed in weighed tubes from which the air had been displaced by nitrogen.

Samples of the product were analyzed for tin by the Carius method.

Anal. Subs., 0.3403, 0.3841: SnO_2, 0.3046, 0.3433. Calcd. for $[(CH_3)_3Sn]_3CH$: Sn, 70.64. Found: Sn, 70.73, 70.40.

The molecular weight of the compound was determined by the cryoscopic method with benzene as solvent.

---

[1] Kraus and Neal, THIS JOURNAL, 52, 695 (1930).

Mol. wt. Solvent, 33.25, 33.25; solute, 0.8495, 0.7541; Δt, 0.400, 0.335°; mol. wt., 319.1, 338.5. Calcd. for $[(CH_3)_3Sn]_3CH$: mol. wt., 504.1.

While the results of analysis correspond fairly well with those required for tri-trimethyl stannyl methane, the mean molecular weight of the substance in benzene is clearly incompatible with this formula. A re-examination of the product initially formed in liquid ammonia showed that it was partly liquid and partly solid at liquid ammonia temperatures and that the solid disappeared at 0°.

It was suspected that the product was a mixture, one constituent of which was trimethyl tin. The latter compound combines readily with iodine and the trimethyl tin iodide formed may be precipitated from most solvents by means of gaseous ammonia. Accordingly, known weights of the original preparation were treated with a standard solution of iodine in carbon tetrachloride. In four experiments, from 1.7 to 1.8 atoms of tin in the original mixture reacted with one atom of iodine. In other words, approximately four-sevenths of the original mixture consisted of trimethyl tin. It is difficult to account for this ratio except by assuming a loss of trimethyl tin in the process of purification. This is borne out by the variation observed in this ratio.

The solutions, after iodination, were treated with ammonia. Any trimethyl tin iodide present was precipitated and recovered. Samples of the precipitated product were analyzed for iodine and tin.

Anal. Subs., 0.2332, 0.3757: AgI, 0.1760, 0.2852. Calcd. for $(CH_3)_3SnI\cdot NH_3$: I, 41.25. Found: I, 40.79, 41.03. Subs., 0.1682: SnO_2, 0.0838. Calcd. for $(CH_3)_3SnI\cdot NH_3$: Sn, 38.59. Found: Sn, 39.24.

The analyses, as well as the properties of the compound, show clearly that trimethyl tin iodide is one of the products of iodination of the original mixture. Nearly all the iodine concerned in the reaction is converted to trimethyl tin iodide. In one experiment, 2.716 g. of iodine was required for iodination and 2.566 g. was recovered as trimethyl tin iodide.

Seemingly, one constituent of the original product of reaction between sodium trimethyl stannide and chloroform is trimethyl tin. The second constituent of this product appears to be resistant to the action of iodine and, even, as later experiments have shown, to bromine at ordinary temperatures. The original reaction proceeds smoothly and, seemingly, quantitatively, except for losses that seem to be due chiefly to trimethyl tin. We may account for the products of the reaction by assuming that tri-trimethyl stannyl methane is formed as an intermediate product according to Equation I, and that this, in turn, breaks down according to the reaction equation

$$2[(CH_3)_3Sn]_3CH = 2[(CH_3)_3Sn]_2 + (CH_3)_3SnCH{=}CHSn(CH_3)_3 \qquad \text{(II)}$$

The second constituent of this reaction, di-trimethyl stannyl ethylene, is an unsaturated aliphatic derivative and might be expected to add halogens. This, however, is not the case. Nevertheless, the experiments which we have carried out seem to indicate that this compound is, in fact, formed as one of the products of interaction between sodium trimethyl stannide and chloroform.

Properties of Di-trimethyl Stannyl Ethylene.—The second constituent of the product formed by the interaction of chloroform and sodium trimethyl stannide was isolated by evaporating the ethereal solution after removal of the trimethyl tin by means of iodine and ammonia, as described above. The last traces of ether were removed by means of a vacuum pump. The resulting product appeared to be a substantially pure compound which is quite stable and which boils at 194–195° under atmospheric pressure. It does not solidify at liquid ammonia temperatures.

The molecular weight of the compound was determined by the cryoscopic method, using benzene as solvent. The following results were obtained.

Mol. *wt.* Solvent, 35.60, 18.72, 19.49: solute, 1.7447, 0.2169, 0.9320; *At,* 0.704, 0.166, 0.692"; mol. wt., found, 348.0, 349.0, 345.6; calcd. for $[(CH_3)_3SnCH]_2$, 353.4.

The last experiment was carried out with a sample specially purified, as will be described below.

The compound was analyzed for tin by the Carius method.

Anal. Subs., 0.2521, 0.2038, 0.1952: SnO_2, 0.2153, 0.1729, 0.1665. Calcd. for $[(CH_3)_3SnCH]_2$: Sn, 67.17. Found: Sn, 67.27, 66.83, 67.19: mean, 67.10.

Carbon and hydrogen determinations were also made on the compound but it was difficult to obtain entirely satisfactory results, owing chiefly to the fact that it was very difficult to obtain an even combustion of the material.[2] The following results were obtained.

Anal. Subs., 0.2672, 0.4356, 0.1910: H_2O, 0.1444, 0.2368, 0.3901; CO_2, 0.2604, 0.3901, 0.1779. Calcd. for $[(CH_3)_3SnCH]_2$: H, 5.70; C, 27.15. Found: H, 6.05, 6.09, 6.19, mean, 6.11; C, 26.58, 24.43, 25.39, mean, 25.47.

While the results of these analyses are somewhat variable, when taken in connection with the analyses for tin and the molecular weight of the compound, there seems little doubt but that the formula assigned to it is correct. It seems strange, however, that a compound having a pair of doubly bonded carbon atoms should be so stable, generally, toward the halogens.

If di-trimethyl stannyl methane is one of the primary products of the original reaction, then, in order to account for the results obtained on iodination, it is necessary to assume that some trimethyl tin is lost prior to iodination. It seems that the difference in the tin content of a mixture corresponding to the formula $[(CH_3)_3Sn]_3CH$ and one in which three parts of the ethylene derivative are mixed with four parts of trimethyl tin, might be detected by analysis. Accordingly, careful analyses for tin were carried out by the Carius method with the following results.

Anal. Subs., 0.4761, 0.1698: SnO_2, 0.4238, 0.1511. Found: Sn, 70.12, 70.10; mean, 70.11.

For a mixture corresponding to the formula of tri-trimethyl stannyl methane, 70.64% of tin is required, while for a mixture containing three moles of the ethylene compound to four moles of trimethyl tin, $[(CH_3)_3Sn]_2$, 70.20% is required.

Bromination of $[(CH_3)_3SnCH]_2$.—Although di-trimethyl stannyl ethylene is inactive toward bromine at ordinary temperatures, bromination takes place slowly in boiling carbon tetrachloride. A known weight of the ethylene derivative was accordingly treated with bromine and, when the reaction was completed, the mixture was allowed to cool and ammonia was passed through the solution. A precipitate was formed which, on analysis, was shown to be diammino dimethyl tin dibromide, $(CH_3)_2SnBr_2 \cdot 2NH_3$. The precipitate was thrown on a filter, washed, dried and analyzed.

Anal. Subs., 0.1914, 0.3170: AgBr, 0.2128, 0.3484. Calcd. for $(CH_3)_2SnBr_2 \cdot 2NH_3$: Br, 46.66. Found: Br, 47.34, 46.78. Subs., 0.1461: SnO_2, 0.0632. Calcd. for $(CH_3)_2SnBr_2 \cdot 2NH_3$: Sn, 34.66. Found: Sn, 34.07.

The amount of tin recovered in the form of diiethyl tin dibromide was 1.1 g., while the amount of tin present in the original compound was 1.17 g. It seems that, on bromination, the following reaction occurs

$$(CH_3)_3SnCH{=}CHSn(CH_3)_3 + 4Br_2 = 2(CH_3)_2SnBr_2 + 2CH_3Br + 2C_2H_2Br_2 \quad \text{(III)}$$

Action of Sodium on Di-trimethyl Stannyl Ethylene in Liquid Ammonia.—To gain some further knowledge as to the constitution of the above compound, it was introduced

---

[2] For these determinations we are indebted to Mr. E. Alison Flood of this Laboratory.

into a reaction tube and treated with metallic sodium in liquid ammonia. As reaction proceeded, gas was evolved, the solution acquired a yellow color and a fine granular precipitate was formed. This precipitate was doubtless sodium amide. The evolved gas proved to be methane. On adding ammonium bromide to the reaction products in the tube, the precipitate disappeared and a gas was evolved which proved to be hydrogen. After disappearance of the sodium amide, further addition of ammonium bromide resulted in the precipitation of an oily liquid which was highly volatile. The reactions appeared to be similar to those previously studied in the case of di-trimethyl stannyl methane.'

Weighed samples of di-trimethyl stannyl ethylene in sealed bulbs were introduced into the reaction tube, in which they were then broken. The compound in question had previously been prepared in considerable quantity and was subjected to fractional distillation under a pressure of 17 mm., under which condition it boiled at 85–86.5°. No sign of decomposition was observable. The product was analyzed for tin, the results of which analyses have already been given. The results of these reduction experiments are tabulated.

TABLE I

REDUCTION OF DI-TRIMETHYL STANNYL ETHYLENE

Compound, g.	Sodium, g.	Gas evolved, cc.	Mol. wt. evolved gas
2.5221	0.5979	133.4	16.1
2.2803	.5979	136.6	17.7

M. moles compound	M. atoms sodium	Atoms sodium per mole of compound	Mole of gas per mole of compound
7.13	26.00	3.65	0.84
6.45	26.00	4.03	.95

As may be seen from the table, approximately four atoms of sodium were required to reduce the compound completely. In general, an excess of metal was added, which excess was determined by titrating back with ammonium bromide. This method is not precise, as there is a tendency for particles of ammonium bromide to adhere in the colder portions of the reaction tube, which, in general, leads to values for the reacted sodium that are too low. The evolved gas was passed through a concentrated solution of sodium in liquid ammonia to remove volatile tin compounds. Any loss in the tin compounds leads to low values for the amount of gas evolved. In the two experiments for which the data are given, the compound was dropped slowly into a concentrated solution of sodium in liquid ammonia. Under these conditions, reaction takes place immediately and there is less chance for loss of the compound. The relative amount of gas obtained in these experiments was markedly higher than that obtained in earlier experiments, in which the metal was dropped into a solution of the compound in liquid ammonia.

Samples of gas were analyzed by the explosion method. The results of three such analyses are given below.

Assuming the gas to be methane, the following reaction occurs on explosion

$$CH_4 + 2O_2 = CO_2 + H_2O \text{ (liquid)}$$

TABLE II

ANALYSIS OF EVOLVED GAS

	Cubic centimeters		
Vol. gas taken	20.4	13.8	24.3
Vol. oxygen added	61.4	75.0	67.2
Total vol.	81.8	88.8	91.5
Vol. after explosion	41.0	62.4	42.8
Contraction of vol. on explosion	40.8	26.4	48.6
Vol. after absorbing CO_2	21.0	49.2	18.8
Vol. CO_2 absorbed	20.0	13.2	24.1

The contraction on explosion, should be equal to twice the volume of methane and the contraction of volume, on absorption of carbon dioxide, should be equal to the original volume of methane. As may be seen, the results of analyses are in excellent agreement with the reaction equation for methane. There can be no doubt, therefore, that when di-trimethyl stannyl ethylene is reduced by means of sodium in liquid ammonia, one mole of methane is evolved per mole of compound. The reaction equation may be written as follows

$$(CH_3)_3SnCH{=}CHSn(CH_3)_3 + 4Na + 2NH_3 = (CH_3)_3SnNa + CH_2{=}CHSn(CH_3)_2Na + 2NaNH_2 + CH_4 \quad (IV)$$

Actually, the reaction takes place in two stages. First, the linkage between a trimethyl tin group and an ethylenic carbon atom is broken down according to the reaction equation

$$(CH_3)_3Sn{=}CHSn(CH_3)_3 + 2Na + NH_3 = (CH_3)_3SnNa + CH_2{=}CHSn(CH_3)_3 + NaNH_2 \quad (V)$$

Trimethyl vinyl tin in turn is reduced by sodium, a methyl group being split off according to the equation

$$CH_2CH{=}Sn(CH_3)_3 + 2Na + NH_3 = CH_2{=}CHSn(CH_3)_2Na + CH_4 + NaNH_2 \quad (VI)$$

Thus, as a net result of the reaction, there is obtained an equimolar mixture of sodium trimethyl tin and sodium dimethyl vinyl tin.

Preparation of Trimethyl Vinyl Tin.—According to the above reaction equations, the liquid ammonia solution, on completion of the reaction, contains sodium trimethyl stannide and sodium dimethyl vinyl stannide. It is difficult to separate the trimethyl tin from the dimethyl vinyl derivative. The final product of the reaction, after evaporation of the ammonia, had a markedly different appearance from pure sodium trimethyl tin, The mixture seemed to be much more stable at ordinary temperatures and was of a bright yellow color.

It was thought that some information might be gained as to the existence of the vinyl compound by treating the reaction mixture with methyl iodide, which would lead to the formation of tetramethyl tin and trimethyl vinyl tin. This reaction was accordingly carried out. Since both tetramethyl tin and trimethyl vinyl tin are highly volatile compounds and in order to avoid loss, alcohol was added to the reaction products in the reaction tube and then water. The reaction tube was then removed from the ammonia bath and water was added until the tube was nearly filled. The supernatant aqueous solution was siphoned off and the light oil in the bottom was washed several times with fresh water. The bottom of the reaction tube was then cut off, traces of water were removed with filter paper, the tube was suspended in liquid ammonia to freeze the last drops of water and, while it was still cold, the liquid was transferred to a second tube through a fine capillary. In this tube the liquid was washed several times with liquid ammonia in order to remove traces of water. The tube was then sealed and evacuated. The molecular weight of the vapors of this liquid was then determined by the vapor density method. In general, the temperature of the tube containing the liquid was kept at least several degrees below room temperature. The pressure was read on a specially constructed closed-end manometer, the limbs of which had a diameter of 18 mm. The difference in level of the mercury columns was read by means of a cathetometer and the readings were reproducible within 0.05 mm. Appropriate corrections were applied for the temperature of the mercury, etc.

In a first series of measurements, the density varied from 184.7 initially to 194.2 at the end. There was a small amount of liquid left in the bottom of the tube at the end of these experiments which was much more difficultly volatile than the remainder. The more volatile constituents were accordingly condensed and a second series of density determinations was carried out. As may be seen from Table III, the molecular weight of the vapor increased continuously from 181.1 to 190.9. The molecular weight of tetramethyl tin is 178.8 and that of trimethyl vinyl tin is 190.8.

TABLE III

MEAN MOLECULAR WEIGHT OF VAPOR MIXTURES OF TETRAMETHYL TIN AND TRIMETHYL VINYL TIN

Volume of density bulb = 345.7 cc.

Vapor, g.	Pressure, cm.	Temp. of vapor, °C.	Mol. wt.
0.1351	4.028	26.1	181.1
.1298	3.862	25 9	181.3
.1756	5.188	26.5	183.0
.1895	5.599	26.8	183.1
.1487	4.385	27.1	183.8
.1295	3.805	27.0	184.3
.1475	4.314	27.0	186.0
.1372	3.988	27.4	186.1
.1380	4.014	27.5	186.5
.0873	2.488	28.4	190.9

The determinations of molecular weights by the vapor density method show clearly that the material consisted of a mixture of two substances whose molecular weights correspond closely to those of tetramethyl tin and trimethyl vinyl tin. Further work will be required in order to definitely establish the existence of trimethyl vinyl tin. The results support the experiments previously described as indicating the formation of di-trimethyl stannyl ethylene when sodium trimethyl tin reacts with chloroform.

An attempt was made to prepare di-trimethyl stannyl ethylene by the action of sodium trimethyl tin on acetylene chloride. It was found that, while reaction took place readily, the tin derivative was all converted to trimethyl tin.

Action of Carbon Tetrachloride on Sodium Trimethyl Tin and Sodium Triethyl Tin.—Carbon tetrachloride reacts readily with sodium trimethyl tin, the chief product of the reaction being trimethyl tin or hexamethyl stanno-ethane. The trimethyl tin separates as the reaction proceeds. A sample of the product gave a molecular weight of 319.5 in benzene, which is in good agreement with 327.4, the molecular weight of the stanno-ethane. On analysis, it was shown that the compound contained 72.65% of tin, while that required for hexamethyl stanno-ethane is 72.48.

All the tin originally present in the reacting materials was recovered as stanno-ethane. In one experiment 0.155 cc. of carbon tetrachloride was allowed to react with sufficient sodium trimethyl tin to complete the reaction. The carbon tetrachloride used was equivalent to 0.2208 g. of chlorine. The chlorine was recovered in the form of silver chloride at the end of the reaction. The silver chloride weighed 0.8706 g., which is equivalent to 0.2154 g. of chlorine. This shows that the chlorine was completely removed from the carbon tetrachloride. What happens to the carbon atom of the tetrachloride has not, as yet, been determined. It probably reacts with the solvent.

Sodium triethyl tin reacts with carbon tetrachloride in the same way as does sodium trimethyl tin. The chief product of the reaction is hexaethyl stanno-ethane. The molecular weight (in benzene) of the product obtained was 413.1, as against 411.4 required for the stanno-ethane.

Summary

The reaction between chloroform and sodium trimethyl stannide in liquid ammonia has been investigated. A tertiary substitution product is not formed but there is produced a mixture of trimethyl tin and di-trimethyl stannyl ethylene. The latter compound is a liquid boiling at 194–195° and having a normal molecular weight in benzene. The halogens do not add readily to the ethylenic group. At higher temperatures bromine reacts with the formation of dimethyl tin dibromide.

On reducing di-trimethyl stannyl ethylene with sodium in liquid ammonia

there is formed an equimolar mixture of sodium trimethyl stannide and sodium dimethyl vinyl stannide, along with methane and sodium amide. On adding methyl iodide to this mixture there is produced a mixture of tetramethyl tin and trimethyl vinyl tin. Trimethyl vinyl tin has not as yet been obtained in the pure state.

THE FRIEDEL AND CRAFTS REACTION WITH 8-HYDROXYQUINOLINE

BY KONOMU MATSUMURA

RECEIVED JULY 14, 1930 PUBLISHED NOVEMBER 5, 1930

On adopting the method of Behn and Rosenmund,[1] the Friedel and Crafts reaction was found to be applicable to 8-hydroxyquinoline and this paper deals with the preparation of 5-acetyl-, 5-benzoyl- and 5-chloro-acetyl-8-hydroxyquinoline. That the acyl radicals which have been introduced occupied position 5 could be ascertained by converting these compounds into the known substances either by a Beckmann rearrangement of their oximes or by reduction, respectively.

Experimental

5-Acetyl-8-hydroxyquinoline.—On introducing acetyl chloride (25 g.) into the solution of 8-hydroxyquinoline (43.5 g.) in nitrobenzene (400 g.), yellow precipitates separated. On the addition of aluminum chloride to it 100 g. at a time under shaking, the precipitates disappeared and a clear solution resulted. It was kept at 70° for twelve hours in a flask fitted with a calcium chloride tube. On cooling, some crushed ice and 100 cc. of hydrochloric acid (10%) were added to it and the separated nitrobenzene was driven off with steam. On standing overnight, the separated hydrochloride of 5-acetyl-8-hydroxyquinoline was filtered. It was dissolved in water and on the addition of sodium acetate to it, the free base separated out. It was recrystallized from hot water; yield, 25.5 g. (45% of the theoretical) after recrystallization.

It forms in colorless hair-like needles from hot water, m. p. 112–112.5°. It is fairly easily soluble in the usual organic solvents, dilute mineral acid or alkali. It gives a green color with ferric chloride and a deep red color with diazotized sulfanilic acid and alkali.

Anal. Subs., 5.043 mg.: CO_2, 13.029; H_2O, 2 111. Subs., 6.715: N_2, 0.421 (15°, 769 mm.). Calcd. for $C_{11}H_9O_2N$: C, 70.59; H, 4.81: N, 7.49. Found: C, 70.46; H, 4.65; N, 7.42.

Beckmann Rearrangement of its Oxime.—A mixture of the oxime (0.2 g.), glacial acetic acid (1.6 g.) and acetic anhydride (0.4 g.) was saturated with hydrogen chloride gas in the cold and was kept at 100° for three hours in a sealed tube. On cooling, the contents were made alkaline with sodium carbonate and shaken with chloroform. On concentrating the solvent, colorless crystals were obtained; yield, 0.18 g. It formed in colorless flat needles from chloroform, m. p. 216–217.5°. The mixed melting point with an authentic specimen of 5-acetamino-8-hydroxyquinoline (m. p. 217–218°) which had

---

been prepared by acetylation of the 5-amino-8-hydroxyquinoline of Kostanecki[2] gave 217–218°.

Anal. Subs., 2.681: N_2, 0.324 (24.5°, 761.8 mm.). Calcd. for $C_{11}H_{10}O_2N_2$: N, 13.86. Found: N, 13.50.

Acid sulfate gave yellow stout needles from alcohol, m. p. 263° (decomp.).

5-ω-Chloro-acetyl-8-hydroxyquinoline.—This compound was obtained in the same manner as that described for acetylhydroxyquinoline using chloro-acetyl chloride, except that the reaction temperature was kept at 90–95° for seven hours and that the recrystallization was effected by means of warm benzene; yield, 36% of the theoretical. It forms in colorless glistening needles from benzene, m. p. 158–159°. It is fairly easily soluble in the usual organic solvents, dilute mineral acid or caustic soda and moderately soluble in hot water. It gives a green color with ferric chloride and a deep red color with diazotized sulfanilic acid and alkali.

Anal. Subs., 4.984: CO_2, 10.875; H_2O, 1.676. Subs., 4.791: N_2, 0.270 (23.5°, 753 mm.). Calcd. for $C_{11}H_8O_2NCl$: C, 59.59; H, 3.61; N, 6.32. Found: C, 59.51; H, 3.73; N, 6.24.

Reduction of **5-Chloro-acetyl-8-hydroxyquinoline.**—A mixture of 0.15 g. of 5-chloro-acetyl-8-hydroxyquinoline, 1 g. of iron powder and 25 g. of alcohol (80%) with the addition of two drops of hydrochloric acid (10%) was refluxed for three hours. The reaction fluid, after filtration while hot, was evaporated to dryness. On the addition of hydrochloric acid (10%) and trituration, yellowish-white crystals separated out. It was filtered and dissolved in hot water. On addition of sodium acetate to it, colorless flocculent needles separated. These were recrystallized from hot water into colorless needles; m. p. 110–111°; yield, 0.05 g. The mixed melting point with 5-acetyl-8-hydroxyquinoline (m. p. 112–112.5°) gave m. p. 110–112°.

Anal. Subs., 4.022: N_2, 0.269 (22.6°, 758.4 mm.). Calcd. for $C_{11}H_9O_2N$: N, 7.49. Found: N, 7.48.

5-Benzoyl-8-hydroxyquinoline.—Benzoyl chloride (9 g.), 8-hydroxyquinoline (8.7 g.) and aluminum chloride (20 g.) were dissolved in nitrobenzene (80 g.) in the same manner that was described in the previous case. The solution was kept at 110–120° for seven and one-half hours. On cooling, after the addition of ice and hydrochloric acid, the separated nitrobenzene was distilled with steam. Then the separated crystalline mass was filtered, after standing overnight, and washed with hydrochloric acid (10%) until the filtrate became colorless.

It was recrystallized from dilute hydrochloric acid and then the free base was isolated by means of sodium acetate; yield, 11.5 g. (77% of the theoretical). It forms in colorless needles from hot alcohol; m. p. 118–119°. It is fairly easily soluble in the usual organic solvents or in dilute mineral acid, moderately soluble in hot water but difficultly in dilute caustic soda. It gives a green color with ferric chloride and a red color with diazotized sulfanilic acid and alkali.

Anal. Subs., 5.181: CO_2, 14.691; H_2O, 1.967. Subs., 5.152: N_2, 0.261 (21°, 757.7 mm.). Calcd. for $C_{16}H_{11}O_2N$: C, 77.11; H. 4.42; N, 5.62. Found: C, 77.33; H, 4.22; N, 5.73.

Beckmann Rearrangement of its Oxime.—Two-tenths gram of the oxime was treated in exactly the same manner as that described for the rearrangement of the oxime of 5-acetyl-8-hydroxyquinoline; yield. 0.2 g. It forms in yellowish-white small plates from chloroform; m. p. 237–238°. The mixed melting point with an authentic specimen of 5-benzoylamino-8-hydroxyquinoline (m. p. 237–238°) which had been pre-

pared by benzoylation of 5-amino-8-hydroxyquinoline showed no depression. Moreover, by hydrolysis with hydrochloric acid (20%) the formation of benzoic acid could be ascertained by the mixed melting point method.

Anal. Subs., 3.066: N_2, 0.290 (24°, 766 mm.). Calcd. for $C_{16}H_{12}O_2N_2$: N, 10.61. Found: N, 10.63.

Acid sulfate gave yellow columns from alcohol; m. p. 221–222' (decomp.).

8-Benzoyloxyquinoline.—The benzoylation of 8-hydroxyquinoline with benzoyl chloride was carried out in the presence of pyridine in the cold; yield, 90% of the theoretical after recrystallization. It forms in colorless tables from alcohol; m. p. 122–122.5''.

This compound was prepared first by Bedall by the interaction of 8-hydroxyquinoline and benzoyl chloride at a high temperature; he found a melting point of 118–120° for his product.[3]

Anal. Calcd. for $C_{16}H_{11}O_2N$: N, 5.62. Found: N, 5.54.

The hydrochloride was obtained by treating an ice cold ethereal solution of the free base with dry hydrogen chloride gas. It forms in colorless needles; m. p. 124°. It is easily soluble in water.

Anal. Calcd. for $C_{16}H_{11}O_2N\cdot HCl$: HCl, 12.78. Found: HCl, 12.54.

On submitting this hydrochloride to a Friedel and Crafts reaction, benzoic acid and 8-hydroxyquinoline could be recovered and no condensation product could be isolated.

I hereby desire to express my hearty thanks to Professor Hata for the interest which he has kindly taken in this work and to Mr. C. Sone for his assistance in this investigation.

Summary

The preparation of 5-acetyl-, 5-chloro-acetyl- and 5-benzoyl-8-hydroxyquinoline has been reported.

THE DETERMINATION OF THE STRENGTH OF WEAK BASES AND PSEUDO BASES IN GLACIAL ACETIC ACID SOLUTIONS[1]

BY J. B. CONANT AND T. H. WERNER

RECEIVED JULY 17, 1930 PUBLISHED NOVEMBER 6, 1930

Previous papers of this series have shown that the titration of bases with strong acids in glacial acetic acid solution may be followed by means of the chloranil electrode. We have been interested in extending this study of weak bases to weak pseudo-bases of the type of triphenyl carbinol. It is only by the use of a solvent such as glacial acetic acid that these weak pseudo-bases can be studied and the oxidation–reduction systems composed of free radicals and halochromic salts can be investigated. Before continuing the study of these more strictly organic problems, it was necessary

[3] Bedall and Fischer, Ber., 14, 1367 (1881).

[1] This is Paper 4 in a series on Superacid Solutions. For earlier papers of this series, see THIS JOURNAL. 49,3047,3062 (1927); and 50,2367 (1928).

to obtain more information in regard to the factors influencing the dissociation constants of weak bases in glacial acetic acid. From the earlier work it was clear that the neutral salt concentration was an important factor. For example, the shape of the titration curves obtained by Hall and Werner[2] clearly pointed to a marked effect of the changing ionic strength on the strength of the base being titrated.

We shall first present in this paper certain results obtained in a study of the effect of the ionic strength on dissociation constants of weak bases in glacial acetic acid solution. The results were obtained by two different methods. One was the electrochemical method using the chloranil electrode in exactly the manner previously described. The other method was to take advantage of the color changes which take place when crystal violet is further neutralized by the addition of strong acids. These changes have been studied in detail in water solution by Adams and Rosenstein.[3] Since the results obtained by the e. m. f. method with colorless bases, and by a spectrophotometric method with crystal violet, are closely related, they will be discussed together.

The results obtained with crystal violet may be considered first. Adams and Rosenstein have proved that the change of color of this substance from violet through blue and green to yellow on adding strong acid, is due to the formation of the green and yellow ions which correspond to the addition of one and two protons, respectively, to the violet ion, according to the equations

$$\underset{\text{violet}}{B^+} + H^+ \rightleftharpoons \underset{\text{green}}{BH^{++}} \qquad (1)$$

$$\underset{\text{green}}{BH^{++}} + H^+ \rightleftharpoons \underset{\text{yellow}}{BH_2^{+++}} \qquad (2)$$

One is thus in a position to evaluate the equilibrium constants for the first and second reactions written above (K_1' and K_2') from spectrophotometric data. Actually, the values of K_2' are subject to a much greater experimental error and the agreement among them we found to be unsatisfactory, and the change of this constant with change in ionic strength was irregular, for reasons which are not entirely clear. For these reasons we shall attempt to interpret only the changes of K_1' with change of ionic strength, giving only an approximate value for K_2'.

Briefly, the method consisted in measuring the extinction coefficients of solutions of crystal violet in buffer solutions of definite ionic strength and measured $P_{\text{H}}^{(\text{HAc})}$. The concentration of dye was so small (4×10^{-6} to 2×10^{-6} molar) that its contribution to the ionic strength could be neglected. The extinction coefficient was measured at intervals of 10 mμ from 470 to 680. From the curves thus obtained with solutions which

---

[3] Adams and Rosenstein, *ibid.*, 36, 1452 (1914).

varied from violet ($P_{H}^{(HAc)}$ + 4.75) to yellow (**−3.96**) through blue and green, it is possible to obtain by a process of trial and error the fundamentals corresponding to the extinction coefficients of the violet, the green and the yellow forms (B^+, BH^{++} and BH_2^{+++}). As a first approximation, the molecular extinction coefficients of crystal violet in 3 molar pyridine in glacial acetic acid ($P_{H}^{(HAc)}$ + 4.75) were used for the fundamentals of the violet form and those for the yellow were taken from a 0.05 molar perchloric acid solution in glacial acetic acid. Beyond 540 mμ the absorption due to the yellow species, even if present in large amounts, is practically negligible. Therefore by studying a green solution (by using the appropriate buffer) it is possible to obtain a rough approximation of the green fundamental from the assumed violet fundamental. Finally, the three fundamentals were adjusted by a trial and error method so that the absorption curves obtained with all the fifty solutions yielded satisfactory agreement on the assumption of a certain composition for each solution. Three typical curves are shown in Fig. 1 and the fundamentals finally chosen are given in Table I. It may be noted that the equation for the extinction coefficient of a particular solution at a particular wave length is

$$V\epsilon_v + G\epsilon_G + Y\epsilon_y = \epsilon$$

where ϵ_v, ϵ_G and ϵ_y are the fundamentals and V, G and Y the fraction of the material present in the violet, green and yellow forms. Since there was no evidence of a colorless form, the sum of those fractions was taken as one. The fading, noted by Adams and Rosenstein, which was due to hydrolysis, was not evident in our work because the amount of water present was negligible. The algebraic solution of the above equation is impossible but satisfactory results may be obtained by the laborious trial and error method just described.

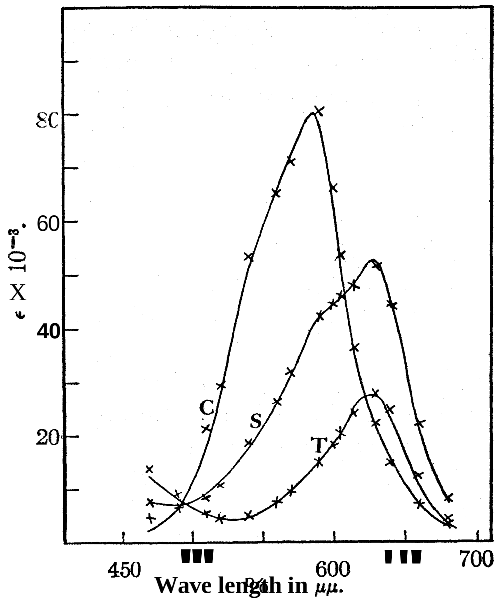

Fig. 1.—Typical absorption curves for crystal violet in acetic acid buffers. Solid lines are experimental curves. Crosses indicate points calculated on assumption of following compositions:

Curve	% Violet	% Green	% Yellow
C	82	8	10
S	20	43	37
T	1	25	74

Expressed logarithmically, the mass law equations for the two equilibria are

$$pK_1' = P_H^{(HAc)} - (\log V - \log G) \qquad (1a)$$
$$pK_2' = P_H^{(HAc)} - (\log G - \log Y) \qquad (2a)$$

The data obtained in the measurements of the $P_H^{(HAc)}$ values are summarized in Table II and the results of the spectrophotometric measurements in Table III.

Throughout this paper we have used the same arbitrary convention in regard to the placing of the $P_H^{(HAc)}$ scale as that used in the previous papers of this series. The actual numerical values of the pK's are therefore given in terms of the zero point of that scale. The uncertainty in the reproducibility of the PH values is probably about ±0.02.

The data given in Table III are plotted in Fig. 2. The smooth curves correspond to equations relating pK' and $\sqrt{\mu}$ developed from the fundamental Debye–Hückel Equation **3.**

$$-\log \gamma = \frac{Az^2 \sqrt{\mu}}{1 + Ba \sqrt{\mu}} \qquad (3)$$

Taking the dielectric constant of the medium as 10 and the temperature as 25°, the values of A and B are found to be 11.15 and 0.921×10^8. Substituting we obtain Equation 4

$$-\log \gamma = \frac{11.15 z^2 \sqrt{\mu}}{1 + 0.921 \times 10^8 a \sqrt{\mu}} \qquad (4)$$

Defining the term pK_1 by Equation 5 and substituting the value of $-\log \gamma$ from (4) with appropriate values for z (+1 for z_1 and +2 for z_2), Equation 6 results

$$pK_1 = pK'_1 - \log \frac{\gamma_1}{\gamma_2} \qquad (5)$$

$$pK_1 = pK'_1 - \frac{33.5 \sqrt{\mu}}{1 + 0.921 \times 10^8 a \sqrt{\mu}} \qquad (6)$$

The denominator of the fraction in Equation 6 may be taken as unity for small values of $\sqrt{\mu}$. The resulting equation defines the limiting slope for the change of pK'_1 in dilute solutions; this is shown by line E, Fig. 2. For purposes of comparison, the corresponding slope in aqueous solutions is shown by line A. Applying the limiting equation to the values for pK'_1 obtained in the more dilute solution we estimate pK_1 as -1.7. Substituting this value in Equation 6, and taking "a" as 1.3×10^{-7}, an equation corresponding to Curve B results. Curves C and D were obtained by choosing values of "a" of 1.24 and 1.16×10^{-7}. In deriving Equation 4 the value of the dielectric constant for acetic acid at 25° was taken as 10; the recent measurements of Smyth[4] indicate that the correct value is more nearly 6 for 100% acetic acid. However, since the effect of the presence of salts and a small amount of water (the acetic acid employed in this work melted at 16.4° and contained

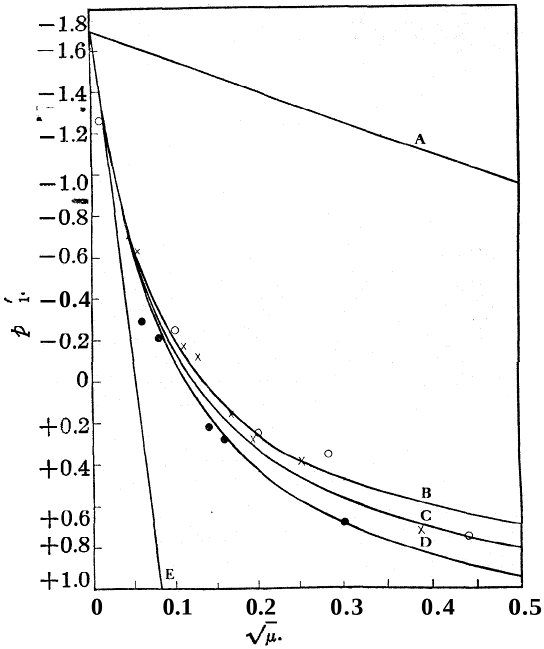

Fig. 2.—Change of pK'_1 for crystal violet with change in ionic strength. ---

[4] Smyth, This Journal, 52, 1825 (1930).

about *0.2%* of water) is uncertain, we have not thought it worth while to carry through another set of calculations using the dielectric constant of 6. The smaller value would merely give a steeper limiting slope and a different value of *"a"* (essentially an arbitrary constant) would be required in fitting the equation to the experimental points.

The tremendous effect of change of ionic strength on the value pK_1' for crystal violet is evident from Fig. 2. This effect is particularly large in this case, of course, because of the fact that the reaction involves the addition of a proton to a singly charged positive ion with the formation of the doubly charged positive ion. The limiting slope of the Debye theory corresponds to a change of more than 2 PH units for an increase of $\sqrt{\mu}$ from 0 to *0.05.* This is about twenty times the corresponding effect in water, due to the extremely low dielectric constant of glacial acetic acid. However, as a matter of actual fact, the experimental points show a departure from the theoretical limiting slope long before this value is reached, and the total change of pK_1' from the limiting value at $\mu = 0$ to $\sqrt{\mu} = 0.5$ is about 2.6 PH units.

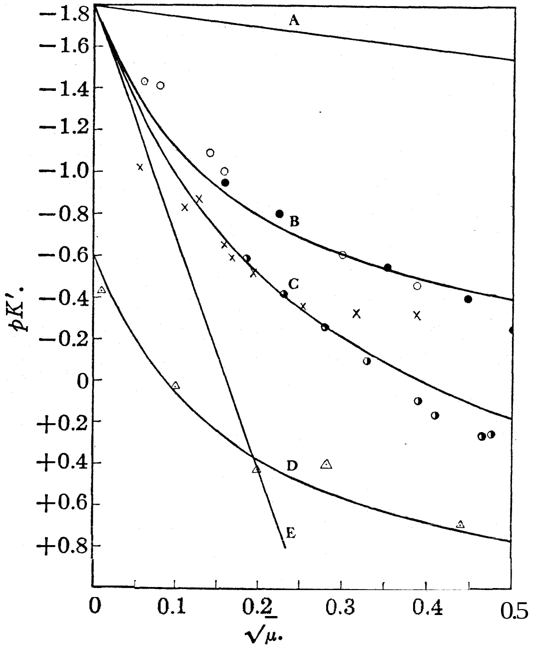

Fig. 3.—Change of pK' for urea and acetoxime with change in ionic strength. A, Theoretical slope for very dilute water solutions; E, theoretical slope for very dilute solutions in glacial acetic acid; B, ○, ●, urea–perchloric acid; C, × ◑, urea–sulfuric acid; D, △, acetoxime-sulfuric acid; ◑, effect of neutral salt (trimethylammonium *p*-toluene sulfonate) on pK' of urea half neutralized with H_2SO_4; ● urea–perchloric acid points from data by Hall and Werner.

The results shown in Fig. 3, which represent the effect of changing ionic strength on the values of pK' for urea and acetoxime, reveal a situation similar to that discussed in the preceding paragraph, except that the limiting slope is here only one-third of that found in the case of crystal violet since the reaction involves the formation of a singly charged ion from a neutral molecule. Neither these results nor those obtained with crystal violet are sufficiently accurate to give a very significant extrapolated value for pK_1 since it is very difficult to obtain measurements in solutions of low ionic strength. In fact, the first value in Section b of Table II has been omitted from Fig, 3 since it is clearly out of line with the other results, presumably because of the difficulties of measuring significant e. m. f.'s with very dilute solutions. In the case of the crystal violet measurements, which were made spectrophotometrically, the solution may be very dilute with respect to the base, but one is dependent on electrical measurements for the $P_H^{(HAc)}$ values of the buffer solutions which must, therefore, be relatively concentrated.

Three different sets of data were used in plotting Fig. 3, as indicated by the symbols. The measurements of the $P_H^{(HAc)}$ values of the buffers employed for the crystal violet work comprised one set; these data are given in Table II. Another set of facts was obtained by adding measured increments of a molar solution of $(CH_3)_3NHSO_3C_6H_4CH_3(p)$ in glacial acetic acid to a 0.05 molar solution of urea in the same solvent half neutralized with sulfuric acid. The ionic strength was calculated as the sum of that contributed by the urea salt and the added neutral salt. The $P_H^{(HAc)}$ was measured in the usual way and since the urea was half neutralized these numbers corresponded directly to the pK'. The third set of values was calculated from the titration of urea with perchloric acid given by Hall and Werner.[2] The value of pK for urea was taken as -1.8 by extrapolation by means of the limiting law Debye equation (Curve E). Curves B and C were drawn from the application of Equations 4 and 5 ($z_1 = 0, z_2 = +1$) and "a" being taken as 0.65 X 10^{-7}, and 0.4 X 10^{-7}, respectively; the equations for Curves B and C were thus

$$pK' = pK + \frac{11.15\sqrt{\mu}}{1 + 5.98\sqrt{\mu}} \tag{7}$$

and

$$pK' = pK + \frac{11.15\sqrt{\mu}}{1 + 3.68\sqrt{\mu}} \tag{8}$$

Curve D for acetoxime was the same as Curve B, the extrapolated value for pK being taken as -0.6.

It is evident from the data summarized in Figs. 2 and 3 that in the more concentrated solutions there are specific effects depending on the nature of the neutral salt. These effects are larger than the corresponding effects in water because of the low dielectric constant of acetic acid. The agreement between the urea–perchloric acid points from the data of Hall and Werner and from Table II is gratifying as showing the reproducibility of our methods. It is clear that both the nature of the cation and anion of the neutral salt are important (divergence of the points on Curves C and D, Fig. 1, and B and C, Fig. 2). The application of these facts to the use of indicators in glacial acetic acid is evident and until the very large "salt effect" with each compound is carefully plotted, conclusions drawn from the use of indicators are only very approximate.

We have been particularly concerned in reducing to a practical working basis our knowledge of strong acids and weak bases in glacial acetic acid with the idea of constructing buffer solutions. The information which we have now obtained from the study of crystal violet, urea and acetoxime, shows clearly the great importance of the ionic strength. In comparing a series of results in buffer solutions, the ionic strength must be constant. If possible, the same neutral salt should be used in every case but even if this is not possible it is better to make all the solutions of the same ionic strength than to neglect this factor. Variations as great as a Ph unit might perhaps be caused by a difference in the nature of the neutral salt, although most of the effects recorded in this paper are only of the order of a few tenths of a Ph unit.

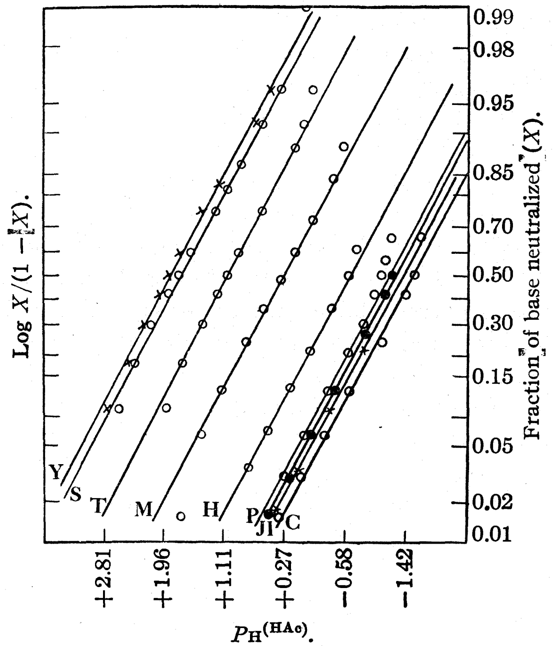

Fig. 4.—Titration curves of bases with sulfuric acid at ionic strength of 0.2 (trimethyl ammonium *p*-toluene sulfonate) plotted on a "Logistic Grid." C, Triphenyl carbinol; I, dianisylcarbinol; J, dianisalacetone; P, acetanilide; H, diphenylanisylcarbinol; M, urea; T, acetoxime; S, o-chloro-aniline; Y, phenylxanthanol.

If the ionic strength is kept constant by employing a relatively large amount of a neutral salt, satisfactory values of pK' can be obtained in a series of experiments. This is illustrated by the results summarized in Table IV for crystal violet in solutions of $\mu = 0.20$. The titration curves of nine bases (including three pseudo bases discussed below) obtained in solutions of $\mu = 0.20$ are plotted in Fig. 4. Since the ionic strength due to the neutral salt (trimethylammonium *p*-toluene sulfonate) is here large compared to the concentration of base (0.05 molar), the increase of ionic strength during the titration is negligible. For this reason the points lie much closer to the theoretical curve than was the case in the investigation by Hall and Werner where no neutral salt was employed. The neutral salt employed in the experiments recorded in Table IV was triethylammonium perchlorate. The values of pK' for urea given in Col. 4 of Table IV vary only slightly more than the probable experimental error; the average value -0.35 ($\sqrt{\mu} = 0.446$) is to be compared with the values of -0.42 and $+0.1$ obtained at the same ionic strength but with the ionic strength contributed by urea perchlorate and trimethylammonium *p*-toluene sulfonate, respectively (Fig. 3). The specific effect of the different neutral salts is evident.

TABLE IV

CONSTANTS FOR CRYSTAL VIOLET OBTAINED WITH BUFFER SOLUTIONS OF CONSTANT IONIC STRENGTH

As mentioned earlier in this article, the determination of pK'_2 for crystal violet was not satisfactory. The results have already been given in Tables III and IV. If one plots pK'_2 against $\sqrt{\mu}$ a rather irregular distribution of the points is obtained, the values being more negative in the more dilute solution, as would be expected. The range of values obtained at constant ionic strength is large and we are inclined to attribute the spread to experimental error in determining the percentage of yellow form with its very low extinction coefficient, although there is a regular trend in the data for which we have no explanation.

In connection with the comparison of the dissociation constants of weak bases in water and in acetic acid, it is interesting to consider the results we have obtained with crystal violet and those of Adams and Rosenstein. The values of pK'_1 and pK'_2 in aqueous solution are given by these authors as $+1.94$ and $+1.15$, and we may assume that these are also the values for pK_1 and pK_2 in water. Our extrapolated values are -1.7 and approximately −1.4, although the latter value can hardly be considered of much significance due to the difficulties connected with the measurement of pK'_2. Adams and Rosenstein's value for pK_1 is more positive by about 3.6 units than our value. Taking the value of pK for urea as −1.8 and comparing it with the value in water of about 0, we note that the latter is more positive by about two units. The contrast between water and acetic acid is less with urea than with crystal violet for the reason pointed out by Brönsted,[5] namely, that we are dealing with the reaction $B \longrightarrow BH^+$ instead of $B^+ \longrightarrow BH^{++}$. Any attempt to make correct adjustment between the PH scale in water and acetic acid (if indeed an accurate adjustment is really conceivable),[6] will obviously have to wait until more data can be accumulated which will enable the value of the pK' for different acids and bases in both solvents to be extrapolated to infinitely dilute solution. For practical purposes in the immediate future, we shall continue to use the scale as originally defined, realizing its empirical nature but believing that the position of the zero expresses the qualitative difference between the behavior of solutions of strong acids in water and glacial acetic acid.

Pseudo Bases.—Four of the bases whose titration curves are plotted in Fig. 4 are pseudo bases which react according to the following equation:

$$B^+ + H_2O \rightleftharpoons BOH + H^+$$

These are triphenylcarbinol (C), dianisyl carbinol (I), diphenylanisylcarbinol (H), and phenylxanthanol (Y). It is clear that the titration method in glacial acetic acid provides for the first time a method of obtaining really significant values for the basic strength of these very weak pseudo bases. In order to be able to formulate the neutralization of these compounds in the same general scheme as that used for the other bases, we will consider the positive ion in the presence of water as an acid and write the equation

$$pK' = \mathrm{P_H} - \log \frac{[\mathrm{BOH}]}{[\mathrm{B^+}]} + \log \text{(activity of the } H_2O) \qquad (9)$$

Because the compound BOH is a pseudo base, water is necessary for B^+ to be an acid. The strength of B^+ as an acid thus depends on the activity of the water in the solvent. When considering pseudo bases in solutions containing large quantities of water, the activity of the water may be taken as constant; Equation 9 then reduces to the usual form.

In this manner Kolthoff[7] and Lund[8] formulated their interesting results obtained with acetone–water solutions of the polymethoxytriphenyl carbinols. The apparent pK' of a pseudo base measured in acetic acid is a function of the activity of the water according to Equation 10.

[7] Kolthoff, THIS JOURNAL, 49, 1218 (1927).

[8] Lund, *ibid.*, 49, 1346 (1927).

$$\text{App. value of } pK' = pK' - \log A_{H_2O} = P_H^{(HAc)} - \log \frac{[BOH]}{[B^+]} \qquad (10)$$

The glacial acetic acid used in the experiments reported in Fig. 4 melted at 16.6° and probably contained an amount of water less than that produced by the neutralization of the pseudo-base.[9] The pK' measurements corresponded to half neutralization of a 0.05 molar solution of the pseudo base so that the total water concentration may be taken as approximately 0.025 (mole fraction, 0.0014). If we assume that in such dilute solutions the activity of the water is equal to its molar concentration, we may approximate the values of pK' from the measured values by subtracting 1.6 units.

If the concentration of water in glacial acetic acid is increased, the measured value of pK' will become more negative according to Equation 10. If this were the only factor involved, the $P_H^{(HAc)}$ value of an equimolecular mixture of BOH and B^+ should become more negative with increasing water content. However, the addition of water to any glacial acetic acid solution of an acid makes the $P_H^{(HAc)}$ value more positive, presumably because of the formation of the H_2OH^+ ion in increasing quantities. Two opposing effects are thus at work; in solutions of very negative $P_H^{(HAc)}$ values the second effect is so marked as to obscure the first entirely, while in all solutions it becomes the predominant factor after the mole fraction of water is about 0.060. The results shown graphically in Fig. 5 illustrate these conclusions. Solutions of a variety of bases (real and pseudo) were titrated with sulfuric acid to the midpoint and then a dilute solution of water added and the change of $P_H^{(HAc)}$ values recorded. The

[9] Kendall and Gross, This Journal, 43, 1426 (1921); Webb, *ibid.*, 48, 2265 (1926); Smyth, *ibid.*, 52, 1824 (1930); all give 16.6° as the melting point of pure acetic acid.

ionic strength was 0.2 (the neutral salt was $(CH_3)_3NHSO_3C_6H_4CH_3$) and the initial concentration of the base 0.05 molar. -Four pseudo bases, diphenylanisyl carbinol, phenylxanthanol, dinaphthoxanthanol and trianisylcarbinol, show a decrease and then a rise of $P_{\mathrm{H}}^{(\mathrm{HAc})}$ values with increasing water concentration. With the very weak pseudo bases, triphenylcarbinol, α-naphthyldiphenylcarbinol and dianisylcarbinol, the effect cannot be detected since the decrease of proton activity due to the increased water content predominates from the start. All the real bases show a progressive increase in $P_{\mathrm{H}}^{(\mathrm{HAc})}$ values, as would be expected.

The apparent values of pK' for the pseudo bases we have examined are given in Table V. These values are for 23 ± 1°, 0.05 molar solution of the base titrated with sulfuric acid, ionic strength, 0.2 and glacial acetic acid of m. p. 16.6°. The measure of the basicity by these numbers is independent of any assumptions about color and ionization. In order to evaluate pK, it will be necessary to take into account both the change of pK' with ionic strength and the activity of water in acetic acid. In the case of the stronger bases a further complication results from the fact that the weak second hydrogen of sulfuric acid may be involved; this tends to make the values of pK' too negative.[2] A sulfonic acid would be preferable for titrations of these strong pseudo bases. Further work along these lines is in progress in this Laboratory and the present results must be considered as preliminary. For this reason a discussion of the interesting relationships between structure and pK values will be postponed. It may be noted, however, that our value for trianisylcarbinol (4,4′,4″-trimethoxycarbinol) is +2.6, while the value found by Lund in 50% acetone and water is —0.77. Assuming that the apparent pK' value changes with ionic strength in the same way as with urea (—2 units $\mu = 0.2$ to $\mu = 0$) and that the comparison between water and glacial acetic acid is also the same ($pK^{(\mathrm{H_2O})} - pK^{(\mathrm{HAc})} = +2.0$), it is clear that the two effects cancel. The difference between our value of +2.7 and Lund's —0.77 (a total of 3.5 units) should be a measure of the difference in activity of the water in a 0.025 molar concentration in glacial acetic acid and in 50% aqueous acetone. No data appear to be

available to check this but the direction of the effect is correct and the order of magnitude seems reasonable.

Experimental

(a) Materials.—The acetic acid was purified by repeated freezing of redistilled commercial synthetic acetic acid. The melting point was 16.4° except in the work with the pseudo bases when material of m. p. 16.6° was employed. Anhydrous perchloric acid was prepared from 60% aqueous acid and acetic anhydride as previously described. The solution of sulfuric acid in glacial acetic acid was prepared from 99.9% sulfuric acid. It was standardized by electrometric titration in glacial acetic acid with sodium acetate. The crystal violet employed was Dr. Grübler's "Höchst" brand. Its absorption spectrum was determined in aqueous solution and was found to be identical with that given by Adams and Rosenstein within our experimental error.

All the organic substances used in this work except the "neutral salts" are familiar compounds easily purified and characterized by their melting points; no description of them is therefore required. The neutral salts were prepared by passing the amine into a water solution of the acid, evaporating to dryness in vacuum and drying over phosphorus pentoxide. Both substances were colorless crystalline solids.

(b) Apparatus.—The spectrophotometer employed was a Keuffel and Esser color analyzer. Its adjustment was tested by means of a blue and yellow glass whose extinction coefficients over a wide range had been determined by the Bureau of Standards. The solution was placed in a 10-cm. glass cell with fused glass ends; a cell of the same length containing acetic acid was placed in the comparison beam. The temperature was kept at 25 ± 0.3°. Three readings were taken at each wave length and averaged.

The electrometric measurements were made with a cell similar to that previously used but so constructed that only 10 cc. instead of 50 cc. could be employed. It is shown in Fig. 6; a micro-buret was used in the titrations. The temperature was 23 ± 1°. The $P_{\mathrm{H}}^{(\mathrm{HAc})}$ values were obtained from the measured e. m. f. (E) by the equation previously employed.

$$P_{\mathrm{H}}^{(\mathrm{HAc})} = \frac{0.566 - E}{0.059}$$

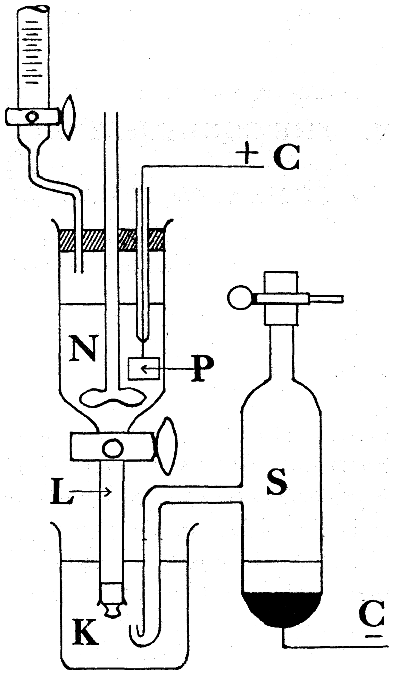

Fig. 6.—Cell for titrations in glacial acetic acid using chloranil electrode. S, Saturated calomel electrode; K, saturated KCl in water; L, LiCl in acetic acid; N, 10 cc. of solution to be measured; P, platinum electrode; C, connections to electrometer and potentiometer.

Summary

1. A spectrophotometric study has been made of the acid–base equilibria in solutions of crystal violet in buffered glacial acetic acid solutions.

2. **An** electrometric study of a number of weak bases and pseudo bases in glacial acetic acid has revealed the large effect of changing ionic strength **which** was also noted in the spectrophotometric study.

3. The effect of added water on the apparent constants of a number of **weak** pseudo bases has been investigated and a method outlined for obtaining significant values for the relative basicity of the "halochromic" carbinols.

V. THE CONDENSATION OF HYDROCARBONS BY ELECTRICAL DISCHARGE.

COMPARISON WITH CONDENSATION BY ALPHA RAYS[1]

BY S. C. LIND[2] AND GEORGE GLOCKLER[3]

RECEIVED JULY 18, 1930 PUBLISHED NOVEMBER 5, 1930

In a former paper[4] it has been shown that the condensation of ethane by electrical discharge in an ozonizer is in many ways similar to the same reaction when produced by the ionization due to the alpha particles from radon.[5] The experiments have now been extended to the gases methane, propane, butane and ethylene. It has been found *that there exists a similarity in the condensations as produced by the ionization due to α-particles and by electrical discharge in an ozonizer* for all the gases studied. It is the object of the present paper to describe these experiments and to discuss certain experimentally determined ratios which support the statement made. The experiments on ethane have been repeated with the new apparatus and confirm the former study. They are included for the sake of completeness and for comparison.

Experimental Procedure

The apparatus used to study these condensations is shown in Fig. 1 and consists of an all-glass pyrex ozonizer, a Liebig condenser and a manometer. The system as a whole is of the circuit type and a slight circulation was probably attained by the thermal siphon principle since the ozonizer would naturally heat up (to about 40°) during a run due to power losses and since the condenser kept the other leg of the system cold, by

having tap water (18°) running through it. The pressure in the ozonizer changes on account of the changes of temperature due to the reaction. A correction of 12 mm. was applied at the maximum pressure, which was determined by noting the pressure drop in the butane reaction that occurred when the reaction had been stopped near the maximum pressure when the system was allowed to cool to room temperature (Fig. 3). The drop in pressure at the end of the experiments due to cooling was noted to be about 10 mm. and these two corrections were applied to the curves shown in Fig. 2. The trap at the bottom of the ozonizer should catch any liquid condensates and was also used in the first step of the fractional distillation of the gases resulting from the condensations. The ozonizer proper was placed into the circulating system by means of two ground seals (stopcock grease and mercury-seals) in such a manner that it could easily be removed for cleaning before each run. The electrical set-up consisted of a Thordarson Transformer which would furnish about 18,000 volts to the ozonizer with 94 volts and 7.4 amperes in its primary. The electrical conditions were kept constant at these values during all the experiments. The first series of experiments consisted of runs of eight and one-half hours' duration. The pressure changes were observed during the whole period and after the conclusion of each experiment the remaining gases were analyzed for hydrogen, methane, ethane, propane, butane and pentane by fractional distillation, beginning at liquid-air temperatures. The hydrogen in the hydrogen–methane mixture was removed by diffusion through a palladium tube. The remaining methane was checked by combustion and a correction applied for any ethane that might have been pumped off with the hydrogen–methane fraction. Ethane was distilled off at −150°, propane at −120° and butane at −90°. The remaining gas was taken to be pentane. The liquid composition (empirical formula) could be determined from these gas analyses by constructing an "atomic balance sheet." It is possible to find the number of carbon and hydrogen atoms that must have gone into the liquid condensate from the amount of hydrocarbon used, its composition and the

analyses of the resulting gases. The initial gases were obtained from commercial sources except methane, which was prepared from sodium acetate. They were reasonably pure as the following analysis (by fractionation) shows.

These gases were distilled into the apparatus and any permanent gases were pumped off. The experimental results are shown in Table II, which contains the average of at least two experiments carried out with each gas. It was always possible to obtain graphs of **the** "pressure–time **relation**" which checked very satisfactorily indeed, showing that the experiments are entirely reproducible. In Col. 4 of Table II the details of a

short run (eighty minutes) on butane are given, which was stopped at the maximum pressure attained during the longer (510-minute) run. This experiment was performed to find out whether or not unsaturates are formed during the reaction. This point will be discussed later. The detailed runs are shown in Figs. 2 and 3.

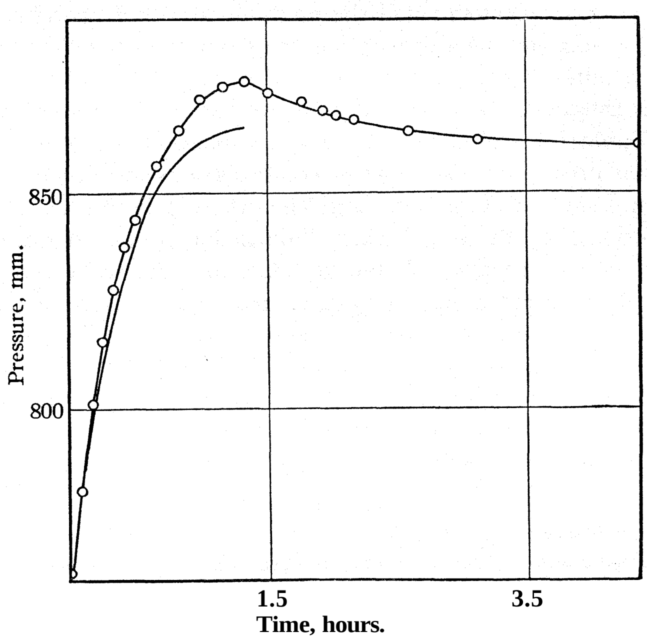

Fig. 3.—Pressure changes during a short (80-minute) run with butane, showing temperature effect.

Discussion of Results

1. The Pressure Changes during Reaction.—It is seen that the saturated hydrocarbons all show the same general pressure change as the reaction proceeds in time. They all show a maximum pressure one to two hours after the beginning of the reaction. Especially remarkable is the decrease of pressure during the later stages of the reaction. The one unsaturated hydrocarbon tried (ethylene) shows a decrease in pressure to about one-third of the initial pressure. Since the object of the present research is a comparison of the alpha-ray condensations of the hydrocarbons with the same reactions produced by electrical discharge in an ozonizer, the data of Lind and Bardwell[6] of the alpha-ray condensations have been recalculated and replotted so as to be easily comparable with the present material.

In the case of the saturated hydrocarbons the a-ray experiments were

---

[6] **Reference 5 and also THIS JOURNAL, 48, 1556 (1926).**

carried out in stages in such a manner that at the end of each period hydrogen and methane were pumped off. When the data are inspected it is seen that in the case of butane a slight increase in pressure is noticeable. In order to compare the pressure data with the present experiments, it was assumed that during each interval the pressure would have increased the same proportionate amount had the methane and hydrogen been present. This assumption may be a drastic one but the object is only to show that there is a slight increase in pressure during the alpha-ray condensations and this is immediately apparent from the data. The essential data are given in Table III and in Fig. 4. For comparison the pressure changes (final/initial press.) for the ozonizer condensations are given for the first ninety minutes of reaction. It should be noted that the abscissas for the radon reaction are "the time" where "ionization produced since the commencement of the reaction" should be taken in order to be comparable to the corresponding curves for the ozonizer reactions. Since in the ozonizer reactions it may be assumed that a constant current was flowing producing a definite ionization the total ionization may be taken proportional to the time. It was not thought necessary to reduce the alpha-ray reactions since this would merely result in a relative shortening of the abscissas. The only thing of interest was the general picture showing the relative pressure

changes in the case of the two types of condensation and it is seen that there is a comparable increase in pressure in these two modes of condensation. It is believed then that the curves of pressure increase as a function of time of reaction establish the first point of our thesis: that *there is for the saturated hydrocarbons an analogy in their pressure changes during reaction when under the influence of the two activating agents.*

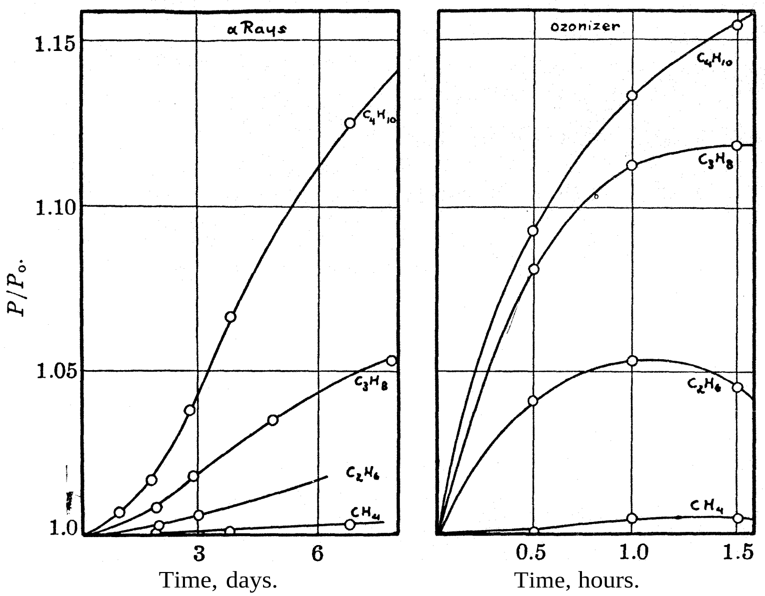

Fig. 4.—Comparison pressure changes in the alpha ray and ozonizer condensations for saturated hydrocarbons.

In an entirely similar manner it has been found that the pressure decreases during the condensation of the unsaturated ethylene both when reaction is brought about by the activation due to alpha rays and in electrical discharge in an ozonizer. Here the data of Lind, Bardwell and Perry[6] were rearranged as shown in Table IV and the comparison is made in Fig. 5 with the data of the present experiments. In the case of the condensation of ethylene it is seen from Fig. 5 that the relation between (P/P_0) and the total ionization is a straight line, showing in a graphical way that the M/N ratio is constant during the reaction. While the two curves show the same general trend (a decrease in pressure to about one-third the initial pressure), they are not of the same shape. This may mean a difference in the detailed mechanism of the two reactions and needs further investigation. For the present purpose only the most obvious features are to be considered.

The main point is: *both condensations of ethylene show a pressure decrease to about one-third the initial pressure.*

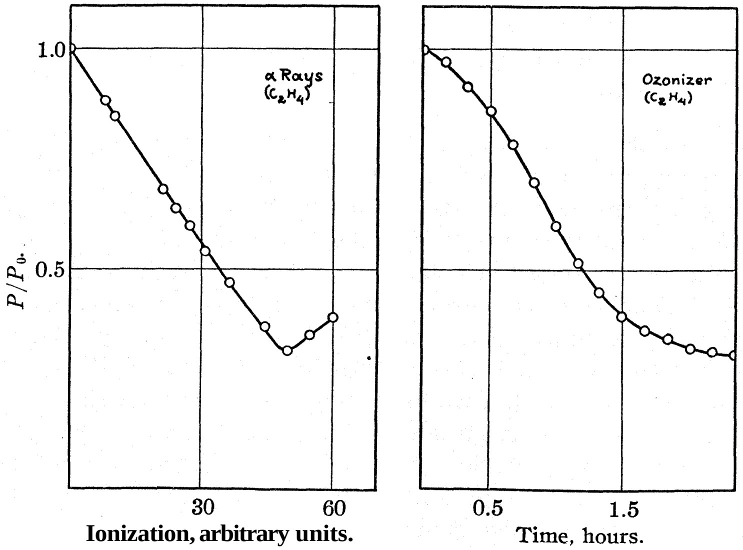

Fig. 5.—Comparison of pressure changes in the alpha ray and ozonizer condensations for ethylene.

The study relating to pressure changes can be made in another way by comparing the volume changes during the two condensations **and** the ratios of the final to the initial pressure and the maximum to the initial pressure. The pertinent data are collected in Table V. It is seen that the same general trend exists for both types of reactions (Col. **3** to be compared with Cols. 4 and 5).

C_2H_4	60	222	0.27	0.29	..

2. **Free Hydrogen Production.—A** further point **of** comparison between the alpha ray and the ozonizer condensations is the "free hydrogen production" as related to the amount of initial hydrocaron reacted. This quantity may also be expressed as the ratio ($-\Delta$H.C./ΔH_2) "hydrocarbon disappearing to hydrogen appearing." The necessary data for its calculation are given in Table VI and for the alpha-ray reactions the figures are taken from the work of Lind and Bardwell.[5] It should be

TABLE VI

FREE HYDROGEN PRODUCTION

Analysis of free hydrogen production of saturated hydrocarbons by electrical discharge (ozonizer) and comparison with alpha-ray reaction.[5]

		CH_4	C_2H_6	C_3H_8	C_4H_{10}	C_2H_4
Initial gas (cc. N. T. P.) taken		231.5	229.4	228.1	231.0	222.2
% of gas reacted		72.7	87.6	93.0	94.5	100.0
H_2 of init. gas reacted (cc. N. T. P.)		167 X 2	201 X 3	212 X 4	218 X 5	222.2 X 2
Free hydrogen (ozonizer)		143	147	143	148	47
From ozonizer reaction % = (Free H_2 X 100)/(H of init. H. C. reacted)		42.8	24.4	16.8	13.6	10.6
The same % (a-reaction)		37.8	25.5	16.1	13.9	11.9
$\frac{-\Delta HC}{\Delta H_2}$	α	1.32	1.31	1.54	1.44	4.18
	oz.	1.17	1.37	1.44	1.60	4.70

noted that the two modes of expressing the "free hydrogen appearing during the reaction" are related as follows:

$-\Delta \text{H.C.}/\Delta H_2 = 1/(\text{free H} \times n)$, where $n = 2,3,4,5$ for CH_4, C_2H_6 C_3H_8 and C_4H_{10}, respectively.

By comparing lines five and six and lines seven and eight of Table VI it is seen that these ratios are the same for both types of condensations.

The second point in our argument that the condensations of hydrocarbons by alpha rays and by electrical discharge are similar reactions is then: *"the amount of free hydrogen produced is of the same order in both types of condensations."* The ratio in question changes to a larger value (about 4) for the unsaturated ethylene.

3. The Percentage of Hydrogen in the Hydrogen–Methane Fraction.—The ratio $\Delta H_2/\Delta(H_2 + CH_4)$ was calculated from the data on gas analysis of the gases after the condensation. It is seen (Table VIII) that the percentage of hydrogen in the hydrogen–methane mixture is about 80% for the reactions of the saturated hydrocarbons and a little greater (86%) for the unsaturated ethylene. The comparison with the similar data on the alpha-ray reaction shows that *in both types of condensation hydrogen and methane appear in the same relative amounts.*

4. Percentage of Liquid Conversion.—The fraction of the hydrocarbon that has undergone reaction which appears as liquid product is seen to be greater in the order: methane, ethane, propane, butane and ethylene. Again this behavior is the same for both kinds of reaction and it may be said that it appears to be easier to convert these hydrocarbons into liquid in the order given.

5. The Liquid Composition.—As has been noted above, it is possible to calculate the average empirical composition of the liquid product from the gas analysis of the reaction products. This calculation has been carried out from the data of Table II and the results are given in Table VIII. It is seen that the average composition of the liquid mixture cor-

(6) Hydrocarbon Reacted					
Per cent. (ozonizer)	73	88	93	95	100
Per cent. (alpha rays)	18	27	45	68	92

responds to an empirical formula C_nH_{2n} for the saturated hydrocarbons and to $C_nH_{1.7n}$ for the unsaturated ethylene. Similar results have been obtained for the alpha-ray reactions, as is shown in Table VIII. The composition of the liquid condensate derived from ethylene by alpha-ray condensation has been calculated as shown in Table VIII. Another point of similarity has thus been established: *The empirical composition of the liquid mixtures derived from both types of condensations is the same.*

6. Total Hydrocarbon Reacted.—The percentage of the total hydrocarbon reacted in a given interval of time under similar conditions is greater in the order given above. The same order is found in the alpha-ray reactions. However, these factors are not comparable since the radon reactions were not carried so far toward completion as the ozonizer reactions; but the data do fit into the general picture very well and again it can be said that both reactions show the same general trend.

7. Statement of Results.—The factors studied have been collected in Table VIII and it is believed that the data shown there support the thesis which it is expected to prove: *"for all of the hydrocarbons studied the condensations by alpha rays and in electrical discharge have many points in common, which lead to the belief that they both are brought about by the same agency."*

8. Mechanism of Reaction.—The question which remains to be answered is: What is the mechanism of these condensations? On the ion-cluster theory the following steps should be taking place: (1) the formation of an ion; (2) the formation of a cluster; (3) the formation of a larger hydrocarbon molecule with elimination of hydrogen and methane; (4) the ionization of the larger molecule by direct electron impact; (5) the formation of an ion of the larger molecule by electron transfer. This mode of ionization is important because it favors the larger molecules for reaction.

On the basis of these reaction steps it is possible to construct many reaction schemes which will conform to the data of Table VIII. It is easily seen that the possibilities for splitting, rebuilding and rearrangements under the above reaction plan are enormous for any of the hydrocarbons investigated and no satisfactory reaction mechanism can be given unless *all* of the reaction products have been determined. This would mean that not only must the gaseous reaction products be completely analyzed but also the liquid condensation products. As is well known, the analytical difficulties in the separation of the hydrocarbons are considerable. Even if such analyses were made it must be realized that all of the products of the initial reaction except hydrogen condense in a similar manner and in some cases even more readily than does the initial hydrocarbon. This makes the whole problem one of great complexity and while it has been possible to derive a series of reaction schemes which have the advantage of simplicity, uniformity, compliance with the empirical reaction rules laid down above, we prefer to postpone the discussion to a later date when more analytical data have been procured and shorter runs have been studied. The mechanism of these condensations may be studied by shortening the reaction period, so that the initial reaction products are obtained before they have been changed. This method was employed with butane and it appears that unsaturates are formed during the reaction. However, we have only initiated this study and much more work needs to be done.

9. Unsaturates in the Gas Phase.—While it has been found that the average composition of the liquid condensates corresponds to an olefin, no indication has been found that there existed unsaturates in the gas phase at the end of the eight and one-half hour runs. The fractionations carried out on the gaseous reaction products always showed fractions of hydrocarbons which corresponded closely in vapor pressure to the saturated hydrocarbons. However, one experiment on butane was stopped with eighty minutes' duration (Fig. 3) and the pressure had then reached the maximum pressure recorded in the former experiment. The analysis by fractionation showed at once that fractions were now present of different vapor pressures from those obtained previously. Ethylene and acetylene thus appear to exist in the gas phase. The disappearance of these unsatu-

rates during the later stages of the reaction may be the cause of the pressure drop observed. In our further work it is expected to study the composition of the reaction products obtained in runs of short duration where the total pressure has reached the maximum pressure of the longer runs. It is hoped that information from these and even shorter runs may help in the derivation of a possible reaction scheme for these condensations.

The authors wish to thank Mr. J. L. Wilson, who has assisted in this work as American Petroleum Institute Research assistant.

Summary

The condensation of methane, ethane, propane, butane and ethylene has been studied in electrical discharge. It has been found that these reactions are quite similar to the condensations caused by alpha rays. The following factors give evidence of this similarity of reaction: (1) the pressure changes as a function of the time; (2) the free hydrogen produced during the reaction; (3) the relative amount of hydrogen and methane in the hydrogen–methane fraction of the resultant gases; (4) the percentage of liquid conversion; (5) the average composition of liquid condensate; (6) the percentage of the hydrocarbons reacted All of these factors are quite similar for both types of condensation and it is argued that both types of reaction must be caused by the same mechanism. A reaction scheme is discussed on the basis of the ion cluster theory. The usual ideas are amplified in one respect in that it is assumed that the larger molecules are ionized not only by electron impact but also by electron exchange.

THE COMPOSITION AND STRUCTURE OF MESQUITE GUM[1]

BY ERNEST ANDERSON AND LOUISE OTIS

RECEIVED JULY 18, 1930 PUBLISHED NOVEMBER 5, 1930

Previous investigations[2] have shown that mesquite gum yields 2-arabinose and d-galactose on hydrolysis and that it contains a hexose uronic acid. When the work described in this article was begun, the gum was assumed to be the salt of a complex organic acid composed of the above substances. This investigation has established the presence of methanol and *d*-glucuronic acid as constituents of the gum and has shown conclusively that it

Sturgis, *Am. J. Pharm.*, 97, 589 (1925); E. Anderson and L. Sands, *Ind. Eng. Chem.*, 17, 1257 (1925); THIS JOURNAL, 48, 3172 (1926).

is the salt of an organic acid composed of four molecules of Earabinose, three molecules of d-galactose, one molecule of methanol and one molecule of d-glucuronic acid, combined with the loss of eight molecules of water.

During the course of the research the free monobasic acid of which mesquite gum is a salt, was prepared and analyzed. This complex molecule was then hydrolyzed in 3% sulfuric acid, first at 80° and finally in the autoclave at fourteen pounds' pressure. This process gave successively less complex monobasic acids, which were isolated in the form of calcium salts and analyzed. From a study of the composition and reactions of the various products isolated it is possible to deduce some facts in regard to the method of linkage of the original molecule.

Identification of an Ether Linked Methoxy Group in Mesquite Gum.—It was shown by von Fellenberg[3] that a glucosidic methoxy group can be removed from naturally occurring compounds by heating at 80 to 90° with a 2% solution of sodium hydroxide. An ether linked methoxy group, on the other hand, cannot be removed by the above method but is removed by mixing the compound with 72% sulfuric acid and boiling for ten minutes. The presence of any free methanol formed in this way can be accurately detected by use of Denigès' method.[4] When the above test was applied to mesquite gum it was negative for the glucosidic methoxy but positive for the ether methoxy group. However, all the salts formed by partial hydrolysis of mesquite gum gave positive tests for both the glucosidic and ether methoxy groups. As a check on the accuracy of the method for distinguishing between the two types of methoxy groups when applied to methylated sugars, a sample of tetramethylglucose[5] was tested. This sample showed the presence of both glucosidic and ether methoxy groups. It thus appears that while von Fellenberg's method is suitable for distinguishing between the two types of union in the natural products for which it was devised, it cannot be used to distinguish between the two types of union in the methylated sugars.

The linkage of the methoxy group in mesquite gum seems more stable than a glucosidic linkage could be. This is shown by the following facts. Mesquite gum was hydrolyzed at 100° for twenty-six hours in 3% sulfuric acid solution. The salts obtained from this hydrolysis were further hydrolyzed in 3% sulfuric acid in the autoclave at fourteen pounds' pressure for seven hours. The liquid in which this last hydrolysis was carried out showed only a trace of methanol and the salts obtained after neutralization gave a very strong test for methanol, showing that very little methanol had been removed during the hydrolysis. It was also found that oxidizing the

[4] M. G. Denigès, Compt. rend., 150, 529 (1910).

[5] We are indebted to Dr. F. W. Upson of the University of Nebraska for the sample. It melted at 85° and boiled at 153–156° under 0.2-mm. pressure.

salts with nitric acid of specific gravity 1.15 did not remove the methoxy group to any appreciable extent. It thus appears that the methoxy group is present in mesquite gum as an ether.

The Position of the Methoxy Group in the Organic Acid Occurring in Mesquite Gum.—The approximate position of the methoxy group in the molecule was determined by studying the methoxy content of the various hydrolytic products of mesquite gum. If the gum is hydrolyzed at 80° for six hours, all of the arabinose is removed. Crystalline E-arabinose can be obtained quantitatively, and as the salt formed at the same time contains galactose, a uronic acid and a methoxy group, the methoxy is not attached to the arabinose. If this salt is hydrolyzed further, pure crystalline galactose can be obtained as well as a salt containing only a trace of galactose, a uronic acid and the methoxy group. Therefore, the methoxy is not attached to the galactose but is attached to the uronic acid. Nothing definite can be said as to which carbon atom in the uronic acid this methoxy group is joined, except that it cannot be to carbon atom one or six, since it is present as an ether, not as a glucosidic group.

The Identification of *d*-Glucuronic Acid.—The presence of *d*-galacturonic acid or d-glucuronic acid in the free condition in a mixture can be established by oxidizing the uronic acid with bromine and obtaining mucic acid or saccharic acid, both of which can be identified. In mesquite gum, however, no simple uronic acid is present but a stable methoxyuronic acid. The gum must be hydrolyzed and the methoxy group removed if the uronic acid is to be identified by conversion to mucic or saccharic acid. Numerous unsuccessful attempts were made to identify mucic or saccharic acid among the products by hydrolyzing mesquite gum and oxidizing the resulting mixture with bromine. Finally some calcium salts obtained by hydrolyzing the gum first in the boiling water-bath and then in the autoclave were freed from sugars by dissolving in water and precipitating with alcohol. These salts were converted to the free acid by treatment with sulfuric acid and the acid was purified by dissolving in alcohol. Approximately 30 g. of this acid was placed in an evaporating dish with 200 cc. of nitric acid, specific gravity **1.15,** and the solution concentrated on the water-bath to a gum. This gum was dissolved in water and again concentrated. The acids were neutralized with calcium carbonate, the mixture heated and the calcium oxalate filtered off from the hot solution. The calcium in the filtrate was precipitated by addition of potassium carbonate, filtered and the solution made acid with glacial acetic acid, filtered and concentrated on the water-bath to a small volume. After standing in the refrigerator for some days, the crystals were filtered off and recrystallized from water and acetic acid. They appeared to be identical with potassium acid saccharate crystals made from glucose and with the crystals pictured in van der Haar.[6] The percentage of potassium was determined by conversion to potassium sulfate.

Anal. Calcd. for $KHC_6H_8O_8$: K. 15.75. Found: K, **15.89, 15.81.**

By the above method approximately 1 g. of pure recrystallized potassium acid saccharate was obtained. Since this work was repeated on *a* later occasion, it is certain that d-glucuronic acid is present. **A** strong positive

test for methanol was obtained on the mother liquor from which the potassium acid saccharate separated out, showing that the methoxy group was interfering with the formation of the saccharic acid.

The Analytical Methods Used and the Value of the Various Determinations.—Since the methods used in the analysis of the gums are often inaccurate, a brief summary will be given of the determinations that were made and the value that should be attached to each before discussing the quantitative results of this work.

The substances were analyzed for calcium oxide as ash, carbon dioxide evolved by the d-glucuronic acid, free aldehyde, d-galactose, *l*-arabinose, methanol, carbon and hydrogen.

All samples, except those used for the carbon and hydrogen determinations, were dried to constant weight in *vacuo* over phosphorus pentoxide using an Abderhalden vacuum drier and a bath of boiling toluene. The samples for the carbon and hydrogen determinations were dried to constant weight in *vacuo* over phosphorus pentoxide at 85°.

The percentages of calcium oxide reported as ash in this article are slightly high. This is a logical result of the method used in the preparation of the salts, which was to add calcium carbonate to a water solution of sulfuric acid and the organic acid, filter off the calcium sulfate and precipitate the calcium salt of the organic acid by addition of alcohol. It is difficult under these conditions to free the salt completely from calcium sulfate even by repeatedly dissolving in water and precipitating by alcohol. A trace of calcium sulfate in the salt increases considerably the percentage of ash without seriously affecting the other determinations.

The naphthoresorcinol test[7] was used as a qualitative test for a hexose uronic acid, while the carbon dioxide method of Lefèvre[8] as given by van der Haar was followed in the quantitative determination of the uronic acid. This is an accurate method and the results are reliable.[8c,d]

The method employed for determining the free aldehyde group was that of Cajori,[9] using an alkaline iodine solution as the oxidizing agent. The percentage of free aldehyde found by this method in the calcium salts of the monobasic acids was slightly less than the theoretical. This may in part be due to a slight oxidation of the aldehyde group of the salts during their formation.

The free acid of which mesquite gum is a salt, as well as the dibasic acids formed by oxidizing the aldehyde group of the monobasic acids with barium hypoiodite, all absorbed some iodine although they should have no free aldehyde group. This is easily explained. The free acid was prepared by

[9] F. A. Cajori, *J. Biol. Chem.*, 54, 617 (1922).

treating mesquite gum in water solution with cold hydrochloric acid, precipitating the product with alcohol. If in this process an occasional molecule was partly hydrolyzed, the product would absorb iodine and thus show a small percentage of free aldehyde. Also if during the oxidation of the monobasic acids with barium hypoiodite insufficient time were allowed for the completion of the process, the resulting acids would show a small amount of aldehyde.

The percentages of d-galactose were determined by the mucic acid method, following as closely as possible the directions of van der Haar.[10] The results were in all cases low. It is now generally recognized that this determination should not be classed as a quantitative process.[11] When the method is applied to gums and pectins the results are often very inaccurate. In one case von Fellenberg reports[1'] 54.8% galactose where the calculated is 75.6%. It seems that the accuracy of the determination depends largely on the nature of the linkage in the molecule. In the case of gum arabic the last molecule of galactose is easily removed[12] and in this case the galactose can be accurately determined.[13] On the other hand, the last molecule of d-galactose is very difficult to remove from mesquite gum and in this case the method yields lower percentages than the theoretical.

The percentage of arabinose was determined by mixing the sample with 12% hydrochloric acid, distilling off the furfural and precipitating it as the phloroglucide.[14] The directions given in the "Official Methods of Analysis" were followed. The results obtained on the free organic acid were about 2% lower than the theoretical. All of the other substances analyzed gave from 3 to 7% arabinose by this method, though no arabinose was actually present. This method is known to be only approximately quantitative. The yield of furfural from arabinose is not quantitative and the amount varies with different operators.[15] Furthermore, the furfural is contaminated with products that vitiate the results. Hexoses give hydroxymethylfurfural, which precipitates along with the furfural.[16] In addition hexose uronic acids yield furfural under the conditions of the determination and the yield is less than the theoretical.[8d] In the case of d-glucuronic acid an accurate factor has been worked out for correcting the

weight of the furfural phloroglucide for the furfural evolved by the hexose uronic acid.[17] No such factor is known for methoxyglucuronic acid. It is obvious that the accuracy of this determination is not great.

The presence of the methoxy group was determined qualitatively by means of the Denigès test for methanol.[3,4] The amount of methoxy was determined quantitatively by the Zeisel method.[18] The percentage found in all the monobasic acids checked the theoretical very closely. In the case of the dibasic acids formed by oxidizing the monobasic acids with an alkaline solution of barium hypoiodite, the percentages of methoxy were slightly low. This is easily accounted for by the fact that an alkaline solution seems to remove traces of methoxy from the methylated sugars.

The percentages of carbon and hydrogen were determined by Dr. E. Yusa at the University of Vienna and checked satisfactorily.

Attempts were made to determine the molecular weight of the free acid from mesquite gum by the cryoscopic method. However, no constant freezing point could be obtained. Since the substance is a free acid, its minimum molecular weight was determined by titrating with sodium hydroxide solution

Preparation and Analysis of the Free Acid of Mesquite Gum.—The method used by Ehrlich in preparing pectic acid[19] was found to work satisfactorily in preparing and purifying the free acid of mesquite gum: 300 g. of mesquite gum was dissolved in 600 cc. of water, filtered, 60 cc. of concentrated hydrochloric acid added and the gum precipitated by addition of 15 liters of 85% ethanol. This precipitate was dissolved in 300 cc. of water and 40 cc. of concentrated hydrochloric acid diluted with 40 cc. of water added. The precipitate was again dissolved and thrown down by addition of 5.5 liters of 88% ethanol. This process was repeated five times. The gum was then dissolved in 250 cc. of water and 1350 cc. of 95% ethanol added to precipitate a small amount of gum and thus eliminate any metallic salts that might be present. The solution was centrifuged and the clear solution poured into a large volume of 95% ethanol. The precipitated material was allowed to settle, triturated with a pestle, filtered, washed with absolute alcohol and ether. The free organic acid finally obtained was a white amorphous powder which was practically free from ash, completely free from chlorides and readily soluble in water. A 0.008 N solution showed a P_H of 3.4. Table I gives the results of the analysis of this acid. The figures obtained check very closely the values calculated for a compound consisting of one molecule of methoxyglucuronic acid joined to three molecules of d-galactose and four molecules of *l*-arabinose with the loss of seven molecules of water.

Partial Hydrolysis of Mesquite Gum to Digalactoso and Trigalactoso Methoxy-*d*-glucuronic Acids.—When mesquite gum was hydrolyzed at 80° with 3% sulfuric acid, all the *l*-arabinose and part of the d-galactose were removed. The resulting solution was

neutralized with calcium carbonate, the calcium sulfate filtered off and the calcium salts precipitated by pouring into alcohol. These crude salts were separated by the method of Levene[20] into five fractions, all of which were analyzed. The most soluble and least soluble portions corresponded to definite compounds. The details of this experiment are given below.

Four kilos of mesquite gum was hydrolyzed in 500-g. lots as follows.

Five hundred grams of mesquite gum was dissolved in **3** liters of distilled water, strained through a fine piece of cheese cloth, **60** cc. of concentrated sulfuric acid added (making approximately a **3%** sulfuric acid solution) and the flask immersed in a water-bath at 80° and heated for eleven hours. The solution was neutralized with calcium carbonate, filtered and concentrated on a large evaporating dish over boiling water in the presence of an excess of calcium carbonate. When the volume was about **500** cc., it was filtered with suction and the filtrate poured into a large volume of **95%** ethanol and left to stand overnight to settle. The alcohol was poured off, the thick sirupy material stirred with fresh 95% ethanol, and then extracted twice for one hour each time with boiling ethanol. The thick, gummy residue was dissolved in enough water so that a fine flocculent precipitate was obtained on pouring it slowly into a large volume of 95% ethanol to precipitate the salts. The gummy residue was extracted twice for two hours with hot 95% ethanol and dissolved in water, heated in the boiling water-bath with norit, filtered and precipitated by pouring into a large volume of 95% ethanol; **744** g. of air-dried, dark brown salts was obtained from the **4** kg. of gum. These dark brown salts were purified as follows: **100** g. of salts was dissolved in **750** cc. of water and then **150** cc. of **6** N sulfuric acid and **150** g. of norit (previously boiled with 6 *N* sulfuric acid and washed with water) were added. The mixture was heated rapidly and boiled for one minute, cooled under the tap and filtered. The filtrate was neutralized with calcium carbonate, filtered and the filtrate concentrated by vacuum distillation in a water-bath at 80°, filtered again and the salts precipitated by pouring into a large volume of 95% ethanol. This treatment gave a white salt. The total yield from the 744 g. of crude salts was **423** g.

This salt was separated by fractional precipitation as follows. It was dissolved in three times its weight of water (**400** g. of salt dissolved in **1200** cc. of water). This solution was filtered through a double filter paper to remove the calcium sulfate. After standing overnight and being filtered again, **2400** cc. of **95%** ethanol (two times the

volume of water) was added. It was left to stand overnight, thus allowing the gummy matter to separate out, and in the morning the clear supernatant liquid was decanted and concentrated in vacuum. From this solution the calcium salt was precipitated as described before and 67 g. of this most soluble salt was obtained. The gummy residue was dissolved in 535 cc. of water, 1070 cc. of 95% ethanol added and the liquid centrifuged to hasten the separation of the liquid and residue. In this way five different fractions were precipitated. The final residue gave the least soluble salt (96 g.). All the fractions were analyzed, but the most soluble and least soluble were the only fractions that were pure compounds. The analyses of these two compounds are given in Table I. The least soluble salt (Salt 1) is the calcium salt of methoxyglucuronic acid joined to three molecules of galactose with the loss of three molecules of water. The most soluble salt (Salt 2) is the calcium salt of the methoxyglucuronic acid joined to two molecules of galactose with the loss of two molecules of water.

Oxidation of Digalactoso and Trigalactoso Methoxyglucuronic Acids to Dibasic Acids.—The calcium salts of digalactoso and trigalactoso methoxy-d-glucuronic acids (Salts 1 and 2) were oxidized by barium hypoiodite solution[21] and the resulting dibasic acids isolated as the calcium salts in the form of a white amorphous powder. These salts gave the naphthoresorcinol test and on treatment with 12% hydrochloric acid gave carbon dioxide, thus proving the presence of a hexose uronic acid. This fact proves that the free aldehyde group in the digalactoso and trigalactoso methoxyglucuronic acids was on the galactose and not on the uronic acid. The dibasic salt 1A obtained by oxidation of the monobasic salt (1) is the calcium salt of one molecule of methoxyglucuronic acid joined to two molecules of galactose and one molecule of galactonic acid with the loss of three molecules of water. The dibasic salt 2A obtained by the oxidation of the monobasic salt (2) is the calcium salt of one molecule of methoxyglucuronic acid joined to one molecule of galactose and one molecule of galactonic acid with the loss of two molecules of water. The analyses of these salts are given in Table II.

Partial Hydrolysis of Mesquite Gum to Monogalactoso Methoxyglucuronic Acid.—When mesquite gum is hydrolyzed for a longer time than when preparing the digalactoso and trigalactoso methoxyglucuronic acids, the monogalactoso methoxyglucuronic acid can be obtained. The following procedure was used. One kilo of mesquite gum was hydrolyzed in 500-gram lots as follows: 500 g. of mesquite gum was dissolved in 3

---

[21] W. F. Goebel, *J. Biol. Chem.*, 72, 809 (1927).

liters of water and 60 cc. of concentrated sulfuric acid dissolved in 200 cc. of water added. This solution was hydrolyzed in a water-bath at 85° for twenty hours. It was neutralized with calcium carbonate, treated with norit, filtered and the filtrate concentrated in vacuum, using paraffin to prevent foaming, until the liquid had a refractive index of 1.38. The salt was reprecipitated by pouring into a large volume of ethanol and worked up as described under the preparation of the other salts. It was dissolved in 250 cc. of hot water, filtered and precipitated again by pouring into a large volume of ethanol. One kilo of gum gave practically 300 g. of salt. This 300 g. of salt was dissolved in water, 57 cc. of concentrated sulfuric acid added and the solution diluted to 1800 cc. It was heated in a water-bath at 80 to 85° for fourteen hours, neutralized with calcium carbonate, heated with norit, filtered and the filtrate concentrated in vacuum. The salt was precipitated from this solution by pouring into a large volume of alcohol; the yield of salt was about 200 g. This salt was separated by fractional precipitation, It was dissolved in 300 cc. of water, 600 cc. of 95% ethanol added and the liquid concentrated, etc., giving the most soluble salt. The gummy residue was dissolved in 225 cc. of water and some salt precipitated by addition of 450 cc. of 95% ethanol. This process was repeated four times, when the gummy residue was worked up giving the least soluble portion of the salts.

All the fractions were analyzed and the least soluble portion was found to be a fairly pure sample of the calcium salt of methoxyglucuronic acid joined to one molecule of galactose with the loss of one molecule of water. The analysis for this salt (Salt 3) is given in Table I.

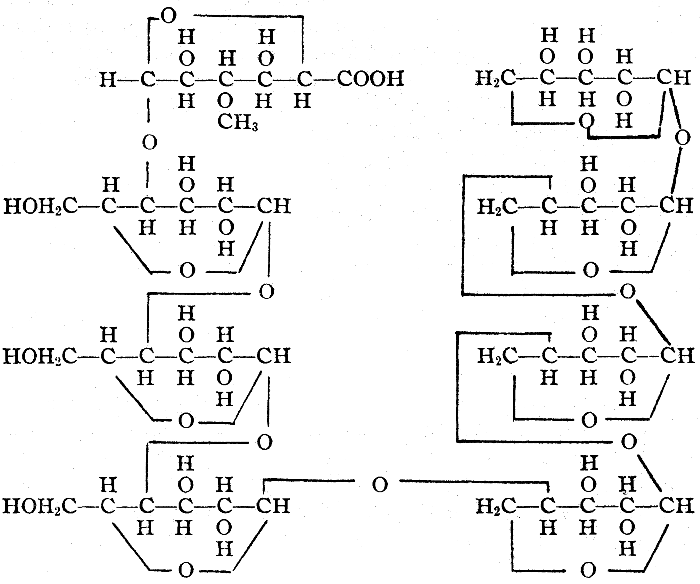
The Structure of Mesquite Gum.—From the work reported above certain facts can be deduced in regard to the structure of the complex organic acid occurring in mesquite gum.

The arabinose must be joined to the molecule by some kind of loose union, since it can be removed completely when the gum is hydrolyzed for six hours with 3% sulfuric acid at 80°. As the free gum does not reduce Fehling's solution, there must be either a dicarbonyl union involving at least one molecule of arabinose or a glucosidic union between the aldehyde of the end arabinose and some hydroxyl in the molecule. Since the compounds of the uronic acid with one, two or three molecules of galactose reduce Fehling's solution, there are only four possible positions for a dicarbonyl union—between the first and second, second and third, third and fourth molecules of arabinose or between the fourth molecule of arabinose and the first molecule of galactose. As immediately upon hydrolysis the molecule begins to reduce Fehling's solution, it seems logical to assume that the dicarbonyl union is between the first two molecules of arabinose, but as no compounds containing part of the arabinose attached to the molecule could be obtained, this position could not be proved. If, however, it is a glucosidic linkage, it could be between the aldehyde group of the first arabinose and any of the numerous hydroxyl groups in the molecule.

On the other hand, the galactoses are quite firmly attached in the molecule. As the different degradation products contain only one free aldehyde group and as one after another of the galactose molecules can be removed by hydrolysis, it seems as if these molecules must be joined together in a chain by means of glucosidic linkages with a free aldehyde group on the end galactose molecule. To which hydroxyl of the sugar the aldehyde is joined is mere conjecture. As in many polysaccharides the aldehyde is joined to the hydroxyl of the fourth carbon atom, this is likely to be the case here. Whatever this linkage is, it can be broken when the gum is hydrolyzed at 80° with 3% sulfuric acid.

As was pointed out when considering the dibasic acids, there is conclusive evidence that the linkage between the galactose and the uronic acid is through the aldehyde

group of the acid and an hydroxyl of the sugar. Methylation studies will be necessary to prove which atom of the galactose is involved in this union. The structure given in the diagram summarizes the results of this study of the acid occurring in mesquite gum.



Tentative structural formula of the complex organic acid occurring in mesquite gum.

Summary

Mesquite gum is the inorganic salt of an organic acid consisting of four molecules of arabinose, three molecules of galactose and one molecule of methoxyglucuronic acid united with the loss of seven molecules of water. This pure acid was prepared and its composition substantiated by preparation of three degradation products: (1) the calcium salt of methoxyglucuronic acid joined to three molecules of galactose with the loss of three molecules of water, (2) the calcium salt of methoxyglucuronic acid joined to two molecules of galactose with the loss of two molecules of water, (3) the calcium salt of methoxyglucuronic acid joined to one molecule of galactose with the loss of one molecule of water. The composition of Salts 1 and 2 was further verified by oxidizing them and obtaining: (1A) the calcium salt of methoxyglucuronic acid joined to two molecules of galactose and one molecule of galactonic acid with the loss of three molecules of water, (2A) the calcium salt of methoxyglucuronic acid joined to one molecule of galactose and one molecule of galactonic acid with the loss of two molecules of water.

Work is now in progress on the methylation of mesquite gum.

[Contribution from the Chemical Laboratory of the University of Illinois]

THE STEREOCHEMICAL STUDY OF DIPHENYL 2,2'-DISULFONIC ACID. VIII[1]

By W. M. Stanley and Roger Adams

Received July 21, 1930 Published November 5, 1930

The existence of optical isomers in substituted diphenyl compounds is, according to the obstacle theory, due to the fact that the ortho-substituted groups are sufficiently large to prevent free rotation. In a previous paper[2] it was shown that x-ray data on the sizes of atoms and groups of atoms may be used to calculate the relative interferences of the ortho substituents and thus to predict whether or not a compound might possibly be resolved. It was pointed out also that the values for each group should not be regarded as representing merely linear effects since the forces around an atom or group are certainly three dimensional in character. The interference values for certain definite molecules were designed to represent the interference due to the effective realms of influence of the various combinations of atoms or groups. Some confusion regarding the interpretation of the obstacle theory appears to exist, since Bergmann[3] suggests the obstacle theory is unnecessary and yet considers the "mutual influence of the electron shells of the atoms or groups" to be the chief consideration. The influence of the electron shells, in so far as they affect the size of the atom or group by causing it to have a larger or smaller realm of force or influence, has been an integral part of the obstacle theory as far as the interpretation in this Laboratory is concerned. By the size of the atom or group is simply meant the volume affected by the electrical forces of the atom, and it is this volume of force that is regarded as the obstacle. The volume of the electrical forces of the atom or group has dimensions and occupies space so that a second volume of force may not be superimposed upon or pass through the first, although the two volumes may approach each other closely. Hence the field of force of the first acts as an obstacle to the field of force of the second atom or group which may strive to pass through or occupy the same space. This is recognized as a simple mechanical interference and the term "obstacle theory" appears quite satisfactory for it. This is in contradistinction to the so-called electrical theory, which represents the atoms or groups as possessing residual affinity of either a negative or a positive electrical charge which, in turn, prevents free rotation in the diphenyl molecule. The attraction of ortho-substituted groups of unlike charge and the repulsion of groups similarly charged are thus assumed to

---

[1] For the previous paper (VII) in this series see, Maxwell and Adams, This Journal, 52, 2959 (1930).

[3] Bergmann and Engel, *Z. physik. Chem.*, Abt. B, 8, 111 (1930).

be determined chiefly by the magnitude of such charges, and with no consideration of the size of the groups.

According to the obstacle theory the size of the group or atom, as determined by the fields of force without regard to the sign or amount of any residual affinity, is the determining factor as to whether or not interference occurs and thus makes resolution of such diphenyl compounds possible. It must be recognized that the angle at which substituents are attached to the benzene ring, as well as the angle between two benzene rings, may vary slightly according to the character of the substituents. This must be taken into consideration, as has been pointed out and exemplified in a previous article.[2]

Although diphenyl derivatives having three and four ortho-substituents have been and are the subject of considerable study, only one compound having but two ortho-substituents has been investigated. This compound, diphenic acid, failed to resolve. On the basis of x-ray data, the following possible interferences of the substituents in the 2,2′,6,6′-positions were obtained: C-H, 0.94Å.; C-COOH, 1.56Å.; C-C (2,2′ and 6,6′), 2.9Å. The carboxyl groups would fail to collide with the hydrogen atoms by 0.4Å.; 1.56Å. + 0.94Å. = 2.5Å. − 2.9Å. ⟶ −0.4Å. It is thus seen that resolution would not be expected. However, it should be possible to resolve such an α,α'-disubstituted diphenyl compound into optical isomers, provided the two substituting groups are sufficiently large and provided also that a hydrogen atom may serve as a blocking group. For example, if each of the two substituting groups was 0.4Å. or more larger than a carboxyl group, they would not only collide with each other but should also collide with the hydrogen atoms when the molecule becomes arranged so that the substituting groups are on opposite sides.

In this investigation diphenyl-2,2′-disulfonic acid was prepared in an attempt to secure groups larger than the carboxyl groups. Pauling[4] and Goldschmidt[5] have calculated the ionic radii of the sulfur ion in sulfates as 0.29 and 0.34Å., and the ionic radii of the carbon atom in carbonates as 0.2Å. The C-O distance in a carbonate group has been estimated by means of crystal analysis as 1.08 Å.,[6] the S-O distance in a sulfate group as 1.55Å.,[7] the C-C distance in aromatic compounds as 1.45Å. and the S-S distance in gaseous S_2 as 1.81Å. and as 2.08Å.[8] in Fe_2S. This indicates that the sulfur atom is from 25 to 50% larger than the carbon atom, or from 0.38 to 0.76Å. larger. If other factors do not interfere and the increase in the sulfonic acid group as indicated by the C-O and the S-O dis-

[8] Mecke, *Z. Physik*, 42, 390 (1927).

tances is effective, the total sulfonic acid group should be more than 0.4Å. larger than the carboxyl group. Interference with the hydrogen atoms would thus be made possible with the subsequent possibility of resolution of the compound. However, it was found impossible to resolve diphenyl-2,2′-disulfonic acid through the di-brucine, di-quinine and di-morphine salts. These salts were fractionated from several different solvents and gave no indication of resolution. An intermediate product, 4,4′-diamino-diphenyl-2,2′-disulfonic acid was also found to be unresolvable in the form of the di-brucine and di-strychnine salts. It would appear, therefore, that the sulfonic acid group may not be sufficiently large to interfere with a hydrogen atom and prevent free rotation. It may have a more compact structure than was supposed or else the hydrogen atom may be smaller as a blocking group than has previously been assumed. The second possibility appears plausible because the hydrogen atom represents a special case, in that it is different from all other substituting groups by not having an electron shell.

Other possible atoms or groups which, substituted in the α,α' positions in diphenyl, might make free rotation impossible are the bromine atom, the iodine atom and certain ring structures. Thus, 2,2′-dibromodiphenyl should be resolvable for the C-Br distance is approximately 2.11Å., which would cause the bromine atoms to interfere with the hydrogen atoms approximately 0.15Å. A 2,2′-di-iododiphenyl, if no abnormality occurs in the iodine atom when substituted in the benzene ring, should also resolve, for the C-I distance is about 2.2Å. This would cause the iodine atoms to interfere with the hydrogen atoms by 0.24Å. Diphenyl compounds having rings as the large disubstituted groups, may also be prepared. These conclusions depend on the validity of the assumption that the hydrogen atom has an appreciable interfering effect (0.94Å.). Representatives of the above type are now under investigation.

The diphenyl-2,2′-disulfonic acid was prepared by the sulfonation of nitrobenzene to *m*-nitrobenzene sulfonic acid, reduction to azobenzene disulfonic acid by means of zinc dust and alkali and further reduction and rearrangement by means of stannous chloride and hydrochloric acid to 4,4′-diaminodiphenyl-2,2′-disulfonic acid. Removal of the two amino groups by diazotization and treatment with copper powder in ethyl alcohol gave diphenyl-2,2′-disulfonic acid. Several attempts to prepare the disulfonic acid by reducing m-nitrobenzene sulfonic acid in alkaline solution to the hydrazo compound and filtering rapidly into concentrated hydrochloric acid to cause rearrangement to 4,4′-diaminodiphenyl-2,2′-disulfonic acid resulted in failure.

Experimental Part

***m*-Nitrobenzene Sulfonic Acid.*-**Nitrobenzene sulfonic acid was prepared by the sulfonation of nitrobenzene.[9]

---

[9] Holleman, *Rec. trav. chim.*, 24, 198 (1905).

Azobenzene Disulfonic Acid.[10,11]—A mixture of 200 g. of potassium *m*-nitrobenzene sulfonate and 255 g. of sodium hydroxide in 1700 g. of water was heated on a steam cone and 204 g. of powdered zinc was added during six hours. The mixture was filtered hot and washed with hot water. The wash water was combined with the filtrate and saturated with carbon dioxide and then concentrated by evaporation until crystals appeared. After cooling a 40-g. crop of white crystals was removed and the filtrate was concentrated to about one liter. On cooling overnight a crop of 115 g. of yellow crystals of the sodium salt of azobenzene disulfonic acid came out. These were removed by filtration and used without drying in the next step.

4,4′-Diaminodiphenyl-2,2′-disulfonic Acid.[11]—A solution of 80 g. of stannous chloride in 160 cc. of concentrated hydrochloric acid was slowly added to a solution of 115 g. of the sodium salt of azobenzene disulfonic acid in 400 cc. of hot water. Upon addition of the stannous chloride the solution gradually loses its yellow color, finally becomes colorless and then white crystals of 4,4′-diaminodiphenyl-2,2′-disulfonic acid precipitate out. After standing overnight these were removed, dissolved in dilute ammonium hydroxide, filtered from a small amount of insoluble material, and reprecipitated by the addition of hydrochloric acid. The run was repeated and the total yield was 160 g.

Diphenyl-2,2′-disulfonic Acid.[11]—Dilute sodium hydroxide was added to a mixture of 100 g. of 4,4′-diaminodiphenyl-2,2′-disulfonic acid in 1.5 liters of ice water until solution was effected. Then 41 g. of sodium nitrite was added and after solution was complete a cold solution of 120 cc. of concentrated sulfuric acid in 500 cc. of water was slowly added and the clear solution allowed to remain at 0° for three days. During this time long yellow needles crystallized out. These were removed, washed with 100 cc. of cold water and air dried for fifteen minutes. The weight of the partially dried product was 100 g. The product was placed in an 800-cc. beaker, covered with 200 cc. of 95% ethyl alcohol and copper bronze added slowly with stirring. The mixture warmed up and nitrogen was evolved. When the reaction was ended, the mixture was heated on the steam cone for fifteen minutes and filtered from the unreacted copper bronze. The filtrate was concentrated until practically free of alcohol and then taken up in 200 cc. of water. A solution of 80 g. of barium hydroxide in 600 cc. of water was then added and the 800 cc. of solution was filtered hot from a small amount of black insoluble material. On cooling a 50-g. crop of white crystalline barium salt of diphenyl-2,2′-disulfonic acid came out. This precipitate was removed and warmed with 12 g. of concentrated sulfuric acid in 200 cc. of water and filtered from the precipitated barium sulfate. Dilute sulfuric acid was then added dropwise to the filtrate until the addition gave no additional white precipitate of barium sulfate. The precipitated barium sulfate was then removed by filtration and the filtrate evaporated to a thick sirup which solidified on standing over phosphorus pentoxide for two days. Diphenyl-2,2′-disulfonic acid is very soluble in water and alcohol, soluble in acetone, and insoluble in chloroform, benzene and petroleum ether. It is very deliquescent.

Preparation and Fractionation of the Alkaloid Salts

Brucine Salt of Diphenyl-2,2′-disulfonic Acid.—A mixture of 5 g. of diphenyl-2,2′-disulfonic acid and 12.5 g. of brucine was boiled with 100 cc. of water until complete solution was effected. On cooling the salt separated as an oil which solidified after standing for a day. The salt was washed with water and then with 100 cc. of hot benzene. After drying the weight of the salt was 17.5 g. and the melting point was 244–246°. ***Rotation.*** (a) 0.3121 g. made up to 25 cc. in chloroform at 20° gave $\alpha_D = -0.8°$;

---

[10] Mahrenholtz and Gilbert, *Ann.*, 202, 332 (1880).

[11] Limpricht, *ibid.*, 261, 327 (1891).

$l = 2$; $[\alpha]^{20}_{\rm D}$ −32.0; (b) 0.3382 g. made up to 15 cc. in chloroform at 20° gave $\alpha_{\rm D}$ = −0.76"; $l = 1$; $[\alpha]^{20}_{\rm D}$ −33.6.

The salt was washed with 50 cc. of acetone, *Rotation.* 0.2413 g. made up to 20 cc. with chloroform at 20° gave $\alpha_{\rm D}$ = 0.38°; $l = 1$; $[\alpha]^{20}_{\rm D}$ −31.6. This product was analyzed after drying over phosphorus pentoxide for an hour at 100° and 10-mm. pressure.

Anal. Calcd. for $C_{58}H_{62}O_{14}N_4S_2$: S, 5.81; neut. equiv., 551.3. Found: S, 5.62; neut. equiv., 548.2.

Petroleum ether was added to a solution of 4 g. of the salt in 50 cc. of chloroform until about half of the salt was precipitated out. The remainder of the salt was obtained by evaporation of the filtrate. Both fractions gave essentially the same rotation and melting point as the original material. A solution of 8 g. of brucine salt in 100 cc. of hot water was allowed to cool to 30° with stirring. A 3.5-g, crop of crystals which separated was removed by filtration. On standing overnight a second crop of 0.85 g. of crystals had separated from the filtrate. These were removed and the filtrate was evaporated to 40 cc. and on cooling a 3.2-g. crop of crystals was obtained. The rotation and melting points of all three fractions were identical. A third portion of di-brucine salt was fractionated by crystallization from 95% ethyl alcohol. Both fractions melted at 245–248° and had a rotation in chloroform of $[\alpha]^{20}_{\rm D}$ −33.2.

Quinine Salt of Diphenyl-2,2′-disulfonic Acid.—A mixture of 5 g. of diphenyl-2,2′-disulfonic acid and 10.3 g. of quinine was boiled with 400 cc. of water without effecting solution. The water was removed by evaporation on a steam cone and the residue was dissolved in 200 cc. of chloroform. The addition of petroleum ether caused a 7.5-g. portion of salt melting at 188–192° to precipitate. *Rotation.* 0.3045 g. made up to 15 cc. with chloroform at 20° gave $\alpha_{\rm D}$ = −1.6′; $l = 1$; $[\alpha]^{20}_{\rm D}$ −78.9.

This salt was washed with 100 cc. of ether and analyzed after drying over phosphorus pentoxide for two hours at 100° and 10-mm. pressure. The melting point was then 191–193" with sintering at 185°. *Rotation.* 0.285 g. made up to 15 cc. with chloroform at 20° gave $\alpha_{\rm D}$ = −1.63′; 1 = 1; $[\alpha]^{20}_{\rm D}$ −85.9.

Anal. Calcd. for $C_{52}H_{58}O_{10}N_4S_2$: S, *6.66;* neut. equiv., 481.3. Found: S, 6.41; neut. equiv., 485.4.

The further addition of petroleum ether caused a 7-g. portion of di-quinine salt melting at 188–193° to precipitate. *Rotation.* 0.2453 g. made up to 15 cc. with chloroform at 20° gave $\alpha_{\rm D}$ = −1.3°; 1 = 1; $[\alpha]^{20}_{\rm D}$ −79.5. *A* solution of the di-quinine salt in 40% ethyl alcohol was fractionated into two fractions of 3.3 and 3.7 g. Both fractions melted at 189–192° and the rotations were −83.5 and −81.2, respectively.

Morphine Salt of Diphenyl-2,2′-disulfonic Acid.—A mixture of 3 g. of diphenyl-2,2′-disulfonic acid and 1.65 g. of morphine was boiled with 75 cc. of water until complete solution was effected. The solution was cooled and filtered from 0.01 g. of insoluble material and further evaporated. The salt was so soluble that it was impossible to fractionate it from water, so the aqueous solution was evaporated to a sirup. This sirup was dissolved in 150 cc. of hot ethyl alcohol. On cooling the solution a 0.75-g. portion of salt came out. This fraction of salt began to swell at 240° and melted at 260–265" with decomposition. *Rotation.* 0.1513 g. made up to 15 cc. with water at 20" gave an = −0.73; 1 = 1; $[\alpha]^{20}_{\rm D}$ −72.5.

The filtrate was evaporated to 75 cc. and a 0.5-g. portion of salt came out on cooling. This fraction began to swell at 240° and melted at 261–267° with decomposition. *Rotation.* 0.2237 g, made up to 15 cc. with water at 20° gave $\alpha_{\rm D}$ = −1.11; 1 = 1; $[\alpha]^{20}_{\rm D}$ −74.6.

The filtrate was evaporated to dryness and gave 1.65 g. of salt, which began to swell at 240° and melted at 261–267° with decomposition. *Rotation.* 0.1952 g. made up to 15 cc. with water at 20° gave $\alpha_{\rm D}$ = −0.98; $l = 1$; $[\alpha]^{20}_{\rm D}$ −75.1.

Anal. Calcd. for $C_{46}H_{48}O_{12}N_2S_2$: neut. equiv., **442.** Found: 441.

The di-morphine salt was insoluble in chloroform, benzene, petroleum ether, ethyl acetate and acetone. The salt was also insoluble in absolute ethyl alcohol, but after moistening the salt with a small amount of water it dissolved in ethyl alcohol quite readily.

Strychnine Salt of 4,4′-Diaminodiphenyl-2,2′-disulfonic Acid.—A mixture of 5 g. of 4,4′-diaminodiphenyl-2,2′-disulfonic acid and 9.7 g. of strychnine was boiled for a half hour with 250 cc. of water. On cooling a 7.4-g. crop of salt melting at 310–318° (dec.) was obtained. *Rotation.* 0.2207 g. made up to 15 cc. with water at 20° gave $\alpha_D = -0.33$; $l = 1$; $[\alpha]^{20}_D$ −22.4.

Anal. Calcd. for $C_{54}H_{56}O_{10}N_6S_2$: Neut. equiv., 506.2. Found: 513.

The filtrate was evaporated to 120 cc. and on cooling 2 3 g. of salt was obtained. The filtrate was then evaporated to dryness, giving 3.3 g. of salt melting at 310–318° with decomposition. *Rotation.* 0.3060 g. made up to 15 cc. with water at 20° gave $\alpha_D = -0.43$; $l = 1$; $[\alpha]^{20}_D$ −21.4.

Brucine Salt of 4,4′-Diaminodiphenyl-2,2′-disulfonic Acid.—A mixture of 5 g. of 4,4′-diaminodiphenyl-2,2′-disulfonic acid and 11.4 g. of brucine was gently boiled for a half hour with 250 cc. of water. On cooling a 7.5-g. crop of dibrucine salt melting at 310–313° (dec.) was obtained. *Rotation.* 0 2715 g. made up to 15 cc. with water at 20° gave $\alpha_D = -0.38$; $l = 1$; $[\alpha]^{20}_D$ −21.0.

Anal. Calcd. for $C_{58}H_{64}O_{14}N_6S_2$: neut. equiv., 566.2. Found: 576.

The filtrate was evaporated to 190 cc. and on cooling a 5.5-g. crop of salt melting at 311–314° (dec.) was obtained. *Rotation.* 0.3010 g. made up to 25 cc. with water at 20° gave $\alpha_D = -0.24$; $1 = 1$; $[\alpha]^{20}_D$ −20 0.

The filtrate was evaporated to dryness, giving 3 g. of salt melting at 310–314° with decomposition. *Rotation.* 0.3107 g. made up to 15 cc. with water at 20° gave $\alpha_D = -0.52$; $l = 1$; $[\alpha]^{20}_D$ −24.6.

Summary

The di-brucine, di-quinine and di-morphine salts of diphenyl-2,2′-disulfonic acid, and the di-brucine and di-strychnine salts of 4,4′-diaminodiphenyl-2,2′-disulfonic acid have been prepared. Fractionation of these salts from several different solvents gave no indication of resolution.

THE CHEMISTRY OF FURFURAL. THE PREPARATION OF TETRAETHYLDIAMINODIPHENYLFURYLMETHANE HYDROCHLORIDE AND OF DIPHENYLFURYLMETHANE[1]

BY S. A. MAHOOD AND HELEN F. ALDRICH

RECEIVED JULY 21, 1930 PUBLISHED NOVEMBER 5, 1930

Unlike benzaldehyde, furfural does not condense with the hydrogen atoms para to the amino group of two molecules of aniline when furfural and aniline are treated with a dehydrating agent, but condenses with the hydrogens of the amino group. For this reason, in the synthesis of the diphenylfurylmethane dyes, the amino hydrogen atoms must be absent as in the tertiary amines, or protected by the formation of a sulfate or acetyl derivative.

In 1877, at the same time that he made malachite green, Otto Fischer[2] prepared, by the condensation of dimethylaniline and furfural, the first diphenylfurylmethane dye. He described the furyl analog as lighter in color than malachite green and unstable to light. Renshaw and Miss Naylor[3] found it darker than, and as stable as, malachite green.[4]

This paper describes the preparation of tetraethyldiaminodiphenylfurylmethane hydrochloride, from the condensation of diethylaniline and furfural, and the properties of this dye.

From the figures given on the yields in the synthesis of the leuco base of this dye and of the oxidized product, it can be said that in neither case do the reactions involved proceed easily under the conditions maintained. The following conclusions may be added: (1) the replacement of a phenyl group of malachite green by the furyl group causes a change in the stability of the dye; (2) the ease of condensation of an aldehyde with an aromatic amine is decreased when a furyl group is substituted for a phenyl group in the aldehyde; and (3) diethylaniline condenses with furfural less readily than dimethylaniline. There is a possibility that the stability of these dyes might be increased by substitution in the α'-positions of the furan ring.

Mahood and Harris[5] were able to prepare the furan analog of the dye

benzoflavin from m-toluylene-diamine sulfate, refluxed with furfural. Mahood and Fenner,[6] however, were able to isolate, only in minute quantities, any diaminodiphenylfurylmethane formed by the condensation of furfural with acetanilide, while Mahood and Martin[7] were unable to isolate any of the above product from the condensation of furfural with aniline sulfate.

Because diaminodiphenylfurylmethane was not isolated in quantity, the preparation of diphenylfurylmethane directly from the latter by diazotization, according to the method used by Otto Fischer to prove the structure of the triphenylmethane dyes, was impossible. Mahood and Jordan[8] attempted to prepare this compound by several methods. In each case they were unsuccessful, either because under the influence of the heat or reagents necessary the furfural polymerized before taking part in the reaction, or because no product could be isolated.[9]

This paper also describes the preparation of the above product, diphenylfurylmethane, by a synthesis which involves first transforming the furfural to a more stable derivative, pyromucic acid, and then treating the ethyl ester of the latter with phenylmagnesium bromide to obtain diphenylfurylcarbinol, which on reduction with zinc and acetic acid gives the desired product.

The combustion values given in the experimental data agree with the calculated values for diphenylfurylmethane. The temperature of the reduction was kept low to prevent the formation of a fluorene linkage between the two phenyl groups.

Experimental Part

Preparation of **Tetraethyldiaminodiphenylfurylmethane.**—In a 500-cc. flask were placed 61.5 g. of freshly distilled diethylaniline, 18.1 g. of refined furfural and 20 g. of fused zinc chloride, finely pulverized. The flask, connected with a reflux condenser and a mechanical stirrer, was heated on a water-bath for eleven hours. At the end of this time there was still much unchanged diethylaniline, but more prolonged heating did not increase the yield of the product. The somewhat viscous, dark colored reaction mixture was subjected to steam distillation in the same flask, to remove unchanged furfural and diethylaniline. The crystalline leuco base left behind in the flask after steam distillation was washed with water to remove excess zinc chloride, dissolved in alcohol, boiled with boneblack and filtered while hot. Light yellow crystals separated, which darkened on exposure to air. This product, on recrystallization from ligroin, melted

[7] Mahood and Martin, "Tulane Theses," 1925, Vol. 3, p. 491.

[8] Mahood and Jordan, *Science,* 60, 453 (1924).

[9] Recently, Peters and Fischer [THIS JOURNAL, 52, 2079 (1930)] have isolated impure phenylfurylcarbinol, the product which Jordan failed to isolate, and from which he intended to prepare the corresponding chloride, as a step in the synthesis of diphenylfurylmethane. All efforts to chlorinate this carbinol were found, by Peters and Fischer, to result in the formation of resins.

completely at 78° but softened several degrees below this. *A* yield of *22* g. or 31% was obtained in this way.

Anal. Calcd. for $C_{25}H_{32}N_2O$: N, *7.45*. Found: *N, 6.82, 6.91.*

Preparation of **Tetraethyldiaminodiphenylfurylmethane** Hydrochloride.—Following the proportions given by **Gattermann**[10] for the oxidation of the leuco base of malachite green, the product obtained above was oxidized in acid solution with lead peroxide paste. The oxidation was carried on for two hours in the cold, accompanied by mechanical stirring. After elimination of the lead salts, the dye was precipitated as the double zinc chloride salt by means of a saturated solution of sodium chloride. *A* yield of 17.2% was obtained.

This dye is crystalline and dark green in color. It dyes silk a yellower color than malachite green, and, in the lighter tones, gives a clear bright green. Dyed samples were fast to washing, but faded somewhat on two week's exposure to bright light, whereas samples dyed with malachite green were unaffected.

Preparation **of Diphenylfurylcarbinol.**—Phenylmagnesium bromide was prepared according to **Gilman,**[11] from 10 g. of magnesium and *76* g. of phenyl bromide, in the presence of *200* cc. of ether. When the reaction was complete, *75* cc. of toluene was added and the ether distilled off; *19.6* g. of ethyl pyromucate,[12] prepared from pyromucic acid,[13] was dissolved in 25 cc. of toluene and added to the Grignard reagent with sufficient rapidity to cause vigorous refluxing. The temperature maintained was about *112°*.

When the reaction was complete, the cooled mixture was decomposed with ice to which the theoretical amount of 30% acetic acid had been added. The toluene layer was separated. After removal of the toluene and diphenyl by steam distillation, a crystalline mass of a light brown color was left behind. This residue was only slightly soluble in cold ligroin and could be recrystallized from this medium in the form of beautiful, light colored, rhombic crystals, melting at *91°* (corr.).[14] Fine white crystals of the same melting point could also be obtained by precipitation from a dilute solution in 87% ethyl alcohol, on the slow addition of water. After standing for a few days, these crystals of diphenylfuryl carbinol soften into a reddish mass. An 85% yield of this carbinol was obtained.

Preparation of **Diphenylfurylmethane.**—Three grams of the carbinol obtained above was dissolved in about 150 cc. of glacial acetic acid, in a large glass test-tube; *15* g. of zinc dust was added in small amounts to the solution. During this time the contents of the test-tube were heated in a water-bath, the temperature of which was kept below 70°. When the solution had changed in color from red to a pale yellow brown, it was poured into water and partially neutralized with sodium hydroxide. A spongy yellow precipitate, which hardened on drying, collected in a mass and was ground to a powder, washed until neutral and dried. It melted at 51° (corr.). The zinc residue left in the test-tube was further boiled with acetic acid. In this way more of the precipitate was obtained. The product was unstable, softening in a few days to a gummy mass. It was soluble in alcohol, ether, ligroin and hot glacial acetic acid. The yield was 95% of the theoretical, calculated as diphenylfurylmethane.

Anal. Calcd. for $C_{17}H_{14}O$: C, *87.14;* H, *6.02.* Found: C, *87.23, 86.83;* H, *5.77, 5.81.*

Summary

1. A new dye, tetraethyldiaminodiphenylfurylmethane hydrochloride, has been prepared and its properties have been determined.

2. The parent compound of the diphenylfurylmethane dyes, diphenylfurylmethane, has been obtained by reduction of the corresponding carbinol.

THE DISTILLATION OF GRIGNARD REAGENTS

BY HENRY GILMAN AND ROBERT E. BROWN

RECEIVED JULY 21, 1930 PUBLISHED NOVEMBER 5, 1930

Introduction

Solutions of Grignard reagents are mixtures of $RMgX$, R_2Mg, MgX_2, $R—$ and $—MgX$ (or $MgX_2 + Mg$) in a series of equilibria. The following equilibria and dissociation reactions[1] account for the compounds just mentioned.

$$2\ RMgX \rightleftarrows R_2Mg + MgX_2 \qquad (I)$$

$$RMgX \rightleftarrows R— + —MgX \qquad (II)$$

In order to lend additional support to these reactions, studies have been made on the sublimation and distillation of organomagnesium compounds. First, in an attempted high vacuum distillation of methylmagnesium chloride, a distillate or sublimate of magnesium dimethyl, free of halogen, was obtained.'" The magnesium dimethyl, a solid like magnesium diethyl,[3] owes its formation undoubtedly to a displacement of the equilibrium pictured in Reaction I. Second, a search was made for a liquid organomagnesium compound in order to facilitate a study of Reaction I. The relative stability of the liquid beryllium di-*n*-butyl,[4] suggested that greater success might be had with magnesium di-n-butyl. Accordingly, magnesium di-n-butyl was prepared,[2b] but unfortunately it also is a solid. Like its homologs, magnesium dimethyl and magnesium diethyl, it can also be sublimed in a high vacuum but less smoothly than the lower members of this series because of its lesser volatility or lesser stability at elevated temperatures or for both of these reasons.

With this partial success, we turned to a method of distillation used earlier[4] in a study of organoberyllium compounds, namely, ether distillation. This method, which was highly successful for the distillation of solid

beryllium dimethyl, was found applicable to the magnesium dialkyls, which are, however, distinctly less volatile than the related beryllium dialkyls. After having demonstrated that magnesium dialkyls can be distilled by this procedure (see Experimental Part), a study was made of the ether distillation of RMgX compounds. When alkylmagnesium halides were treated in this manner, the distillate was found to contain the alkylmagnesium halide. Unfortunately, however, this does not prove that the RMgX compound as such distilled over. This is so because we have shown that under the conditions of our distillation magnesium halide or its etherate also distils. Accordingly we are in no position as yet to state whether the RMgX compound contained in the distillate was due to the separate distillations of R_2Mg and of MgX_2 (see Reaction I), each of which is known to distil, or to the distillation of these two compounds *and* some of the RMgX as such.

If equimolecular parts of R_2Mg and of MgX_2 distilled, then the ratio of Mg:X in the distillate should be one. In two analyses of a distillation of methylmagnesium iodide, the ratio Mg:I was found to be 1.105 and 1.092, respectively. These results merely indicate that almost equimolecular parts of R_2Mg and MgI_2 distil, but they do not tell us whether any RMgI distilled. Even though the ratio agreed with the theoretical for Mg:I, we would still have no compelling evidence of the distillation of RMgX as such. Apart from our primary objective, the results are interesting in showing that RMgX or its ***equivalent*** ($R_2Mg + MgX_2$) does distil, because a combination of $R_2Mg + MgX_2$ reacts immediately[1] to give RMgX. It may be possible to find a more definite answer with solvents other than ether.

Apparently arylmagnesium halides cannot be distilled in this manner. At least, when phenylmagnesium bromide was used no magnesium diphenyl and no magnesium bromide distilled during the eighteen consecutive full days of distillation. Just why the magnesium bromide which we know to be present in solutions of phenylmagnesium bromide was held back, we do not at present know. From the distillation of this Grignard reagent there was isolated some diphenyl. This indicates that with RMgX compounds of this type it may be possible to remove[6] the radical R– or its coupling or disproportionation product (see Reaction II).

---

[5] Experiments with this in view are in progress with RMgX compounds like benzohydrylmagnesium chloride, $(C_6H_5)_2CHMgCl$. See Gilman and Zoellner, THIS JOURNAL, 52, 3984 (1930). Benzohydrylmagnesium chloride and related types. like triphenylmethylmagnesium chloride,' convert benzophenone to benzopinacol (studies by K. E. Marple).

It may prove possible to prepare some R_2Mg compounds from Grignard reagents by distilling off the MgX_2 and leaving the R_2Mg behind. However, an apparently more general and satisfactory method for the preparation of R_2Mg compounds directly from Grignard reagents is that of Schlenk and Schlenk, Ber., 62, 920 (1929), wherein 1.4-dioxane is used.

Experimental Part

Apparatus.—The apparatus is shown in Fig. 1. It was constructed entirely of glass, and the long neck above the flask A (of about 150 cc. content) was indented to produce good fractionation and to prevent mechanically entrained particles from reaching the receiver B. A ring seal with a sharp edge was also sealed into the upper part of the neck of flask A to prevent any material from creeping out of A. The trap below the water condenser insured a flow of ether and other volatile substances in one direction only. It was found necessary to have the system sealed with a mercury test-tube seal because pressure was gradually built up in the system.[6]

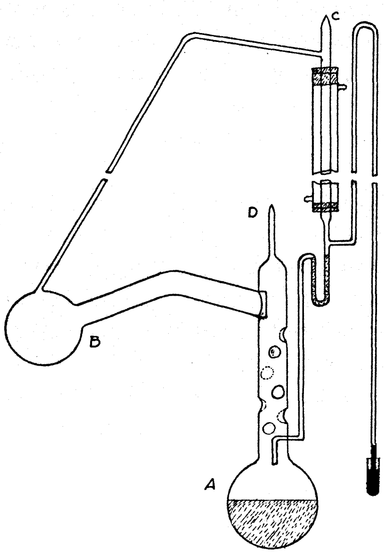

Fig. 1.

The manipulation and operation of the system is as follows. With the tubes C and D open, the apparatus is first thoroughly swept out with dry nitrogen. A solution of the Grignard reagent or MgR_2 compound or MgX_2 compound was then carefully filtered through glass wool into tube C, while the nitrogen continued to flow through D. Tubes C and D were then sealed off. An oil-bath was placed under flask A and the bath was maintained at a temperature of 75–80° by a hot-plate during the course of the experiment. In cool weather a second hot-plate was placed under flask B to drive the ether over into the water condenser and to prevent an undue accumulation of ether in flask B. In warm weather sufficient heat radiated from the plate under A to keep the system in good balance and so make unnecessary a hot-plate under flask B.

At the termination of the experiment, the heating of A was discontinued and the two tubes leading to receiving flask B were sealed off. The smaller of these tubes was next opened to a source of nitrogen, and the contents of B were then investigated. With this apparatus[7] we have found no evidence of creeping, and mechanical entrainment has apparently been annulled. Evidence in support of this is found in the experiment with phenylmagnesium bromide wherein it was shown that the distillate contained neither halogen nor magnesium.

Tests and Analyses.—The R_2Mg and RMgX compounds were tested qualitatively

---

[6] Gilman and St. John, *Bull. soc. chim.*, **45**, 1091 (1929), have shown that several typical Grignard reagents can be refluxed at moderately elevated temperatures for several days without any essential impairment in yield of product from the RMgX compound. Possibly the unusually long refluxing used in the present studies may result in a gradual decomposition of the ether or the rate of decomposition of RMgX compound over very long periods may be significant or both of these factors may be involved in the building up of pressure in the system.

[7] This apparatus has some essential improvements over that used in the beryllium dialkyl studies.' It is possible to use a simpler type of apparatus for the ether distillation of other organometallic compounds such as zinc dialkyls which, incidentally, can be prepared in satisfactory yields by the reaction between zinc halides and Grignard reagents.

by the color test[8] and quantitatively by the acid titration[9] method of analysis. They were further characterized by the preparation of α-naphthalides as derivatives.[10]

Time Required and Quantities of Distillate in Ether Distillation.—In the ether distillation experiments with magnesium bromide, magnesium iodide, magnesium diethyl, methylmagnesium iodide, ethylmagnesium bromide, ethylmagnesium iodide and phenylmagnesium bromide about 0.1 mole of compound was used in 75-100 cc. of ether.

With methylmagnesium iodide there was slight evidence of distillate (after distilling ether from receiver B) in about one week from the start of distillation. With ethylmagnesium bromide and iodide there was no evidence of distillate until about the tenth day. Each distillation was run for eighteen full days, and the distillation when once started required practically no attention. This time was arbitrarily selected because it gave a quantity of distillate which though quite small could nevertheless be analyzed. Duplicate distillations were made with practically every compound investigated.

The acid titration of one distillate from methylmagnesium iodide indicated approximately 0.15 g. of distillate calculated as methylmagnesium iodide. The distillates from ethylmagnesium bromide and iodide were not titrated, but they appeared to be somewhat smaller. In the phenylmagnesium bromide experiments the quantity of diphenyl isolated in each distillation was about 0.2 g. Its identity was confirmed by mixed melting point determinations with an authentic specimen.

The apparently inordinate time required for the ether distillation of appreciable quantities of compounds can probably be reduced by the use of other solvents or combinations of solvents.

High Vacuum Sublimation.--The technique used for the high vacuum sublimation was that described earlier. Of the three magnesium dialkyls which were sublimed in a high vacuum, magnesium dimethyl was most volatile. Magnesium di-n-butyl was less volatile than magnesium diethyl. The same order applies to the relative thermal stability of these compounds, magnesium dimethyl being most stable. A free flame was used in the distillation of the magnesium dialkyls, and methylmagnesium chloride was heated in an oil-bath. We have also shown that it is possible to sublime magnesium acetylacetone in a high vacuum.

Summary

In connection with studies on the following systems present in solutions of Grignard reagents

$$2\mathrm{RMgX} \rightleftarrows \mathrm{R_2Mg} + \mathrm{MgX_2}, \text{ and}$$
$$\mathrm{RMgX} \rightleftarrows \mathrm{R}{-} + {-}\mathrm{MgX}$$

it has been shown that some RMgX compounds, or their equivalents, can be distilled in a stream of ether. The high vacuum sublimation of RMgX compounds gives R_2Mg compounds.

ACTION OF AROMATIC ALCOHOLS ON AROMATIC COMPOUNDS IN THE PRESENCE OF ALUMINUM CHLORIDE. V. BENZYLATION OF ORTHO-CRESOL

BY R. C. HUSTON, H. A. SWARTOUT AND GLADYS K. WARDWELL

RECEIVED JULY 24, 1930 PUBLISHED NOVEMBER 5, 1930

In September, 1923, an investigation was started in this Laboratory on the condensation of benzyl alcohol and *o*-cresol in the presence of aluminum chloride. The main product of the reaction crystallized as hard flattened needles which melted at 49.5–50.5° and gave analytical results which indicated a formula of $C_{14}H_{14}O$.

Holleman's amplification of the Beilstein rule[1] would predict that the entering benzyl group would take a position ortho or para to the phenolic hydroxyl. In order definitely to prove this, the compound was heated in a closed tube with $Zn(NH_3)Cl_2$. The resulting amine was diazotized and reduced to the hydrocarbon, which was finally oxidized to *m*-benzoylbenzoic acid.

Our work with the condensation of primary and secondary aromatic alcohols with phenol,[2] as well as the work of Rennie,[3] Gattermann[4] and others with similar reactions, led us to assume that the product containing the benzyl group in the para position to the phenolic hydroxyl would predominate and we tentatively assigned the formula 
. Final proof of this structure was found in the preparation of the isomeric 1-methyl-6-benzylphenol by the Claisen method, as described later in this article.

We were able to isolate from the petroleum ether mother liquor from which the 2-methyl-4-benzylphenol was crystallized a small amount of crystalline material which came down in bundles of very fine needles with a soft silky sheen. A melting point determination gave the rather surprising results of 49.5–50.5°.

A higher-boiling fraction of the reaction product came over after repeated fractionation at 225–227° (5 mm.) as a yellow oil from which we were unable to obtain crystals. Analysis gave results indicating a dibenzyl derivative of o-cresol, $C_{21}H_{20}O$. Because of the powerful directing influence of the phenolic hydroxyl and the behavior of the compound toward strong alkali, we have called it 2-methyl-4,6-dibenzylphenol.

---

[3] Rennie, J. Chem. *Soc.*, 41, 37 (1882).

[4] Gattermann, Ber., 22, 1129 (1889); 23, 1199 (1890).

Upon application of the Claisen[5] method of benzylation to *o*-cresol, we obtained a good yield of a benzylated derivative which was identical in melting point, boiling point, solubility and crystal appearance with the compound which we obtained from the mother liquors of the main product of the aluminum chloride condensation. Besides the 2 methyl-6-benzylphenol, the Claisen process gave a smaller amount of 2 methylphenyl benzyl ether. The o-methyl group of the cresol precluded the formation of *a* di-*o*-dibenzyl derivative.

A short time after the experiment just described had been completed, Schorigin[6] published a description of the benzylation of *o*-cresol by the Claisen method. He stated that 2-methyl-6-benzylphenol melted at 51–52" and boiled at 182–188° (15 mm.).

A comparison of the physical properties of the two monobenzyl derivatives (both of which melt at 49.5–50.5°) brings out some rather striking differences, aside from the difference in appearance of the crystals.

2-Methyl-4-benzylphenol dissolves readily in the calculated amount of dilute potassium hydroxide (5%), is soluble in eighty-seven parts of petroleum ether (40–60°) at 20° and boils at 167–169° (5 mm.).

2-Methyl-6-benzylphenol is insoluble even in a large excess of dilute potassium hydroxide (5%). It dissolves when warmed in the equivalent amount of strong potassium hydroxide (50%), but separates out when an equal volume of water is added. It is soluble in 18.2 parts of petroleum ether at 20°. Its boiling point is seventeen degrees lower than that of its isomer.

The monobromo derivatives of the two monobenzyl cresols were prepared by treating them in chloroform solutions with the calculated amounts of bromine. In the case of 2-methyl-4-benzylphenol we assumed that the bromine entered the phenolic ring in the only available ortho or para position with the formation of 6-bromo-2-methyl-4-benzylphenol.

Making the same assumption, 2-methyl-6-benzylphenol would give 4-bromo-2-methyl-6-benzylphenol. In this last case we were able to prove the validity of the assumption by benzylating 2-methyl-4-bromophenol by the Claisen method to obtain the same product that was formed by the bromination of 2-methyl-6-benzylphenol. This gives additional proof of the structure of the last-named compound.

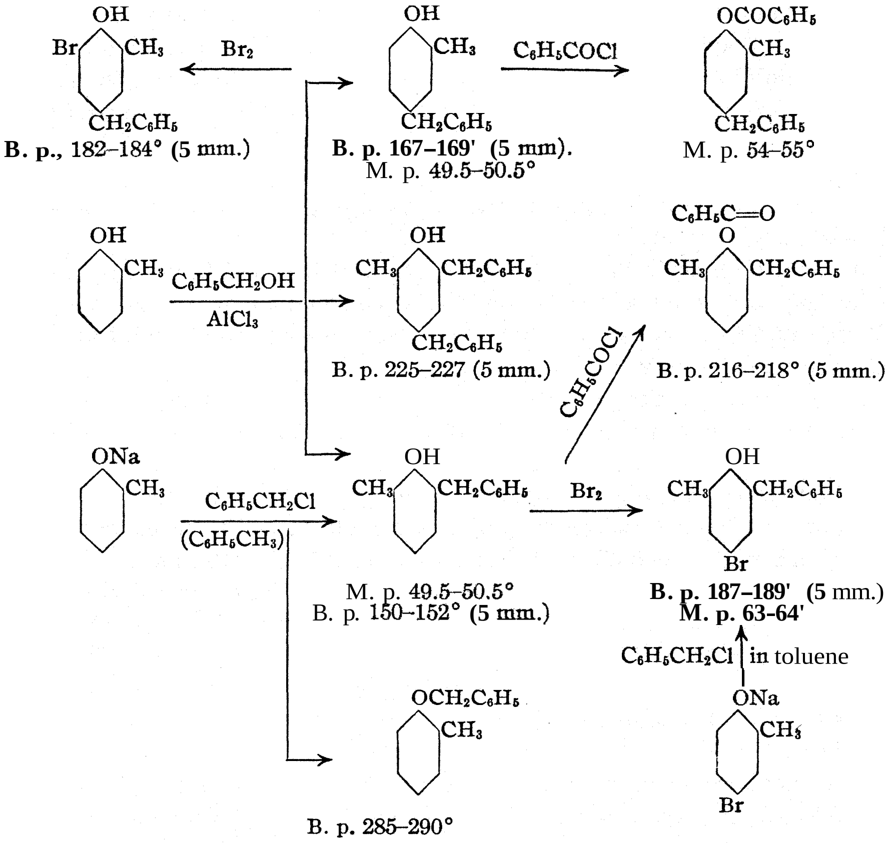
The two monobenzyl derivatives were further characterized by the preparation of their benzoyl derivatives. It is worthy of note that the 2-methyl-6-benzylphenol in which both ortho positions are occupied reacted much less readily under the Schotten–Baumann treatment than did the isomeric 2-methyl-4-benzylphenol.

The following is a graphic outline of the field covered.

---

[5] Claisen, *Ann.*, 442, 221 (1924).

[6] Schorigin, *Ber.*, 58B, 2033 (1925).



Experimental

Benzyl Alcohol and o-Cresol with Aluminum Chloride.—A mixture of 100 g. of o-cresol, 100 g. of benzyl alcohol and 200 g. of petroleum ether (40–60°) was placed in a tall vessel, surrounded by water and stirred mechanically while 65 g. of anhydrous aluminum chloride was added in small portions over a period of an hour. The temperature was maintained at 30–35°. At times troublesome frothing occurred which was controlled by the addition of further portions of cold petroleum ether. When the evolution of hydrogen chloride had nearly ceased, the mixture was allowed to stand overnight. The brown semi-solid intermediate product was decomposed with ice and a little hydrochloric acid and extracted with ether. The ether extract was dried over potassium carbonate, the ether distilled off and the residue fractionated under reduced pressure.

Fifth fractionation (5 mm.)

90–150°	12.2 g.
150–170°	51.5 g.
170–215°	3.3 g.
215–235°	26.2 g.
Residue	13.5 g.

The first fraction was crude *o*-cresol.

The second fraction (150–170°) crystallized. The crystals were pressed between filter papers and recrystallized repeatedly from petroleum ether. The purified compound melted at 49.5–50.5° and boiled at 167–169^{e} (5 mm.). It crystallized in clusters or rosets of fine brittle needles. Two 50-cc. portions of a solution of purified crystals in petroleum ether (40–60°) at 20° gave on evaporation 0.5715 g. and 0.5743 g. of residue.

Anal. Subs., 0.523: CO_2, 0.4746; H_2O, 0.0971. Calcd. for $C_{14}H_{14}O$: C, 84.8; H, 7.12. Found: C, 84.99; H, 7.19.

The filter papers which were used to remove the oily impurity from these crystals were extracted with ether and the ether extract was distilled. Two and one-half grams came over at 150–155° (5 mm.). This crystallized when seeded with 2-methyl-6-benzylphenol (see p. 4488) and was further identified by bromination and by its benzoyl derivative.

The 215–235" fraction was repeatedly distilled until most of it came over at 225–227° (5 mm.). All attempts to induce this oil to solidify failed. It is insoluble in dilute potassium hydroxide. In hot 50% potassium hydroxide it changed to a blue, gummy mass, but did not dissolve. Its ready solution in Claisen's alcoholic potassium hydroxide proved it to be a phenol. Its failure to absorb bromine readily when dissolved in chloroform indicated that all positions ortho and para to the phenolic hydroxyl were occupied and justified the assignment of the structure 2-methyl-4,6-dibenzylphenol.

Anal. Subs., 0.2147: CO_2, 0.6861; H_2O, 0.1343. Calcd. for $C_{20}H_{21}O$: C, 87.45; H, 7.00. Found: C, 87.62; H. 7.01.

4-Amino-3-methyl-diphenylmethane.—The phenol which formed the bulk of the 150 to 170° fraction (b. p. 167–169°) was mixed thoroughly in a mortar with twice its weight of zinc ammonia chloride and one-fifth its weight of ammonium chloride. The mixture was sealed in Carius tubes (care being taken not to fill each tube more than one-quarter full) and heated in a bomb furnace for twenty hours at 330".

The reaction product was thoroughly shaken with hydrochloric acid (1:1), allowed to stand overnight and extracted with ether to remove the unchanged phenol. The acid solution was just neutralized with ammonium hydroxide and then treated with dilute sodium hydroxide to precipitate the amine. This came down as very fine light brown plates and was not further purified. Five grams was obtained from 50 g. of phenol.

Preparation of 3-Methyldiphenylmethane and m-Benzoylbenzoic Acid.—Five grams of 4-amino-3-methyldiphenylmethane was dissolved in 15 g. of hydrochloric acid (sp. gr. 1.2) and diluted with 30 cc. of water, Sodium nitrite was added (in 10% solution) until a positive test for nitrous acid was obtained with starch–iodide paper. The solution of diazonium chloride was added slowly to a well-cooled solution of 10 g. of sodium hydroxide in 30 cc. of water and reduced in the cold with sodium stannite (prepared from 20 g. of stannous chloride). Extraction with ether gave 0.6 g. of 3-methyldiphenylmethane boiling at 274–276°.[7] This was oxidized by means of potassium dichromate and sulfuric acid to m-benzoylbenzoic acid melting at 142–144°.[8]

Benzylation of o-Cresol by the Claisen Method.—Twelve grams of sodium was melted under 130 cc. of toluene and shaken to produce "bird-shot" so um. After cooling to room temperature, this was treated with 54 g. of *o*-cresol. The reaction appeared to be complete at the end of two hours, but the mixture was gently heated for another hour under a reflux condenser. The flask was again cooled and 64 g. of benzyl chloride was added. After standing overnight, the mixture was refluxed on an oil-bath for five hours at 150–160°. When cool, the sodium chloride was removed by washing

---

[8] Senff, *Ann.*. 220, 237 (1883).

twice with water and the toluene was removed by distilling until the temperature reached 125°.

The residue was dissolved in 250 cc. of Claisen's alcoholic potash[9] and shaken out with 200 cc. of petroleum ether (40–60°) in 50-cc. portions. Distillation of the petroleum ether extract gave 16 g. of 2-methylphenylbenzyl ether boiling at 285–290°.[10]

The alcoholic solution left after extraction with petroleum ether was made distinctly acid with hydrochloric acid (1:1), diluted until the potassium chloride first formed was redissolved, and extracted three times with ether. Distillation of the ether left a reddish-brown oil, which was fractionated three times at 5 mm. Seventy-one grams came over at 140–160°, and solidified in the receiver. Repeated recrystallization from petroleum ether gave long white needles or fibers with a soft silky sheen which showed a tendency to form in bundles or a felted mass. The pure compound melted at 49.5–50.5' and boiled at 150–152° (5 mm.) or at 187–189° (15 mm.). This melting point differs from that recorded by Schorigin[11] for 2-methyl-6-benzylphenol by 1.5". Two 50-cc. portions of a solution of the purified crystals in petroleum ether saturated at 20° gave on evaporation 2.7210 g. and 2.7392 g. of residue.

Anal. Subs., 0.1443: CO_2, 0.4473; H_2O, 0.0915. Calcd. for $C_{14}H_{14}O$: C, 84.8; H, 7.2. Found: C, 84.5; H, 7.07.

We were unable to isolate a constant-boiling fraction from the higher-boiling residue.

Bromine Derivatives

6-Bromo-2-methyl-4-benzylphenol was prepared by treating 2-methyl-4-benzylphenol in chloroform solution with a molecular equivalent of bromine at 0°. Evaporation of the chloroform left an oil which distilled at 180–182° (5 mm.). The assignment of structure is based upon the assumption (which has been proved in many cases) that the bromine enters the phenolic ring and upon the directive influence of the hydroxyl group.

Anal. Subs., 0.2582, 0.2071: AgBr, 0.1763, 0.1426. Calcd. for $C_{14}H_{13}OBr$: Br, 28.48. Found: Br, 28.68, 28.87.

4-Bromo-2-methyl-6-benzylphenol was prepared in two ways: (a) by the bromination of 2-methyl-6-benzylphenol in chloroform at 0° and (b) by the benzylation of 4-bromo-2-methylphenol (m. p. 64°) by the Claisen method. It recrystallized from petroleum ether in characteristic rosets. It melted at practically the same temperature as the unbenzylated phenol 63–64', and boiled at 187–189° (5 mm.).

Anal. Subs., 0.2259, 0.2867: AgBr, 0.1550, 0.1961. Calcd. for $C_{14}H_{18}OBr$: Br, 28.48. Found: Br, 28.82, 28.65.

Benzoyl Derivatives

The benzoyl derivative of 2-methyl-4-benzylphenol was readily prepared by the Schotten–Baumann reaction. It crystallized from petroleum ether or alcohol (75%) in small colorless rhombic crystals melting at 54–55°.

The benzoyl derivative of 2-methyl-6-benzylphenol could not be prepared by the Schotten–Baumann reaction because of the insolubility of the phenol in dilute potassium hydroxide. When the latter compound was warmed with an equivalent amount of 50% potassium hydroxide it formed a solution which solidified on cooling. The crude potassium salt was warmed with an equivalent amount of benzoyl chloride. The reaction product was washed with water and distilled. It came over as a very viscous

light yellow oil at 216–218° (5 mm.). This ester was more readily prepared from the phenol and benzoyl chloride by the pyridine method.

Summary

1. *o*-Cresol was benzylated by means of benzyl alcohol in the presence of aluminum chloride. The main product was 2-methyl-4-benzylphenol. Smaller amounts of 2-methyl-6-benzylphenol and 2-methyl-4,6-dibenzylphenol were formed.
2. Benzylation by the Claisen method gave an excellent yield of 2-methyl-6-benzylphenol.
3. The monobromo derivatives and benzoyl derivatives of the two monobenzylcresols were prepared.

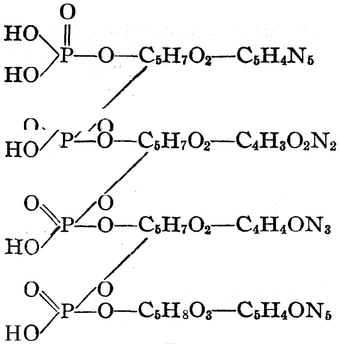
RESEARCHES ON PYRIMIDINES. CXVII. A METHOD FOR THE SYNTHESIS OF NUCLEOSIDES

BY G. E. HILBERT[1] AND T. B. JOHNSON

RECEIVED JULY 26, 1930 PUBLISHED NOVEMBER 5, 1930

The present generally accepted structure of a nucleic acid molecule is based chiefly on the results of experimental work by Levene and his coworkers. They represent it as being a tetranucleotide construction, in which the individual nucleotides are combined through phosphoric acid ester linkages as expressed in the formula of yeast nucleic acid I. In this acid the functioning sugar is d-ribose.



I

The approach to a synthesis of a nucleic acid molecule calls first for methods of preparation of the pyrimidine and purine nucleosides, which may be considered as the glucosidic constructions characterizing the structure of nucleosides. If one accepts Levene's conception of the constitution of pyrimidine-nucleosides, in support of which he has contributed considerable indirect experimental evidence, the problem of nucleoside synthesis resolves itself into one of finding a practical method of coupling a sugar with a pyrimidine (uracil, thymine or cytosine) at the 3-position of the ring. The purpose of this paper is to describe a method of synthesis which has made it possible to obtain such a glucoside.

A comprehensive study of the behavior of 2,6-dioxy- and 2-thio- or 2-alkyl mercapto-6-oxypyrimidines toward different alkyl halides in alkaline

---

[1] Sterling Research Fellow in Chemistry, 1928–1930.

solution by Johnson and his co-workers[2] led to results which did not enable one to formulate definite rules predicting the favorable position of substitution in such alkylation reactions. The active positions were **1** and **3** of the pyrimidine cycle forming nitrogen derivatives, and also the oxygen of the lactam grouping –CONH– forming cyclic imino ethers. Mixtures of mono- and di-substitution products were formed in varying proportions in practically every case examined. Other alkylating agents have also been used. Davidson and Baudisch[3] found that dimethyl sulfate interacted with uracil to form exclusively 1,3-dimethyluracil. Case and Hill[4] employed diazomethane as an alkylating agent, but here also they obtained results quite in accord with the previous observations of Johnson.

That direct alkylation of the pyrimidine and purine cycles is an unsuccessful method for the synthesis of nucleosides has been shown by Fischer[5] and co-workers and more recently by Levene and Sobotka.[6] The same general method was used by all these workers, namely, the action of acetobromoglucose or related combinations on the alkali or silver salts of purines and pyrimidines. The presence of a COMH linkage in both the pyrimidine and purine cycles favored the formation of glucosides which were easily decomposed by hydrolysis. These products were without doubt glucosides in which the sugar was attached to the ring in ether linkage. Fischer was able to obtain glucoside derivatives of purines in which the sugar was attached to the nitrogen of the imidazole ring only in those cases where the enolic isomerization of the cyclic acid amide grouping CO-NH of the ring was excluded, as in the case of theophyllin. Fischer confined his attempts at synthesis chiefly to purine combinations and only **a** few experiments were conducted with pyrimidines.[7] In both cases no products were obtained which resembled the natural nucleosides.

Levene and Sobotka[8] made a rather comprehensive study of the action of

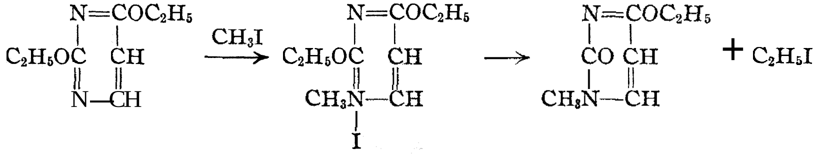
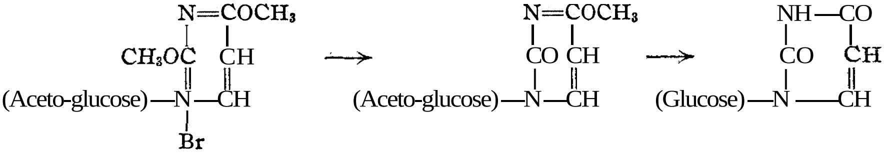
acetobromoxylose on salts of pyrimidines. A great variety of substituents in the pyrimidine cycle were used so as to cover any possible change in reactivity of the molecule. The silver salts of 1-methyluracil, 5-nitrouracil and 2-ethylmercapto-6-oxypyrimidine on treatment with acetobromoxylose led to the formation of oxygen ethers. The silver salt of cytosine did not react. The use of the potassium instead of the silver salts was also unsuccessful. The great difference in behavior toward hydrolytic agents of these synthetic nucleosides and the natural uridine and cytidine was assumed as offering further indirect evidence that the sugar in the pyrimidine nucleosides is linked in the 3-position of the ring.

As a result of the recent work of Hilbert and Johnson,[9] it is now possible to apply a method of alkylation which enables one to control substitution in the 3-position of the pyrimidine ring. This involves the reaction between a 2,6-dialkoxypyrimidine and an alkyl halide which interact in accordance with the equation below, giving a 3-substituted pyrimidine IV. Constructions of this type, IV, easily undergo hydrolysis, giving a normal uracil derivative of known structure.



II III IV

It has now been found that an analogous reaction takes place by treating 2,6-dimethoxypyrimidine with acetobromoglucose, yielding 2-oxy-6-methoxy-3-tetra-acetylglucosido-pyrimidine VI. The intermediate addition product V is unstable at 50°, at which temperature the reaction is carried out. The methyl bromide thus liberated also reacts with 2,6-dimethoxypyrimidine, yielding a large quantity of 2-oxy-3-methyl-6-methoxypyrimidine. The acetylated glucoside VI and 2-oxy-3-methyl-6-methoxypyrimidine were separated by taking advantage of their different solubilities in water, the former being insoluble and the latter very soluble. It was then easily purified by recrystallizing from 50% alcohol, from which it separated in long needles melting at 220–221°.



V VI VII

The 2-oxy-6-methoxy-3-tetra-acetylglucosido-pyrimidine VI was simultaneously de-ethylated and deacetylated on treatment with alcoholic

---

[9] Hilbert and Johnson, THIS JOURNAL, 52, 2001 (1930).

hydrochloric acid, yielding 3-glucosido-uracil VII. In its chemical behavior this is similar in every respect to the natural uridine. It is stable toward dilute hydrochloric acid, however, when the double bond is reduced, forming 4,5-dihydro-3-glucosido-uracil; the latter is hydrolyzed with 3% sulfuric acid, yielding glucose and hydrouracil. This remarkable reaction was originally shown to take place by Levene and LaForge[10] with uridine, and the fact that our 3-glucosido-uracil parallels in its stability their findings would seem to be experimental evidence confirming the structure assigned to uridine.

3-Glucosido-uracil was brominated, forming 5-bromo-3-glucosido-uracil, and when acetylated yielded 3-tetra-acetylglucosido-uracil. It also gave a negative Wheeler–Johnson color reaction,[11] as is to be expected with a 3-substituted uracil.

This method for introducing a sugar on nitrogen should also be applicable to other ring systems such as quinolines, pyridines and pyrazolones and also to straight-chain compounds of the imino ether type.

Experimental Part

2-Oxy-6-methoxy-3-tetra-acetylglucosido-pymine—A solution of 2 g. of acetobromoglucose in 2 cc. of 2,6-dimethoxypyrimidine was placed in a stoppered tube and heated at 50° for forty-eight hours. After twenty-four hours the contents of the tube solidified to a colorless crystalline mass. The odor of methyl bromide was noticeable. The reaction mass was triturated three times with 5-cc. portions of water. This water extract on standing deposited colorless needles which were identified as 3-methyluracil;[12] yield, 1 g. The crude acetylated glucoside after treatment with water was usually in the form of a thick paste which solidified upon the addition of 5 cc. of ether. The solid was filtered by suction and thoroughly washed with ether to remove any unchanged acetobromoglucose. It was then recrystallized twice from 50% alcohol, from which it separated as a mass of long needles melting at 220–221° without decomposition; yield, 0.5–0.7 g. (23–32% of the theoretical). 2-Oxy-6-methoxy-3-tetra-acetylglucosido-pyrimidine is sparingly soluble in ether, slightly soluble in hot water, soluble in hot alcohol and very soluble in cold chloroform. The statement made in *Science*[13] that it reduces Fehling's solution after treatment with hydrochloric acid is in error.

Anal. Calcd. for $C_{19}H_{24}O_{11}N_2$: C, 50.00; H, 5.3; N, 6.14. Found: C, 50.60; H, 5.8; N, 6.16.

The influence of the variation of the temperature and of the proportions of the reactants upon the yield of the nucleoside was thoroughly investigated. If the reaction was carried out at room temperature, two weeks were required for completion of the reaction; the yield was 5% of that required by theory. At a temperature of 80° crystallization started within a few hours. However, the yield was only 9%. If equivalent amounts of the reactants were used the yield was not only very poor but the product was also more difficult to obtain pure because of the large preponderance of 3-methyl-

[12] 2-Oxy-6-methoxy-3-methyl-pyrimidine on standing in the aqueous extract is hydrolyzed to 3-methyluracil.

[13] Johnson and Hilbert, *Science*, 69, 579 (1929).

uracil. In large quantity production the reaction was generally smooth. In one case, however, the end-product was partially deacetylated. This on treatment in the appropriate manner with acetic anhydride yielded the desired 2-oxy-6-methoxy-3-tetra-acetylglucosido-uracil.

3-Glucosido-uracil.—A solution of 9 g. of 2-oxy-6-methoxy-3-tetra-acetylglucosido-pyrimidine in 125 cc. of hot absolute methyl alcohol was treated with 30 cc. of a solution of *dry* hydrochloric acid in absolute ethyl alcohol (22% hydrochloric acid by weight). The reaction mixture was allowed to stand at room temperature for twenty-four hours. During this time a solid cake of colorless chunky crystals separated. The product was filtered and after drying weighed 5.6 g. (97% of the theoretical). It was recrystallized from 90% alcohol, from which it separated in the form of hexagons which contained water of crystallization and melted between 195–203°, depending upon the rate of heating. The water of crystallization was very firmly bound and required heating at 115° at 2-mm. pressure for its complete removal.[14] The anhydrous substance melted at 207–209" with decomposition to a milky liquid. Its rotation is $[\alpha]^{23}_{\mathrm{D}} = \$21.4$ in aqueous solution.

Anal. Calcd. for $C_{10}H_{14}O_7N_2(H_2O)_{1/2}$: H_2O, 3.18. Found: H_2O, 3.27, 3.41, 3.48.

Anal. Calcd. for $C_{10}H_{14}O_7N_2$: C, 43.80; H, 5.11; N, 10.22. Found: C, 43.56; H, 5.25; N, 10.12.

3-Glucosido-uracil does not reduce Fehling's solution after boiling with various concentrations of hydrochloric acid for several hours. It also gives a negative Wheeler–Johnson color reaction for pyrimidines of the uracil type.

3-Tetra-acetylglucosido-uracil.—A gram of 3-glucosido-uracil was treated with a solution of 0.5 g. of anhydrous sodium acetate in 10 g. of acetic anhydride and heated on a steam-bath for two hours. The pyrimidine derivative rapidly dissolved, forming a solution with a pale yellow color. On pouring the reaction mixture into 40 cc. of ice water, an oil separated which on standing at 0° slowly crystallized. The solid was filtered, thoroughly washed with water and dried. After treatment with boneblack it was recrystallized twice from 50% alcohol, from which it separated in clusters of prisms; melting point, 154–155°; yield, 1 g.

Anal. Calcd. for $C_{18}H_{22}O_{11}N_2$: N, 6.34. Found: N, 6.33.

5-Bromo-3-glucosido-uracil.—Nine-tenths of a gram of 3-glucosido-uracil was treated with bromine water until the solution had a permanent pale yellow color. The water was removed by distillation under diminished pressure. A pale yellow, sirupy residue remained, which was dissolved in 15 cc. of absolute ethyl alcohol and the resulting solution evaporated to dryness twice in an open vessel with constant stirring. The solid product was recrystallized twice from 90% alcohol, from which it separated as small colorless glistening prisms; yield 1 g. It contained 1% of water of crystallization and melted at 224° with effervescence, turning dark brown. The water of crystallization was very firmly bound and required drying at 115° at 2-mm. pressure for its complete removal. The decomposition point of the anhydrous 5-bromo-3-glucosido-uracil was 238". It was extremely soluble in water and insoluble in organic solvents. The rotation was $[\alpha]^{25°}_{\mathrm{D}} + 10.3°$ in aqueous solution.

Anal. Calcd. for $C_{10}H_{13}O_7N_2Br$: C, 33.99; H, 3.68; N, 7.93. Found: C, 34.18; H, 3.59; N, 8.04.

4-5-Dihydro-3-glucosido-uracil.—A solution of 2 g. of 3-glucosido-uracil in 50 cc. of 80% alcohol was shaken with 0.2 g. of Adams and Shriner[15] platinum oxide catalyst

---

[14] Fischer[5,7] found that the water of crystallization in the purine glucosides was also difficult to remove.

[15] Adams and Shriner, Tms JOURNAL, 45, 2171 (1923).

and hydrogen under a pressure of **2-3** atmospheres. Reduction was completed in an hour. The catalyst was removed from the solution and the alcohol distilled under diminished pressure. A colorless sirup remained, which on trituration with absolute alcohol and scratching eventually solidified. The product was recrystallized from **100** cc. of 90% alcohol, yielding 1.2 g. of anhydrous colorless diamond-shaped crystals; 4,5-dihydro-3-glucosido-uracil turns slightly brown at 220° and decomposes at **233°.** It is very soluble in cold water and insoluble in organic solvents. It showed $[\alpha]_D^{24°}$ +9.3° in aqueous solution.

Anal. Calcd. for $C_{10}H_{16}O_7N_2$: C, **43.48; H, 5.80; N, 10.15.** Found: **C, 43.65; H, 5.66; N, 10.19.**

Hydrolysis of **4,5-Dihydro-3-glucosido-uracil with 3% Sulfuric** Acid to **4,5-Di**hydrouracil and Glucose.—One and six-tenths grams of 4,5-dihydro-3-glucosido-uracil was dissolved in 50 cc. of 3% sulfuric acid and refluxed for two hours. The brown colored solution was treated with **8** g. of powdered barium carbonate and heated on a steam-bath until effervescence of carbon dioxide ceased and then finally filtered. The water was removed by distillation under diminished pressure and the crystalline residue dissolved in 5 cc. of boiling water, treated with boneblack and filtered. On cooling, colorless plates of 4,5-dihydrouracil separated; yield, **0.2** g. After recrystallizing from hot water the product melted at 276–277". A mixed melting point with an authentic specimen was unchanged.

'The filtrate from 4,5-dihydrouracil was treated with 0.8 g. of phenylhydrazine hydrochloride and 0.6 g. of sodium acetate and heated on a steam-bath for a few hours. After heating a short time yellow needles of phenylglucosazone started to separate. After recrystallization from dilute alcohol it melted at **207-208".** A mixed melting point with a genuine sample was unchanged.

Conclusion

1. A method for the synthesis of pyrimidine nucleosides has been described. 3-Glucosido-uracil has been prepared by this procedure.

2. 3-Glucosido-uracil is not hydrolyzed by dilute acids, whereas its reduction product, 4,5-dihydro-3-glucosido-uracil, is hydrolyzed by 3% sulfuric acid to hydrouracil and glucose. They thus behave similarly to uridine and its reduction product 4,5-dihydrouridine. This is believed to be the strongest direct experimental evidence yet obtained in favor of the structure of uridine, being 3-ribosido-uracil.

THE REDUCTION OF PARA-DIMETHYLAMINOBENZIL[1]

BY SANFORD S. JENKINS[2] WITH JOHANNES S. BUCK AND LUCIUS A. BIGELOW

RECEIVED JULY 30, 1930 PUBLISHED NOVEMBER 6, 1930

The work described in this paper is a continuation of that reported in an earlier communication[3] which dealt with the catalytic reduction of a number of symmetrical a-diketones by means of a modified form of the Adams apparatus, using hydrogen under pressure in the presence of a platinum-black platinum oxide catalyst. It seemed desirable to extend this study to include the reduction of the unsymmetrical a-diketone, *p*-dimethylaminobenzil, and this has led to some interesting and not altogether expected results.

The starting material was obtained conveniently by oxidizing *p*-dimethylaminobenzoin, which in turn was prepared in the usual manner by condensing *p*-dimethylaminobenzaldehyde with benzaldehyde in the presence of potassium cyanide according to the method of Staudinger.[4]

Upon reduction by the method already described, the benzil readily took up either one or two molecules of hydrogen, yielding in the one case the corresponding benzoin, and in the other, the analogous p-dimethylaminohydrobenzoin, melting at 112°, which has not previously been reported. It was possible either to isolate the intermediate product, or not, as desired, without affecting the ultimate result.

The hydrobenzoin, on treatment with a mixture of acetic and hydrochloric acids, was readily dehydrated, with the production of *p*-dimethylaminodesoxybenzoin, melting at 128°, and this, on further catalytic reduction, was converted without difficulty into the corresponding *p*-dimethylaminostilbene hydrate, melting at 78°. The hydrate lost a molecule of water in the presence of the acetic–hydrochloric acid mixture, forming the related stilbene, already known,[5] and this on final catalytic reduction yielded, as would be expected, the saturated p-dimethylaminodiphenylethane, which melted at 63°.

Up to this point, the results obtained did not differ in any essential respect from what might have been expected from the earlier work. When, however, an attempt was made to reduce the benzoin with tin and hydrochloric acid in alcohol solution, two isomeric *desoxy* derivatives were obtained, and none whatever of the hydro compound, which is the sole

---

[1] This paper is constructed from portions of a thesis presented by Sanford S. Jenkins in partial fulfilment of the requirements for the degree of Doctor of Philosophy in the Graduate School of Arts and Sciences, Duke University.

[5] F. and L. Sachs, *ibid.*, 38, 515 (1905).

product of the direct hydrogenation. The existence of these isomers is possible, of course, upon theoretical considerations, but as the benzoin itself gave every evidence of being a single substance, the appearance of the two desoxy compounds at this point was not particularly expected. They are very easily separated, as one is quite soluble in dilute acid while the other is relatively insoluble in this reagent. The first, or *α-p*-dimethylaminodesoxybenzoin melted at 128°, and was identical with the material obtained by catalytic dehydration of the hydro compound, while the other, or *β*-desoxy derivative, melted at 164°.

Each of these substances, upon further reduction with hydrogen, yielded a corresponding stilbene hydrate. The a-derivative, as mentioned above, showed a melting point of 78°, and the *β*-compound, which has been described in the literature,[5] fused at 60°. Both lost water under the influence of the acetic and hydrochloric acid mixture, forming one and the same stilbene, identical with that already described.

A sample of *β-p*-dimethylaminostilbene hydrate was prepared by the Sachs method. It melted at 60°, and when mixed with some of the corresponding material prepared by reducing the desoxy compound, the melting point was not depressed. From this it follows that the structures of the two isomers are as follows

$(CH_3)_2NC_6H_4CH_2CHOHC_6H_5$	$(CH_3)_2NC_6H_4CHOHCH_2C_6H_5$
α-p-Dimethylaminostilbene hydrate, m. p. 78°	*β-p*-Dimethylaminostilbene hydrate, m. p. 60°

Furthermore, the desoxybenzoins from which these compounds are derived by reduction may reasonably be assumed to possess corresponding structures, in which the (CHOH) group is replaced by (CO).

The changes which have been described may conveniently be represented by the diagram.

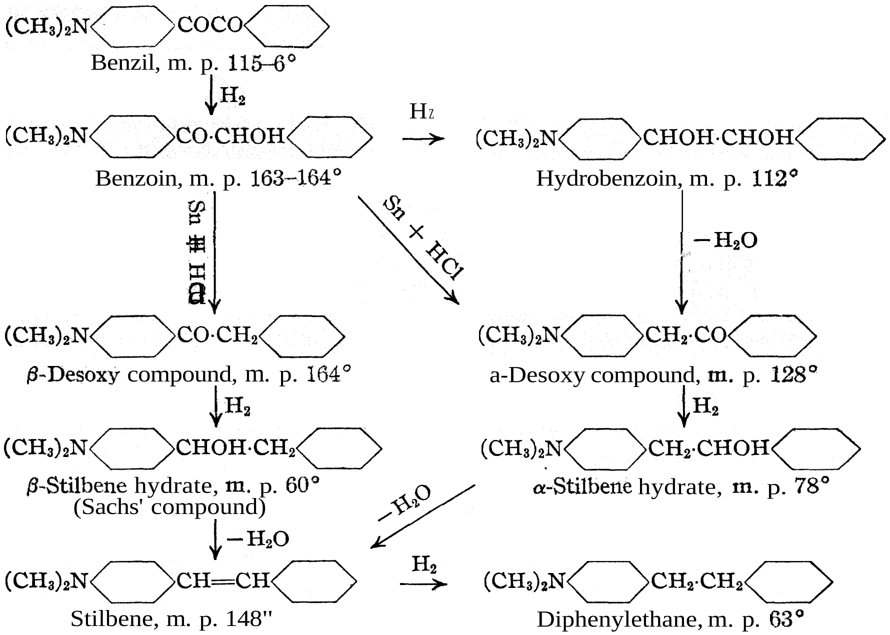
It will be noticed that in this scheme one formula has been assigned arbitrarily to the benzoin, which itself is capable of existing in two isomeric modifications. The reasons for this will be set forth in another paper, which will deal with the structure of this benzoin. It may be stated at this point, however, that while the appearance of two desoxy derivatives made it seem likely that the benzoin itself might be a mixture of isomers, repeated efforts to separate it into a- and *β*-components have not been successful.

Experimental

***p*-Dimethylaminobenzoin.**—This substance was prepared according to the method of Staudinger, already cited. It crystallized in prisms melting at 163–164°.

***p*-Dimethylaminobenzil.**—This compound resulted from the oxidation of the corresponding benzoin with concentrated Fehling's solution as recommended by Staudinger. Ten grams of the benzoin yielded 9.0 g. of benzil (90% of calcd.), which, after crystallization from alcohol, melted at 115–116°.

***p*-Dimethylaminobenzoin by the Catalytic Reduction of the Benzil.**—In this procedure, the modified form of the Adams apparatus, already described, was used. An



THE REDUCTION OF *p*-DIMETHYLAMINOBENZIL

accurate calibration showed that when 0.01 mole of pure benzoin (unsubstituted) took up 0.01 mole of hydrogen, forming hydrobenzoin, the gage showed a drop in pressure of 12 lb. Glacial acetic acid was found, after a number of trials, to be the best solvent. Accordingly, 2.50 g. (0.01 mole) of *p*-dimethylaminobenzil, 0.05 g. of platinum oxide and 50 cc. of glacial acetic acid were placed in the apparatus, and the reduction carried on at room temperature until the requisite drop in pressure was obtained. It should be noted that in mixing the reagents it is best to add the solvent last, to prevent spontaneous ignition of the mixture. After filtering off the catalyst, the solution was diluted with an equal volume of water and the precipitated benzoin filtered and dried. It weighed 1.62 g. (68% of calcd.), and, after one crystallization from alcohol, was obtained as white prisms which melted at 163–164° (corr.). A mixed melting point with a sample prepared by Staudinger's method showed no depression.

***p*-Dimethylaminohydrobenzoin.**—This material was prepared in a manner similar to that described above, except that absolute alcohol proved to be the best solvent, and the reduction was allowed to proceed until the gage registered a drop in pressure of 25 lb., which required about thirty minutes. After removal of the catalyst, the solvent was evaporated under reduced pressure, and the product crystallized twice from ligroin (b. p. 60–70°). Two and one-half grams of the benzil yielded 2.3 g. of the hydro derivative (90% of the theoretical), as snow white prisms, melting at 112° (corr.).

Anal. Calcd. for $C_{16}H_{19}NO_2$: N, 5.44. Found: N (Kjeldahl), 5.44, 5.50.

α-*p*-Dimethylaminodesoxybenzoin. (First Method.)—The a-desoxy compound was formed without difficulty by dehydrating the hydrobenzoin just described. Accordingly, 5.1 g. (0.02 mole) of the substance was heated for twenty minutes with 40 cc. of a mixture of glacial acetic acid and hydrochloric acid. (sp. gr. 1.19) 4:1 by volume. After adding 200 cc. of water, the solution was neutralized with sodium carbonate and the yellow precipitate filtered off and recrystallized from alcohol. The product was obtained in white prisms melting at 128° (corr.), and weighed 3.5 g. which is 70% of the theoretical.

Anal. Calcd. for $C_{16}H_{17}NO$: N, 5.85. Found: N (Kjeldahl), 5.82, 5.95.

β-*p*-Dimethylaminodesoxybenzoin.—It is interesting to note that while this isomer is formed readily in the reduction of the benzoin with tin and hydrochloric acid, not a trace of it appeared in the dehydration of the hydrobenzoin just described. A mixture of 20 g. of *p*-dimethylaminobenzoin, 16 g. of mossy tin, 30 cc. of hydrochloric acid (sp. *gr.* 1.19), 80 cc. of alcohol and 0.5 g. of $CuSO_4 \cdot 5H_2O$ was heated under a reflux condenser for five hours, after which the unchanged tin was filtered off, the solution diluted with 100 cc. of water, and allowed to cool somewhat. After a short time crystals began to form and another 100 cc. of water was added. The mixture was allowed to stand in a cool place for two hours, and the product finally filtered off and recrystallized from alcohol. A yield of 9.0 g. was obtained, which consisted of white or at times cream-colored plates, melting at 164" (corr.). A mixed melting point with the original benzoin, which also melted at 163–164°, showed a large depression.

Anal. Calcd. for $C_{16}H_{17}NO$: C, 80.33; H, 7.11; N, 5.85. Found: C, 80.34; H, 7.22; N (Kjeldahl), 5.78.

α-*p*-Dimethylaminodesoxybenzoin. (Second Method.)—The solution from which the β-desoxy compound had been filtered (see above) was made alkaline with sodium carbonate. and a large precipitate obtained. This was separated, washed well with water. sucked as dry as possible and extracted twice with boiling alcohol. The combined extracts were evaporated to a volume of 50 cc. and allowed to cool. The crystals which separated weighed 7.0 g. and, after recrystallization from alcohol, formed white prisms, melting at 128'. A mixed melting point with a sample of the a-desoxybenzoin obtained by the dehydration of the hydro compound showed no depression. The combined yield of the *a*- and β-isomers was 16.0 g., which is 85% of the theoretical.

Anal. Calcd. for $C_{16}H_{17}NO$: C, 80.33; H, 7.11; N, 5.85. Found: C, 80.31, 80.55; H, 7.27, 7.36; N (Kjeldahl), 5.92.

a-p-Dimethylaminodesoxybenzoin Oxime.—This compound was prepared by dissolving 2.0 g. of the corresponding desoxybenzoin, and 1.0 g. of hydroxylamine hydrochloride in 10 cc. of pyridine and heating the mixture on the water-bath for three hours. After this, 100 cc. of water was added and the solution allowed to crystallize. The product was filtered, washed with water, dried, and recrystallized from ligroin (b p. 95–98°). It separated in long white needles melting at 139° (con.).

Anal. Calcd. for $C_{16}H_{18}N_2O$: N, 11.02. Found: N (Kjeldahl), 11.00, 11.20.

β-*p*-Dimethylaminodesoxybenzoin Oxime.—This oxime was formed in exactly the same manner as the corresponding a-compound. It separated from alcohol in white prisms melting at 142° (corr.). A mixed melting point with the a-oxime showed a large depression.

Anal. Calcd. for $C_{16}H_{18}N_2O$: N, 11.02. Found: N (Kjeldahl), N, 10.90. 11.02.

a-p-Dimethylaminostilbene Hydrate.—Two and four-tenths grams (0.01 mole) of a-p-dimethylaminodesoxybenzoin, 0.10 g. of platinum oxide and 50 cc. of absolute alcohol were heated to 60° and shaken with hydrogen until the pressure had dropped 13 Ib., which required two hours. The catalyst was filtered off, and the solvent removed under reduced pressure. The crude product was crystallized from ligroin (b. p. 95–98') and separated in long colorless needles, weighing 2.25 g. (93% of calcd.) and melting at 78° (corr.).

Anal. Calcd. for $C_{16}H_{19}NO$: N, 5.80. Found: N (Kjeldahl), 5.79, 5.87.

β-*p*-Dimethylaminostilbene Hydrate. (First Method.)—Considerable difficulty was experienced in the catalytic reduction of β-*p*-dimethylaminodesoxybenzoin, as slight amounts of impurities appeared to inhibit the reaction entirely. However, after repeated crystallization from alcohol, a pure white product was obtained which would reduce slowly. Two and four-tenths grams (0.01 mole) of the desoxy derivative, 0.10 g. of platinum oxide and 100 cc. of absolute alcohol were shaken with hydrogen at 60° for four hours, after which the catalyst was filtered off and the solvent evaporated under reduced pressure. The product crystallized from ligroin (b. p. 95–98°) in clusters of colorless needles weighing 2.10 g. (85% of calcd.) and melting at 60° (corr.).

β-p-Dimethylaminostilbene Hydrate. (Second Method.)—As this stilbene hydrate has been described in the literature, the writers have prepared a sample of it by Sachs' method, already cited, in which *p*-dimethylaminobenzaldehyde is reacted with benzylmagnesium bromide. The product separated in 62% yield from ligroin (b. p. 95–98°) as white needles, melting at 60° (corr.). When the material of known structure was mixed with that prepared by catalytic reduction, the melting point was not depressed.

p-Dimethylaminostilbene.—To prepare this substance, 5.0 g. of *β-p*-dimethylaminostilbene hydrate was heated for twenty minutes with a mixture of glacial acetic acid and hydrochloric acid (sp. gr. 1.19) 4:1 by vol., after which the solution was diluted with 200 cc. of water, neutralized with sodium carbonate and the precipitated product filtered. This was recrystallized from alcohol and separated in colorless scales, weighing 4 g. (90% of calcd.) and melting at 148°. *α-p*-Dimethylaminostilbene hydrate, treated in exactly the same manner, gave an 80% yield of the stilbene, which melted at 148°, and a mixture of the two also fused at 148°.

p-Dimethylaminodiphenylethane.—To prepare this compound, 2.23 g. (0.01 mole) of p-dimethylaminostilbene, 0.05 g. of platinum oxide and 50 cc. of glacial acetic acid were shaken with hydrogen at room temperature for twenty minutes, after which time the pressure had dropped 12 lb. The catalyst was filtered off, the mixture diluted with 200 cc. of water and neutralized with sodium carbonate. The precipitated product was filtered, washed and recrystallized from 60% alcohol. It weighed 1.80 g. (80% of calcd.) and formed nearly white flakes melting at 63° (corr.).

Anal. Calcd. for $C_{16}H_{19}N$: N, 6.22. Found: N (Kjeldahl), 6.35, 6.52.

Addition Product of Methyl Iodide to *p*-Dimethylaminodiphenylethane.—This substance resulted when methyl iodide was added to a solution of *p*-dimethylaminodiphenylethane in absolute ether. The mixture was allowed to stand overnight and the product crystallized out in white plates melting at 260–262° (uncorr.).

Anal. Calcd. for $C_{17}H_{22}NI$: I, 34.6. Found: I (Pringsheim), 34.3.

Summary

1. The complete series of reduction products of *p*-dimethylaminobenzil has been studied.

2. The corresponding benzoin, which seems to be a single substance, yielded the two theoretically possible desoxy derivatives upon reduction under suitable conditions. These compounds in turn can be reduced further to form two isomeric stilbene hydrates. Seven new substances have been prepared and characterized.

THE REDUCTION OF CYSTINE IN LIQUID AMMONIA BY METALLIC SODIUM[1]

BY VINCENT DU VIGNEAUD, L. F. AUDRIETH AND H. S. LORING[2]

RECEIVED JULY 31, 1930 PUBLISHED NOVEMBER 6, 1930

From a consideration of amino acids as ammono compounds it would seem likely indeed that liquid ammonia would be a most suitable solvent for the study of not only these substances, but also of the simple derivatives of the amino acids and possibly for the investigation of the more complex derivatives, the proteins. A study of the solubilities of a number of amino acids in liquid ammonia showed they were quite soluble in most instances. Of particular interest to us was the ready solubility of cystine in this medium, in contrast to its behavior in water. In view of this fact it was decided to investigate the possibility of the reduction of cystine to cysteine, the sulfhydryl form, by means of metallic sodium. It was found that this reaction readily takes place and, in fact, affords an excellent method for the preparation of cysteine.

The general applicability of a solution of sodium in liquid ammonia as a reducing agent has been demonstrated by numerous investigators.[3,4] The experimental procedures outlined below, however, involve the first recorded case which we know of in which reduction of the disulfide linkage to the sulfhydryl group has been effected in this manner.

The slight possibility of a change in cystine itself on treatment with liquid ammonia and subsequent evaporation was eliminated by the quantitative recovery of the cystine having an unchanged rotation. Preliminary reactions were then run to prove that the reduction of the cystine actually leads to the formation of cysteine. Benzylcysteine was obtained in very good yield by adding benzyl chloride directly to the reduced cystine solution in the liquid ammonia. This procedure is the simplest method for the preparation of this derivative of cysteine and should offer a general method for the preparation of similar derivatives. The reduced cystine solution obtained after evaporation of the ammonia and careful neutralization in the cold with acid gave a very strong positive nitroprusside test and a very strong Sullivan reaction.[5] The nitroprusside test was carried out in the usual fashion in aqueous solution but later it was found that the reaction

---

could be carried out directly in the liquid ammonia. Sodium nitroprusside dissolves in liquid ammonia and gives a deep purple-red color with cysteine.

The amount of sodium required for the reduction of the cystine was next investigated. It is well known that sodium dissolved in liquid ammonia. gives a deep blue solution. The disappearance of this blue color was used as the end-point in the reaction with cystine. To a weighed amount of sodium dissolved in liquid ammonia in a liquid ammonia titration apparatus, described by Johnson and Fernelius,[6] cystine was added very slowly until the blue color disappeared. It was found that four atoms of sodium were necessary to reduce one molecule of cystine.

For completeness of reduction probably the best criterion is the optical rotation. Vickery and Leavenworth[7] had come to this same conclusion in their study of the formation of cysteine when cystine is precipitated with silver sulfate. They based their conclusions on the great difference between the rotation of levo cystine and the positive rotation of cysteine obtained from the reduction of levo cystine. Andrews[8] in his study of the reduction of cystine obtained cysteine hydrochloride with a rotation of $+9°$ calculated as cysteine from cystine having a rotation of $-215°$. This positive rotation of cysteine hydrochloride was confirmed by Vickery[7] in the above-mentioned work. Bergmann and Michalis[9] have recently published a method for the preparation of cysteine depending on catalytic reduction with palladium black. These investigators obtained free cysteine, which had a negative rotation of $-10.14°$ in water solution, but a positive rotation of $+6.9°$ in 1 N acid solution. In the present work the rotations of the reduced solutions were followed and found in a great number of runs to have values close to $+7°$. In a number of runs higher values were obtained, in one instance $+12°$.

The method for the preparation of cysteine suggested by the present investigation is particularly simple where the presence of sodium chloride and a trace of ammonium chloride is not undesirable. For the preparation of the free cysteine hydrochloride it is necessary to extract the mixture with alcoholic hydrochloric acid and recrystallize the extracted cysteine hydrochloride from 20% hydrochloric acid. Free cysteine can then be prepared in the usual manner by dissolving the hydrochloride in alcohol and precipitating the cysteine by exactly neutralizing with ammonium hydroxide. The method is particularly advantageous where it is desirable to avoid the introduction of traces of heavier metals in the preparation of cysteine.

Experimental

The liquid ammonia used in the actual preparation of cysteine was obtained from

---

[6] Johnson and Fernelius, J. *Chem.* Ed., 6,441 (1929).

[7] Vickery and Leavenworth, J. *Biol. Chem.*, 86, 129 (1930).

[8] Andrews, *ibid.*, 68, 209 (1926).

[9] Bergmann and Michalis, Ber., 63, 987 (1930).

the usual standard laboratory tank. In those experiments in which the molecular ratio of sodium to cystine was determined, the ammonia was dried over metallic sodium in an auxiliary tank, and then passed into the titration apparatus, where it was condensed by means of a bath of solid carbon dioxide in ether.

The cystine was prepared by the method given in "Organic Syntheses,"[10] the samples having specific rotations of −205° to −208°.

Determination of the Molecular Ratio of Sodium to Cystine.—The liquid ammonia titration apparatus[6] used consists of a cylindrical flask 26 cm. long and 3.5 cm. in diameter. A weighing tube is fitted by means of ground-glass connection into a side arm 2 cm. in diameter, located approximately 8 cm. from the top of the apparatus. A second side arm, 7 mm. in diameter, is located opposite the first and contains a stopcock. The flask is closed by means of a ground-glass stopper, through which a 7-mm. tube also containing a stopcock passes to the bottom of the flask.

Approximately 40 cc. of liquid ammonia was condensed into the titration apparatus after all the air had been displaced by first passing ammonia through the flask. A carefully weighed piece of sodium was then quickly added through the side arm of the apparatus; the mixture was stirred by bubbling gaseous ammonia through the solution until the sodium had dissolved. Cystine was then added slowly from the dropping tube, which had previously been weighed. The addition was continued until the blue color due to free sodium had just disappeared. The amount of cystine was then determined by the difference in the weight of the tube before and after the addition of the cystine. The values of the ratios found are given in Table I.

TABLE I

MOLES OF SODIUM NECESSARY TO REDUCE CYSTINE

	Grams	Moles used	Molecular ratio
	Run No. 1		
Wt. of sodium	0.3648	0.01586	4.092
Wt. of cystine	.9302	.003876	1.0
	Run No. 2		
Wt. of sodium	0.185	0.008043	4.179
Wt. of cystine	.462	.001925	1.0

The fact that the amount of sodium used was very slightly higher than the theoretical may be explained by the presence of a small amount of sodium hydroxide, which formed during the weighing, and the transference of the sodium to the reaction flask.

Preparation of Benzylcysteine.—The presence of a sulfhydryl group in the liquid ammonia solution was shown by a positive sodium nitroprusside reaction. To prove the presence of cysteine, benzylcysteine was prepared. An ammonia solution of the reduced cystine as obtained above was allowed to evaporate spontaneously at room temperature. The flask containing the residue was evacuated to remove the last traces of ammonia. A part of the solid remaining was tested for cysteine by the Sullivan reaction,[5] and was found to give a strong positive test. The remainder was treated with benzyl chloride by the method of Gortner and Hoffman[11] for the preparation of benzylcysteine. On acidifying the solution with acetic acid, a large white precipitate formed. This was filtered, washed and recrystallized from boiling water; m. p. 214° (uncorr.); m. p. of benzylcysteine, 213°. This product was soluble in dilute hydrochloric acid and sodium hydroxide and gave a negative nitroprusside reaction.

Anal. Calcd. for $C_9H_{13}O_2NS$: N, 6.63. Found: N, 6.54, 6.39.

Benzylcysteine in Liquid Ammonia Solution.—Weighed amounts of cystine were reduced with sodium as described above. To the resulting colorless solution the theoretical amount of benzyl chloride (two moles of benzyl chloride for every mole of cystine) was added slowly with stirring. The ammonia solution was evaporated and the sodium salt remaining was dissolved in water and acidified with acetic acid. Benzylcysteine separated out and was purified by recrystallization from hot water; m. p. 212° (uncorr.). Yields of about 70% of the theoretical were obtained.

Anal. Calcd. for $C_9H_{13}O_2NS$: N, 6.63. Found: N, 6.74, 6.88.

Recovery of Cystine from the Reduced Solution.—To determine whether racemization had taken place during reduction, the material obtained after evaporation of the ammonia solution was dissolved in water, neutralized with dilute hydrochloric acid and allowed to stand in contact with air for several days. Cysteine is readily oxidized under these conditions. White particles separated from the solution. Upon recrystallization of this precipitate from dilute acid by the addition of sodium hydroxide, characteristic hexagonal plates of cystine were obtained with an optical rotation of −210°. The optical activity of the original cystine was −208°.

Preparation of Cysteine Solutions and their Optical Activity.—In preparing cysteine solutions for measurements of the optical rotation, it was found that the reaction could be carried out best in a 100-cc. graduated cylinder, cooled in the carbon dioxide–ether cooling bath. A typical procedure consisted in dissolving a weighed amount of sodium, approximately 0.5 g., in about 40 cc. of liquid ammonia, and adding approximately 1 g. of cystine from a weighing bottle, leaving an excess of sodium in the solution. The amount of cystine used was accurately determined. The resulting blue solution, which contained an excess of sodium, was then neutralized by the addition of an amount of ammonium chloride equivalent to the sodium used (1.16 g. for 0.5 g. of sodium). The mixture, which contained sodium chloride and the ammonium salt of cysteine, was evaporated to dryness at room temperature in the absence of air. To remove traces of free ammonia the cylinder was evacuated and finally flushed with oxygen-free nitrogen. The mixture of salts remaining was dissolved in a small volume of cold air-free water (26 cc.) and enough standard acid was added to make an approximately 1% solution in 1 *N* acid (75 cc. of 1.3 N hydrochloric acid). This solution was then forced over by means of a pressure of nitrogen into a polariscope tube for determination of the optical rotation. The values found are given in Table II.

TABLE II

ROTATION OF CYSTEINE PREPARATIONS

Cystine $\alpha^{D}_{26°}$	*Wt. of cystine reduced, g.*	α^{D}, *calcd. as cysteine*	Evidence of decomposition[a]
205°	0.2699	12^{23}	Negative
205°	4.2352	5^{23}	Slightly positive
208°	2.0580	4^{28}	Slightly positive
208°	0.8065	5^{28}	Negative
208°	1.2341	$3''$	Negative
208°	1.3456	7^{30}	Slightly positive
208°	1.1203	5^{31}	Slightly positive

[a] Tested by bubbling pure nitrogen through the solution and passing the gases obtained through a solution of neutral cadmium sulfate.

When the salt remaining after evaporation of the ammonia was acidified directly, it was found that considerable decomposition with the liberation of hydrogen sulfide and the formation of a cloudy solution took place. This decomposition could be reduced and in many cases entirely prevented by the use of an ice-salt cooling bath during the addition of the acid to the water solution. The liberation of hydrogen sulfide during the reduction of cystine with zinc and hydrochloric acid has been mentioned by Okuda.[12] In a few experiments in which cystine was reduced with tin and hydrochloric acid, we have also found small amounts of hydrogen sulfide to be liberated.

Preparation of Cysteine Hydrochloride and Free Cysteine.—The preparation of pure cysteine hydrochloride involves its separation from the sodium chloride and small amounts of ammonium chloride present in the reaction mixture. The reduction as described above is carried out in a Dewar test-tube and the ammonia solution evaporated to dryness. The sodium salt remaining is dissolved in a small amount of cold 95% alcohol and then acidified with cold 2 *N* alcoholic hydrochloric acid. The precipitate of sodium chloride is filtered and washed several times with alcoholic hydrochloric acid. The filtrate and washings are evaporated to dryness at 45° under diminished pressure in an atmosphere of nitrogen, and the residue recrystallized from a small volume of hot 20% hydrochloric acid; 3.44 g. of pure cysteine hydrochloride was obtained from 10 g. of cystine. An approximately 1% solution of this product in 1 *N* hydrochloric acid had an optical rotation of 4.4" at 28°.

Preparation of Cysteine.—Free cysteine may be prepared by dissolving the hydrochloride in a small volume of absolute alcohol at room temperature and neutralizing with a solution of ammonia in absolute alcohol. The precipitate of free cysteine is filtered, washed with alcohol and ether and remains as a white powder. On standing an aqueous solution of this material deposits a white precipitate, which when recrystallized from dilute acid with sodium hydroxide gives characteristic hexagonal plates of cystine.

Summary

Cystine is soluble in liquid ammonia and can be reduced readily by metallic sodium in this medium. The reduction product has been shown to be cysteine.

A new method for the preparation of cysteine has been worked out on the basis of this reaction.

Benzylcysteine was prepared by adding benzyl chloride directly to the liquid ammonia solution of cysteine which had been prepared by the sodium reduction method. This procedure offers an exceptionally convenient method for preparing this and similar derivatives.

ROTENONE.
IX. ALKALI FUSION OF SOME DERIVATIVES OF ROTENONE

BY H. L. HALLER AND F. B. LAFORGE

RECEIVED AUGUST 1, 1930 PUBLISHED NOVEMBER 5, 1930

The rotenone molecule is generally assumed to consist of two component parts joined by a chain of carbon atoms containing the carbonyl group. On treatment with alcoholic potassium hydroxide, tubaic acid, a monohydroxy monocarboxylic acid of formula $C_{12}H_{12}O_4$ is obtained, which is converted into isotubaic acid[1] (rotenic acid) by fusion with potassium hydroxide or by treatment with sulfuric acid, Isotubaic acid is obtained directly by alkali fusion of rotenone or from isorotenone either by fusion or by treatment with alcoholic potassium hydroxide. Butenandt[1] has assumed that the rotenone molecule is cleaved at the carbonyl group either by hydrolysis or oxidation, because dihydrodesoxyrotenone, in which the carbonyl group is not present, is stable toward alkalies.

Tubaic and isotubaic acids are very closely related, differing from each other in the position of the reducible double bond. The characteristic nucleus of tubaic acid is assumed to be present in the rotenone molecule.

Of the four oxygen atoms of tubaic acid, two are contained in the carboxyl group, one is present as a hydroxyl group and the fourth cannot be brought into reaction and therefore is assumed to be in the form of an ether linkage, in which form it is also supposed to be present in rotenone itself.

In a previous article[2] we reported that isotubaic acid is formed from derritol under the same conditions as from rotenone. This fact seems remarkable since all six of the oxygen atoms in derritol can be characterized with certainty, as it had been shown that derritol contains no indifferent oxygen but a phenolic group in addition to the original carbonyl, lactone and two methoxyl groups of rotenone.[3] The acid which Butenandt obtained in minute quantity by boiling derritol in strong alcoholic potassium hydroxide solution may have been tubaic acid.[1] In the process of fusion the tubaic acid which is first formed is isomerized into isotubaic acid.

Since all the oxygen atoms in derritol are accounted for, it must follow that the indifferent oxygen in isotubaic acid is formed in the process of

---

[1] In this article we have used the word isotubaic acid instead of rotenic acid for the reason that the hydroxyl derivative obtained by elimination of the carboxyl group was named rotenol by Takei after this word had been used by Butenandt, *Ann.*, 464, 253 (1928), *to* designate the zinc alkali reduction product of rotenone. This older name should be retained and the more logical isotubaic acid and isotubanol substituted for the terms rotenic acid and rotenol.

[2] H. L. Haller and F. B. LaForge, THIS JOURNAL, 52, 2480 (1930).

[3] (a) A. Butenandt, *Ann.*, 464, 253 (1928); (b) F. B. LaForge and L. E. Smith, THIS JOURNAL, 52, 1088 (1930).

fusion and that the characteristic grouping of tubaic acid is not part of the derritol molecule, but must be regarded as a secondary decomposition product. Whether or not the nucleus of tubaic acid is actually part of the rotenone molecule is therefore open to doubt, even though the isomerization of rotenone to isorotenone and of tubaic to isotubaic acid may be due to the shifting of a double bond in the side chain, as is now generally accepted.

These considerations led us to subject a number of characteristic rotenone derivatives to the alkali fusion process in order to determine which of them yielded acids of the tubaic acid type.

The method employed was in all cases essentially the same as that described for the preparation of isotubaic acid from rotenone.[2,4]

Both derritol and isoderritol[6] yielded isotubaic acid but the yield was less in the case of isoderritol. Dehydrorotenone[1] also gave isotubaic acid. Dihydroxyrotenonic acid, $C_{23}H_{24}O_8$ (Derris saure, Butenandt) and its isomer, isodihydroxyrotenonic acid, which on oxidation with hydrogen peroxide in alkaline solution yield derric acid,[6] also gave isotubaic acid on alkali fusion.

Rotenol (Butenandt),[1] which is supposed to contain no carbonyl group but a secondary alcoholic group in its place, contrary to our expectation, gave a yield of isotubaic acid three times greater than that obtained from rotenone.

It has been generally assumed that the carboxyl group in tubaic and isotubaic acids arises from the ketone group in rotenone which joins the two halves of the molecule, one of which corresponds to tubaic acid and the other to derric acid. The fact that isotubaic acid is easily obtained from rotenol on fusion with alkali contradicts this assumption. The possibility that the hydroxyl group is oxidized to the ketone group during the fusion process still remains, but the smooth manner in which the fusion proceeds, the slight amount of charring which takes place, and the greater yield of isotubaic acid incline us to doubt that this has happened.

On fusion of dihydroderritol methyl ether,[3b] a small quantity of a methoxyl-free phenolic acid was obtained which melted at 186° and gave the same color reaction with ferric chloride as did isotubaic acid. However, when this acid was mixed with isotubaic acid the melting point was twenty degrees lower than the melting point of isotubaic acid, and it could be sharply distinguished from isotubaic acid by an optical examination of the crystals, as well as by its different solubility in 40% alcohol. In another attempt to obtain a larger quantity of this acid, five grams of dihydroderritol methyl ether was fused with alkali under slightly different conditions, but in this case dihydrotubaic acid was obtained.

[5] F B. LaForge and L. E. Smith, THIS JOURNAL, 51,2574 (1929).

[6] F. B. LaForge and L. E. Smith, *ibid.*, 52, 1091 (1930).

All the derivatives mentioned above contain either the original lactone group of rotenone, or, as in the case of the two dihydroxyrotenonic acids, the hydrolyzed lactone group.

The lactone group of rotenone and most of its derivatives may also be opened by catalytic hydrogenation, with the formation of acids.[5] By this process rotenonic acid, $C_{23}H_{24}O_6$, is obtained from rotenone and corresponding acids are obtained by this reaction from dehydrorotenone, rotenol and derritol methyl ether.[3b] Except in the case of rotenone, the double bond originally present is also reduced by this process, and the dihydro acids are obtained. Several acids of this type were fused with potassium hydroxide in the usual manner, but in no case could isotubaic or dihydrotubaic acid be obtained. In most of the experiments only a very small quantity of a crystalline product could be isolated from the reaction mass, and in the case of rotenonic acid, the acid obtained could not be crystallized.

In the case of dehydrodihydrorotenonic acid[6] and dihydrorotenolic acid[3b] a small quantity of a phenolic acid was obtained, but it was definitely established by crystallographic methods that it was neither isotubaic acid nor dihydrotubaic acid.

Such of the above-mentioned compounds as gave isotubaic or dihydrotubaic acids contain the lactone group, or this group has been opened by hydrolysis, and it may be concluded that the hydroxyl group resulting from the opening of the lactone ring is necessary for the formation of isotubaic or dihydrotubaic acid.

The fact that isotubaic acid is obtained from rotenol (Butenandt) contradicts the theory that cleavage takes place at the carbonyl group, and the results as a whole indicate that tubaic acid may be a secondary cleavage product of rotenone.

Experimental

Alkali Fusion of Derritol.—Two grams of derritol was intimately mixed with 2 g. of finely powdered potassium hydroxide in a nickel crucible, and 1 cc. of water was added. Eighteen grams of powdered potassium hydroxide was then added, and the mixture heated in a metal-bath. The reaction mass was held at 205–210° for one hour with constant stirring. The temperature of the metal-bath was 250–270°. The melt was then slowly poured onto cracked ice and the resulting dark reddish-brown solution was saturated with carbon dioxide. The solution, after being filtered to remove a small quantity of tarry matter which sometimes separated, was acidified with dilute sulfuric acid and extracted four times with ether. The combined ether extracts were dried over sodium sulfate and the ether was removed. The remaining tarry residue was extracted with boiling petroleum ether (b. p. 57–70°). On concentrating this extract, isotubaic acid was obtained. The yield was 0.2 g. It was recrystallized from 40% alcohol. It melted at 184° and its optical properties[7] were identical with those of isotubaic acid. A mixture of this substance and isotubaic acid obtained from isorotenone had a melting point of 183°.

---

[7] We are indebted to Mr. George L. Keenan of the Food and Drug Administration for the determination of the optical properties.

The conditions described for the alkali fusion of derritol were duplicated as closely as possible in the fusion of the other compounds.

Alkali Fusion of **Rotenol.**—Two grams of rotenol on fusion at *200–210"* for one-half hour yielded *0.65* g. of substance. After recrystallizing from *40%* alcohol, it melted at 184°, and its optical properties were identical with isotubaic acid. When it was mixed with authentic isotubaic acid, the melting point was *184°*.

Alkali Fusion of **Isoderritol.**—Two grams of isoderritol was fused in the manner described for derritol except that the water was omitted. The fusion temperature was 205°, which was maintained for one-half hour. The yield of substance from petroleum ether was about *0.1* g. After recrystallizing from *40%* alcohol, it melted at 182°, and its optical properties could not be differentiated from those of isotubaic acid. When it was mixed with isotubaic acid, the melting point was 182°.

Alkali Fusion of Dihydroderritol Methyl Ether.—Two grams of dihydroderritol methyl ether was fused in the usual manner at 205° for one-half hour. The acid obtained from petroleum ether was recrystallized from *25%* alcohol. It melted at about *174"* and lost carbon dioxide at 180°. The melting point varied with the rate of heating. It was methoryl free. In alcohol solution it gave a blue color with ferric chloride which could not be differentiated from the color given by isotubaic acid under the same conditions. However, its optical properties did not agree with those of isotubaic acid, and when it was mixed with isotubaic acid the melting point was *160°*.

Anal. Subs., *0.0214:* required *1.08* cc. $N/10$ alkali; *0.0204* g. subs. required *1.01* $N/10$ alkali; acid number calcd., *198, 201.*

In an attempt to prepare a larger quantity of this acid, *5* g. of dihydroderritol methyl ether was fused, but dihydrotubaic acid was obtained. The acid melted at *168"* and a mixture of this acid and dihydrotubaic acid had a melting point of *168"*.

Alkali Fusion of Dihydroxyrotenonic Acid.—Two grams of acid was fused at 205° for one-half hour in the usual manner except that the water was omitted. The acid obtained melted at 184° and was identified as isotubaic acid by its optical properties and its melting point when mixed with isotubaic acid.

Alkali Fusion of Isodihydroxyrotenonic Acid.—This substance when fused in the usual manner yielded isotubaic acid, which was identified in the manner described above.

Alkali Fusion of **Dehydrorotenone.**—Two and one-half grams of dehydrorotenone on fusion in the usual manner at 205° for one-half hour yielded isotubaic acid, which was identified as described above.

Alkali Fusion of Rotenonic Acid.—Two grams of rotenonic acid was fused in the manner described above with and without the addition of water, but in no instance was it possible to obtain a crystalline derivative. Dihydrorotenonic acid behaved similarly.

Alkali Fusion of Dehydrodihydrorotenonic Acid.—Two grams of dehydrodihydrorotenonic acid on fusion in the usual manner yielded a small quantity of acid, which was recrystallized from dilute alcohol. It melted somewhat indefinitely at 175°. Its crystallographic properties were totally different from those of dihydrotubaic acid.

Alkali Fusion of Dihydrorotenolic Acid.—Two grams of dihydrorotenolic acid was fused in the usual manner at 205° for half an hour. On recrystallization from dilute alcohol a very small quantity of acid was obtained which melted at 159° but not sharply. When mixed with dihydrotubaic acid the melting point was 135–140°, with previous softening at 125°. The optical properties of the compound were found to be different from those of dihydrotubaic acid.

Summary

Several derivatives of rotenone have been submitted to the alkali fusion process.

Derritol, isoderritol, rotenol, dihydroxyrotenonic acid and isodihydroxyrotenonic acid on alkali fusion yielded isotubaic acid.

Rotenonic acid, as well as several other derivatives of rotenone in which the lactone group was opened by catalytic reduction, did not give isotubaic or dihydrotubaic acid on fusion with alkali.

Compounds which gave isotubaic or dihydrotubaic acid contain the lactone group or this group has been opened by hydrolysis. The conclusion is drawn that the hydroxyl group resulting from the opening of the lactone ring is necessary for the formation of isotubaic or dihydrotubaic acid.

The fact that rotenol gives isotubaic acid contradicts the theory that cleavage of the molecule takes place at the ketone group.

The nucleus of tubaic acid does not exist in derritol as such, but is a secondary decomposition product. Perhaps it does not exist in rotenone.

Substance	Product of alkali fusion
Derritol	Isotubaic acid
Isoderritol	Isotubaic acid
Rotenol	Isotubaic acid
Dihydroxyrotenonic acid	Isotubaic acid
Isodihydroxyrotenonic acid	Isotubaic acid
Dehydrorotenone	Isotubaic acid
Dihydroderritol methyl ether	Dihydrotubaic acid
Rotenonic acid	....
Dehydrodihydrorotenonic acid	Unidentified phenolic acid
Dihydrorotenolic acid	Unidentified phenolic acid

THE COMPOSITION OF SALKOWSKI'S ARABAN

BY C. L. BUTLER AND LEONARD H. CRETCHER

RECEIVED AUGUST 6, 1930 PUBLISHED NOVEMBER 5, 1930

Introduction

Most of the methods devised in the attempt to prepare pure xylans have involved the use of alkaline copper solutions in the process of purification.[1]

It was shown by Salkowski that no precipitate was formed when Fehling's reagent was added to a solution of gum arabic, but that on further addition of sodium hydroxide a precipitation was brought about. The substance precipitated was hydrolyzed with 2% sulfuric acid and formed large amounts of arabinose. On oxidation of the hydrolysate with nitric acid, there was no evidence of the formation of mucic acid. Because of these facts, Salkowski called the substance an araban.

---

[1] Salkowski, Z. *physiol. Chem.,* 34, 162 (1901); 35, 240 (1902); 117, 48 (1921); Henser and Braden, J. *prakt. Chem.,* 103, 69 (1921); 104, 259 (1922); Link, THIS JOURNAL. 51,2506 (1929); 52, 2091 (1930).

Inasmuch as the original gum is known to contain galactose, the precipitation with copper would naturally seem to be a method for the concentration of the arabinose present in the gum. In fact, the procedure has been used with this end in view.[2]

Though xylans have been prepared which were largely if not wholly polymers of xylose, most of the arabans are known to form other sugars as well as arabinose on hydrolysis.[3] It is probable that the pentosan obtained from beet pectin by Ehrlich[4] is more nearly a true araban than any described previously. This substance gave 90.8% of crystalline arabinose on hydrolysis.

In order to throw further light on a rather confused subject, we have reinvestigated Salkowski's araban. It was analyzed according to methods given by Van der Haar.[5] The results obtained show that the so-called araban contains even less arabinose than arabic acid (the ash-free gum). For purposes of comparison, the analysis of the araban and of arabic acid are given in Table I.

TABLE I

ANALYSES

	Araban	Arabic acid
Pentose (as arabinose)	28.8	34.4
Methyl pentose (as rhamnose hydrate)	12.7	14.2
Hexose (galactose)	41.1	42.1
Uronic acid (glucuronic)[a]	19.5	15.5
Total	102.1	106.2

[a] That the methylpentose and aldehyde acid in gum arabic are rhamnose and glucuronic acid, respectively, was shown by the present authors [Butler and Cretcher, THIS JOURNAL, 51,1519 (1929)].

The presence of glucuronic acid has been confirmed by Weinmann[6] and by Heidelberger and Kendall.[7]

Experimental Part

Preparation of **Salkowski's** Araban.—One hundred grams of gum arabic was dissolved in 2 liters of warm distilled water. To the warm solution was added one liter of Fehling's solution (made by mixing 500 cc. of solution containing 34.65 g. of copper sulfate crystals and 500 cc. of solution containing 125 g. of potassium hydroxide and 175 g. of Rochelle salt). The alkaline copper solution of gum arabic was stirred while concentrated sodium hydroxide solution (300 g. per liter) was added until no further precipitation took place. About 500 cc. of alkaline solution was required. The precipitate

[6] Weinmann, *Ber.*, 62, 1637 (1929).

[7] Heidelberger and Kendall, *J. Biol. Chem.*, *84,639* (1929).

settled in a few minutes. The blue mother liquor was decanted and the blue precipitate was pressed between cotton cloth and filter paper. It was dissolved in 150 cc. of 1:1 hydrochloric acid and precipitated by the addition of one liter of 95% alcohol. The precipitate was allowed to settle and the alcoholic liquor was then decanted. The precipitate was washed with three successive portions of alcohol. It was redissolved in 100 cc. of water and again precipitated by alcohol. The product was washed and dried for several hours in vacuum at 70°. The samples weighed 51 g. and contained only traces of copper. $\alpha = -2.85°$ where $l = 2$ and $C = 3.94$; $(\alpha)_D$ −36.2°.

Anal. Subs., 0.982: CO_2 (Lefèvre method), 0.0435. Found: 4.43% CO_2, equivalent to 19.5% uronic acid. Subs., 0.491: mucic acid, 0.134. Found: galactose, 41.1. Subs., 0.491: alcohol-soluble furfural phloroglucid, 0.033; alcohol insoluble furfural phloroglucid, 0.155. From the latter figure was deducted 0.032 g. to allow for the phloroglucid due to uronic acid.[8] Found: methyl pentose (as rhamnose hydrate), 12.7; pentose (as arabinose), 28.8.

Summary

The araban of Salkowski has been shown not to be a simple polymer of arabinose but to contain arabinose, galactose, rhamnose and glucuronic acid in about the same proportion as they are present in ash-free gum arabic.

RESEARCHES ON PYRIMIDINES. CXVIII. MOLECULAR REARRANGEMENTS IN THE THYMINE SERIES

BY W. SCHMIDT-NICKELS[1] AND T. B. JOHNSON

RECEIVED AUGUST 8, 1930 PUBLISHED NOVEMBER 5, 1930

Hilbert and Johnson discovered that 2,6-dimethoxypyrimidine interacts with bromo-acetoglucose giving an acetyl derivative which is converted by hydrolysis into a 3-glucoside of uracil,[2] namely, "*glucuridine*." This fact was the incentive to develop the present paper, which deals with new rearrangements in the thymine series.

Thymine	I	$\mathrm{NHCONHCH{=}C(CH_3)CO}$

2,6-Diethoxy-5-methylpyrimidine	VII	$\overline{\mathrm{NC(OC_2H_5){=}NCH{=}C(CH_3)C}}\mathrm{(OC_2H_5)}$
2-Oxy-3,5-dimethyl-6-ethoxypyrimidine	VIII	$\overline{\mathrm{NCON(CH_3)CH{=}C(CH_3)C}}\mathrm{(OC_2H_5)}$
2-Oxy-3-ethyl-5-methyl-6-ethoxy-pyrimidine	IX	$\overline{\mathrm{NCON(C_2H_5)CH{=}C(CH_3)C}}\mathrm{(OC_2H_5)}$
2,6-Dioxy-3-ethyl-5-methylpyrimidine	X	$\overline{\mathrm{NHCON(C_2H_5)CH{=}C(CH_3)C}}\mathrm{O}$

The work was started with the investigation of 2,6-dimethoxy-5-methylpyrimidine, III, which is described by Gerngross,[3] who made it by reduction of 2,6-dimethoxy-4-chloro-5-methylpyrimidine with zinc dust and hydrochloric acid. The same compound was, however, prepared for our work by another method. Starting with thymine I, 2,6-dichloro-5-methylpyrimidine II was made by treatment with phosphorus oxychloride as described by Steudel and Kossel[4] and the latter then converted into 2,6-dimethoxy-5-methylpyrimidine III by the action of sodium methylate. We now find that the imido ester linkages in this compound are very susceptible to change, and the methyl groups show a great tendency to migrate to the adjacent nitrogen atoms of the pyrimidine ring. By heating at 200° for forty-eight hours a quantitative rearrangement to 1,3-dimethyl-thymine VI is obtained. Interaction with methyl iodide led to the formation of 2-oxy-3,5-dimethyl-6-methoxypyrimidine IV. The structure of this compound follows from the fact that it gives 3-methylthymine V quantitatively when the methoxy group is destroyed by hydrolysis with hydrochloric acid.

After having discovered this characteristic behavior of 2 6-dimethoxy-5-methylpyrimidine III, we hoped to obtain a nucleoside of thymine by treatment of this pyrimidine with bromo-acetoglucose according to the technique of Hilbert and Johnson. The result was, however, the formation of 3-methylthymine V. It was assumed that by addition of bromo-acetoglucose to the pyrimidine nitrogen in the 3-position a small amount of the nucleoside was probably formed, the bromine and the adjacent methyl attached to oxygen in the 2-position then combining to form methyl bromide. This methyl bromide adds to the 3-nitrogen, whereupon more methyl bromide is formed and the process is continued until the rearrangement is complete and a 3-methylated compound is formed instead of the desired glucoside of thymine.

Guided by the above conception of reaction mechanism, it was thought that by replacing the methyl bromide by the less active methyl chloride, the addition of the alkyl halide might be depressed, affording a better chance for the addition of the sugar. So chloro-acetoglucose was used instead of bromo-acetoglucose; but here, also, no reaction product of the

---

[3] Gerngross, Ber., **38,** 3408 (1905).

[4] Steudel and Kossel, *Z. physiol. Chem.*, 29, 303 (1900).

desired constitution was obtained, When the temperature of reaction was raised from 50 to 100° the mixture underwent decomposition.

Keeping in mind the synthesis of a thymine nucleoside, the methyl group was next replaced by the ethyl group and this led to the synthesis and investigation of 2,6-diethoxy-5-methylpyrimidine VII. This compound, prepared from 2,6-dichloro-5-methylpyrimidine II and sodium ethylate, had a lower melting point (36') than 2,6-dimethoxy-5-methylpyrimidine III, which fact made the compound useful for attempts to melt it together with bromo-acetogfucose or chloro-acetoglucose.

Our first observation was that 2,6-diethoxy-5-methylpyrimidine VII differed considerably from 2,6-dimethoxy-5-methylpyrimidine III in so far as its behavior at high temperatures was concerned. While the methyl compound was completely rearranged at 200° in forty-eight hours, the corresponding ethyl compound was stable under the same conditions. It was, however, observed that methyl iodide acted in the same way as in the case of 2,6-dimethoxy-5-methylpyrimidine III: 2-oxy-3,5-dimethyl-6-ethoxypyrimidine VIII was formed. Its structure follows from the fact that 3-methyl-thymine V was formed by digesting the pyrimidine with hydrochloric acid. The action of ethyl iodide was also studied and the expected substance, 2-oxy-3-ethyl-5-methyl-6-ethoxypyrimidine IX was obtained. This was converted by hydrolysis with hydrochloric acid into 3-ethyl-thymine X.

Since ethyl bromide would be the probable by-product of a reaction between 2,6-diethoxy-5-methylpyrimidine VII and bromo-acetoglucose, and since it was found by experimentation that ethyl bromide does not react with 2,6-diethoxy-5-methylpyrimidine, it was concluded that the reaction between this pyrimidine and bromo-acetoglucose might be of promise for the formation of the desired nucleoside of thymine. By heating the compound with the sugar derivative at 50° for seven days, we obtained a very small amount of a crystalline substance which melted at 316° after recrystallization from alcohol. The amount was, however, too small for investigation. Chloro-acetoglucose did not react with 2,6-diethoxy-5-methylpyrimidine VII, as might 'have been expected from the experiment with the corresponding methyl compound.

All the pyrimidines prepared in the course of this work are easily obtained in a high state of purity. Three of the compounds described (III, V, VI) were already known but prepared by other methods. In each of these cases our compounds showed a higher melting point. With the exception of 1,3-dimethyl-thymine VI, which can be prepared more easily and just as pure by methylation of thymine with methyl sulfate, we believe that we have shown the easiest way for the preparation of absolutely pure alkyl derivatives of thymine. The study of pyrimidine rearrangements will be continued in this Laboratory.

Experimental Part

Preparation of Thymine, I.—Thymine, from which all the compounds described in this paper were prepared, was synthesized by the method of Wheeler and Merriam[5] by condensing ethyl pseudothiourea with the sodium salt of ethyl formylpropionate in aqueous solution, and hydrolysis of the resulting 2-ethylmercapto-5-methyl-6-oxypyrimidine with hydrochloric acid. It was observed, however, that the yield of thymine was best when the mixture of ethyl formate and ethyl propionate was added to the suspension of sodium in dry ether immediately and not added slowly as stated in the original directions for carrying out the ester condensation. Thirty-seven grams of thymine was obtained in one operation by using 46 g. of sodium in 1 liter of ether, 229.5 cc. of ethyl propionate, 240.5 cc. ethyl formate and 92 g. of ethyl pseudothiourea hydrobromide. The same proportions of reagents gave only 27 g. of thymine when the original directions were followed.

2,6-Dichloro-5-methylpyrimidine, II.—The method employed for the preparation of this compound was essentially that of Steudel and Kossel[6] with slight variations in technique. Twenty grams of thymine was heated with 80 cc. of phosphorus oxychloride at 110-120° for five hours, whereafter the excess of phosphorus halide was removed by heating at 80° under vacuum. The cooled residue was then dissolved in ether, the ethereal solution washed with water and dilute sodium carbonate solution and finally dried over sodium sulfate. The pyrimidine was finally purified by distillation and boiled at 108-109° at 11 mm. It melted at 25-26° and the yield was 21.5 g.

2,6-Dimethoxy-5-methylpyrimidine, III.—Twenty grams of the dichloropyrimidine II was dissolved in 100 cc. of methyl alcohol and the liquid poured into a solution of 7 g. of sodium in 100 cc. of methyl alcohol, whereupon sodium chloride separated immediately, the mixture becoming warm. The reaction was complete after heating for five minutes and after filtering from sodium chloride and distilling off excess of alcohol, the resulting oil was dissolved in ether, washed with sodium hydroxide solution and then dried over anhydrous sodium sulfate. On evaporating the solvent the pyrimidine separated in crystalline form. It was purified further by crystallization from petroleum ether and melted at 61°. The yield was 15.5 g.

Anal. Calcd. for $C_7H_{10}O_2N_2$: C, 54.51; H, 6.54; N, 18.17. Found: C, 54.33; H, 6.50; N, 18.14, 18.04.

Rearrangement of the Pyrimidine III into its Isomer 1,3-Dimethylthymine, VI.—Five grams of the pyrimidine III were heated in a sealed tube at 200° for forty-eight hours, when the rearrangement into the alkylated thymine was complete. The pyrimidine was purified by recrystallization from alcohol and melted at 155°.[7] The absence of methoxy groups was proved by recovering the unchanged pyrimidine melting at 155° after evaporation with strong hydrochloric acid.

Anal. Calcd. for $C_7H_{10}O_2N_2$: C, 54.51; H, 6.54; N, 18.17. Found: C, 54.60; H, 6.54; N, 18.06, 18.27.

2-Oxy-3,5-dimethyl-6-methoxypyrimidine, IV.—This compound is easily obtained by allowing 2,6-dimethoxy-5-methylpyrimidine to interact with methyl iodide at ordinary temperature. Solution of the pyrimidine takes place immediately and within fifteen minutes crystals of the rearranged pyrimidine begin to separate. The reaction was complete after fifteen hours. This pyrimidine crystallized from a mixture of alcohol and ether in the form of needles melting at 144°.

Anal. Calcd. for $C_7H_{10}O_2N_2$: C, 54.51; H, 6.54; N, 18.17. Found: C, 54.53; H, 6.63; N, 18.04, 18.09.

When this compound was warmed in aqueous hydrochloric acid solution it was converted quantitatively into 3-methyl-thymine V. The latter crystallized from hot water in the form of needles melting at 291°. Johnson and Clapp[8] reported a melting point of 280–282°.

Anal. Calcd. for $C_6H_8O_2N_2$: C, 51.40; H, 5.76; N, 20.00. Found: C, 51.39; H, 5.69; N, 20.00, 19.96.

2,6-Diethoxy-5-methylpyrimidine, VII.—From 21.5 g. of 2,6-dichloro-5-methylpyrimidine II and sodium ethylate (7.5 g. Na) by interaction in alcohol solution. The pyrimidine crystallizes from alcohol and melts at 36° to an oil. The yield was 16.5 g.

Anal Calcd. for $C_9H_{14}O_2N_2$: C, 59.30; H, 7.75; N, 15.38. Found: C, 59.39; H, 7.80; N, 15.24, 15.55.

An attempt was made to rearrange this pyrimidine into its corresponding nitrogen substituted derivative by heating at 200° for forty-eight hours. Slight decomposition resulted from this treatment, but the greater part of the pyrimidine was recovered, melting at 35". There was no evidence of any molecular rearrangement having taken place.

2-Oxy-3,5-dimethyl-6-ethoxypyrimidine, VIII.—A solution of 3. g. of the pyrimidine VII in 2.1 cc. of methyl iodide was allowed to stand at room temperature for four days. The crystalline substance which separated in excellent yield was purified by crystallization from a mixture of alcohol and ether and melted at 111° to an oil. The structure of this compound was established by the fact that it was converted into 3-methyl-thymine by hydrolysis with boiling hydrochloric acid solution.

Anal. Calcd. for $C_8H_{12}O_2N_2$: C, 57.10; H, 7.20; N, 16.67. Found: C, 57.02; H, 7.18; N. 16.62.

2-Oxy-3-ethyl-5-methyl-6-ethoxypyrimidine, IX.—This compound is formed by molecular rearrangement when 2,6-diethoxy-5-methyl-pyrimidine VII is dissolved in ethyl iodide and the solution allowed to stand for seven days. The pyrimidine was obtained in the form of colorless needles when crystallized from ether, and melted at 78°. Attempts to bring about this same rearrangement of the pyrimidine VII by the use of ethyl bromide were unsuccessful. No change was observed after remaining in contact with an excess of ethyl bromide for two weeks.

Anal. Calcd. for $C_9H_{14}O_2N_2$: C, 59.30; H, 7.75; N, 15.38. Found: C, 59.46; H, 7.81; N, 15.54.

2,6-Dioxy-3-ethyl-5-methylpyrimidine or 3-Ethyl-thymine, X.—This pyrimidine was formed when the compound IX was dissolved in hydrochloric acid and the solution evaporated to dryness. It crystallized from hot water in needles which melted at 223°.

Anal. Calcd. for $C_7H_{10}O_2N_2$: C, 54.51; H, 6.54; N, 18.17. Found: C, 54.42; H, 6.53; N, 18.36.

Attempts to Prepare Glucosidic Derivatives of the Pyrimidine Thymine

1.—A mixture of 2 g. of 2,6-dimethoxy-5-methylpyrimidine and 2 g. of bromoacetoglucose was heated at 60° for forty-eight hours. The resulting product was then extracted three times with 5 cc. of water and then with ether at room temperature. A small quantity of crystalline material did not dissolve and was identified as 3-methylthymine. A large quantity of this same pyrimidine also deposited as the aqueous extract was allowed to stand. In other words, a rearrangement of methyl from oxygen

---

[8] Johnson and Clapp, J. *Biol.* Chem., 5, 57 (1908).

to nitrogen in the pyrimidine ring had been effected by the action of the halogenated glucose compounds.

2.—A second experiment was carried out with chloro-acetoglucose by heating this with the pyrimidine at 50° for eight days and then for one week at 100°. The mixture darkened considerably during this treatment and only a very small amount of an undefined product was left after the extraction with ether.

3.—Experiments 1 and 2 were repeated with 2,6-diethoxy-5-methylpyrimidine using both bromo- and chloro-acetoglucose, respectively. The mixtures were heated at 50° for seven days and in the case of the bromo-acetoglucose experiment a small amount of material was finally separated which crystallized from alcohol and melted at 316° but the quantity obtained was too small for further investigation. The second experiment with chloro-acetoglucose did not lead to the formation of any product which could be identified.

Summary

1. 2,6-Dimethoxy-5-methylpyrimidine and 2,6-diethoxy-5-methylpyrimidine were synthesized.

2. 2,6-Dimethoxy-5-methylpyrimidine rearranged quantitatively to 1,3-dimethyl-thymine at 200° in forty-eight hours. 2,6-Diethoxy-5-methyl pyrimidine was stable under these conditions.

3. 2,6-Dimethoxy-5-methylpyrimidine gave with methyl iodide 2-oxy-3,5-dimethyl-6-methoxypyrimidine. 2,6-Diethoxy-5-methylpyrimidine gave with methyl iodide 2-oxy-3,5-dimethyl-6-ethoxypyrimidine and with ethyl iodide 2-oxy-3-ethyl-5-methyl-6-ethoxypyrimidine. Ethyl bromide did not react.

4. 3-Methyl-thymine was obtained from 2-oxy-3,5-dimethyl-6-methoxypyrimidine and from 2-oxy-3,5-dimethyl-6-ethoxypyrimidine by treatment with hydrochloric acid. 3-Ethyl-thymine was obtained from 2-oxy-3-ethyl-5-methyl-6-ethoxypyrimidine and hydrochloric acid.

5. 2,6-Dimethoxy-5-methylpyrimidine and bromo-acetoglucose gave 3-methyl-thymine. Chloro-acetoglucose did not react. 2,6-Diethoxy-5-methylpyrimidine and bromo-acetoglucose gave a substance, m. p. 316°, the quantity of which was too small for investigation. Chloro-acetoglucose did not react.

RESEARCHES ON CHLORIMINES. III. THE DECOMPOSITION OF CERTAIN AROMATIC ALD-CHLORIMINES TO FORM NITRILES. A METHOD FOR THE PREPARATION OF NITRILES FROM ALDEHYDES[1]

BY C. R. HAUSER AND A. G. GILLASPIE

RECEIVED AUGUST 11, 1930 PUBLISHED NOVEMBER 5, 1930

The first two papers of this series[2] have described the preparation of a number of aromatic ald-chlorimines. It was shown that these compounds decomposed spontaneously at varying rates into hydrogen chloride and a nitrile. In the present investigation a number of ald-chlorimines have been decomposed with bases to form nitriles.

Although the early workers[3] observed that benzalchlorimine readily decomposes into benzonitrile and hydrogen chloride, Raschig,[4] was the only one who recorded a yield of the nitrile. He reported that a 40% yield of benzonitrile (calculated from benzaldehyde) was obtained by subjecting the impure condensation product of benzaldehyde and monochloramine to steam distillation in the presence of sodium hydroxide.

Since the isolation of a number of ald-chlorimines has now been accomplished, a rather simple yet greatly improved method has been developed for the preparation of certain nitriles. The chlorimines in cold alcoholic solution are treated with an alcoholic solution of either potassium hydroxide or sodium ethylate. The sodium or potassium halide is rapidly precipitated even at 0°, and in some cases almost quantitative yields of the nitriles are produced. Table I (Experimental Part) shows the actual yields of nitriles obtained from seven chlorimines. The reaction may be represented by the equation $RCH{=}NCl + KOH \longrightarrow RCN + KCl + H_2O$. This represents a good method for the preparation of nitriles from aldehydes since the latter are readily converted into chlorimines in good yields.

In view of the fact that an acetyl derivative of an ald-oxime is considered to have a *syn* configuration[5] when it yields a nitrile on treatment with alkali, it would appear that the ald-chlorimines described in this paper have *syn* configurations, since the latter readily yield nitriles in an analogous manner. However, as only one of the two possible stereoisomeric ald-chlorimines has been isolated in each case, it would be premature to assign a *syn* configu-

ration to these compounds, for the other isomers if isolated might also be able to react with alkalies to form nitriles. Furthermore in cases where acetyl *anti* ald-oximes are hydrolyzed by alkalies to form oximes, the CH_3COO- group is replaced by hydroxyl, whereas chlorine attached to nitrogen in chloramines and other compounds[6] apparently is not hydrolyzed in this manner. Thus the decomposition of ald-chlorimines by alkalies to form nitriles does not necessarily indicate a *syn* configuration.

Although the decomposition of the chlorimine by the base was rapid in every case, it was plainly evident, by observing the rate of precipitation of the halide salt, that anisal- and piperonalchlorimines were decomposed at a lower rate than the other five compounds described in this paper. By analyses for active chlorine it was shown that o-chlorobenzalchlorimine was completely decomposed by sodium ethylate at 0° within one and one-half minutes, whereas anisalchlorimine was only 43% decomposed under similar conditions within two minutes, and not completely decomposed until after five minutes. This is rather significant since o-chlorobenzalchlorimine in the pure state is much more stable than anisalchlorimine. These observations suggest the study of the decomposition of ald-chlorimines by weaker bases such as amines, as here the reaction rate would doubtless be slow enough to measure more precisely. This work is now in progress.

Experimental

The ald-chlorimines used for the preparation of nitriles were prepared from aldehydes and monochloramine[7] according to the methods described in the first two papers of this series.[2] They were purified by recrystallization from alcohol and dried on a porous plate.

Preparation of Nitriles.—A sample (1.50 to 2.00 g.) of chlorimine is dissolved in the smallest possible amount of alcohol at room temperature and then cooled in an ice-bath. In cases where the chlorimine is sparingly soluble in alcohol a small quantity of acetone[8] will facilitate solution. To the cooled solution of the chlorimine is added a cold concentrated alcoholic solution of 1.25 equivalents of sodium ethylate or potassium hydroxide, and the mixture allowed to stand for several minutes or until the halide salt no longer precipitates. Sufficient cold water is then added to dissolve the halide salt and precipitate as much of the nitrile as possible. After filtering, more of the nitrile may be obtained by extracting the filtrate with small portions of ether, and evaporating the ether on a water-bath. The nitriles were dried in a vacuum desiccator, weighed and the yields calculated. The results are given in Table I. Several of the low yields could doubtless be increased if carried out on a large scale. After recrystallization from petroleum ether, the nitriles were identified by their melting points and by hydrolysis to the corresponding acids.

[6] Sidgwick, "The Electronic Theory of Valency," 1927, p. 158.

[7] The method of preparation of monochloramine is described by Coleman and Hauser, THIS JOURNAL, 50, 1195 (1928). This is a modification of the method of Marckwald and Wille, *Ber.*, 56, 1319 (1923).

[8] Acetone solutions of the nitrochlorimines became deeply colored when treated with the base, and the crude nitriles obtained in these cases possessed a darker color than when only alcohol was used as solvent.

TABLE I

PERCENTAGE YIELDS OF NITRILES

Chlorimine	Base used			
	Sodium ethylate		Potassium hydroxide	
	(1)[a]	(2)[b]	(3)[a]	(4)[b]
Anisal-	81	94	77	95
o-Chlorobenzal-	73	85	70	83
Piperonal-	79	96	85	97
2-Chloro-5-nitrobenzal-	51	82		
p-Chlorobenzal-	47	60		
m-Nitrobenzal-	54	82		
o-Nitrobenzal-	60	70		

[a] Yields of nitrile obtained by precipitating with water only. [b] Total yields of nitrile obtained.

The yields of nitriles given in Table I were obtained from chlorimines which had been purified by recrystallization from alcohol. Excellent yields of good products have been obtained from several crude chlorimines when the latter were decomposed with sodium ethylate. Good yields of nitriles are obtained when calculated from the aldehydes, since yields of 80–85% of chlorimines calculated from aldehyde used are readily obtainable in most cases.

Rates of Decomposition of *o*-Chlorobenzalchlorimine and Anisalchlorimine.—Approximately 0.1 molar alcoholic solutions of the chlorimines in separate flasks were treated with slightly more than the calculated amount of sodium ethylate in alcoholic solution (1 *M*) at 0°. Samples were pipetted off and analyzed for active chlorine. o-Chlorobenzalchlorimine was completely decomposed within one and a half minutes, while anisalchlorimine was only 43% decomposed after two minutes and completely decomposed after five minutes.

Summary

A number of aromatic ald-chlorimines have been decomposed by sodium ethylate or potassium hydroxide in alcoholic solution to form good yields of nitriles. This represents a method for the preparation of nitriles from aldehydes, since the latter are readily converted into ald-chlorimines.

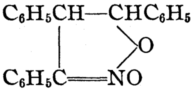
ISOXAZOLINE OXIDES. X. REDUCTION

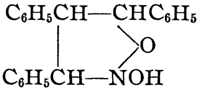
BY E. P. KOHLER AND A. R. DAVIS

RECEIVED AUGUST 12, 1930 PUBLISHED NOVEMBER 5, 1930

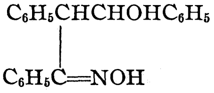
In order to complete the work on isoxazoline oxides it was desirable to make a more careful study of their behavior toward reducing agents. Two of these oxides have been reduced, heretofore, both of them with zinc and acetic acid. Kohler and Barrett[1] added two atoms of hydrogen to triphenyl isoxazoline oxide (A) and interpreted the product as an hydroxy isoxazolidine (B); but it was found later[2] that the substance is, in reality, an hydroxy oxime (C).



A



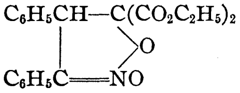
B



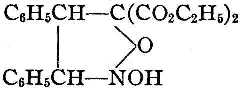
$$\begin{array}{l} C_6H_5CHCHOHC_6H_5 \\ \qquad | \\ C_6H_5C{=}NOH \end{array}$$

C

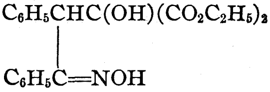
Kohler and Barrett[3] also reduced the ethyl ester of an isoxazoline oxide dicarboxylic acid (D). Here again the reaction stopped with the addition of two atoms of hydrogen, and the product was likewise regarded as an hydroxy isoxazolidine (E). The evidence on which this formula was based is, however, no longer conclusive, and it now seems at least as probable that the substance is the hydroxy oxime (F).



D



E



$$\begin{array}{l} C_6H_5CHC(OH)(CO_2C_2H_5)_2 \\ \qquad | \\ C_6H_5C{=}NOH \end{array}$$

F

We selected for reduction the ketonic isoxazoline oxide III, and decided to reduce it in steps, in order to note the result of a competition for hydrogen by the three reducible components, the carbonyl group, the unsaturated system C=NO, and the oxide group. Since bases very rapidly transform these ketonic oxides into other reducible substances, reduction in alkaline media was not attempted. These oxides are fairly stable in the presence of dilute acids but all attempts at reducing our substance with metal and acid ended in insoluble polymerization products too complex to unravel; reduction in acid media therefore did not prove feasible.

In view of the circumstances which have been described it became necessary to resort to catalytic hydrogenation in neutral solution. Preliminary experiments both with Willstatter's platinum black and with Adams' platinum oxide showed that while the hydrogenation occurs in stages which proceed at different rates, the stages overlap and that there is

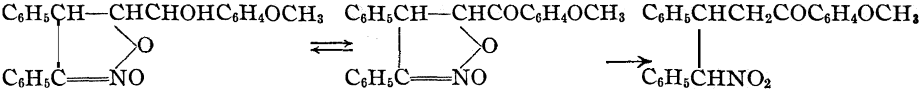
[3] Kohler and Barrett, *ibid.*, 48, 1770 (1926).

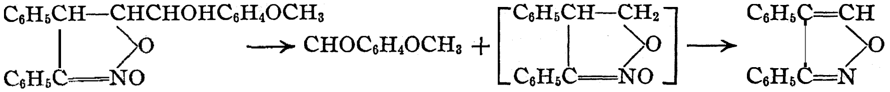
no sharp break in the curve representing the speed of hydrogen absorption. Later operations were therefore carried out in an apparatus with which it was possible to measure the absorbed hydrogen with great accuracy and the process was interrupted as soon as one mole of hydrogen had been consumed. Under these circumstances the product was composed almost entirely of the three substances VIII, IX and X.



VIII and IX III X

The relative amounts of the stereoisomeric carbinols VIII and IX varied slightly with the conditions, but, to our surprise, these two substances constituted by far the largest part of the primary reduction products. Thus in a typical experiment we obtained 55% of the higher-melting isomer VIII, 20% of the lower-melting isomer IX, 5% of X, and 20% of an oil which doubtless was composed largely of secondary products.

No less surprising is the generation of a nitro group by hydrogenation, but the proof of the structure of these primary reduction products is explicit. The nitro compound X is identical with the product obtained by adding phenyl nitro methane to benzal acetyl anisole. The other two reduction products, VIII and IX, liberate iodine from potassium iodide and chlorine from phosphorus pentachloride; they are, therefore, still oxides. Moreover, chromic acid removes the two hydrogen atoms that have been added and oxidizes the reduction products to the oxide from which they came, while potassium hydroxide cleaves them to anisic aldehyde and 3,4-diphenyl isoxazole.

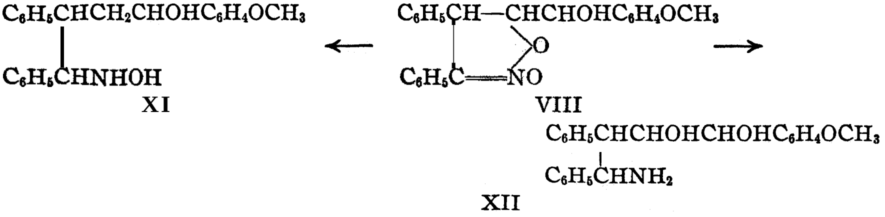


VIII XIII

These new oxides, on further hydrogenation, absorb hydrogen more slowly but with great regularity until six additional atoms have been consumed. The solution then deposits a sparingly soluble compound which is formed in accordance with the equation

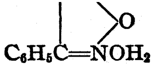
$$C_{23}H_{21}O_4N + 6H = C_{23}H_{25}O_3N + H_2O$$

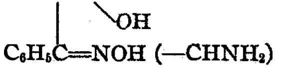
It is not possible to isolate any intermediate between the oxide and this final reduction product. If the operation is stopped short of this final stage, a corresponding quantity of oxide is recovered. For this final reduction product only two formulas have any probability. The formation of a substance with this composition manifestly involves the opening of the isoxazole ring. If this occurred between the oxygen and the carbon atom in the 5-position, as it does in the formation of X, the product would be the hydroxylamine derivative XI. But it is at least equally probable that the ring is opened in the same manner as it is in triphenyl isoxazole, and this would lead to the formula of the amine XII. Since the reduction product is not only a strong base but also is not oxidized by Fehling's solution it evidently is not the hydroxylamine derivative



These results show quite conclusively that the hydrogen combines far more rapidly with the carbonyl group than it does with any part of the system C=NO. Combined with what had been learned heretofore by the reduction of isoxazoline oxides with metal and acid, they show also that the first step in the reduction is not removal of oxygen, as is the case with amine oxides,[4] azoxy compounds[6] and open-chained nitrones.[6] Nor is it 1,3-addition of hydrogen to the unsaturated system in the manner of the reaction between isoxazoline oxides and Grignard reagents.?

It seems not unlikely that the first step in the reduction of all types of oxido compounds is the same. These substances in reality contain an unsaturated oxygen atom. The primary stage in the reduction may well be the addition of hydrogen to this unsaturated oxygen atom; what happens subsequently depends upon the rest of the molecule. In the amine oxides and related substances, loss of water is inevitable because every possible rearrangement product would be unstable; in the isoxazoline oxides the primary product can undergo rearrangement to a stable oxime which may subsequently be reduced to an amine.





Experimental Part

Preparation and Proof of Structure

The starting point in the preparation of the oxide was an addition product previously obtained from benzal acetyl anisole and phenyl nitromethane.[8]

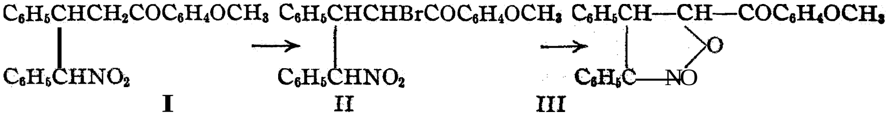
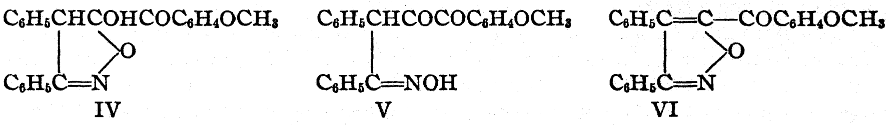
[8] Kohler and Allen, *ibid.*, 50, 884 (1928).

This substance, on bromination, gave a mixture of α-bromo compounds from which hydrogen bromide was eliminated with pyridine,



In proof that the compound thus obtained is an isoxazoline oxide, it was established that potassium acetate isomerizes it to an hydroxy isoxazoline (IV), and that bases convert it both into an open-chained triketone oxime (V) and also into an isoxazole derivative (VI). These are characteristic reactions of isoxazoline oxides.



Bromination: **α-Anisoyl-α-bromo-β,γ-diphenyl-γ-nitro** Propane (II).—A solution of 100 g. of pure dry addition product in hot chloroform was brominated with 45 g. of bromine. At first only a few drops of bromine were added, the solution was boiled until the color disappeared, then the remainder was dropped into it as fast as it decolorized without further heating. When the solution is boiled during the bromination, and excess of bromine is allowed to accumulate in it, more than one equivalent of bromine is consumed and the product contains a polybromide which interferes with subsequent operations. After recrystallization from chloroform–methyl alcohol, the bromo compound melts at 165°. The crude product melting at 163° is sufficiently pure for nearly all purposes.

Anal. Calcd. for $C_{23}H_{20}O_4NBr$: C, 60.8; H, 4.4. Found: C, 60.5; H, 4.6.

3,4-Diphenyl-5-anisoyl Isoxazoline Oxide (III).—A suspension of 100 g. of the finely ground α-bromo compound in 500 cc. of 95% alcohol and 70 g. of pyridine was heated to boiling. Solution was complete in fifteen minutes but the boiling was continued for another ten minutes. On cooling, the isoxazoline oxide separated from the pale purple solution. The crystalline material was collected on a filter, washed with 95% alcohol, then with dilute hydrochloric acid until free from pyridine, and finally with water until free from chloride. The first filtrate and the alcohol washings, on concentration and acidification, yielded 11 g. of crude product which gave 8 g. of recrystallized oxide, making the total yield 79 g. or 92%.

Absolute alcohol gave the same yield as 95% alcohol, but absolute methyl alcohol was found to be unsatisfactory because the reaction was very much slower at the lower boiling point. By recrystallization from chloroform–methyl alcohol the oxide was obtained in colorless needles melting at 158°. It is readily soluble in chloroform, sparingly soluble in methyl alcohol. It can be recrystallized without change from glacial acetic acid, does not reduce permanganate in acetone and is not affected by boiling with sodium dichromate in glacial acetic acid. It liberated iodine from potassium iodide in glacial acetic acid, and it liberated a mixture of chlorine and nitrosyl chloride when heated with phosphorus pentachloride.

Anal. Calcd. for $C_{23}H_{19}O_4N$: C, 74.0; H, 5.1. Found: C, 73.7; H, 5.2.

Rearrangement: 3,4-Diphenyl-5-hydroxy-5-anisoyl **Isoxazoline** (IV).—A solution containing 2 g. of the oxide, 1 g. of potassium acetate and a few drops of glacial acetic acid in 20 cc. of dry methyl alcohol was boiled for an hour. It deposited the crystalline rearrangement product when cooled. The hydroxyl compound is, however, most conveniently prepared directly from the α-bromo compound. For this purpose 15 g. of finely powdered bromo compound was suspended in a mixture of 325 cc. of methyl alcohol, 500 cc. of water, 20 g. of sodium hydroxide, and 200 cc. of ether. The mixture was shaken until all the bromo compound was in solution—about thirty minutes—then acidified with acetic acid and allowed to stand at room temperature for half an hour. It deposited 10 g. of the hydroxyl compound. This was pale yellow in color but on recrystallization from chloroform–methyl alcohol, it became colorless and melted at 177°.

Anal. Calcd. for $C_{23}H_{19}O_4N$: C, 74.0; H, 5.1. Found: C, 74.1; H, 5.1.

The hydroxyl compound was readily soluble in chloroform, sparingly soluble in methyl alcohol. It crystallized from alcohol in colorless prisms, and from ether–petroleum ether in hexagonal plates. It crystallized unchanged from glacial acetic acid. Sodium peroxide oxidized it to anisic acid and diphenyl isoxazolone.

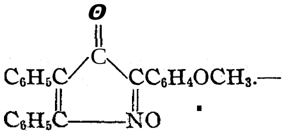
The Benzoate.—Like the hydroxy isoxazolines described in earlier papers in this series, our substance resisted all attempts to methylate it, but it was readily turned into a benzoate. To a solution of 1 g. of the substance in 5 cc. of dry pyridine. 1 cc. of benzoyl chloride was added. The pink solution was kept at room temperature for two hours, during which a solid separated. The mixture was diluted with water, acidified with hydrochloric acid and extracted with ether. The washed and dried solution, on evaporation, deposited the benzoate in silky needles which melted at 173°.

Anal. Calcd. for $C_{30}H_{23}O_5N$: C. 75.5; H, 4.8. Found: C, 75.3; H, 4.6.

α-Anisyl-γ,ϑ-diphenyl-butane-trione Oxime (V).—The yellow oxime is formed by the action of alkalies on both the oxide and the hydroxy isoxazoline, but it is most readily prepared directly from the α-bromo compound. To this end the bromo compound is treated exactly as in the preparation of the hydroxy isoxazoline, but the yellow solution is acidified rapidly with iced hydrochloric acid instead of acetic acid. The yield is 74%.

Anal. Calcd. for $C_{23}H_{19}O_4N(C_2H_5)_2O$: C, 72.5; H, 6.5. Found: C, 72.3; H, 6.6.

Like all other substances of this type that are known, the oxime crystallizes in yellow prisms containing one molecule of ether. It melts with decomposition at 110°. When a methyl alcoholic solution of the oxime is boiled with a little potassium acetate and acetic acid, it is transformed almost quantitatively into the hydroxy isoxazoline, and when a drop of hydrochloric acid is added to a solution of the oxime in chloroform, it turns purple and soon deposits a purple nitrone.



2-Anisal-3-keto-4,5-diphenyl Pyrrolenine Oxide, .—The purple nitrone crystallizes from the chloroform solution in fluffy needles melting at 182° with decomposition.

Anal. Calcd. for $C_{23}H_{17}O_3N$: C, 77.8; H, 4.8. Found: C, 77.7; H, 5.1.

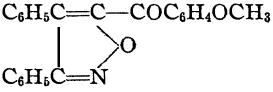
3,4-Diphenyl-5-anisoyl Isoxazole **(VI).**—The isoxazole is formed by the action of bases on the α-bromo compound, the polybromides, the isoxazoline oxide, the hydroxy isoxazoline and the triketone oxime; it represents the final degradation product of all of these substances by weak bases or dilute alkalies. In quantity, it is most conveniently obtained by suspending the α-bromo compound in methyl alcohol, adding an equal weight of potassium acetate and boiling the mixture. The bromo compound soon dissolves and isoxazole begins to separate in compact crystals along with potassium bromide. Since these solids cause serious bumping, it is necessary to filter from time to time and repeat the boiling, but in the end the yield of isoxazole is 94%.

Anal. Calcd. for $C_{23}H_{17}O_3N$: C, 77.7; H, 4.7. Found: C, 77.3; H, 4.9.

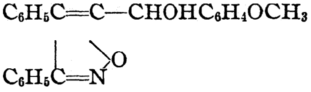
The isoxazole crystallizes in needles which melt at 156°. When pure it is quite colorless, but it usually has a pale yellow color which cannot be removed by recrystallization.

II. Reduction

We examined the behavior toward reducing agents of the isoxazoline oxide, the hydroxy isoxazoline and the isoxazole. With zinc and acid all these substances except the isoxazole gave very sparingly soluble substances which were evidently condensation as well as reduction products. The isoxazole, however, readily combined with two atoms of hydrogen, being reduced to a substance which liberated a mole of gas from methyl magnesium iodide and which chromic acid reoxidized to the isoxazole—therefore evidently the carbinol ring is intact.



VI



VII

Hydrogenation in the presence of platinum likewise gave only complex products with the hydroxy isoxazoline and the yellow oxime, but with the isoxazoline oxide it gave mainly monomolecular products.

Reduction of the Isoxazole.—To a solution of 10 g. of the isoxazole in glacial acetic acid, which was heated on a steam-bath, zinc dust was added in small quantities over a period of two hours. The mixture was filtered, and the filtrate diluted with water, then extracted with ether. The extract, freed from acetic acid, dried and evaporated, deposited a small quantity of solid amid considerable oil which was presumably an acetate. The oil was boiled with methyl alcoholic potassium hydroxide for a short time, the solution diluted with water and extracted with ether. The ether now deposited the solid carbinol; yield, 6.8 g. By recrystallization from carbon tetrachloride–petroleum ether, the substance was obtained in colorless prisms which melted at 146".

Anal. Calcd. for $C_{23}H_{19}O_3N$: C, 77.3; H, 5.3. Found: C, 76.6; H, 5.5.

Oxidation.—To 0 5 g. of the carbinol in 10 cc. of glacial acetic acid, sodium bichromate was added gradually until there was no further evidence of reduction. The mixture was diluted with water and extracted with chloroform. The extract was washed, dried and concentrated, then diluted with methyl alcohol. It deposited 0.35 g. of pure isoxazole.

Reduction of the Oxide.—For the purpose of reduction the oxide was repeatedly recrystallized from the same "reagent methyl alcohol" that was used as solvent in the reductions. The reductions were carried out under atmospheric pressure with a specially constructed apparatus with which it was possible to determine the absorbed hydrogen with great accuracy. The catalyst was Adams' platinum oxide.

In a typical experiment a suspension of 2 g. of the finely ground oxide and 0.2 g. of the catalyst in 100 cc. of methyl alcohol was shaken with hydrogen, using the calibrated apparatus. The oxide was completely in solution after ten minutes. By that time the solution had absorbed 124.9 cc. of hydrogen instead of 120 cc. calculated for two atoms and the operation was stopped immediately.

The yellow solution was decanted from most of the catalyst, filtered and boiled down to about a fourth of its volume. In order to remove a small quantity of colloidal platinum which made trouble unless it was removed at this point, a small quantity of active charcoal was added a few minutes before the boiling was discontinued. The solution was then filtered again and set aside. It deposited a solid which proved to be composed almost entirely of the high-melting reduction product VIII. It was purified by recrystallization from methyl alcohol; yield, 1.1 g.

The filtrate was allowed to evaporate to dryness. It deposited a mixture of large transparent prisms and long silky needles which were separated by hand and purified separately. The prisms (0.4 g.) were found to be a stereoisomer (IX) of the high-melting reduction product and the needles (0.1 g.) were identified as the nitro compound (I).

3,4-Diphenyl-5-(a-hydroxy-4-methoxy-benzyl) Isoxazoline Oxide, VIII.—The higher-melting reduction product crystallized from methyl alcohol in flat needles that melted without decomposition at 170°.

Anal. Calcd. for $C_{23}H_{21}O_4N$: C, 73.6; H, 5.6. Found: C, 73.6; H, 6.0.

The substance liberated iodine from potassium iodide and chlorine from phosphorus pentachloride as readily as did the original oxide.

Oxidation.—To a solution of 0.5 g. of the reduction product in boiling glacial acetic acid, sodium bichromate was added in small quantities until the red color of the bichromate appeared in the solution. The mixture was poured into water, which precipitated a solid product. After recrystallization from methyl alcohol, the solid melted at 156°, and the melting point was not changed when mixed with the original oxide; yield, 0.4 g.

Cleavage.—A suspension of 3 g. of the reduction product and 1 g. of solid potassium hydroxide in 20 cc. of methyl alcohol was boiled for thirty minutes. The yellow solution was diluted with water and extracted with ether. The washed and dried ethereal layer, when evaporated, left an oil. This was divided into two portions. To the first were added phenylhydrazine and a few drops of acetic acid. It deposited a solid which after purification melted at 122° and which was identified as the phenylhydrazone of anisic aldehyde by comparison with a sample made from the aldehyde.

The second half of the oil was dissolved in ether and freed from the aldehyde by means of saturated sodium bisulfite. The ethereal solution was washed with bicarbonate, dried and evaporated. It left an oil, but a solution of this oil in petroleum ether deposited a solid. which melted at 91° and was identified as diphenyl isoxazole. This will be described later.

The Stereoisomeric Reduction Product, IX.—The lower-melting reduction product behaved exactly like the substance which has just been described, liberating iodine from potassium iodide with the same ease and giving the same oxidation and cleavage products It crystallized from methyl alcohol in six-sided prisms and melted at 160°.

Anal. Calcd. for $C_{23}H_{21}O_4N$: C, 73.6; H, 5.6. Found: C, 73.7; H, 5.7.

Reduction of the New Oxide VIII: α,β-Diphenyl-γ,ϑ-dihydroxy-ϑ-anisyl Butyl Amine, XII.—Quantitative experiments showed that the new oxides are reduced much more slowly than the ketonic compound and that there is no break in the curve representing the rate at which hydrogen is absorbed until six atoms have disappeared. Moreover, an examination of the result of interrupting the process before six atoms of hydrogen had been used showed that all intermediates between the oxide and the final product are more rapidly reduced than the oxide.

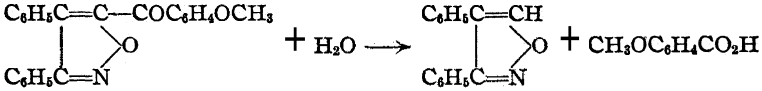
Thus 2 g. of the oxide VXII in 100 cc. of methyl alcohol was shaken with hydrogen in the presence of 0.2 g. of platinum until 120 cc. had been absorbed. This required about two hours. The solution, manipulated in the usual manner, yielded 1.2 g. of the starting material and 0.5 g. of reduction product. Allowing for loss during crystallization, this quantity of reduction product corresponds to the absorption of six atoms of hydrogen.

In another experiment, 2 g, of the same oxide was reduced completely in seven hours and six atoms of hydrogen were used in the process. The product, isolated in the usual manner, crystallized in needles melting at 208°.

Anal. Calcd. for $C_{23}H_{25}O_3N$: C, 76.0; H, 6.9; mol. wt., 363. Found: C, 76.1; H. 6.8; mol. wt., 349.

III. Diphenyl Isoxazole

Inasmuch as the reduction product of anisoyl diphenyl isoxazoline oxide is easily cleaved by alkalies, it seemed worth while to study the behavior of the isoxazole itself because a similar cleavage of this substance would result in a type of disubstituted isoxazole, for which no methods of preparation are known.



It was found that while this cleavage does not take place very readily it can be accomplished and that the yield may be brought to 88%. The structure of the isoxazole was established by ozonization, which led to a product that was hydrolyzed to β-benzil monoxime. Like all other isoxazoles which are not completely substituted, **3,4-diphenyl** isoxazole can be further cleaved with alkalies. The mode of cleavage is similar to that of those mono-substituted isoxazoles which have no substituent in the 5-position.

3,4-Diphenyl Isoxazole,  ⟶ $C_6H_5CH_2CO_2H + C_6H_5C{\equiv}N$.—A suspension of 10 g. of diphenyl anisoyl isoxazole in 50 cc. of 5% ethyl alcoholic potassium hydroxide was boiled for half an hour, then filtered. The operation was repeated with the unchanged isoxazole which had been collected on the filter until none of it was left. The alcoholic filtrates on dilution deposited the new isoxazole as a flocculent precipitate. It was dried and recrystallized from low-boiling petroleum ether; yield 5.5 g. or 88%.

Anal. Calcd. for $C_{15}H_{11}ON$: C 81.4; H, 5.0. Found: C, 81.9; H, 5.1.

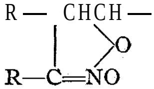
The isoxazole is readily soluble in all organic solvents. It crystallizes from low-boiling petroleum ether in colorless needles which melt at 91.

Ozonization.—A current of ozonized oxygen containing about 6% of ozone was passed through a solution of 0.5 g. of the isoxazole in ethyl bromide for one and one-half hours. Addition of water and removal of solvent left a cream-colored oil, which was dissolved in 10% aqueous sodium hydroxide. The alkaline solution was extracted with ether, then gradually neutralized with carbon dioxide. It deposited a crystalline solid which was identified as the β-monoxime of benzil by comparison with a sample on hand.

Alkaline Cleavage.—A solution of 2 g. of the isoxazole in 20 cc. of 5% methyl alcoholic potassium hydroxide was boiled for two hours, then diluted with water and extracted with ether. The ethereal solution was dried over sodium sulfate and cautiously evaporated. It left an oil which had the odor of benzonitrile and which when boiled with 10% aqueous sodium hydroxide gave benzoic acid. The alkaline solution, from which the benzonitrile had been removed, was acidified and again extracted with ether. The dried extract left an oil when evaporated, but a solution of this oil in petroleum ether deposited a solid melting at 75°. This was identified as phenylacetic acid by comparison with a sample.

Summary

1. When a ketonic isoxazoline oxide



is hydrogenated it first takes up two atoms of hydrogen at the carbonyl group and forms a new oxide.

2. The reduction of isoxazoline oxides in which there is no carbonyl group doubtless always gives an open-chained hydroxy oxime as the first product; but in catalytic hydrogenations these oximes are reduced to amines.

3. 3,4-Disubstituted isoxazoles, heretofore unknown, can be prepared by cleaving ketonic isoxazoles with bases. When these 3,4-disubstituted isoxazoles undergo further cleavage, they behave like those mono-substituted isoxazoles which have no substituent in the 5-position.

STEREOCHEMISTRY OF PHENYLPYRIDINE COMPOUNDS: THE PREPARATION AND INVESTIGATION OF 2-(2-CARBOXY-6-CHLOROPHENYL)-PYRIDINE-3-CARBOXYLIC ACID AND 3-(2-CARBOXYPHENYL)-6-PHENYLPYRIDINE-2,4-DICARBOXYLIC ACID. X.[1]

BY CATHERINE CASSELS STEELE[2] AND ROGER ADAMS

RECEIVED AUGUST 14, 1930 PUBLISHED NOVEMBER 5, 1930

A natural corollary to the development of the study of the optical isomerism exhibited by certain types of substituted diphenyl compounds is an investigation of binuclear compounds similar to diphenyl, and of these the dipyridines and the phenylpyridines resemble diphenyl most closely.

In the case of the phenylpyridines, only one ring—the pyridine nucleus—is different, and they may be divided into three classes; (a) where the N is "ortho," (b) where it is "meta" and (c) where it is "para" to the carbon atom linked to the phenyl nucleus.

(a)

(b)

(c)

Type (a) differs from (b) and (c) in the fact that there cannot be four

---

[1] For the last two papers in this series, see (a) Stanley and Adams, THIS JOURNAL, 52, 4471 (1930); (b) Browning and Adams, *ibid.*, 52, 4098 (1930).

[2] Commonwealth Fund Fellow.

substituent groups in the "ortho" position, and any trisubstituted phenylpyridine of the type (a) will not be directly comparable with the corresponding trisubstituted diphenyl, as the fourth position is not occupied by a hydrogen atom. If the obstacle theory[1a,3] is correct and on the assumption that a pyridine ring resembles in structure a benzene ring, this difference would be unlikely to affect resolution except in so far as a blocking group of size 0.94 to 1.04 Å.[4] is eliminated. If, however, Bell and Kenyon's[5] modified view that the electrical character of the substituting groups has an added influence besides the effective size of the electrical field of force of these groups, then the substituted phenylpyridines though conforming to all the requirements for resolution of the correspondingly substituted diphenyls, may exhibit a marked divergence in behavior.

Trisubstituted phenylpyridines of all three types and tetrasubstituted compounds of types (b) and (c) must be investigated, and various groups used to determine whether or not the calculated amount of interference[4] between such groups will give the same experimental results as the corresponding diphenyls. Neither has it been established that the five carbon atoms and the nitrogen are coplanar in pyridine. If the nitrogen is bent away from the plane of the five carbons, or if the whole ring is distorted, then in the (a) type the distances between the ortho positions in the two rings will be very different from those between identical groups in a diphenyl, and therefore the interference values will also differ.

The methods available for preparing ortho-substituted phenylpyridines of types (a) and (h) are very limited; in fact, the only satisfactory method yet found is the synthesis of substituted naphthoquinolines and then their oxidation to the corresponding phenylpyridine-dicarboxylic acids.

In this work, two acids were prepared: 2-(2-carboxy-6-chlorophenyl)-pyridine-3-carboxylic acid (III), which is of type (a), and 3-(2-carboxyphenyl)-6-phenylpyridine-2,4-dicarboxylic acid (V), of type (b). The first was obtained through a Skraup synthesis of 10-chloro-a-naphthoquinoline (II) from 8-chloro-1-naphthylamine (I), and subsequent oxidation with neutral permanganate, and the second by the oxidation of a-phenyl-β-naphthoquinoline-γ-carboxylic acid (diapurin) IV).

IV V

It was found impossible to resolve either acid; of the chloro acid the following salts were investigated: di-strychnine, di-brucine, di-morphine, mono-cinchonine, di-cinchonine and mono-quinine, and of the tricarboxylic acid, the mono-strychnine, di-strychnine, mono-brucine, di-brucine and mono-cinchonine salts were prepared.

If x-ray data are taken into consideration using the values C–Cl, 1.89 Å.; C–COOH, 1.56 Å.; and C–C (2,2′ for the diphenyl system), 2.90 Å.;[4] in the case of the 2-(2-carboxy-6-chlorophenyl)-pyridine-3-carboxylic acid it is obvious that either the chlorine or carboxyl in the benzene ring should collide with the carboxyl in the pyridine ring and free rotation should be prevented (two carboxyls, 1.56 Å. + 1.56 Å. = 3.12 Å. − 2.90 Å. → + 0.22 Å.; one chlorine and one carboxyl, 1.56 Å. + 1.89 Å. = 3.45 Å. − 2.90 Å. → + 0.55 Å.). In the case of the 3-(2-carboxyphenyl)-6-phenylpyridine-2,4-dicarboxylic acid, similar conditions exist; the carboxyl in the phenyl ring should collide with either of the carboxyls in the pyridine nucleus.

These results may indicate distortion within the molecule with subsequent free rotation, due to the electrical attraction of the basic nitrogen and acid carboxyl groups. Two diastereoisomeric salts were in no case isolated. More types of phenylpyridines must be studied before speculation in regard to the stereochemical character of this class of compounds is extended. Other phenylpyridines and dipyridyls are under investigation in this Laboratory.

It should be noted that the di-brucine salt of the chloro acid gave zero rotation, while all the salts of the tricarboxylic (except the monocinchonine) gave zero rotations. These substances obviously fall into a group which show abnormalities similar to those compounds which Haworth believed demonstrated the existence of labile optical isomers.[6] Such a phenomenon is so general among alkaloidal salts' of many types that the authors believe such conclusions as were drawn by Haworth to be misleading.

Experimental Part

8-Chloro-1-naphthylamine.—The preparation was carried out in two steps. 8-Chloro-1-nitronaphthalene was prepared according to Ullmann and Consonno[8] by the

---

[6] "Annual Reports." 24, 101 (1928).

[7] Hyde and Adams, THIS JOURNAL, 50, 2502 (1928).

[8] Ullmann and Consonno, Ber., 35, 2808 (1902); see also German Patent 99,758.

chlorination of 1-nitronaphthalene in 100-g. lots. The yield of the pure 8-chloro-1-nitro isomer after crystallization from benzene–ligroin was 23 g., m. p. 94–95°. The reduction of 8-chloro-1-nitronaphthalene by tin and hydrochloric acid described by Ullmann was very tedious and good results were not obtained. 8-Chloro-1-naphthylamine was, however, prepared in 97% yield by the following method.

An intimate mixture of 20 g. of 8-chloro-1-nitronaphthalene with 60 g. of iron powder and 30 cc. of water in a 500-cc. found-bottomed flask fitted with a reflux condenser was heated for ten minutes on the steam-bath and a few drops of concd. hydrochloric acid added through the condenser, the flask being well shaken. Heating was thereafter continued for seven hours with occasional shaking. With longer heating decomposition of the molecule becomes a factor, and with less time unreduced nitro compound is recovered. The mixture was cooled and the amine extracted with ethyl alcohol until the filtrate gave no precipitate with water. The alcoholic filtrate was poured into a large excess of water and the precipitate filtered. The latter was then dissolved in dilute hydrochloric acid, filtered from any nitro compound and the amine precipitated with ammonia. The amine separates from ligroin in small colorless needles which turn dark purple in color on exposure to the air; m. p. 95-96' (various values for the melting point are given in the literature; Ullmann, 89"; Atterberg, 93–94°).[9]

Anal. Calcd. for $C_{10}H_8NCl$: (Parr bomb) Cl, 20.00. Found: Cl, 19.93.

10-Chloro-α-naphthoquinoline.—The Skraup synthesis was carried out using arsenic acid as the oxidizing agent in the proportions given by Claus[10] for the conversion of α-naphthylamine to a-naphthoquinoline. To 59.5 g. of 8-chloro-1-naphthylamine in a 1-liter, 3-necked flask fitted with a mechanical stirrer, condenser and dropping funnel, were added 54.2 g. of arsenic acid (sp. gr. 2) and 178.7 g. of glycerol in the order named. Then 113.8 g. of concd. sulfuric acid was added gradually from the dropping funnel, the stirrer being started whenever the mixture became sufficiently liquid. The mixture was heated for one and one-half hours at 100° in an oil-bath, and then for nine hours at 170–180°. The material was poured while hot into a large excess of water and the precipitate allowed to settle overnight. The resinous precipitate was removed by filtration through an ordinary filter funnel and washed with water. The combined filtrates were placed in a 3-liter separatory funnel and a layer of ether followed by an ice-cold solution of 44 g. of potassium hydroxide (one-third the calcd. amount to neutralize the sulfuric acid used) in about 220 cc. of water was added. This ethereal extract consists almost entirely of resinous material. The aqueous layer was then treated similarly with a concd. solution of 88 g. of potassium hydroxide (the remaining two-thirds necessary for neutralization) and the precipitate extracted thoroughly with ether. The ether layer was dried over anhydrous magnesium sulfate and the ether removed. The yield of crude material was 47.5 g. A second run of 27.5 g. of chloronaphthylamine was made and the 17.5 g. of crude material obtained was added to the first product; the resulting 65 g. of crude material after two crystallizations from ligroin gave 26.8 g. with the constant, m. p. 81–82'. The insoluble material was re-extracted with boiling ligroin and 3.7 g. with a melting point of 81.5–82° was obtained. The total yield of pure **10-chloro-a-naphthoquinoline** was 30.5 g. (20%). It crystallized from ligroin in small, hard, bright yellow prisms, m. p. 81.5–82°.

Anal. Calcd. for $C_{13}H_8NCl$: Cl, 16.63. Found: Cl, 16.44.

2-(2-Carboxy-6-chlorophenyl)-pyridine-3-carbolic Acid.—Skraup and Cobenzl[11] found that oxidation of a-naphthoquinoline with chromic acid gave a-naphthoquinoline-

---

quinone, while oxidation with permanganate at 40–50° gave a 70% yield of α-phenylpyridine-dicarboxylic acid. It was found possible to oxidize chloronaphthoquinoline to the dicarboxylic acid with permanganate but the higher temperature of 100" was necessary. The difficulty with such oxidations is the isolation of the acid, as there is no general method suitable for all the acids. After several attempts, the following method gave the best results. A mixture of 10 g. of chloronaphthoquinoline and 800 cc. of water was heated to 100° in a 3-liter, 3-necked flask fitted with a mechanical stirrer, condenser and dropping funnel. To the boiling mixture was added gradually from the dropping funnel a cold saturated solution of 21.8 g. of potassium permanganate (10% excess) in water. Decolorization of the permanganate was almost immediate and the addition was complete in forty-five minutes. The hot liquid was filtered from the manganese dioxide, the latter washed thoroughly with boiling water and the united filtrates allowed to cool. A small amount of unoxidized quinoline usually separated at this point and was removed by filtration. The solution was then made slightly acid with hydrochloric acid and evaporated to a very small volume on the steam-bath, when crystals of the dicarboxylic acid separated. The yield was 5 g. The acid was slightly colored and was purified by dissolving in alcohol, decolorizing with norit, and after concentration of the solution, diluting the latter with hot water until a slight cloudiness appeared. On cooling, the solution deposited small, colorless crystals of 2-(2-carboxy-6-chlorophenyl)-pyridine-3-carboxylic acid. They showed no sharp melting point, but turned dark around 240°, and completely melted at 252–256° with decomposition.

Anal. Calcd. for $C_{13}H_8O_4NCl$: Cl, 12.86. Found: Cl, 13.04.

The yields obtained in the synthesis of this acid may be summarieed as follows: 450 g. nitronaphthalene ⟶ 121.6 g.; 8-chloro-1-nitronaphthalene ⟶ 87 g.; 8-chloro-1-naphthylamine ⟶ 30.5 g.; 10-chloro-a-naphthoquinoline ⟶ 15 g.; **chlorophenylpyridine-dicarboxylic** acid.

Alkaloid Salts of Chlorophenyl-pyridine-dicarboxylic Acid

Di-strychnine Salt.—Warm methyl alcohol solutions of 1.2 g. of acid and 2.87 g. of strychnine were mixed and evaporated to dryness. The hard amorphous solid so obtained crystallized slowly from hot water in large, translucent parallelogram plates. These on exposure to the air effloresced to give a white powder which was dried in a desiccator, m. p. 171–173'. The first fraction, consisting of 1 g. (one-fourth of the total salt) had the specific rotation $[\alpha]_D$ −21.37° in chloroform, and on a second crystallization had $[\alpha]_D$ —25.45". A second fraction from the original mother liquors gave $[\alpha]_D$ −25.3°, and the final mother liquor on evaporation to dryness gave a salt with $[\alpha]_D$ —21.16'.

Rotation. 0.3041 g. made up to 25 cc. with chloroform at 20° gave α_D = —0.52'; $l = 2$; $[\alpha]_D$ —21.37".

Anal. Calcd. for $C_{55}H_{52}O_8N_5Cl$: neut. equiv., 472.7. Found: 473.6.

One gram of the salt was decomposed with dilute ammonia and the strychnine removed by extraction with chloroform. The aqueous solution of the ammonium salt of the acid was evaporated to dryness and showed no optical activity in aqueous solution.

Di-brucine Salt.—The di-brucine salt was made in and crystallized from methyl alcohol. Clusters of long, slender, colorless needles separated and effloresced in air. They were powdered and dried in air; m. p. 168–170°. All the fractions isolated as well as the mother liquors had zero rotation. The salt also crystallized from ethyl acetate in small hard prisms, but no change in rotation was observed.

Anal. Calcd. for $C_{59}H_{60}O_{12}N_5Cl$: Cl, 3.33. Found: Cl, 3.53.

Di-morphine Salt.—This salt was made in methyl alcohol and did not crystallize readily from any of the ordinary solvents. Crystals were obtained by dissolving the salt in the minimum amount of hot ethyl alcohol and adding hot ethyl acetate until one more drop turned the solution cloudy. On cooling, small, colorless crystals separated, m. p. 200–204°. Six fractions in all were isolated, and had the same rotation in absolute methyl alcohol.

Rotation. 0.1067 g. made up to 25 cc. with methyl alcohol at 20° gave an = –0.589"; $l = 2$; $[\alpha]_D$ –69.06°.

Anal. Calcd. for $C_{47}H_{46}O_{10}N_3Cl$; Cl, 4.19. Found: Cl, 4.26.

Mono-cinchonine Salt;-—This was prepared in methyl alcohol, and crystallized from a large volume of ethyl acetate in small colorless prisms, m. p. 154–156°. Three fractions were isolated and the salt in the mother liquors recovered. All gave the same rotation.

Rotation. 0.1014 g. made up to 20 cc. with absolute methyl alcohol at 20° gave $\alpha_D = +0.763°$; $l = 2$; $[\alpha]_D$ +75.2°.

The first fraction, consisting of a gram of salt, was decomposed by shaking with dilute ammonia and chloroform in a separatory funnel. The ammonium salt solution was evaporated to dryness. It gave zero rotation.

Di-cinchonine Salt.—Methyl alcohol solutions of the acid and alkaloid were mixed, evaporated to small bulk and water added to the precipitation point. On cooling small crystals separated, m. p. 194–196°. They could not be recrystallized from any single solvent. All the fractions obtained had the same rotation, and this was not altered by three precipitations of the first fraction.

Rotation. 0.1060 g. made up to 20 cc. with absolute methyl alcohol at 20° gave $\alpha_D = +1.25°$; $l = 2$; $[\alpha]_D$ +117.8°.

Anal. Calcd. for $C_{51}H_{52}O_6N_5Cl$: Cl, 4.1. Found: Cl, 4.26.

A 1-g. portion of the purified first fraction was decomposed with ammonia and the ammonium salt of the acid isolated. It gave a zero rotation.

Mono-quinine Salt.—This salt could not be recrystallized readily, but three fractions of microscopic, colorless crystals were obtained from benzene containing a little ethyl alcohol, m. p. 152–155". The fractions and the salt recovered from the mother liquor all gave the same rotation.

Rotation. 0.1060 g. made up to 20 cc. with absolute methyl alcohol at 20° gave α_D = –0.624'; $l = 2$; $[\alpha]_D$ –58.89'.

Anal. Calcd. for $C_{33}H_{32}O_6N_3Cl$: Cl, 6.13. Found: Cl, 5.91.

α-Phenyl-β-naphthoquinoline-γ-carboxylic Acid.—This was prepared and purified according to the method of Dobner and Kuntze[12] and was obtained in 50% yield, m. p. 290" (Dobner, 53% yield, m. p. 296°).

Anal. Calcd. for $C_{20}H_{13}NO_2$: neut. equiv., 299. Found: 299.3.

3-(2-Carboxyphenyl)-6-phenylpyridine 2,4-dicarboxylic Acid.—Dobner[12] reports that α-phenyl-β-naphthoquinoline-γ-carboxylic acid could not be oxidized to a tricarboxylic acid, while the corresponding α-naphthoquinoline compound was oxidized to the tricarboxylic acid with alkaline permanganate at 50°. Immerheiser[13] reported the oxidation of β-naphthoquinoline-8-sulfonic acid by dissolving the potassium salt of the acid in water and using a neutral solution of potassium permanganate at ordinary temperatures. It was found that by this latter method α-phenyl-β-naphthoquinoline-γ-carboxylic acid could be oxidized very rapidly at ordinary temperatures to the corresponding tricarboxylic acid, and by using a large excess of permanganate until a permanent purple color remained in the reaction mixture, no unoxidized material was ob-

---

[12] Dobner and Kuntze, *Ann.*, 249, 129 (1889).

[13] Immerheiser, *Ber.*, 22, 405 (1889).

tained. No ketone acid was isolated corresponding to those reported by Immerheiser[11] and Dobner.[12]

A solution of 14.5 g. of α-phenyl-β-naphthoquinoline-γ-carboxylic acid in 600 cc. of warm water was treated with a concd. solution of potassium hydroxide until the resulting solution was just alkaline to phenolphthalein. The solution was cooled and placed in a 2-liter, 2-necked flask fitted with a mechanical stirrer and a dropping funnel. A concentrated aqueous solution of potassium permanganate (25 g., 20% excess) was added gradually with rapid stirring. The mixture warmed up considerably and the decolorization was instantaneous. The manganese dioxide was allowed to coagulate overnight, the clear solution decanted off, and the manganese dioxide extracted thoroughly with boiling water. The combined filtrates, on being made strongly acid to methyl orange with sulfuric acid, gave a white oily precipitate which did not crystallize on standing. This was extracted with ether and dried over anhydrous magnesium sulfate. On removal of the solvent, 16.5 g. of crystalline material was obtained, m. p. 123–129°. It was recrystallized by dissolving it in the minimum amount of hot ethyl acetate and adding ligroin to the point of precipitation. On cooling, 13 g. (74%) of small colorless crystals was obtained. Recrystallization from ethyl acetate gave a constant melting point of 202°.

Anal. Calcd. for $C_{20}H_{13}NO_6$: C, 66.1; H, 3.58; neut. equiv., 121. Found: C, 59.9; H, 3.32; neut. equiv., 122.7.

Alkaloid Salts of 3-(2-Carboxyphenyl)-6-phenylpyridine-2,4-dicarboxylic Acid

Mono-strychnine Salt.—The salt was made in methyl alcohol, and would not crystallize readily from any solvent. The crude material gave zero rotation with sodium light, and so did a small crystalline fraction obtained from a mixture of chloroform and ethyl acetate.

Di-strychnine Salt.—This separated in small, colorless prisms from benzene containing a little ethyl alcohol; m. p. about 238' with decomposition.

Anal. Calcd. for $C_{62}H_{57}O_{10}N_5$: neut. equiv., 344.3. Found: neut. equiv., 341.7.

A constant rotation was shown by all fractions; *rotation:* 0.2022 g. made up to 20 cc. with chloroform at 20° gave $\alpha_D = -0.173°$; $l = 2$; $[\alpha]_D -8.57"$.

The first fraction and the salt recovered from the mother liquors were both decomposed with ammonia and the ammonium salt isolated in the usual manner. Neither showed rotation.

Mono-brucine Salt.—This salt could not be recrystallized readily from any solvent. A few crystals were obtained from water, and they, as well as the crude material, gave zero rotation.

Di-brucine Salt.—The salt was crystallized from a small volume of absolute ethyl alcohol. It separated in small, regular prisms and all the fractions obtained showed no rotation. The salt had no definite melting point; it partially melted at 204° with decomposition, and was completely melted by 225°.

Anal. Calcd. for $C_{66}H_{65}O_{14}N_5$: neut. equiv., 383.6. Found: neut. equiv., 383.6.

Mono-cinchonine Salt.—The crude salt had a rotation of +75.46°.

Rotation. 0.2068 g. made up to 25 cc. with absolute methyl alcohol at 20° gave $\alpha_D = +1.249°$; $1 = 2$; $[\alpha]_D +75.46°$.

Four fractions were isolated by crystallization from water containing a little ethyl alcohol and none showed any change in rotation; the crystals melted and resolidified at 174–176°, and finally melted with further decomposition at 200–204°. The first fraction, after two recrystallizations rotated as follows: rotation, 0.2016 g. made up to 25 cc. with methyl alcohol at 20° gave $\alpha_D = -1.214°$; $l = 2$; $[\alpha]_D +75.26°$.

This fraction and the salt from the original mother liquor were decomposed and the ammonium salts isolated. Neither showed rotation.

Esters of 3-(2-Carboxyphenyl)-6-phenylpyridine-2,4-dicarboxylic Acid

It was thought that the ortho-substituted groups might be enlarged by esterification of the three acid groups with an alcohol of comparatively large size. If a crystalline tri-ester could be obtained, then resolution might be possible by forming salts of the pyridine nitrogen. Alternatively, a tri-ester of an optically active alcohol might separate into two diastereoisomers on recrystallization.

Tricarboxylic Acid Trichloride.—The acid was treated with an excess of thionyl chloride in a flask fitted with a ground-in water condenser until there was no further reaction. This required about two hours. The acid chloride was then washed out with ligroin and the latter decanted. The acid chloride was dried in a vacuum desiccator; m. p. 127–130°. It was found impossible to recrystallize it from any of the ordinary solvents.

Anal. Calcd. for $C_{20}H_{10}NO_3Cl_3$: Cl, 25.47. Found: Cl, 24.7.

Tri-*n*-butyl Ester of the Tricarboxylic Acid.—One mole of the acid trichloride was treated with 3 moles of *n*-butyl alcohol and warmed on the water-bath until the mass was homogeneous. The product was poured into water, made slightly alkaline with sodium carbonate and extracted with ether. The ethereal layer, after being washed with water and dried, gave a thick sirup which could not be crystallized.

Trimenthyl Ester of the Tricarboxylic Acid.—This was prepared in an analogous manner to the tributyl ester. The sirup so obtained could not be recrystallized.

Rotation. 0.2559 g. made up to 20 cc. with acetone at 20° gave $\alpha_D -0.97°$; $1 = 2$; $[\alpha]_D -38°$.

Summary

1. The possibilities of optical isomerism in the phenylpyridines as compared with the diphenyl series is discussed.
2. 10-Chloro-α-naphthoquinoline and 2-(2-carboxy-6-chlorophenyl)-pyridine-3-carboxylic acid were prepared. Salts of this acid with several alkaloids were made, but no separation into diastereoisomers was observed.
3. 3-(2-Carboxyphenyl)-6-phenylpyridine-2,4-dicarboxylic acid was prepared; its alkaloid salts appeared to exist in only one form.

SYNTHESIS OF NERVONIC ACID

BY J. B. HALE, W. H. LYCAN AND ROGER ADAMS

RECEIVED AUGUST 16, 1930 PUBLISHED NOVEMBER 5, 1930

Klenk[1] isolated from cattle and human brains a cerebroside which upon hydrolysis gave galactose, sphingosin and an unsaturated acid melting at 41°. He established its formula as $C_{24}H_{46}O_2$ and its exact constitution as tetracosene-13-oic acid (I) by oxidizing it to pelargonic acid and tridecamethylene dicarboxylic acid. Moreover, on catalytic reduction it yielded a saturated acid melting at 85° identical with lignoceric acid from beechwood tar and with n-tetracosanic acid synthesized from behenic acid. He also reported that by melting over nitric acid, a new isomeric acid melting at 61° was obtained. Nervonic acid was shown to be identical with selachaleic acid isolated from whale oil.[2]

$$CH_3(CH_2)_7—CH{=}CH—(CH_2)_{13}—COOH \qquad (I)$$

It is obvious that nervonic acid is probably the cis form of erucylacetic acid. By synthesis this has been shown to be the case. Ethyl erucate was reduced to erucyl alcohol (II) which was converted to the bromide and this in turn carried through a malonic ester synthesis to erucylacetic acid (III):

$$CH_3(CH_2)_7CH{=}CH(CH_2)_{11}—CH_2—OH \longrightarrow$$
$$\underset{\text{II}}{CH_3(CH_2)_7CH{=}CH(CH_2)_{11}—CH_2—CH(COOC_2H_5)_2} \longrightarrow$$
$$\underset{\text{III}}{CH_3(CH_2)_7CH{=}CH(CH_2)_{11}—CH_2CH_2COOH}$$

Several runs of product were made and only once was the yield essentially all acid melting at 39–40° (Klenk 41°). In general the product was a mixture of cis and trans isomers which could, however, be separated by crystallization, giving the low melting at 39–39.5° and the high melting at 61°. On account of the high boiling point of all the intermediates the tendency to isomerize to the stabler trans forms of the intermediates was probably increased.

The low-melting erucylacetic acid was readily converted to the high-melting form by melting over nitric acid and both forms were reduced to *n*-tetracosanoic acid identical with an authentic sample of this acid. Moreover, the mixed erucylacetic acids were esterified and reduced and gave a product melting at 55°, identical with that of ethyl tetracosanate made by a different method.

Experimental

Erucyl Alcohol.—To a mixture of 200 g. of methyl erucate (0.5 mole) and 2000 *cc.* of anhydrous n-butyl alcohol in a 5-liter flask equipped with a reflux condenser was added

---

[1] Klenk, Z. *Physiol. Chem.*, 145, 244 (1925); 157, 283 (1926); 166, 268 (1927); 166, 287 (1927).

[2] Tsujimoto and Mitsumaru, Z. *deut. Öl. Fett.-Ind.*, 46, 385 (1926); J. *Soc. Chem. Ind. Japan* (*Suppl.*), 30, 868 (1927); Hilditch and Houlbrook, Analyst, 53, 246 (1928).

slowly 50 g. of sodium in large chunks. It was necessary to control the reaction occasionally with an ice jacket. When nearly all the sodium had been consumed, 80 cc. of water was added to the flask and the contents refluxed vigorously for half an hour. After partial cooling, 600 cc. more water was added, whereupon two layers separated. The lower layer was siphoned off and discarded and the upper layer was washed twice with 500-cc. portions of 20% sodium chloride solution. An aqueous solution of 25 g. of calcium chloride was added and the mixture subjected to steam distillation until removal of the butyl alcohol was complete. After cooling, the solid material was removed from the flask by hand, pressed between filter paper to remove as much water as possible and dissolved in two Liters of toluene by gentle heating. On cooling with tap water, a slush of calcium erucate separated out and was removed by filtration. The filtrate was separated from the small quantity of water that had been carried along and then the toluene removed by distillation. The crude product thus obtained was purified by distillation under diminished pressure; b. p. 200–205° at 1 mm. The yields varied up to 55% of the theoretical amount. A small sample of this product after several recrystallizations from petroleum ether melted at 34–35°. Willstätter and Mayer,[3] who have prepared erucyl alcohol by a somewhat similar method, record the melting point of their product as 34.5".

Erucyl Bromide.—A solution of 129 g. of erucyl alcohol (0.4 mole) in 400 cc. of anhydrous toluene was cooled to −10° in a 2-liter flask equipped with a mechanical stirrer, thermometer and dropping funnel. To this solution 40 g. of phosphorus tribromide (0.44 mole) in 200 cc. of anhydrous toluene was added, with stirring, at such a rate that the temperature never rose above −5°. The mixture was then heated on a steam-bath for four hours and the toluene removed by distillation. The product was dissolved in 500 cc. of ether, washed with two 100-cc. portions of a solution containing 10% potassium hydroxide and 10% sodium chloride and finally with water. The ether solution was dried with anhydrous magnesium sulfate, the ether removed and the product purified by distillation under diminished pressure. The yields were from 50–60% of the theoretical amount of erucyl bromide; b. p. 203–207° at 1 mm.

Erucyl Malonic Ester.—To a solution containing 4 g. of sodium dissolved in 104 cc. of absolute alcohol was added 33 g. of diethyl malonate (6 2 moles). Then 68 g. of erucyl bromide (0.175 mole) was run in slowly and the mixture refluxed with stirring for thirty-six hours, after which time it was only faintly alkaline to moist litmus paper. The alcohol was distilled off and 400 cc. of water containing about 3 cc. of hydrochloric acid was added. The product appeared on the surface as a brown oil which was separated from the rest of the mixture. This was dried by distilling from it 50 cc. of benzene. The yield of crude product thus obtained was 95 g.

It was found that the ester boiled above 270° at 1-mm. pressure so a high vacuum distillation system was arranged, This apparatus consisted of a high vacuum pump in connection with a mercury vapor pump which in turn was connected through all glass seals to a distilling flask and receiver. A liquid-air trap between the mercury vapor pump and the distilling flask prevented any fouling of the vacuum-producing system with volatile organic material. The pressure was recorded by means of a McLeod gage sealed in between the mercury vapor pump and the liquid-air trap. Bumping was prevented by inserting a small piece of clay plate into the liquid in the distilling flask before sealing it off. All low-boiling compounds were removed before placing the erucyl malonic ester in this system by heating to 220° first on a water pump and finally at 1 mm.-pressure on an oil-pump as long as any volatile material distilled. In this manner the product was found to boil at 203–207° at 0.001 mm. (It should be recorded that the pressure measured in this system was that existing between the mercury vapor pump

---

[3] Willstatter and Mayer, *Ber.*, 41, 1478 (1928).

and the cold trap. The pressure on the ester itself may have been as high as 0.01 mm.) The yield of erucyl malonic ester was 62.5 g. (78%).

Anal. Subs., 0.2113: CO_2, 0.5400; H_2O, 0.1971. Calcd. for $C_{29}H_{54}O_4$: C, 74.68; H, 11.69. Found: C, 74.68; H, 11.99.

Erucylacetic Acid or Nervonic Acid.—The crude erucyl malonic ester obtained above was saponified without further purification.

A mixture of 95 g. of crude erucyl malonic ester, 56 g. of potassium hydroxide and 350 cc. of 60% alcohol was refluxed for forty-eight hours. The condenser was changed for downward distillation and after most of the alcohol had been removed, 500 cc. of water containing 60 g. of sulfuric acid was added. The resulting precipitate was extracted with several portions of ether, dried with anhydrous magnesium sulfate and filtered. After removal of the ether the product was heated at 175° for one hour to remove carbon dioxide, then distilled under diminished pressure. This distillation was carried out as rapidly as possible to minimize decomposition, and 40 g. of a product, b. p. 235–250° at 1 mm , was obtained. This was a mixture melting at 25–43° but was separated into three pure components by a scheme of fractional recrystallization as follows.

The entire 40 g. was dissolved in 300 cc. of absolute alcohol and cooled very slowly to −10°. The precipitate of fine white crystals was filtered and the mother liquor again cooled to −10°, when a second crop appeared which was filtered and added to the first. The combined product was then recrystallized twice more from 100-cc. portions of alcohol and a 10-g. yield of pure presumably *trans*-erucylacetic acid, m. p. 61°, was obtained. This corresponds to the trans form of nervonic acid, m. p. 61°, obtained by Klenk on melting the cis form over dilute nitric acid.

The original mother liquor was now evaporated on the steam-bath to about 76 cc. and cooled until a small precipitate of white crystals appeared, which were filtered without further cooling. A melting point indicated that this was a mixture of the cis and trans forms of the acid. On further cooling the mother liquor to −10° a generous crop of crystals separated which after drying melted at 36–38°. Two subsequent recrystallizations yielded 3 g. of a product, m. p. 39–39.5°; the melting point did not change after a third recrystallization. This corresponds to the nervonic acid of Klenk, m. p. 4041°.

Anal. Subs., 0.1668: CO_2, 0.4795; H_2O, 0.1886. Calcd. for $C_{24}H_{46}O_2$: C, 78.60; H, 12.64. Found: C, 78.39; H, 1265.

Further working of the mother liquor yielded only an oil which, although unidentified, was probably ethyl erucyl ether formed during the malonic ester condensation.

Conversion of the Cis Form of Erucylacetic Acid to the *Trans* Form.—A small sample of the cis nervonic acid, m. p. 39–39.5°, was melted over 15 cc. of dilute nitric acid, to which a pinch of sodium nitrite had been added. The product was separated by cooling and after two recrystallizations from absolute alcohol melted at 62–63'. A sample of this mixed with a sample of the trans form obtained before melted at 61–62°.

Anal. Calcd. for $C_{24}H_{46}O_2$: C, 78.60; H, 12.64. Found: C, 78.35; H, 12.59.

Reduction of Cis and *Trans* Forms of Nervonic Acid to n–Tetracosanoic Acid.—A sample of 0 2 g. of cis nervonic acid, m. p. 39–39.5°, was dissolved in 25 cc. of absolute alcohol, and the solution shaken with hydrogen under a pressure of 3 atm for one hour, in the presence of 0.1 g. of platinum oxide catalyst. The reduced acid separated as fine white crystals as the reduction proceeded. The product thus obtained after removal of the platinum was recrystallized three times from absolute alcohol, and three times from acetone. It then melted at 83–84°.

A sample of trans nervonic acid was reduced and the product purified according to the same procedure. This product also melted 83–84°, and a mixed melting point of the two acids showed no depression.

Anal. Calcd. for $C_{24}H_{48}O_2$: C, 78.17; H, 13.13. Found: C, 78.54; H, 13.29.

Various values have been recorded in the literature for the melting point of la-tetracosanoic acid. Levcne and Taylor,* who have synthetically prepared all the normal acids of this series, report 85–86° as the melting point of this member. Meyer, Brod and Soyka[5] obtained 85.5–86°, Brigl[6] 85°, and Levene, West, Allen and von der Scheer[7] 87.5–88°. Shriner, Nabenhauer and Anderson[8] obtained n-tetracosanoic acid from corn wax, and report as its melting point 85–86'. The last authors made mixed melting-point determinations with a sample of the same acid prepared by Taylor and Levene.[4] The acid prepared in this investigation melted at 83–84° and a mixed melting-point determination with a sample of Shriner's naturally occurring acid was made. It was found under the melting point conditions used that the melting point of the *n*-tetracosanoic acid, from reduction of erucylacetic acid, the natural n-tetracosanoic acid of Shrincr, Nabenhauer and Anderson and a mixture of the two was exactly the same, 83–84°. Recrystallization from various solvents failed to alter the melting point of either acid.

Ethyl Erucylacetate.—The ethyl ester of erucylacetic acid was prepared by refluxing 110 g. of the acid (0.3 mole) (which was presumably a mixture of the cis and trans isomers) with 1 liter of absolute alcohol to which 2 cc. of concentrated sulfuric acid had been added, overnight. The product boiled at 233–234° at 1 mm., and the yield was 117 g.

Anal. Subs., 0.1553: CO_2, 0.4489; H_2O, 0.1774. Calcd. for $C_{26}H_{50}O_2$: C, 79.11; H, 12.77. Found: C, 78.83; H, 12.79.

Ethyl *n*-Tetracosanoate.—A solution of 5 g. of ethyl erucylacetate in 100 cc of 95% alcohol was shaken with hydrogen under 2.5–3 atmospheres' pressure, in the presence of 0.2 g. of platinum oxide catalyst. The reduction required only a few minutes and the product crystallized out as it was formed. The pressure was released and the alcohol heated to boiling to take the ester back into solution. The hot solution was filtered free from platinum and cooled again. The white plates which crystallized out were filtered and recrystallized three times from ethyl alcohol and four times from acetone; m. p. 55–56' (corr.). Lcvene and Taylor[4] record the melting point of the same compound prepared by esterifying the ester as 55.5–56.5°.

Summary

Erucylacetic acid has been prepared from erucyl alcohol through the bromide and malonic ester synthesis and has been shown to be identical. with nervonic acid obtained from hydrolysis of the cerebroside isolated from human brains.

THE PYROLYSIS OF ALLENE AND METHYLACETYLENE[1]

BY RICHARD N. MEINERT[2] AND CHARLES D. HURD[3]

RECEIVED AUGUST 21, 1930 PUBLISHED NOVEMBER 5, 1930

Prior to this work, no record exists concerning the behavior of methylacetylene, $CH_3—C≡CH$, at high temperatures. Except for Lebedev's work, the same may be said for allene, $CH_2=C=CH_2$. Lebedev[4] heated allene at 140° under pressure for several days and obtained a series of polymers. He also subjected trimethylallene, sym- and *unsym*-dimethylallene to the same conditions of warmth, pressure and time and found that they also gave rise to polymers.

General Results with Allene

The present experiments were made over a temperature range of 400 to 600° and the hot contact time was made a matter of seconds rather than a matter of hours and days as in Lebedev's experiments. Here, also, it was found that polymerization was the predominant reaction of allene. At a temperature of 500° and with a contact time of eighty-six seconds, four-fifths of the allene entering the reaction tube was consumed and 90% of the product appeared as liquids. These liquid products were distilled repeatedly so as to obtain pure fractions. The properties of the lower-boiling fractions were found to be very nearly identical in physical constants and general appearance with two of Lebedev's polymers, namely, the dimer and the alpha tetramer. The higher-boiling fractions differed from Lebedev's polymers but were high-boiling tarry substances. Lebedev stated that several of the polymers, in particular the trimer and the beta tetramer, were unstable at elevated temperatures, so it is not surprising that they were not encountered in the present experiments.

A temperature of 500" seems to be the best for the formation of these liquids by the flow method. At lower temperatures, the reaction proceeds too slowly, while at higher temperatures less polymeric liquids and more gaseous products are formed although the percentage of allene pyrolyzed is greater. Thus, at 600°, with a hot contact time of fifty seconds, only 43%

---

[1] This paper contains results obtained in an investigation on "The Thermal Decomposition of Pure Hydrocarbons and Related Compounds," listed as Project No. 18 of American Petroleum Institute Research. Financial assistance in this work has been received from a research fund of the American Petroleum Institute donated by the Universal Oil Products Company. This fund is being administered by the Institute with the cooperation of the Central Petroleum Committee of the National Research Council.

[4] Lebedev, J. *Russ. Phys.-Chem. Soc.*, *45*, **1249–1388 (1913); J.** *Chem. Soc.* (abst.). **104, 1285 (1913).**

of the non-recoverable allene appeared as liquids. Concurrently, each 10 cc. (gaseous) of this allene gave rise to about four cc. of gas. At 500°, with a hot contact time of eighty-six seconds, nine-tenths of the non-recoverable allene was changed into liquids and only 1 cc. of gas was formed from each 10 cc. of allene. Carbon and tar formation played a major role in the 600° experiments, whereas at 500° almost no tar or carbon was formed.

The gases formed in the pyrolysis of allene were methane, hydrogen, ethane, ethylene and small amounts of acetylenes. Methane represented the larger part at 500°, but at 600° the volumes of methane and hydrogen were almost equal. In all cases, however, the gases represented but a small part of the reaction products.

Mechanism of the Pyrolysis.—Earlier studies on the behavior of butane, isobutane[5] and isobutylene[6] at high temperatures furnish a basis with which to predict something of the mechanism of allene pyrolysis. The butanes, having no double bonds in their structure, change exclusively into compounds of simpler structure, evidently by complete rupture of C–C or C–H bonds. Isobutylene, with one double bond and one single bond, gives rise not only to simpler compounds but also to more complex ones. The simpler compounds appear to be formed by single bond C–C scission, whereas the complex liquid hydrocarbons are formed because of double bond C=C activation which is followed by a polymerization process. Allene presents no opportunity to break into simpler compounds by scission of single bonds since only double bonds are present in the allene chain. Therefore, it would be logical to assume that only complex liquid polymerization products should be formed on pyrolysis. As has been shown, this is indeed the major, and nearly the exclusive, primary effect. It may be symbolized as follows

$$x\ CH_2{=}C{=}CH_2 \longrightarrow x\ [\underset{|}{C}H_2{-}\underset{|}{C}H{=}CH_2] \longrightarrow (C_3H_4)_x$$

Probably, as Lebedev suggested, these polymers are cyclobutane derivatives, the dimer being dimethenylcyclobutane. This dimer, with two double bonds still in its structure, may undergo further polymerization reactions.

General Results with Methylacetylene.—Methylacetylene which contained about 5% of allene as an impurity was prepared by the action of alcoholic potassium hydroxide on propylene bromide. This was used in the first experiments. As in the case of allene, liquids were by far the most abundant product of the pyrolytic reaction. With a hot contact time of one hundred seconds at 500° the liquids accounted for 78% of the methylacetylene pyrolyzed, while at 575° and forty-eight seconds the percentage

---

[5] Hurd and Spence, THIS JOURNAL, 51, 3353 (1929).

[6] Hurd and Spence, *ibid.*, 51, 3501 (1929).

of liquids rose to 88. At 650° there was a great increase in the amount of ethylene, hydrogen and methane formed, while the yield of liquids dropped to 61%. This behavior paralleled that of allene under similar conditions. Furthermore, when these liquid products were fractionally distilled as carefully as the small amounts available would permit, the fractions were found to be very nearly identical with the lower-boiling allene polymers. There was no trace of the formation of any aromatic hydrocarbons.

When the off-gas which resulted from the pyrolysis of methylacetylene was analyzed, there was always a considerable portion which was gradually absorbed in 82.4% sulfuric acid. This portion might represent either allene or propylene. Aside from the fact that some allene was a contaminant in the original methylacetylene, the reasons for thinking that it was allene are as follows: (1) because of its slow rate of solution; (2) because propylene could not have been formed except by hydrogenation, an improbability in view of the small concentration of hydrogen in the off-gas; (3) because the liquid products were so very similar to those obtained from pure allene. To settle the point definitely, however, it was deaded to pyrolyze an allene-free specimen of methylacetylene and to identify the off-gas in question as bromides. Propylene would give its dibromide, whereas allene would give rise to its di- and tetrabromides, the latter of which would be recognized by its lachrymatory properties, its high boiling point and its comparatively high melting point.

Accordingly, some pure methylacetylene was prepared by the interaction of sodium acetylide and either methyl iodide or dimethyl sulfate. The use of dimethyl sulfate, which is a new method, is preferable. This methylacetylene was pyrolyzed at 500°. The off-gas was carefully collected and all acetylenes were extracted from it by alkaline potassium iodomercurate reagent. The gas which remained was passed several times through a solution of bromine in carbon tetrachloride so as to form bromides of all unsaturated hydrocarbons still remaining. On fractionation these bromides were found to consist principally of allene dibromide and allene tetrabromide. This proves that allene was formed during the pyrolysis of methylacetylene. The similarity of the liquids obtained from methylacetylene to those obtained from allene suggests that these liquids are formed from allene, rather than directly from methylacetylene.

Theoretical Considerations

Acetylene, when heated, undergoes pyrolysis to a large extent into benzene[1] and other aromatic hydrocarbons. Analogously, one might assume that methylacetylene should change into mesitylene and other aromatics. Such, however, is not the case. The fundamental change in methylacetylene is one of isomerism into allene, a change which is predictable on the

---

[1] Pease, THIS JOURNAL, 51, 3470 (1929).

basis of the "three carbon system."[8] If E represents any such element as C, N or O, the expression: $H—E—E{=}E' \rightleftarrows E{=}E—E'—H$ represents a general formulation of this type of rearrangement. Familiar cases of this type are keto–enol, nitroso to oxime, and the three-carbon system.

With a triple bond in the chain rather than a double bond, similar mobility of hydrogen exists: $H—E—E{\equiv}E \rightleftarrows E{=}E{=}E—H$. Because of its similarity to the keto–enol isomerism, the name "keteno-ynol" is suggested for this type of change. Some well-known illustrative cases are HOCN and HNCO, $C_6H_5CH_2—CN$ and $C_6H_5CH{=}C{=}NH$, $H_2N—CN$ and $HN{=}C{=}NH$, ketene and hydroxyacetylene. Methylacetylene and allene also fit into this scheme: $H_3C—C{\equiv}CH \rightleftarrows H_2C{=}C{=}CH_2$. Allene may be converted into its isomer by the action of sodium. The reverse reaction is the pyrolysis of methylacetylene. It is interesting to point out that all the "keteno" structures mentioned above are the forms into which the "ynol" isomers change at high temperatures. No doubt this is associated with the fact that the former represent more symmetrical structures.

Experimental Part

Apparatus.—The flow method was used. The gaseous hydrocarbon was stored in a gasometer of 57-liter capacity, in an 8-liter bottle, or in a closed steel cylinder under pressure. The gas was passed from its container through a wet test meter, thence through two drying towers, a flowmeter of the capillary type, a calcium chloride tube, and then it was conducted into the reaction tube. The tube was of pyrex glass 2.5 cm. in diameter and was heated over 76 cm. of its length by an electric tube furnace. The volume of the tube within the furnace limits, after deduction of the volume of the thermocouple sheath, was 290 cc. The furnace was supported in a vertical position so that any liquids formed in the reaction could be removed from the tube by gravity. The effluent gases were passed through a trap at 0° which was placed directly beneath the furnace. This trap served to collect the liquid products.

The temperature of the furnace was measured and automatically controlled by a Leeds–Northrup potentiometer type recorder-controller. A chromel-alumel thermocouple was used, and it was protected by a thin pyrex sheath which was placed directly within the reaction tube.

The gases were analyzed in the manner previously outlined by Hurd and Spence.[9]

Preparation of Allene and Methylacetylene.—Allene was prepared from dibromo-2,3-propene-1, as outlined by Hurd, Meinert and Spence.[10] The gas was washed and stored in a gasometer over saturated sodium chloride solution.

Methylacetylene, contaminated with about 5% of allene, was prepared from propylene bromide and hot alcoholic potassium hydroxide solution. This preparation, and also the preparation of pure methylacetylene from methyl iodide and sodium acetylide, is given in detail in the same reference.[11] The methylacetylene, after purification, was liquefied and stored in a small steel gas cylinder.

Methylacetylene from Dimethyl Sulfate.—A one-liter, 3-necked flask was fitted with a mercury-sealed stirrer, an exit tube, and a wide-mouthed inlet tube which reached nearly to the bottom of the flask. After replacing air in the flask with dry hydrogen, 36 g. of sodium was inserted, the flask cooled to −60° with a bath of acetone and solid carbon dioxide, and then dry ammonia was condensed in the flask. The stirrer was started as soon as a little ammonia had condensed. In all, about 500 cc. of liquid ammonia was required. When the sodium had dissolved, the stream of ammonia was detached and a current of acetylene was passed into the well-stirred mixture. When all of the sodium-blue color had disappeared due to the formation of colorless sodium acetylide, the current of acetylene was stopped, and a dropping funnel was inserted to replace the stirrer. The top of the funnel was connected with a tube to the reaction flask, the tube serving as a pressure equalizer.

The exit tube was connected to a gas washing train consisting of a Wolff bottle with water, another with 10% sulfuric acid, and a calcium chloride drying tower. Bunsen valves were inserted between the two wash bottles and between the reaction flask and the first wash bottle. From the drying tower a connection led to a spiral glass condenser with receiver attached, which was immersed in a Dewar flask and maintained at −78°. The methylacetylene condensed therein.

Two hundred grams of dimethyl sulfate was added very slowly into the reaction flask from the dropping funnel, keeping the Bask at −60°. As each drop fell there was a rush of gas from the exit tube. This necessitated careful control during the addition of the reagent. Most of the methylacetylene had passed over into the condenser by the time the last of the dimethyl sulfate was added. Then the reaction flask was allowed to warm up to drive over the remainder of the product. The methylacetylene was distilled from a large test-tube, using the Davis spiral, vacuum-jacketed column. The yield and the ease of manipulation were about the same with dimethyl sulfate as with methyl iodide. The relative cheapness of the former, however, is greatly in its favor.

The boiling point of the methylacetylene was found[12] to be −23". Since this differs from the literature value of −27.5°, the accurate vapor pressure of methylacetylene has been studied in considerable detail by Professor G. B. Heisig of the University of Minnesota. This will be published separately.

Products Obtained from the Pyrolysis of Allene.—The data for the pyrolysis of allene are given in Table I.

These data show clearly that when allene was pyrolyzed, most of it was converted into liquids. As would be expected, the conversion was more

nearly complete when the gas was heated for a longer time and when the temperature was between 500 and 600°. A comparison of Runs 2, 3, 1 and 4, all of which had similar contact times, shows the increasing percentage of decomposition of allene with the increase in temperature. A comparison of Runs 1 and 4 shows that at 600° about five times the volume of gases was formed as was noticed at 500°, while the percentage of liquids was considerably less. It should be stated that the deposit of carbon and viscous tarry matter in the tube was quite considerable at 600° and almost negligible at 500". Comparison of Runs 1 and 5 shows that if the allene was heated for a longer time, the amount of gaseous products increased. This suggests that a large part of the gases is formed by the decomposition of the allene polymers if the reaction is carried out at 600°, or for too long a time at 500°.

The Liquid Products from **Allene.**—The 15.8 g. of liquids formed in Run 5 was fractionally distilled, taking care to obtain cuts as nearly pure as possible. The refractive index of each fraction was determined. In Table II the physical properties of these liquids are compared with similar data as given by Lebedev.[4] The properties in question are boiling point, odor, refractive index and general appearance.

A comparison of Fraction I with Lebedev's dimer and Fractions II and III with his α-tetramer shows that they possess similar properties. Lebe-

dev stated that only the dimer and the α-tetramer were stable at elevated temperatures. Therefore, in our polymerization at 500°, one would not expect to find much of the other polymers as they tend to form tarry material. The first four fractions all gave a test for unsaturation with bromine.

Pyrolysis of Methylacetylene.—The data for the pyrolysis of methylacetylene which contained 5% of allene as impurity are given in Table III.

[a] "Allene" represents the gases dissolved in 82.5% sulfuric acid; it may contain propylene, but later work has shown that allene is the chief if not the exclusive product.

In Runs 1 and 3 the gaseous products formed were of such a small volume that a complete analysis was not made. In making the calculations it was assumed that the small amount of allene present in the entering gas was polymerized for the most part, inasmuch as the work on allene showed this to be the case at temperatures above 500°. In addition to the gaseous and liquid products, there was a considerable amount of carbon and some very viscid tarry material which was deposited on the walls of the reaction tube. At the higher temperatures, this deposit became so great as to nearly clog the exit of the reaction tube.

Liquid Products from Methylacetylene.—The comparatively small volume of liquids which were obtained from methylacetylene made it impossible to carry the fractionation as far as was done in the case of the allene polymers. However, they were fractionated and the boiling points and refractive indices taken. These data are listed in Table IV.

TABLE IV

PROPERTIES OF THE LIQUID PRODUCTS FROM METHYLACETYLENE

Run number	2			5

The properties of the lower-boiling fractions greatly resembled the properties of the low-boiling allene polymers. The liquid fractions were distinctly not aromatic in type. They all decolorized bromine in carbon tetrachloride. Nor did they form any nitro derivatives when they were treated with a nitrating mixture of nitric and sulfuric acids. There was no evidence of any pure compound in quantity since the boiling point ascended steadily during the distillation. An examination of the boiling point and refractive index data shows that they lie outside of the range of the aromatic compounds. Considering the evident impurity of the methylacetylene liquid fractions, it is apparent that they lie within the range of the corresponding data from allene liquid fractions (compare Tables II and IV). This, together with the very strong resemblance which they have to the allene liquids in odor and general appearance, indicates that these liquids also consisted mostly of polymers of the same nature as those obtained from allene. The presence of considerable amounts of allene in the off gas shows that these liquids were probably formed from allene, which in turn was formed by an isomerization of the methylacetylene.

The Pyrolysis of Pure Methylacetylene.—Table V gives the data for this experiment, and includes the analysis of the entering gas and the exit gases.

Since 82.4% sulfuric acid dissolves both allene and propylene, it was decided to remove the acetylenes from the gas and to convert the remaining unsaturated hydrocarbons into their bromide derivatives. Differentiation between olefin dibromides and diene tetrabromides would then be fairly simple.

The off gas from the run (Table V) was passed from its storage bottle into a bottle filled with potassium iodomercurate solution in order to remove all of the unchanged methylacetylene. The bottle was shaken from time to time and finally allowed to stand overnight. The volume became constant, indicating complete removal of all acetylenes. The original volume of gas was 3300 cc., and the volume after removal of acetylenes was 1700 cc. The volume of acetylenes in the original gas, based on the gas analysis was 1518 cc., so it was certain that all acetylenes were taken out. The residual gas was then dried and passed into a solution of bromine'in carbon tetrachloride. The unbrominated gas was collected and passed again through the bromine solution, and the apparatus was flushed out with a liter of air.

The bromides in the brominating bottle were then worked up. Their volume was 2 cc.; refractive index 1.533; initial boiling point, 140°. The liquid did not solidify at −75°. This 2 cc. of bromides was separated into two very small fractions by distillation at 9 mm. The boiling points could not be determined accurately due to the small amount of material distilled, but that of the first fraction was between 60 and 90°. Its refractive index was 1.523 and it did not solidify at −75°. The higher-boiling fraction which remained in the distilling flask had a refractive index of 1.582. It solidified at −20° in an ice–salt mixture. It began to melt at −5° and melted over a considerable range, indicating that it was not pure. This fraction of the bromides had an odor like that of allene tetrabromide and it had the powerful lachrymatory properties which are characteristic of allene tetrabromide.

The results provide satisfactory evidence that the portion of unsaturated hydrocarbons which were removed in the 82.4% sulfuric acid during the gas analysis consisted of allene. The bromides were evidently a mixture of allene dibromide and allene tetrabromide. Previous experience in brominating allene has shown that there is always some allene dibromide formed which is difficult to convert to the tetrabromide. The fact that highly purified allene tetrabromide solidifies in a salt–ice mixture[13] and melts at 10.7°, while the impure bromide obtained in this experiment also solidified and melted in the range of −5 to 0°, is a satisfactory proof of the identity of the latter. That the refractive index, 1.582, is lower than that of pure allene tetrabromide, 1.6206, is not surprising in view of the evident impurity of the former. Some of the dibromide undoubtedly remained in the tetrabromide residue. To obtain allene tetrabromide of high purity, it has been shown[13] that fairly large quantities, enabling several crystallizations, are essential.

Summary

In the pyrolysis of allene, it has been shown that the predominant reaction is a polymerization to form a dimer, a tetramer and higher polymers. There is no evidence of the formation of aromatic hydrocarbons.

The pyrolysis of methylacetylene has also been investigated. Evidence is offered to show that it first isomerizes to allene, which then polymerizes in its customary manner. The relationship of methylacetylene to the "three-carbon system" has been developed, and the classification of allene and methylacetylene as of the keteno-ynol type has been suggested.

A method for the preparation of methylacetylene from dimethyl sulfate and sodium acetylide has been given.

THE PREPARATION OF 1-NAPHTHOIC NITRILE FROM 1-NAPHTHYLAMINE

BY JOHN A. MCRAE

RECEIVED AUGUST 22, 1930 PUBLISHED NOVEMBER 5, 1930

In summing up their results on the preparation of 1-naphthoic nitrile by various methods, Whitmore and Fox[1] stated recently that "treatment of 1-naphthylamine by the Sandmeyer reaction gave none of the nitrile." This statement is surprising in itself and is contrary to previous authors to whose work Whitmore and Fox make no reference. Thus, Bamberger and Philp[2] reported that the Sandmeyer reaction is a good method for the preparation of 1-naphthoic nitrile and Richter[3] commented favorably on the same method. Clarke and Read,[4] using their modification of the usual Sandmeyer process, obtained a yield of 55% of 1-naphthoic nitrile. It was thought of interest to test the validity of Whitmore and Fox's results and accordingly a study of the preparation of 1-naphthoic nitrile has been carried out, principally as a student's exercise, in the course of which various methods used in well-known laboratory textbooks (Gattermann, Cohen, Henle, Fisher) for preparing *p*-toluic nitrile from *p*-toluidine have been employed as a basis, as well as the important improvements described by Clarke and Read and the interesting process of Korczynski[5] in which potassium nickel cyanide is substituted for potassium cuprocyanide but which had not been applied hitherto to diazotized 1-naphthylamine.

In agreement with earlier work no difficulty has been encountered in obtaining 1-naphthoic nitrile from 1-naphthylamine by the Sandmeyer reaction, the yields varying from 25 to 35%. We were unable to increase the yield beyond 35% but on the other hand we did not discover conditions under which no naphthoic nitrile was produced. The Korczynski method did not give sensibly greater yields than the ordinary Sandmeyer process but by adding the acid diazo solution to potassium nickel cyanide containing sufficient alkali to neutralize the free acid of the diazo solution, the nitrile has been produced repeatedly in yields of 58 to 65%.

My thanks are due to Messrs. F. S. Wilder and J. W. McCutcheon for their assistance in carrying out most of the experimental work.

Experimental

Preparation of 1-Naphthoic Nitrile from 1-Naphthylamine

(a) Using Potassium Nickel Cyanide.—1-Naphthylamine was diazotized by dis-

solving the amine (28.6 g. = 1/5 mole) in 600 cc. of hot water and 20 cc. of concentrated hydrochloric acid. With vigorous mechanical stirring the solution was cooled to 0° and maintained at that temperature during the addition first of 50 cc. of concentrated hydrochloric acid and then of a solution of 14.4 g. of sodium nitrite in 60 cc. of water. Any slight excess of nitrous acid was destroyed by the addition of urea.

The cyanide solution was made by adding a solution of 72.7 g. of a good grade of nickel nitrate in 100 cc. of water to a solution (250 cc.) containing 81.4 *g.* of potassium cyanide and 20 g. of sodium hydroxide. The cyanide solution, contained in a 5-liter flask, was mixed with 150 cc. of benzene and some crushed ice and vigorously stirred while the diazo solution was added during the course of one-half hour. The stirring was continued for another half hour while the temperature was maintained throughout at 0–5° and for a further two hours while the mixture was allowed to come to room temperature. It was then heated to 50°, cooled and the aqueous layer removed. The residual benzene solution was steam distilled until 5 liters was collected. The benzene which came off was used to collect the nitrile from the distillate. The benzene extract was washed with caustic soda, dried and after removal of the benzene the residue was fractionated under reduced pressure. Redistillation of the first fraction obtained boiling at 120–200° (20 mm.) gave 17.8 g. of 1-naphthoic nitrile, b. p. 165–170° (20 mm.), which quickly solidified.

The purity of the nitrile was confirmed by hydrolysis to 1-naphthoic acid, the yield being almost quantitative. No difficulty was experienced in obtaining pure 1-naphthoic acid of m. p. 161° by distillation of the crude acid under reduced pressure, b. p. 229–231° (50 mm.), and recrystallization of the distilled acid from toluene. This obviated the more lengthy purification of the acid by conversion into the ethyl ester followed by purification and hydrolysis of the ester which Whitmore and Fox found necessary.

(b) Using Potassium Cuprocyanide.—1-Naphthylamine was diazotized as described above in preference to diazotization in more concentrated solution corresponding with the laboratory directions given for *p*-toluidine by Fisher[6] and with that and the further exception that after steam distillation the nitrile was isolated as described above, the diazotized amine was converted into the nitrile according to Fisher's directions for p-toluic nitrile. Eight experiments using each time 28.6 g of amine gave an average yield of 27%. Steam distillation under reduced pressure of the crude product recommended by Clarke and Read[4] did not increase the yield appreciably. The addition of sodium carbonate to the diazotized naphthylamine seemed to result always in considerable decomposition and to avoid this the acidic diazo solution in several experiments was poured into potassium cuprocyanide solution containing alkali sufficient to neutralize the free acid of the diazo solution as used above with potassium nickel cyanide and as described by Henle[7] for p-toluic nitrile but without more favorable results. Increasing the ratio of potassium cyanide to correspond with $K_3Cu(CN)_4$ gave no better results. To avoid the lengthy steam distillation, extraction of the reaction mixture with ether–benzene was tried but the separation of the extracting liquid is poor and tedious. However, a yield of 26% of the nitrile was obtained from the extract. Addition of the acidic diazo solution to cuprocyanide solution made from potassium cyanide and copper sulfate as described in many laboratory manuals gave similar results.

1-Naphthoic acid may be obtained directly from the crude reaction mixture. The tar which separates in the absence of benzene or after the benzene is removed hardens on cooling and may be collected easily. The tarry residue from treatment of 28.6 g. of 1-naphthylamine was heated for seven hours under a reflux with 100 cc. each of sulfuric

acid, acetic acid and water—the hydrolyzing mixture used by Whitmore and Fox. The mixture was poured into water and from the solid which separated the 1-naphthoic acid was extracted with dilute ammonia. After precipitation from its ammoniacal solution, the crude naphthoic acid was purified as described above. The yields obtained were from *20–25%* of the calculated.

Summary

1. Contrary to a recent statement, 1-naphthoic nitrile is produced readily from 1-naphthylamine by the Sandmeyer reaction.
2. Very good yields of this nitrile can be obtained by a slight modification of the Korczynski method.

THE CHEMICAL BEHAVIOR OF SOME BENZENOID HYDROCARBONS IN THE TESLA DISCHARGE

BY JAMES BLISS AUSTIN[1] AND IAN ARMSTRONG BLACK[2]

RECEIVED AUGUST 22, 1930 PUBLISHED NOVEMBER 5, 1930

Several years ago, during the course of a study of the Tesla luminescence spectra of benzene and some of its simple derivatives, some very interesting facts came to light in connection with the decomposition and behavior of these substances under the action of the Tesla discharge. Aside from the recent note of Harkins[3] and Gans on the decomposition of benzene, there appears to be no reliable literature on the subject of the chemical behavior of organic vapors in the electrical discharge; hence it has been thought worth while to record our experiences. It should perhaps be mentioned here that in our preliminary work several methods of excitation were tried. The results with the electrodeless discharge, later discarded because it failed to produce the desired spectra, have already been published[4] and are in agreement with the findings of Harkins and Gans.

The method finally selected was the Tesla discharge and is described in our previous paper.[5] However, it soon became evident that even with this discharge chemical changes were occurring in the vapors. This was indicated primarily by the formation on the discharge tube of shellac-like coatings similar to those formed in the electrodeless discharge, although no trace of the hydrogen lines, Swan bands, or ionized carbon lines appeared in the spectra obtained by this method. Moreover, further investigation

revealed that crystalline solids were being condensed along with the unchanged vapor in the liquid-air trap. In some cases these crystallized by themselves in rings high up on the walls of the trap, in others they were found dissolved in the condensed liquid; in every case, however, the quantity obtained was very small.

For general convenience in description these products will be divided into two classes, those remaining in the discharge tube and those condensed by the liquid air.

Products Remaining in the Discharge Tube.—With every material investigated save one, cyclohexane, the walls of the discharge tube became coated with a thin film of a shellac-like substance ranging in color from a deep reddish-brown and black to buff. These coatings, which seemed to adhere to the walls when fresh, showed a tendency to crack and peel off on standing.

The conditions which appeared to produce the largest yields of these materials were slightly elevated temperatures (40–50°), comparatively high pressures (0.1 mm. to 1 mm.) and large electrode surface. Since the tube tended to heat up while in operation, no external heating appliances were employed. In order to take advantage of the other factors, a new tube was designed increasing the electrode surface (Fig. 1). This tube was essentially a glass Dewar flask with the inner space between the walls, ordinarily the vacuum space, serving as the reaction chamber. Two external electrodes were used, one formed by silvering the external surface of the inner wall and the other by wrapping lead foil around the outside wall. Unfortunately this design made it necessary to cut off the tube in order to remove the coatings on the inner wall, but with this tube greatly increased yields were obtained so that enough material for study was easily made.

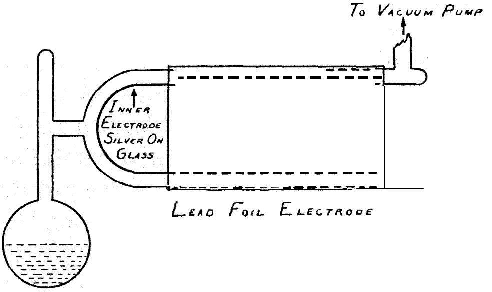

Fig. 1.—Apparatus for production of decomposition products.

An attempt to determine the properties of these materials showed them to be extraordinarily inert. They have no melting point but burn slowly with a luminous flame when heated to a sufficiently high temperature. They are insoluble in alcohol, acetone, ether, water, benzene, toluene, xylene, turpentine and ordinary acids and alkalies. Their densities as estimated by floating them in a series of alcohol–water mixtures are as follows: benzene product 0.94; toluene product 0.95; p-xylene 0.97. They appeared to have all the characteristics of highly polymerized or condensed aromatic molecules and seemed to have a number of properties in common with the products obtained by bombarding acetylene with high-speed cathode rays.[6]

Unlike the similar compounds described by Harkins and Gans they do not have the composition (CH), but appear to contain some oxygen. The C and H analyses of several of them as determined by Professor J. B. Niederl are given in Table I.

TABLE I

ANALYSES

	C, %	H, %
Benzene product	73.38	4.77
Toluene product	79.16	5.90
p-Xylene product	77.14	6.52

These are average values for five determinations, the greatest deviation from the mean being 0.30%.

It will be seen that there remains to be accounted for from 15 to 20% of the weight of these compounds. Qualitative tests for nitrogen made with a method which under ordinary conditions detects nitrogen in a sample containing 0.1%. NH_4Cl gave completely negative results; hence it has been assumed that the remaining portion is oxygen, which is the only other element likely to be present under the circumstances.

The difference between our powders and those of Harkins and Gans is, however, easily accounted for since they took great precautions to dry their vapors and in our work at least a trace of water vapor was undoubtedly present. Indeed on making a careful study of our plates we find a faint band at about λ3064, which is the position of the strongest of the so-called "water vapor" bands. Furthermore, Urey and Lavin[7] have shown that an activated oxygen carrier, probably the OH molecule, will cause the formation of acetaldehyde in ethane under the action of an electrical discharge.

It would seem probable, therefore, that under our conditions the hydrocarbon is caused to react with the free OH radicals or ions in the vapor. The simplest empirical formula corresponding to the analysis of the powder from benzene is $(C_9H_7O_2)_x$. This formula must be regarded as an approximation to a type of compound which occurs in various polymerized forms since the product obtained is probably a complex of many related substances.

It will be shown in the section on crystalline products that diphenyl is formed from benzene vapor by the discharge. There is no reason to suppose that this coupling action ceases when two rings have been joined so that we should expect to find compounds composed of a great number of benzene rings coupled in various ways. If in addition we consider the presence of the water vapor ions, it is not difficult to imagine the formation

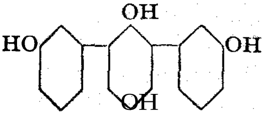
---

[6] McLennan, Perrin and Ireton, *Proc. Roy. Soc.* (London), 125A, 246 (1929).

[7] Urey and Lavin, THIS JOURNAL, 51, 3290 (1929).

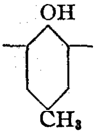
of phenolic compounds which would possess an even greater tendency to condense because of their phenolic character. This change is analogous to that observed in ethane by Urey and Lavin except that phenols are formed instead of aldehydes; this is not surprising since aldehyde formation in this case would involve the rupture of the ring.

Assuming that this coupling and phenol formation does take place, we are led to the possibility of some such compound as the following, whose formula would be $(C_9H_7O_2)_2$ (A). It should be emphasized here that we are suggesting not that this is the actual formula of the powder but that it may represent a unit in a larger complex.



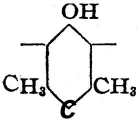
A

A study of the toluene and xylene powders lends some support to these views. The analysis of the product obtained from the former leads to the formula $(C_{21}H_{19}O_3)_x$. This may be explained by assuming a large molecule built up of (B) units, which would have the same general character as the molecule formulated for the benzene product.



B

The analysis of the xylene derivative leads to the approximate empirical formula $(C_{19}H_{19}O_3)_x$. This may be accounted for if we regard the molecular unit as (C) or C_8H_8O and if we consider the chain long enough to make the effect of the extra hydrogen atoms in the terminal rings negligible. The observed oxygen content, which is slightly above the proposed theoretical value, may be explained as arising from the presence of several phenol groups in some of the units.



C

It must be admitted that the lack of solubility in alkalies is not in accord with the phenolic character postulated, unless we assume a behavior similar to that observed in the monohydric phenols, where increasing molecular weight is accompanied by decreasing solubility. All of these remarks must await the accumulation of more data before they may be regarded as more than mere speculations; it is hoped, however, that they will provide a basis for discussion and will suggest new fields of endeavor and it is for these purposes that they are offered.

Crystalline Products

The evidence in the case of these compounds is much more conclusive than in the previous one. Since a general discussion is rather difficult until the data have been presented, the reactions of each vapor will be treated separately.

(a) **Benzene.**—After the condensate from the liquid-air trap was evaporated, the residue was examined, and was found to be a resinous matrix in which some small clear crystals were embedded. The identification of these crystals presented a number of difficulties, chief among which was the fact that so little material was available. The crystals were finally separated from the matrix by extraction with alcohol followed by partial evaporation of the resulting solution. They possessed the characteristic odor of diphenyl, their melting point was 69.5° in agreement with that of diphenyl and a mixture of these crystals with some diphenyl obtained from the Eastman Kodak Company showed an identical melting point. Moreover, the general optical properties of the unknown agreed with those of the Eastman sample. Both crystallized as flat monoclinic plates; both were strongly birefringent. Because of these conditions it was not deemed feasible to make an accurate determination of the refractive indices. However, the agreement of the general optical character added to the other evidence was regarded as sufficient proof that the unknown crystals were indeed diphenyl. It is interesting to note that these products are exactly the same as those obtained by Berthelot[8] in passing benzene vapor through a hot tube. No clue to the nature of the resinous material was obtained.

(b) Toluene.—With toluene several crystalline products were recovered. The first of these, which was found in a ring at the top of the trap, melted at 50.5°, which is in agreement with the melting point of dibenzyl. It was considered desirable to have some definite proof of the identity of this material, since it is in a sense the keystone of the series of compounds obtained with other substances. With the small amount of the unknown available, a determination of the optical properties seemed to be the most conclusive test.

In this case the refractive indices, which do not appear to have been previously recorded, were determined approximately. Since dibenzyl is soluble in the usual refractive index oils, a series of potassium iodide–mercury iodide solutions in a 50% glycerol–water mixture was used.

Dibenzyl crystallizes in monoclinic prisms which are strongly birefringent, making the exact determination of the indices rather difficult. The approximate values for the low and high indices are 1.53 and 1.74. The unknown crystals, in addition to having the crystalline form of dibenzyl, possessed approximately the correct indices. This was regarded as sufficient evidence to establish their identity.

When the liquid in the bottom of the liquid–air trap had been tapped off it was placed in an ice box for keeping. During the cooling some well-defined crystals appeared which were filtered off and dried. These were found to have the melting point (17.0") of 2,2′-dimethyldiphenyl. No determination of the indices was made but in view of the formation of diphenyl from benzene it seems likely that the identification is correct.

A small amount of sirupy liquid was obtained on evaporating the remaining condensate from the trap. This liquid did not freeze at zero and had a high boiling point (above 200°). It was impossible to identify positively such a small amount of material but it is our belief that the liquid in question was a mixture of isomers of 2,2′-dimethyldiphenyl, several of which are high-boiling liquids.

(c) *p*-**Xylene.**—In this case a few crystals melting at 81° were found. This corresponds quite well with the melting point of di-p-tolylethane (82°); this reaction is analogous to the formation of dibenzyl from toluene and receives some confirmation from the known occurrence of that reaction. Here again a bit of sirupy liquid was obtained which, while unidentified, is believed to be a mixture of high-boiling liquid isomers.

(d) Nitrobenzene.—The accumulation of tar was so great that any attempt to separate crystals seemed futile.

(e) **Chlorobenzene.**—The chlorobenzene vapor decomposed to a very considerable extent under the discharge. A strong chlorine odor was observed when the system was opened and a strong benzene spectrum was obtained. Moreover, a few crystals of diphenyl were identified in the liquid-air trap.

---

[8] Berthelot, *Compt. vend.*, 62, 947 (1866).

(f) Cyclohexane.—No products were found. These reactions are summarized in Table II.

TABLE II

SUMMARY OF REACTIONS OBSERVED IN THE TESLA DISCHARGE

$2C_6H_6 = C_6H_5C_6H_5$
$2CH_3C_6H_5 = C_6H_5CH_2CH_2C_6H_5$
$2CH_3C_6H_5 = CH_3C_6H_4C_6H_4CH_3$
$2CH_3C_6H_4CH_3 = CH_3C_6H_4CH_2CH_2C_6H_4CH_3$
$4C_6H_5Cl = 2C_6H_6 + 2Cl_2 + C_6H_5C_6H_5$

Discussion

No discussion of these observations would be complete without a few speculations as to the mechanism of the reactions. Under the conditions of excitation several possibilities must be considered. Considering it axiomatic that reaction does not occur between normal unexcited molecules, we have a choice of the following: reaction between two ions, between an ion and a normal molecule, between two activated though un-ionized molecules, or between an activated and a normal molecule. Since products similar to our brown powders are produced by the electrodeless discharge and by the action of high-speed cathode rays, in which cases ionization seems to play a definite role, it would seem that we must look for reaction between ions in the present case. On the other hand, the conditions favoring increased yields, i. e., higher temperatures and pressure, lead one to suppose that collisions must also be a factor. It is probable therefore that the process by which these substances are produced requires ionization of the vapor followed by a collision of the ions with other ions or normal molecules.

The authors wish to express their appreciation to Dr. E. T. Wherry for help and advice in the matter of the optical properties of the dibenzyl, to Dr. Elizabeth Gilman Roberts for help in the qualitative tests for nitrogen, to Professor J. B. Niederl for his analyses of the brown powders and to Mr. L. E. Faulhaber for help in preparing the manuscript.

Summary

The Tesla discharge in the vapors of benzene and its simple derivatives causes chemical action with the formation of two types of compounds; first, brown shellac-like compounds containing oxygen which are left in the discharge tube and appear to be condensed molecules of a phenolic type; second, relatively simple molecules which condense in well-defined crystals. In this latter class, diphenyl is produced from benzene and dibenzyl from toluene; isomers of these compounds are also formed. The low and high refractive indices of dibenzyl have been determined and are approximately 1.53 and 1.74.

THE DECOMPOSITION OF ETHYLENE GLYCOL IN THE PRESENCE OF CATALYSTS. I. VANADIUM PENTOXIDE AS CATALYST

BY NATHAN L. DRAKE AND THOMAS B. SMITH[1]

RECEIVED AUGUST 22, 1930 PUBLISHED NOVEMBER 5, 1930

The generation of an ethylene oxide linkage by the direct addition of oxygen to a double bond would be a useful reaction. In particular, starting from ethylene, it would be easy to prepare ethylene glycol

$$2CH_2{=}CH_2 + O_2 + 2H_2O = 2CH_2OHCH_2OH \qquad (1)$$

Francis[2] has calculated an expression for the free energy of formation of ethylene from its elements

$$AF = 12,260 + 11.6T$$

and Parks and co-workers[3] have revised their earlier calculations of the free energy of formation of liquid ethylene glycol, **giving** as their revised value

$$\Delta F_{298} = -81,800 \text{ cal.}$$

From Francis' equation, for ethylene

$$\Delta F_{298} = +15,717 \text{ cal.}$$

For liquid water[4]

$$\Delta F_{298} = -56,560 \text{ cal.}$$

Consequently, for the reaction

$$CH_2{=}CH_2(g) + {}^1/_2O_2(g) + H_2O(l) = CH_2OHCH_2OH(l)$$
$$\Delta F_{298} = -40,957 \text{ cal.}$$

There is, therefore, nothing thermodynamically unsound in an attempt to devise a method for carrying out this reaction. The use of pressure would certainly aid much in bringing about Reaction 1, and if a catalyst could be found which would render possible the production of ethylene oxide, the synthesis of glycol from ethylene, air and water should be possible.

Obviously the simplest method of testing a number of catalysts would be to examine their effect on the decomposition of ethylene glycol under various conditions. The present paper is concerned with the beginning of such a study. This method of attack permits operation at ordinary pressure in simple apparatus, and is undoubtedly the most economical of time and

material. A gas analysis of the products of decomposition enables the operator to follow very easily the course of the decomposition.

Practically no work has been done on the influence of catalysts on ethylene glycol. Sabatier[5] found that glycol passed over alumina at 400° yielded chiefly acetaldehyde which polymerized partially to paraldehyde. Trillat[6] passed glycol over a platinum spiral at 90° and noted that the spiral was raised to incandescence, with decomposition of the glycol into formaldehyde, glycolic aldehyde and glyoxal.

The extended use of vanadium pentoxide as an oxidation catalyst led the authors to choose it for use in their preliminary studies. There is no reported work on the influence of vanadium pentoxide on ethylene glycol.

Preparation and Purification of Materials.—The catalyst used in these investigations was prepared from ammonium vanadate. Fused vanadium pentoxide was treated with hot concentrated (sp. gr. 1.42) nitric acid, about 150 cc. of acid for each 5 g. of vanadium pentoxide, and the solution filtered and evaporated nearly to dryness. The product separating from the solution during evaporation was filtered off, washed twice with cold distilled water to remove the greater part of the acid and dissolved in concentrated aqueous ammonia (sp. gr. 0.90). The resulting solution was again filtered and nearly saturated with ammonium nitrate which had been recrystallized from water. The solution was then allowed to stand for a period of twelve hours to allow crystallization of the ammonium metavanadate to take place. This material was dissolved in dilute aqueous ammonia and again caused to crystallize as above. The ammonium metavanadate so prepared was filtered from the solution, washed once with cold water and dried over calcium chloride in a vacuum.

The catalyst used in the decomposition studies was obtained by heating in a stream of oxygen 0.5 g, of ammonium vanadate contained in a small porcelain boat. The temperature of the furnace in which the boat was heated was raised slowly to 350°, and maintained there until no trace of ammonia could be detected issuing from the furnace. Matignon[7] has shown that vanadium pentoxide is produced from ammonium metavanadate only in this way. If the metavanadate is not heated under oxidizing conditions, a substance of the composition $5V_2O_5{\cdot}2VO_3NH_4$ results. Some preliminary experiments described below were conducted with this substance as the contact material.

The ethylene glycol used was obtained by carefully distilling commercial ethylene glycol, called Prestone, and collecting the fraction boiling at 197°.

Apparatus

The apparatus used is shown in Fig. 1: G, a pyrex tube, containing the ethylene glycol, was heated by means of the oil-bath H, whose temperature was maintained at 205" by a Bunsen burner protected from drafts by an asbestos shield. Glycol was introduced by means of a capillary into G through I, which was then closed by a piece of glass rod and a short piece of tightly fitting rubber tubing. Connecting G with the furnace F was a small capillary orifice M, electrically heated to 200°. Glycol vapor generated in G under slight pressure, passed through this orifice at a constant rate into the furnace F. The latter consisted of a 16 X 250-mm. pyrex tube fitted snugly into

[6] Trillat, *Bull. soc. chim.*, [3] 29, 35 (1903).

[7] Matignon, *Chem.-Ztg.*, 75, 986 (1905).

another of 20 mm., the larger tube wound with chromel ribbon for electrically heating the reaction chamber. A 35-mm. tube wrapped with asbestos sheet enclosed the reaction chamber. By means of a lamp-bank the temperature in the furnace could be regulated at will. The thermometer projected into the reaction chamber to within a few mm. of the porcelain boat containing the catalyst. E, a coil condenser, which was cooled in an ice- and salt-bath during the experiments, was provided with a condensate trap and connected to the low head scrubber D. The scrubber had a volume of 300 cc. and contained 4 *N* magnesium sulfate solution. The scrubber was connected by means of the ground-glass joint in the tube C to a gasometer B, which was provided with a tenth degree thermometer, a mercury manometer, A, an outlet tube and a connection to the analyzer. The volume of gas contained in B could be read off directly by means of graduations marked on the gasometer.

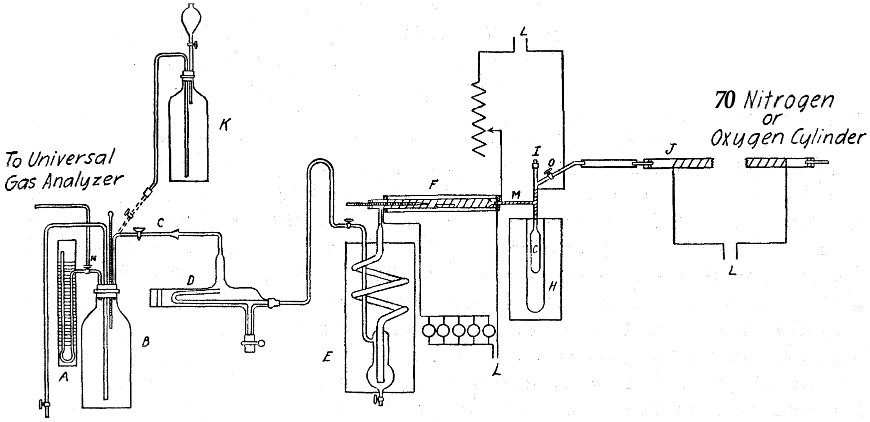

Fig. 1.—A, Manometer; B, gasometer; *C*, movable tube; D, scrubber; E, condenser; F, reaction furnace; *G*, glycol vaporizing bulb; *H*, crisco bath; **I**, bulb inlet; **J**, nitrogen purifier; K, aspirator; *L*, to 110-volt line.

The catalyst was introduced or removed through the left end of the reaction furnace, after removing the thermometer with its accompanying stopper. The products of decomposition together with the undecomposed glycol passed into the condenser, where the glycol, water and the major portion of the acetaldehyde were removed. The remainder of the acetaldehyde was removed in the scrubber. By means of the stopcock on the siphon from the gasometer, the pressure within the system from gasometer to capillary orifice could be maintained very near to atmospheric.

At the conclusion of an experiment, the tube C was disconnected at the ground joint and attached to the magnesium sulfate reservoir K. This reservoir supplied magnesium sulfate solution to replace the gas withdrawn for analysis, thus making it possible to store the gas at approximately atmospheric pressure. A Fisher Universal Gas Analyzer was used for the analytical work.

The apparatus used in fractionating the condensate consisted of a modified Claisen flask with a fractionating side arm, provided with a thermometer and connected to a small coil condenser which was cooled in an ice and salt mixture. The end of the condenser extended several centimeters below the surface of ice water contained in a 100-cc. Erlenmeyer flask.

Method.—0.5000 g. of ammonium metavanadate (equivalent to 0.3889 g. of V_2O_5) was placed in a small porcelain boat in the reaction chamber and converted into pentoxide as described above. Meanwhile, 0.1060 mole of glycol was run into the bulb G, and the reduced copper in the furnace J heated to 250°. The scrubber was filled with 4 N magnesium sulfate and the gasometer disconnected at the ground-glass joint. The system was then flushed out with nitrogen and connection again established with the gasometer. At this point gasometer and tube C were filled with the confining liquid and connected to the scrubber by means of the ground-glass joint. With the system thus prepared for collecting the reaction products, the temperature of the oil-bath H was raised to 205° and maintained there until the glycol had been vaporized completely from the container. Throughout the experiment the stopcock of the siphon tube of the gasometer was so adjusted that a 10-mm. pressure was maintained within the system. Approximately two hours was required to vaporize the glycol, whereupon a stream of nitrogen was again blown through the apparatus to sweep out the remainder of the reaction products. When approximately 1200 cc. of nitrogen had passed through the apparatus, the stopcock in C was closed and the gasometer disconnected. The catalyst was allowed to cool in a stream of nitrogen before it was removed.

Analytical Methods.—The gaseous decomposition products were analyzed in a Fisher Universal Gas Analyzer; carbon dioxide, oxygen, ethylene, carbon monoxide. hydrogen and methane were determined in the order mentioned. Successive analyses were run until the results checked to within 0.3%. Ethylene was determined by absorption in 24% fuming sulfuric acid, but a check determination was run by absorbing the gas in bromine water to confirm the results obtained by the sulfuric acid method.

In the aqueous condensate were found acetaldehyde, acetic acid and undecomposed glycol. The major portion of the acetaldehyde was slowly distilled from the mixture in the apparatus described above and collected in approximately 100 cc. of water contained in the receiver. This receiver was then replaced by another and the remaining aldehyde, the acetic acid and water were distilled into it. The Claisen flask was then weighed and the glycol distilled *in vacuo*. The distillation flask was reweighed to determine the weight of glycol distilled.

The acetaldehyde in the first portion of the distillate was determined as follows:[8] 0.5 g. of hydroxylamine hydrochloride was added to a 250-cc. portion and the resulting solution allowed to stand for thirty minutes, whereupon the hydrochloric acid liberated was titrated with $N/4$ alkali using tetrabrom phenol blue as indicator.[9]

The second fraction was analyzed as follows. The acetic acid was titrated with $N/4$ alkali, using phenolphthalein as indicator. In another portion the aldehyde was oxidized to acetic acid by alkaline hydrogen peroxide (3%), and the excess alkali was titrated with $N/4$ hydrochloric acid using phenolphthalein as indicator.[10] The difference between the amounts of acetic acid found in the two operations enables one to calculate the amount of aldehyde present in the mixture.

Any aldehyde contained in the scrubber was driven off and collected, using the same distillation apparatus as above. The amount of aldehyde in the distillate was determined by the hydroxylamine method.

Discussion of Results

By means of a carbon balance, the percentage of glycol which was decomposed on passing over the catalyst was calculated. Curve I, Fig. 2, represents graphically the results of such a calculation. The error in-

---

[8] Allen's "Commercial Organic Analysis," pp. 124–140, Vol. I; original method, *Zeitschrift fur Untersuchung der Nahrungs- und Genussmittel*, *42*, 81 (1921).

[9] Harden and Drake, THIS JOURNAL, 51, 2278 (1929).

[10] Hoepner, *J. Soc. Chem. Ind.*, 38, 735 (1919).

volved in this method of computing percentage of glycol decomposed is far less than would be the case if the recovered glycol were taken as a basis for the computation. In the region between 297 and 357°, the slope of the curve is large, but below and above these points the slope decreases. Evidently, from the slope of Curve I, there is little to be gained by operating at temperatures above 400°. With the apparatus described, operation at temperatures above 400° was impossible, but the apparatus has been redesigned and we will be able in the near future to continue the curve in the region above 400°.

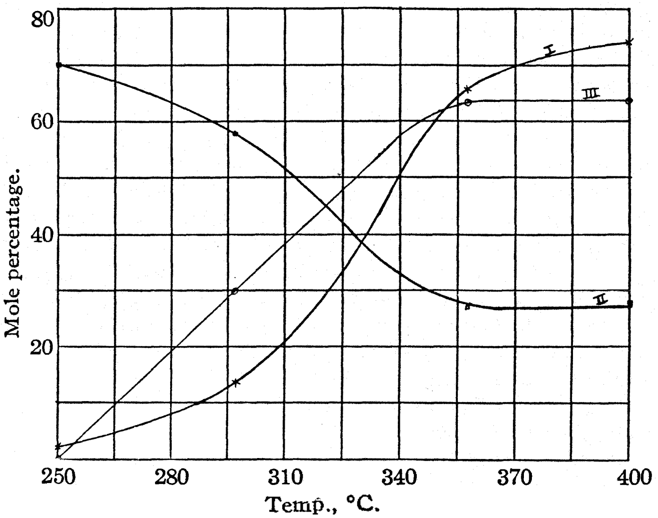

Fig. 2.—Decomposition of glycol in mole per cent. as a function of temperature.

The curves of Fig. 3 show the relation between the mole percentages of the various carbon-containing reaction products. It is very interesting and significant to note that up to a temperature of about 317°, more ethylene than any other product was produced. At 297°, for example, 7.75% of the total glycol was converted into ethylene. Referring to Fig. 2, however, we see that at this temperature 13.4% only of the glycol passing over the catalyst was decomposed. Consequently 58% of the *decomposed* glycol was converted into ethylene. Curves II and III of Fig. 2 show the relative percentages of ethylene and acetaldehyde formed, based on the glycol decomposed. It is more clearly evident from a consideration of these curves that nothing is to be gained by operation at a higher temperature. The curves for aldehyde and ethylene reach a maximum and a minimum, respectively, in the neighborhood of 357°, although the percentage of glycol decomposed increases nearly 10% between 357 and 400°.

During each experiment considerable reduction of the vanadium pentoxide took place, as shown by a color change from brick red to jet black. In the experiments from which the data for the curves of Figs. 2 and 3 were obtained, fresh catalyst was used at each temperature. That reduction of the oxide caused a considerable variation in the nature of the decomposition products was shown by using a specimen of catalyst a second time. These two experiments were conducted at a temperature of 360° in the usual fashion; the products formed are given in moles.

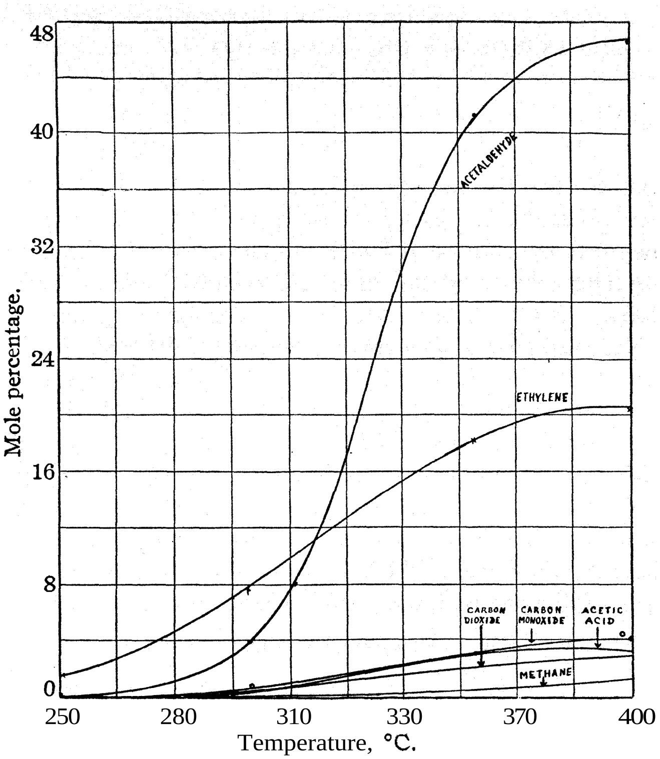

Fig. 3.—Percentage of total glycol used decomposed into acetaldehyde, ethylene, carbon monoxide, carbon dioxide, methane and acetic acid.

	I	II
CO_2	0.0045	0.0023
C_2H_4	.0196	.0145
CO	.0071	.0044
CH_3CHO	.0440	.0436
CH_3COOH	.0033	.0019

Evidently ethylene formation was more favored by the presence of fresh vanadium pentoxide than by the used catalyst, but either contact mass produced acetaldehyde in about equivalent amounts.

Two mechanisms are suggested to account for the production of aldehyde

$$CH_2OHCH_2OH \longrightarrow CH_2{=}CHOH + H_2O \qquad (2)$$

$$CH_2{=}CHOH \longrightarrow CH_3CHO \qquad (3)$$

and

$$CH_2OHCH_2OH \longrightarrow CH_2{-}CH_2\ (-O-) + H_2O \qquad (4)$$

$$CH_2{-}CH_2\ (-O-) \longrightarrow CH_3CHO \qquad (5)$$

Ipatiev[11] has studied the behavior of oxides on heating both in the presence and absence of catalysts. Ethylene oxide passed through a glass tube was found to begin to decompose at 500°. In the presence of aluminum oxide, however, rearrangement of the oxide into acetaldehyde took place readily between 200 and 300°. The work of Nef[12] confirms in a general way that of Ipatiev. Nef observed a slow rearrangement of ethylene oxide into acetaldehyde in glass tubes at 400–420°. No evolution of gas took place in this temperature interval. The behavior of many substituted ethylene oxides on heating has been studied by Tiffeneau and Lévy[13] and Lévy and Sfiras.[14] Many of the oxides investigated undergo a rearrangement like that of ethylene oxide into acetaldehyde. This rearrangement, therefore, is common to a-oxides, and it is possible, consequently, that ethylene oxide was the intermediate from which both acetaldehyde and ethylene were formed. The following reaction would account for the ethylene

$$CH_2{-}CH_2\ (-O-) \longrightarrow CH_2{=}CH_2 + {}^1/_2O_2 \qquad (6)$$

The acetic acid is undoubtedly formed by the oxidation of acetaldehyde, and it will be seen that the contour of the acetic acid curve follows roughly that of the aldehyde curve, a condition to be expected if the acid is produced from aldehyde by oxidation.

For the production of carbon monoxide, two mechanisms are possible, and probably monoxide is formed through both. It is known that vanadium pentoxide acts as a dehydrogenation catalyst[15] and the reactions

$$CH_2OHCH_2OH \longrightarrow CHOCHO + 2H_2 \qquad (7)$$

$$CHOCHO \longrightarrow 2CO + H_2 \qquad (8)$$

readily account for the formation of carbon monoxide. It has also been

shown[16] that at elevated temperatures acetaldehyde readily decomposes according to the equation

$$CH_3CHO = 60 + CH_4 \qquad (9)$$

This reaction accounts not only for the presence of carbon monoxide, but also predicts the simultaneous formation of methane in equivalent amount. Although the methane curve of Fig. **3** follows roughly in shape those for carbon monoxide and acetaldehyde, the methane found was always considerably less than would correspond to the carbon monoxide It is probable therefore, that Reactions 8 and 9 were each responsible for some carbon monoxide, and that the methane is produced according to 9. A small amount of hydrogen was always found in the gases. Undoubtedly most of the hydrogen formed was oxidized to water by the catalyst, but the presence of a small amount of it is evidence that Reactions 7 and 8 took place to some extent.

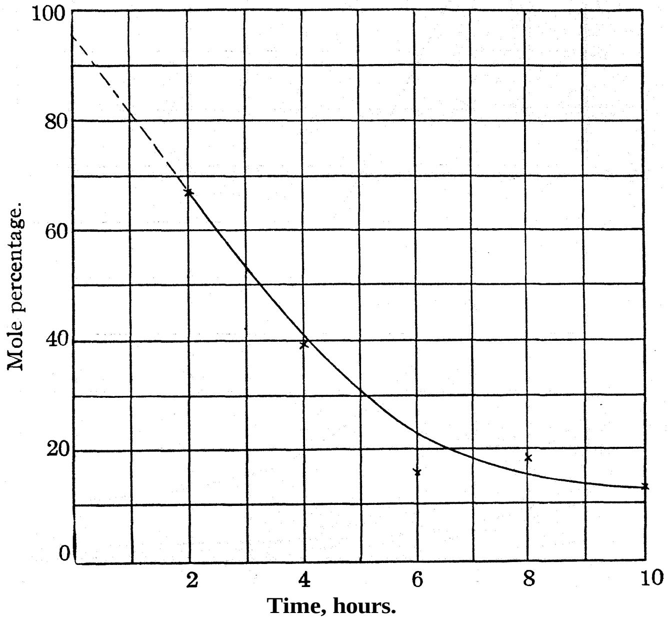

Fig. 4.—Decomposition of glycol in mole percentage plotted as a function of catalyst aging expressed in hours (temperature, 360°).

The carbon dioxide and carbon monoxide curves have the same shape, the former below the latter. Oxidation of carbon monoxide is without doubt the mechanism by which the dioxide is formed.

Figures 4 and 5 represent a series of preliminary experiments in which the compound described by Matignon[7] was used as catalyst. It will be noted that the amounts of the various products formed become rapidly less as

---

the catalyst ages. How much of this effect is due to change in physical structure of the catalyst and how much to reduction it is impossible to say. With this contact mass even the acetaldehyde concentration decreased rapidly as the catalyst aged, a situation not paralleled when vanadium pentoxide was used.

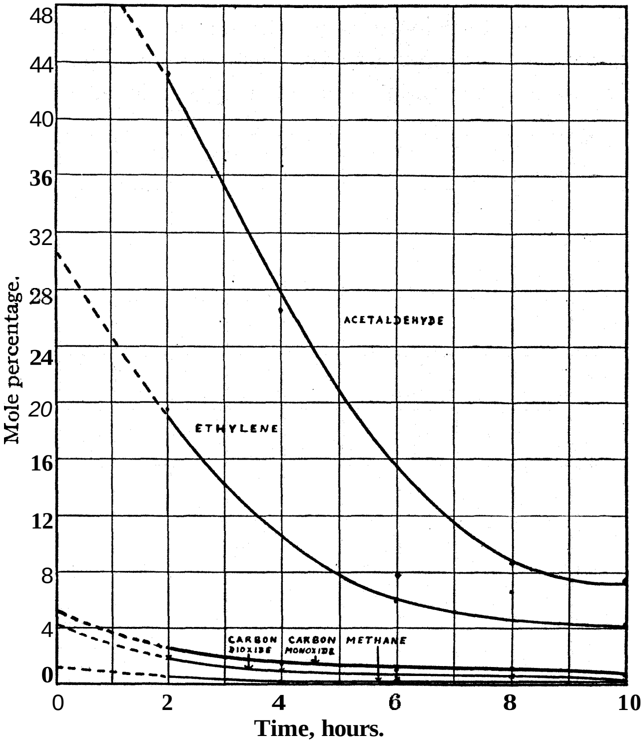

Fig. 5.—Acetaldehyde, ethylene, carbon dioxide, carbon monoxide, and methane as mole percentage of glycol used plotted as a function of the catalyst aging expressed in hours (temperature, 360°).

If the two hour points on the curves of Figs. 4 and 5 are compared with the corresponding points on Figs. 2 and 3, there is seen to be little to choose between the two catalysts.

Summary

1. The decomposition of ethylene glycol in the presence of vanadium pentoxide has been studied.
2. Acetaldehyde and ethylene are the principal products.
3. Curves showing the relative amounts of the individual products formed are given.

THE QUINONOID STRUCTURE OF SOME TRIPHENYLMETHYL SALTS

BY LEIGH C. ANDERSON

RECEIVED AUGUST 25, 1930 PUBLISHED NOVEMBER 5, 1930

Previous papers from this Laboratory[1] have shown that a very marked change occurs in the quantitative absorption spectra when colorless @-hydroxytriarylcarbinols possessing the benzenoid structure **(I)** are converted to the tautomeric colored quinonoid carbinols (II). This type of change is especially apparent when the benzenoid carbinols are converted to the corresponding fuchsones (III) of whose quinonoid structure no question has ever been raised. It has now been found that this same marked change occurs in the quantitative absorption spectra when a colorless dimethyl sulfate solution of triphenylchloromethane is converted to triphenylmethyl sulfate or perchlorate by silver sulfate or silver perchlorate, respectively. The solution becomes yellow and at the same time the absorption of light by the solution changes in a manner similar to that which has been shown to occur when the benzenoid carbinols are converted to the quinonoid fuchsones. We have found by means of absorption spectra that triphenylchloromethane possesses the same benzenoid structure in dimethyl sulfate solutions that it possesses in ether solutions and from the similarity in the curves obtained from these two sets of reactions—benzenoid carbinols to quinonoid fuchsones and benzenoid chloride **(IV)** to sulfate or perchlorate—we are led to conclude that the salts, the sulfate and the perchlorate, exist in a quinonoid state **(V, VI)** in dimethyl sulfate solutions.

[1] (a) Anderson and Gomberg, THIS JOURNAL, 50, 203 (1928); (b) Anderson, *ibid.*, 51, 1889 (1929).

This conclusion is in agreement with the chemical evidence presented by Gomberg,[2] who pointed out that the sulfates of the *p*-halogenated triphenylcarbinols are quinonoid compounds. He showed that diphenylquinomethane (fuchsone) was one of the products obtained upon hydrolysis of the sulfate of *p*-bromotriphenylcarbinol.

Former investigators have been unable to study such changes in the spectra of these salts because no one solvent had been used in which all of these compounds could be dissolved without chemical change. Gomberg[3] used dimethyl sulfate as a solvent for the preparation and purification of some of these salts, e. g., the sulfates, and he pointed out that when the solvent had been carefully purified, it yielded colorless solutions of triphenylcarbinol and triphenplchloromethane. The quantitative absorption spectra of the colorless solutions of triphenylcarbinol and triphenylchloromethane are almost identical with those curves obtained from the ether solutions of these compounds.[4] These data, together with Gomberg's work, show that pure dimethyl sulfate is without chemical effect upon these solutes. The use of dimethyl sulfate as a solvent makes it possible, therefore, for us to compare, in one solvent, the absorption spectra of the benzenoid and quinonoid salts of the triarylcarbinols.

It has been found, also, that the quantitative absorption spectra between frequencies 4200–1350 mm.^{-1} of solutions of the sulfate and perchlorate salts of triphenylcarbinol in pure sulfuric acid and pure perchloric acid, respectively, are almost identical with those obtained for each salt in its dimethyl sulfate solution; the difference between the two sets of curves lies only in the height of the quantitative curves. The similarity in the absorption bands constitutes evidence in favor of the hypothesis that these salts exist as quinonoid compounds in their solutions in these acids.

In the light of these results it appears that the questions concerning the nature of the constitution of the various salts of triarylcarbinols, which have been discussed in articles recently published by Dilthey,[5] Brand,[6] Madelung,[7] Lund[8] and others have been largely clarified and rather in favor of quinoidation.

Experimental

A drawing of the apparatus which was used to prepare solutions of the sulfate and perchlorate salts of triphenylcarbinol in dimethyl sulfate is shown in Fig. 1. Absorption

flasks were available which had a capacity in bulb H of either 50 or 100 cc. together with absorption cells K which were fitted with parallel quartz plates through which the light was passed to be absorbed and in which the distance between the inside faces of the quartz plates was 2.4, 5.0, 7.5 or 10.0 mm. Pure silver sulfate or silver perchlorate was placed in the tube I, and a small sample of pure triphenylchloromethane, weighed directly into a micro-beaker L, was placed in the upper part of the absorption flask. In order to seal the apparatus and yet not contaminate the solvent with the lubricant, stopcocks G,G and the ground-in stopper M had very small amounts of stopcock grease on the outside edges of the ground surfaces only. Dimethyl sulfate, previously distilled under reduced pressure, was placed in flask A and the whole apparatus was evacuated by means of a water aspirator. When the manometer N indicated a pressure of 12–15 mm. of mercury within the apparatus, the silver salt in I was heated to 120–130° for fifteen to twenty minutes by means of a small electrically heated coil. After the silver salt had been dried and cooled the dimethyl sulfate was distilled through the fractionating column B and condenser C. Having collected the first fraction in F, the main portion was diverted by means of stopcock D through a 30-cm. column of freshly ignited potassium carbonate which had been placed in tube E, and from there was led into the bulb H. When H and I had been filled, stopcock D was turned to allow the last portions of the dimethyl sulfate to collect in F. The volume of the solvent contained in H and I was ascertained from calibrated graduations on the tube J immediately above the bulb H; a correction for the volume occupied by the solid silver salt in I was always applied. Following this, air was slowly admitted through the calcium chloride tube O until the pressure inside the apparatus was again equal to atmospheric. Stopcocks G,G were closed and the absorption flask, after being disconnected from the distillation set-up, was inverted to dissolve the triphenylchloromethane. The mixture was then shaken until the reaction was completed.

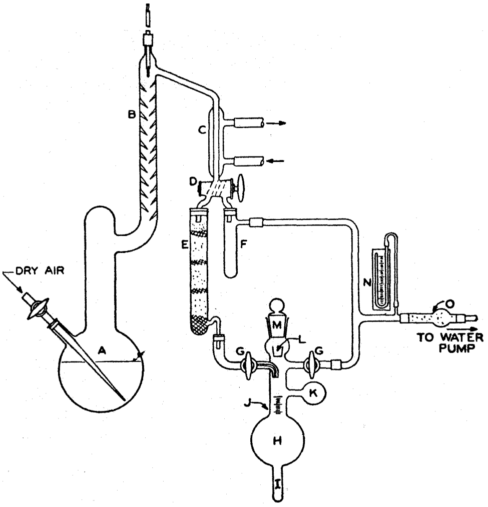

Fig. 1.

Silver perchlorate reacts rapidly with triphenylchloromethane in dimethyl sulfate and the solution acquires a brilliant yellow color. The silver chloride that is formed in the reaction is very finely divided but when the solution is allowed to stand, settles out readily. It possesses the property, however. in the dimethyl sulfate solutions, of adhering to the walls of the vessel and care was taken in the method of shaking to see that none of it was introduced into the quartz absorption cell K.

In preparing the n-sulfate of triphenylcarbinol it was necessary to keep the solution at 50–55° for a day or two before the reaction was completed and a mechanical shaking machine in an enclosed air-bath was employed. The delay in the completion of this reaction is believed to be due to the very slight solubility of silver sulfate as compared to silver perchlorate in dimethyl sulfate. The quantitative absorption spectrum of each solution was determined within a few minutes after making up the solution, and was redetermined at intervals thereafter until it was certain that the reaction was at an end.

From the fact that the absorption curves for the solutions prepared in the above manner approach a height only one-half that reached by the corresponding solutions in either sulfuric acid or dimethyl sulfate containing sulfuric acid leads to the inference that the solutes are different in the two cases. We therefore infer that in the former case, in the purified dimethyl sulfate, we were dealing with a solution of the n-sulfate.

When the potassium carbonate was omitted in the purification of the dimethyl sulfate, colored solutions were instantly obtained with either triphenylchloromethane or triphenylcarbinol. From the similarity of the absorption curve (Curve 1, Fig. 2) with that of the acid sulfate in sulfuric acid (Curve 1, Fig. 3) the inference was drawn that we were here dealing with solutions of the acid sulfate. These data corroborate the conclusion reached by Gomberg[3] that the last traces of sulfuric acid cannot be removed from dimethyl sulfate by distillation.

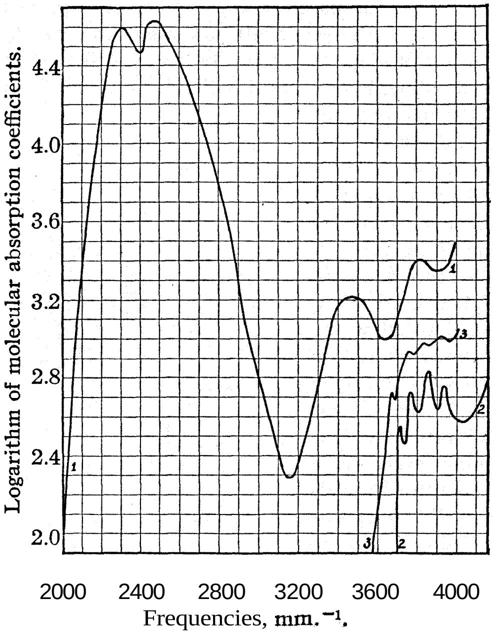

Fig. 2.—1, Triphenylmethyl acid sulfate in dimethyl sulfate; 2, triphenylcarbinol in dimethyl sulfate; 3, triphenylchloromethane in dimethyl sulfate.

The quantitative absorption spectra of triphenylcarbinol and triphenylchloromethane in dimethyl sulfate were obtained from solutions made in a manner identical with that used for the preparation of the n-sulfate and perchlorate except that no silver salt was present. Solutions of the carbinol and the chloride in dimethyl sulfate have been kept for more than a week without any development of color or of change in their absorption spectra.

Solutions for the determination of the quantitative absorption spectra of triphenylmethyl sulfate and perchlorate in sulfuric acid (95%) and perchloric acid (72%), respectively, were made by dissolving weighed amounts of either triphenylcarbinol or triphenylchloromethane in known volumes of the pure acid and taking the absorption spectra of successive dilutions.

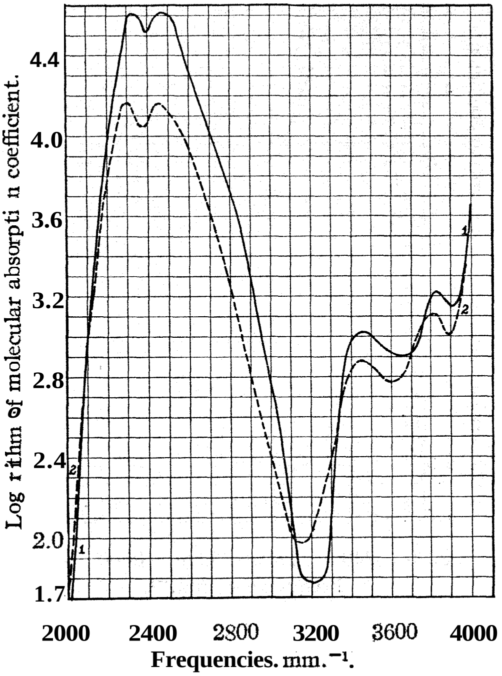

Fig. 3.—1, Triphenylmethyl acid sulfate in sulfuric acid (95%); 2, triphenylmethyl normal sulfate in dimethyl sulfate.

Attempts were made to determine the absorption spectrum of triphenylmethyl nitrate. The results thus far have not been quantitative. Silver nitrate is quite insoluble in dimethyl sulfate, and before all the triphenylchloromethane is converted to the nitrate, part of the nitrate already formed undergoes decomposition. The results that have been obtained, however, indicate that its quantitative absorption spectrum is very similar to that of the sulfate and perchlorate.

The points of maximum absorption of each—the sulfates, perchlorate and nitrate of triphenylcarbinol—were determined by a method which has been previously described[1b] and were found to be identical with each other within experimental limitations. The averages of the determinations of these points of maximum absorption lie at frequencies 2305, 2467, 3432, 3825 mm.$^{-1}$.

The writer wishes to acknowledge his deep indebtedness to Professor M. Gomberg for the suggestions and advice which have made this work possible.

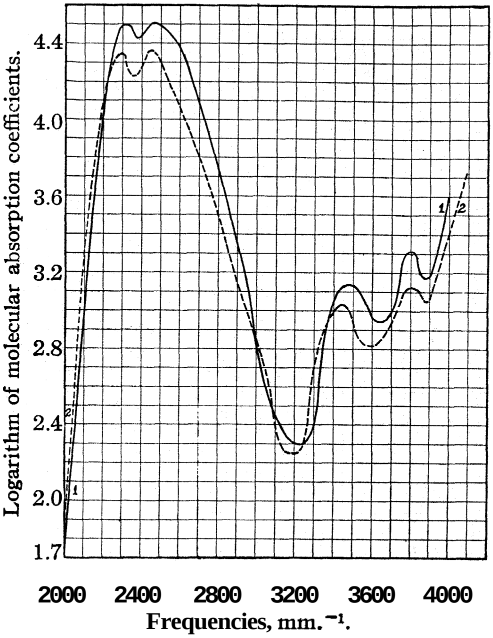

Fig. 4.—1, Triphenylmethyl perchlorate in perchloric acid (72%); 2, triphenylmethyl perchlorate in dimethyl sulfate.

Summary

1. The quantitative absorption spectra of solutions of triphenylcarbinol, triphenylchloromethane, triphenylmethyl sulfate and triphenylmethyl perchlorate in dimethyl sulfate and of solutions of the acid sulfate and of the perchlorate in sulfuric acid and perchloric acid, respectively, have been ascertained.

2. The data obtained from the absorption spectra of the above salts constitutes evidence in favor of the hypothesis that triphenylmethyl n-sulfate, acid sulfate and perchlorate exist in a quinonoid modification in their solutions in dimethyl sulfate, in sulfuric acid or perchloric acid, respectively.

THE FORCED REACTIOR BETWEEN ANILS AND PARA-THIOCRESOL. THE REDUCING ACTION OF THE MERCAPTO GROUPING

By Henry Gilman and J. B Dickey

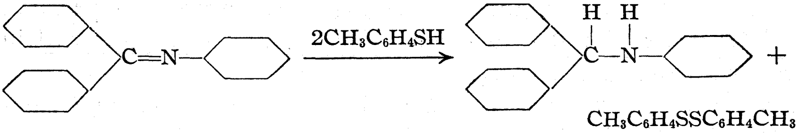
Received September 2, 1930 Published November 5, 1930

Introduction

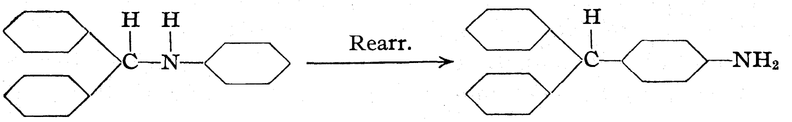
Recently, Gilman, Kirby and Kinney[1] described an unusual type of 1,4-addition to a conjugated system that is part aliphatic and part aromatic. This unique reaction which might have a significant bearing on the structure of benzene and the mechanism of substitution reactions of benzene certainly warranted confirmation with addenda other than organomagnesium halides. With this in mind, we selected *p*-thiocresol, $CH_3C_6H_4SH$, for another forced reaction study with benzophenone-anil because thiophenols lend themselves admirably as reagents for the characterization of conjugated systems.

In a preliminary experiment, in which a xylene solution of benzophenone-anil and p-thiocresol was refluxed for several hours, there was isolated a small quantity of di-*p*-tolyl disulfide, $CH_3C_6H_4SSC_6H_4CH_3$. Disulfides are formed by atmospheric oxidation of thiophenols; however, because the experiments were carried out in a trap[2] to exclude air, we concluded that the formation of di-*p*-tolyl disulfide was concomitant with reduction of the anil. This found support when the reaction products revealed *p*-thiocresol and di-p-tolyl disulfide equivalent to the initial quantity of *p*-thiocresol, and a basic compound free of sulfur, as well as some unaltered benzophenone-anil.

The basic product of reaction melted at 83–84° and it appeared altogether reasonable that it might be *p*-aminotriphenylmethane formed as a consequence of the reactions



$CH_3C_6H_4SSC_6H_4CH_3$ (II)



(III)

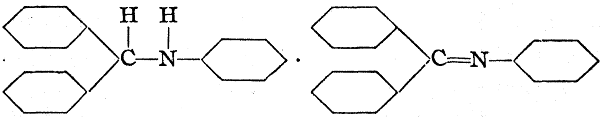
[1] Giman, Kirby and Kinney, This Journal, 51, 2252 (1929). Kohler and Nygaard, *ibid.*, 52, 4128 (1930), have just described a similar addition to the system $-CO-C_6H_5$.

[2] Gilman and Hewlett, *Rec. trav. chim.*, 48, 1124 (1929).

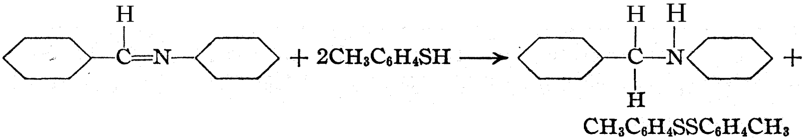
because Busch and Rinck[3] have shown that benzohydrylaniline (Reaction II) rearranges to *p*-aminotriphenylmethane when heated at an elevated temperature with aniline hydrochloride.

However, the compound was shown not to be the *p*-aminotriphenylmethane by comparison with an authentic specimen. It was subsequently established that Reaction II is correct, and that the benzohydrylaniline so formed united with a molecule of unaltered benzophenone-anil to give the complex



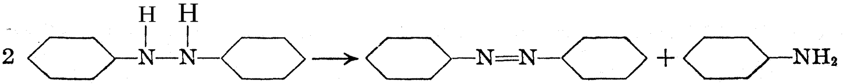
which melts at 83–84° and which is readily prepared by mixing equimolecular quantities of the two components in alcohol.[4]

The reduction of an anil is apparently a general reaction for this class of compounds inasmuch as benzalaniline was reduced rather smoothly under corresponding conditions to benzylaniline, as follows



(IV)

Likewise, azobenzene was reduced to hydrazobenzene, but under our forced conditions the hydrazobenzene underwent the known[6] thermal decomposition to azobenzene and aniline



(V)

and in the presence of an excess of the reductant (p-thiocresol) the azobenzene was progressively converted to aniline. Of course, it is possible that a part of the azobenzene may have been reduced directly to aniline, but the isolation of some hydrazobenzene (as its rearrangement product, benzidine) indicates that the reduction to aniline probably proceeded in accordance with Reaction V.

There is, then, no question concerning the reducing action of *p*-thiocresol. However, it is only a mild reducing agent, as might have been predicted from the related hydrogen sulfide and alkaline sulfhydrates. Actually, it did not reduce, under our conditions, nitrobenzene or benzophenone. It is altogether reasonable to expect that a study of other mer-

capto groups, alkyl as well as aryl, might reveal such compounds as useful, preferential, mild reductants.[6] However, this is beyond our immediate interests, which are concerned with the search of other addenda to support the unusual type of 1,4-addition shown by phenylmagnesium bromide.

We noted also that *p*-thiocresylmagnesium iodide, $CH_3C_6H_4SMgI$, did not react with either benzophenone-anil or benzalaniline in an ether–xylene solution. It was shown previously by Gilman and King[7] that this mercaptomagnesium halide underwent 1,4-addition with the ethylenic ketonic conjugated system in benzalacetophenone, $C_6H_5CH{=}CHCOC_6H_5$.

Experimental Part

Benzophenone-anil and *p*-Thiocresol.—In a typical experiment, 23.0 g. (0.105 mole) of benzophenone-anil[8] and 39.0 g. (0.315 mole) of p-thiocresol were dissolved in 200 cc. of xylene and refluxed for twenty-four hours in a flask connected with a trap[2] to exclude air. The cold reaction mixture was extracted with 10% sodium hydroxide to remove 13 g. or 33.3% of the thiocresol. Then the resulting mixture was concentrated under reduced pressure to remove the xylene, and the resulting oil was extracted with petroleum ether (b. p. 40–60°) and filtered. The molecular complex of benzohydrylaniline and benzophenone-anil is but slightly soluble in petroleum ether. By this treatment 15 g. or a 58% yield of the benzohydrylaniline and benzophenone-anil complex was isolated and identified by a mixed melting point determination.

The oily residue from the petroleum ether yielded 10 g. or 37% of benzohydrylaniline. This was converted to its hydrochloride, which was identified by a mixed melting point determination with an authentic specimen prepared in accordance with the directions of Busch.[9] The isolation of the benzohydrylaniline indicates that the complex with benzophenone-anil is first formed and then undergoes reduction.

Other products recovered were 22.1 g. or 56.6% of di-p-tolyl disulfide and a trace of aniline. Like products were obtained in another experiment when a small quantity of piperidine was used as a catalyst.

Benzalaniline and *p*-Thiocresol.—In one experiment 25.5 g. (0.141 mole) of benzalaniline[10] and 69.4 g. (0.564 mole) of p-thiocresol in 200 cc. of xylene were refluxed for twenty-six hours. The products obtained were 36 g. or 50.2% of p-thiocresol, 32 g. of di-p-tolyl disulfide (equivalent to 45.7% of p-thiocresol) and 19.4 g. of benzylaniline. All of the benzylaniline was not recovered, because of the difficulty of effecting a complete separation from traces of aniline and some unaltered benzalaniline. The identity of benzylaniline was confirmed by mixed melting point determinations of the hydrochloride and oxalate prepared from it, with authentic specimens of these salts.

---

[6] Possibly such reduction of organic compounds by organo-mercapto groups may have been noted by others. We are unfamiliar with such studies.

[7] Gilman and King, THIS JOURNAL, 47, 1136 (1925).

[8] The benzophenone-anil was prepared in accordance with the direction of Reddelien, *Ber.*, 42, 4759 (1909). Unfortunately, the yields so obtained in several preparations were only about 20%. Single preparations were also made after the modifications of Reddelien, *Ber.*, 48, 1462 (1915), and of Knoevenagel, J. prakt. Chem., [2] 89, 37 (1913), and again with yields distinctly below those reported. Possibly the difficulty lies in varying purities of the condensing agents.

[9] Busch, *Ber.*, 37, 2691 (1904); Busch and Rinck, *Ber.*, 38, 1769 (1905).

[10] Prepared in accordance with the directions given in "Organic Syntheses," John Wiley and Sons, Inc., New York, 1928, Vol. VIII, p. 22.

The same products were obtained in another experiment in which 0.5 cc. of piperidine was used as a catalyst.

Azobenzene and *p*-Thiocresol.—A solution of 18.2 g. (0.1 mole) of azobenzene and 37.2 g. (0.3 mole) of p-thiocresol in 200 cc. of xylene was refluxed for twenty-five hours. As in all other experiments, a trap[a] was used to exclude air. The products obtained were 9.5 g. of aniline, 0.1 g. of benzidine (from a sulfuric acid treatment of the hydrazobenzene present), 5.5 g. of p-thiocresol and 90% of the di-p-tolyl disulfide which should have formed on the basis of the reduction products isolated.

Miscellaneous.—After heating 0 075 mole of benzophenone-anil with four molecular equivalents of *p*-thiocresylmagnesium iodide in an ether–xylene solution at 103–107° for twelve hours, 96% of the anil was recovered. In addition, 0.3 g. of aniline was isolated. Another experiment under corresponding conditions yielded a 95% recovery of the anil, and traces of aniline and di-p-tolyl disulfide.

Subsequent to refluxing three equivalents of *p*-thiocresylmagnesium iodide with benzalaniline in an ether–xylene solution at 114–124° for forty hours, 96% of the *p*-thiocresol was recovered.

The recovery of p-thiocresol in an experiment in which four molecular equivalents of it were refluxed with benzophenone in xylene for twenty-six hours was 97.8%. A like recovery of p-thiocresol was had in an experiment wherein eight equivalents were heated with nitrobenzene in xylene for twenty-six hours.

Summary

In continuation of studies on the unique 1,4-addition to a conjugated system which is part aliphatic and part aromatic, benzophenone-anil and benzalaniline, respectively, were heated with *p*-thiocresol. No 1,4-addition was observed. Instead the thiocresol acted as a reducing agent, and was converted to di-p-tolyl disulfide. It also reduces azobenzene, but not nitrobenzene or benzophenone. *p*-Thiocresylmagnesium iodide did not react with the anils.

THE CHLORINE DERIVATIVES OF VANILLIN AND SOME OF THEIR REACTIONS

BY L. CHAS. RAIFORD AND J. G. LICHTY

RECEIVED SEPTEMBER 8, 1930 PUBLISHED NOVEMBER 5, 1930

In previous work in this Laboratory[1] the bromine substitution products of vanillin were studied for the purpose of completing the list and to obtain derivatives with which to test further the observations of Brady and Dunn,[2] who found that "no evidence of the existence of a second isomeride has been obtained in the cases of any hydroxybenzaldoximes," but that "certain negative substituents in the benzene ring seem to favor the existence of two isomeric oximes." Since stereoisomers were not obtained from

---

[1] Raiford and Hilman, THIS JOURNAL, 49, 1077, 1571 (1927); Raiford and Stoesser, 50, 2556 (1928).

[2] Brady and Dunn, J. *Chem. Soc.*, 105, 825 (1914); 107, 1859 (1915).

the bromine derivatives an adequate test of the question required the study of products containing the "more negative" substituent chlorine. The present report covers some of the data collected in that work.

The Action of Chlorine on Vanillin.—Prior to the present work Peratoner[3] chlorinated vanillin and obtained a product that was probably an impure sample of the monochloro derivative, m. p. 165°, more recently isolated by Hann,[4] which was regarded as the 5-chloro compound. Menke and Bentley[5] chlorinated vanillin in a chloroform solution and obtained a product that melted at 166°, and which was reported as a monochloro derivative, but no analytical data were recorded.[6]

To determine the positions of halogen in the three possible isomeric monochloro derivatives of vanillin, the start was made with that amino compound in which the position of the amino radical was fixed[7] as 2 by bringing it into relationship with hemipinic acid. This amino compound was diazotized and the chlorine derivative, m. p., 128°, obtained by Sandmeyer's method must be 2-chlorovanillin.

Direct chlorination of vanillin gave a monohalogenated product, m. p. 163°, in which it has been argued by Hann that chlorine occupies position 5. The third monochloro derivative, m. p. 167–168°,[8] was obtained by chlorination of 3-methoxy-4-acetoxybenzal diacetate.[9] To decide the position of chlorine in this compound, it was converted into a monobromochloro derivative, m. p. 214°, the properties of which were compared with those of an isomeric monobromochloro compound obtained from 2-amino-5-bromovanillin, the structure of which has been established by Raiford and Stoesser.[10] When the amino radical of this substance was replaced by chlorine, a monobromochlorovanillin, m. p. 187°,[11] was obtained which has chlorine in position 2, and the product must be 2-chloro-5-bromovanillin. From this it follows that the substance melting at 214° is the 5-bromo-6-chloro

---

[3] Peratoner, [*Gazz. chim.* ital., *28,* 1, 235 (1898)], reported a product that melted at 158–160" and for which he recorded a chlorine content of 20.5% (calcd., 19.0).

[4] Hann, THIS JOURNAL, 47, 2000 (1925).

[5] Menke and Bentley, *ibid.,* 20, 316 (1898).

[6] In the present work it was found that although a monochloro compound, m. p. 163°, is the chief product of direct chlorination of vanillin, large excess of chlorine gives also small quantities of the isomeric 2,5- and 5,6-dichloro derivatives. This problem will be studied further to learn whether it is possible to start with pure 5-chlorovanillin and obtain these dichloro compounds in quantity.

[7] Pschorr and Sumuleanu, *Ber.,* 32, 3408 (1899).

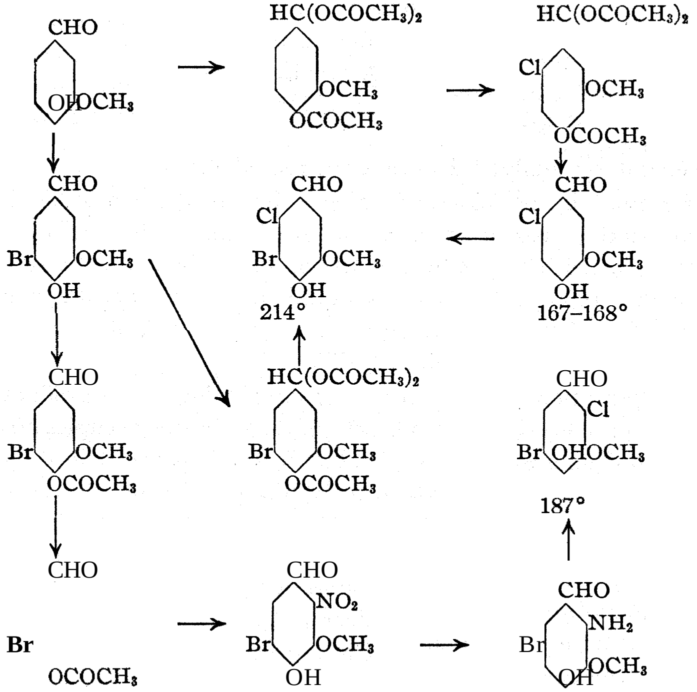
[8] A mixture of this product and that melting at 163° melted between 137 and 146°.

[9] It is of interest here to note that 6-bromovanillin was obtained in high yield [THIS JOURNAL, 49, 1079 (1927)] by bromination of acetylvanillin in the presence of sodium acetate.

[10] Raiford and Stoesser, *ibid.,* 50, 2560 (1928).

[11] ***Anal.*** Subs., 0.2041: AgHal, 0.2544. Calcd. for $C_8H_6O_3ClBr$: Hal., 43.50. Found: Hal., 43.43.

derivative, and that the chlorovanillin, m. p. 167–168°, from which it was prepared must have halogen in position 6. The monochlorovanillin, m. p. 163°, previously recorded must therefore have halogen in position 5. These relations are indicated in the diagrams.



Proof of Structure of 6-Chlorovanillin

When acetyl-5-chlorovanillin was nitrated it gave a chloronitro derivative, m. p. 137°. Reduction of this product to the corresponding amine and replacement of the amino radical by chlorine gave a dichlorovanillin that melted at 179°. Since this product was also obtained by direct chlorination of 2-chlorovanillin, the positions of the halogen atoms in this dichloro compound are shown to be 2 and 5.

It was shown above that the monochlorovanillin that melts at 167–168° is the 6-derivative. Direct chlorination of this substance gave a dichloro compound, m. p. 192°. Since this product was also obtained by chlorination of 3-methoxy-4-acetoxy-5-chlorobenzal diacetate and subsequent hydrolysis of the acetyl derivative, it follows that the final product must be 5,6-dichlorovanillin.

To obtain the third possible dichloro compound, 3-methoxy-4-acetoxy-6-chlorobenzal diacetate was nitrated, the acetyl groups removed by hydrolysis, the resulting nitro compound reduced and the amino radical replaced by chlorine. This product, melting at 139–140°, is the only remaining dichlorovanillin and must have halogen in positions 2 and 6. **Chlorination** of this compound gave a low yield[12] of 2,5,6-trichlorovanillin.

Experimental Part

The Three Monochloro Derivatives

2-Chlorovanillin.—A mixture of 14.5 g, of 2-aminovanillin,[13] 20 cc. of hydrochloric acid and 10 cc. of water was cooled below 0° and diazotized by gradually adding 6.5 g. of solid sodium nitrite. After diazotization was ,complete, a solution of 10 g. of dry cuprous chloride dissolved in 50 cc. of concentrated hydrochloric acid was added. When the copper complex was decomposed, the mixture was heated on a water-bath for a few hours, cooled and filtered. The residue was washed with dilute hydrochloric acid and then with water: yield 88%. Recrystallization from ligroin or chloroform gave pale yellow prisms, m. p. 128–129.

Anal. Subs., 0.4006: 21.65 cc. of 0.1 *N* $AgNO_3$. Calcd. for $C_8H_7O_3Cl$; Cl, 19.03. Found: Cl, 19.19.

This chlorovanillin was further characterized by the study of the derivatives indicated in Table I.

TABLE I

DERIVATIVES OF 2-CHLOROVANILLIN

No.	Compound	Solvent	Crystal form	Yield. %
1	Oxime	Dil. alcohol	Colorless needles	85
2	*p*-Bromophenylhydrazone	Dil. alcohol	Brown plates	97
3	Semicarbazone	Alcohol	Colorless plates	86
4	*Bis*-benzidine	Alcohol	Fine orange needles[a]	92

No.	Formula	M. p., °C.	Subs., g.	Cc. of 0.1 N $AgNO_3$ or wt. of AgX	Halogen, % Calcd.	Halogen, % Found
1	$C_8H_8O_3NCl$	157–158	0.4098	20.37	17.60	17.65
2	$C_{14}H_{12}O_2N_2ClBr$	144–146	.2089	0.1916	32.46	32.54

[a] When dried at 120° the color changed to red, but no evidence of solvent of crystallization was obtained.

[b] After removal of alcohol of crystallization. Anal. Subs., 0.6346: loss in wt. at 120°, 0.0836. Calcd. for one mole of C_2H_6O: 15.89. Found: 13.17.

5-Chlorovanillin.—This was obtained by a modification of Menke and Bentley's[14] method as indicated below. Excess of chlorine beyond that required for a mono-derivative was bubbled at the rate of about 10 g. of gas in fifteen minutes into a well-stirred solution of 43 g. of vanillin dissolved in 200 cc. of chloroform. Work was begun at room temperature and the temperature of the mixture was not allowed to rise above 60".

---

[12] It is of interest to note here that after positions 2 and 6 have been filled by halogen, position 5 is much more readily attacked by bromine than by chlorine. Raiford and Stoesser [THIS JOURNAL, 50,2562 (1928)] obtained a 95% yield of tribromovanillin by bromination of the 2,6-derivative. In the present work a yield of only 31% of the trichloro compound was obtained, although twice the theoretical amounts of free chlorine and sulfuryl chloride, respectively, were used in separate experiments. When 2,6-dichlorovanillin was brominated a yield of 96% was obtained.

[13] Pschorr and Sumuleanu, Ber., 32,3408 (1899).

[14] Menke and Bentley, THIS JOURNAL, 20,316 (1898).

Crystals separated during the experiment and when all the chlorine had been passed in, the mixture was cooled and the solid removed by filtration. Fifty grams of vanillin was placed in the filtrate, enough chloroform added to dissolve all solid, chlorine passed in as before and the product filtered off after cooling. Repetition of the process with a second 50-g. portion of vanillin gave a total yield of 162 g. of chlorinated product or 92%. Recrystallization from acetic acid gave colorless plates; m. p. 163°. Hann found 165°. In a repetition of the experiment, treatment of the first filtrate indicated above with a much larger excess of chlorine gave a small quantity of solid which after repeated crystallizations from alcohol gave colorless needles; m. p. 174–176°. A mixture of this and pure 2,5-dichlorovanillin, m. p. 179° (see below) melted at 175–177°.

Concentration of the filtrate left after removal of the above dichloro product gave a mass of reddish colored crystals. Most of the color was removed by washing with ligroin (70–80°). Repeated crystallization of the residue from alcohol gave pale yellow needles; m. p. 188–191°. A mixture of this and pure 5,6-dichlorovanillin, m. p. 192° (see below), melted at 191–192°.

3-Methoxy-4-hydroxy-5-chlorocinnamic Acid.—A mixture of 48 g. of 5-chlorovanillin, 40 g. of freshly fused sodium acetate and 100 cc. of acetic anhydride was heated under reflux for three hours and then poured into water. The acetyl derivative separated as an oil and later solidified; yield, nearly quantitative. Extraction with boiling alcohol to remove starting material and crystallization from acetic acid gave light yellow granules; m. p. 201°.

Anal. Subs., 0.1715: AgCl, 0.2434. Calcd. for $C_{12}H_{11}O_5Cl$: Cl, 13.12. Found: Cl, 13.23.

Hydrolysis of the above product with a dilute solution of potassium hydroxide gave the free acid, which was crystallized from dilute acetone; m. p. 235–236°, with shrinking a few degrees lower.

Anal. Subs., 0.2171: AgCl, 0.1395. Calcd. for $C_{10}H_9O_4Cl$: Cl, 15.53. Found: Cl, 15.89.

5-Chlorovanillin was further characterized by study of the derivatives indicated in Table II.

[a] Obtained after drying for eight hours at 125° to remove alcohol of crystallization. *Anal.* Subs., 0.2077: AgCl, 0.1045. Calcd. for $C_9H_{10}O_3N_3Cl \cdot C_2H_6O$: Cl, 12.28. Found: Cl, 12.45. [b] Obtained after drying for two hours at 120°. The volatile product from a second sample was conducted into ice cold water and gave the iodoform test for alcohol. *Anal.* Subs., 0.2460: loss in wt., 0.0387. Calcd. for 2 moles of C_2H_6O: 15.00. Found: 15.37. *Anal.* Subs., 0.2374: AgCl, 0.1079. Calcd. for $C_{28}H_{22}O_4N_2Cl_2 \cdot 2C_2H_6O$: Cl, 11.58. Found: Cl, 11.24.

6-Chlorovanillin.—This was obtained by chlorination of 3-methoxy-4-acetoxybenzal diacetate, which was prepared as follows. To a solution of 10 g. of vanillin dissolved in 25 cc. of acetic anhydride at about 50°, fifteen drops of concentrated sulfuric acid was added, and the red-colored mixture allowed to stand overnight. The solid was filtered off, washed with a little glacial acetic acid and the combined filtrate and washings poured into water; total yield, 97%. Crystallization from alcohol gave colorless plates; m. p. 90–91°.[15] Ten grams of this product was dissolved in 95 cc. of hot glacial acetic acid, 8 g. of finely powdered anhydrous sodium acetate added, the mixture cooled to about 40°, then about twice the calculated amount of chlorine passed in while the whole was stirred. Sodium chloride precipitated as the action proceeded. The mixture was poured into water and allowed to stand; yield, 91%. Repeated crystallization from alcohol gave colorless plates: m. p. 143–144°.

Anal. Subs., 0.2258: AgCl, 0.0989. Calcd. for $C_{14}H_{15}O_7Cl$: Cl, 10.74. Found: Cl, 10.83.

Ten grams of the chlorobenzal diacetate was boiled with a dilute solution of potassium hydroxide until all had dissolved, the mixture was cooled and 6-chlorovanillin precipitated by adding excess of hydrochloric acid; yield, 98%. Crystallization from alcohol gave colorless feathers; m. p. 167–168°.

Anal. Subs., 0.1676: AgCl, 0.1281. Calcd. for $C_8H_7O_3Cl$: Cl, 19.03. Found: Cl, 18.91.

5-Bromo-6-chlorovanillin.—This was obtained in nearly quantitative yield by slowly adding bromine to a warm glacial acetic acid solution of 6-chlorovanillin and anhydrous sodium acetate, with stirring. Crystallization from acetic acid gave colorless needles; m. p. 214".

Anal. Subs., 0.2590: AgX, 0.3233. Calcd. for $C_8H_6O_3ClBr$: X, 43.50. Found: X, 43.50.

5-Chloro-6-bromovanillin.—Excess of chlorine was bubbled with stirring into a chloroform solution of 6-bromovanillim at about 40". The product crystallized out during the reaction. By working up the mother liquor an almost quantitative yield was obtained. Recrystallization from alcohol gave nearly colorless needles; m. p. 202'.

Anal. Subs., 0.2202: AgX, 0.2741. Calcd. for $C_8H_6O_3ClBr$: X, 43.50. Found: X, 43.36.

6-Chlorovanillin was further characterized by the study of the derivatives indicated in Table III.

[15] Tiemann and Nagai, Ber., 8, 1143 (1875), found 88–89" for a product that appears to have the same composition as ours, but they reported no yield.

The Three Dichloro Derivatives

Acetyl-2-nitro-6-chlorovanillin.—Twenty grams of **3-methoxy-4-acetoxy-6-chloro**-benzal diacetate was added during a period of three minutes to 50 cc. of fuming nitric acid at 20–30° with shaking, and after standing for fifteen minutes the mixture was poured on cracked ice. The green oil that separated solidified on standing; yield, 61%. Crystallization from alcohol after boiling with norite gave nearly colorless plates that became lemon-yellow on exposure to sunlight; m. p. 81–82°.

Anal. Subs., 0.2083: AgCl, 0.1088. Calcd. for $C_{10}H_8O_6NCl$: Cl, 12.97. Found: Cl, 12.92.

2-Nitro-6-chlorovanillin.—This was obtained by hydrolysis of the acetyl derivative by alkali and by acid. The latter requires a longer time but gives a purer product with less color than was obtained with alkali. Crystallization from water gave colorless needles; m. p. 155–157°.

Anal. Subs., 0.2387: AgCl, 0.1474. Calcd. for $C_8H_6O_5NCl$: Cl, 15.33. Found: Cl, 15.27.

2-Amino-6-chlorovanillin.—Ten grams of the above nitro compound was added in small portions to a boiling mixture made from 100 g. of ferrous sulfate in 350 cc. of water and 110 cc. of concentrated ammonia water. The whole was boiled for fifteen minutes, 200 cc. of boiling water was added and the mixture was filtered while hot. The residue was repeatedly extracted with ammonia water and the collected filtrate was neutralized by dilute sulfuric acid in order to cause the amine to separate; yield, 92%. Crystallization from alcohol gave yellow needles that softened at 190° and melted at 192–193°.

Anal. Subs., 0.2750: AgCl, 0.1958. Calcd. for $C_8H_8O_3NCl$: Cl, 17.61. Found: Cl, 17.61.

2,6-Dichlorovanillin.—The amino group in the above described compound was replaced by chlorine by means of the Sandmeyer reaction; yield, 40%. Crystallization from carbon tetrachloride gave colorless needles; m. p. 139–140°.

Anal. Subs., 0.2246: AgCl, 0.2888. Calcd. for $C_8H_6O_3Cl_2$: Cl, 32.12. Found: Cl, 31.81.

This compound was further characterized by the study of the derivatives indicated in Table IV.

TABLE IV

DERIVATIVES OF 2,6-DICHLOROVANILLIN

No.	Compound	Solvent	Crystal form	Yield, %
1	Oxime	Dil. alcohol	Colorless needles	88
2	*p*-Bromophenylhydrazone	....	....	..
3	Semicarbazone	90% alcohol	Colorless needles	98
4	Bis-benzidine	Insoluble	Red, amorphous granules	Nearly quant.

No.	Formula	M. p., °C.	Subs., g.	Cc. of 0.1 *N* $AgNO_3$ or wt. of AgCl	Halogen, % Calcd.	Halogen, % Found
1	$C_8H_7O_3NCl_2$	141	0.2391	0.2910	30.08	30.12
3	$C_9H_9O_3N_3Cl_2$	213	.2134	.2199	25.53	25.54
4	$C_{28}H_{20}O_4N_2Cl_4$	232	.1880	.1788	24.06	23.52

Acetyl-5-chlorovanillin.—A mixture of 10 g. of 5-chlorovanillin, 10 cc. of glacial acetic acid and 20 cc. of acetic anhydride was refluxed for an hour and then poured into water. The oil that separated solidified after standing for one day. Many recrystallizations from ligroin gave colorless needles that melted at 67°. When distilled at 5 mm. it passed over at 167–172°, and solidified to colorless crystals; yield, nearly quantitative.

Anal. Subs., 0.2428: AgCl, 0.1525. Calcd. for $C_{10}H_9O_4Cl$: Cl, 15.53. Found: Cl, 15.53.

Acetyl-2-nitro-5-chlorovanillin.—Five grams of the above described product was slowly added to 20 g. of fuming nitric acid with shaking, while the mixture was kept at 20" or below, and then poured on cracked ice; yield, nearly quantitative. Repeated crystallization from alcohol gave colorless needles that contained one molecular proportion of alcohol of crystallization; m. p., 95–96°.

And. Subs., 0.2118: AgCl, 0.0957. Calcd. for $C_{10}H_8O_6NCl{\cdot}C_2H_6O$:[16] Cl, 11.11. Found: Cl, 11.18,

2-Nitro-5-chlorovanillin.—The acetyl derivative was warmed with potassium hydroxide solution until a clear liquid was obtained, and then an excess of dilute sulfuric add was added. Crystallization of the yellow precipitate from 20% alcohol gave pale yellow needles; m. p. 137°.

Anal. Subs., 0.1950: AgCl, 0.1214. Calcd. for $C_8H_6O_5NCl$: Cl, 15.33. Found: Cl, 15.40.

2-Amino-5-chlorovanillin.—Ten grams of the above nitro compound was reduced by means of ferrous hydroxide as explained above, with the exception that the filtrate was not neutralized by acid. The amine crystallized from the filtrate on cooling, and concentration of the mother liquor gave a second crop; yield, 87%. Recrystallization from water gave light brown needles; m. p. 136–137".

Anal. Subs., 0.1935: AgCl, 0.1374. Calcd. for $C_8H_8O_3NCl$: Cl, 17.59. Found: Cl, 17.56.

2,5-Dichlorovanillin.—A portion of the amine was dissolved in dilute hydrochloric acid cooled to about 0" and diazotized by slowly adding sodium nitrite. Cuprous chloride dissolved in concentrated hydrochloric acid was now added to the dark red mixture, which was next heated on a water-bath for two hours. The solid was filtered off, washed with dilute acid, dried and extracted with hot acetone. The extract was boiled with norite, filtered and the filtrate mixed with water; yield. 83%. Recrystallization from acetone gave colorless needles; m. p. 179°.

Anal. Subs., 0.2691: AgCl, 0.3494. Calcd. for $C_8H_6O_3Cl_2$: Cl, 32.12. Found: Cl, 32.12.

When an excess of chlorine was bubbled into 100 cc. of chloroform solution containing 1 g. of 2-chlorovanillin and the solvent distilled off, there was left nearly a quantitative yield of dichloro derivative mixed with some red resinous material. Crystallization from acetone gave colorless needles that melted at 179°, and were found by a mixed melting point to be identical with the 2,5-derivative described above.

This dichlorovanillin was further characterized by a study of the derivatives indicated in Table V.

3-Methoxy-4-acetoxy-5-chlorobenzal Diacetate.—This product was obtained in 97% yield by refluxing for one and one-half hours a solution containing 15 g. of 5-chlorovanillin in 45 cc. of acetic anhydride with one drop of concentrated sulfuric acid and pouring into water. By boiling the alcoholic solution of the deep red solid with norite, filtering and crystallizing, it was obtained in light brown plates; m. p. 115–116°.

---

[16] A sample dried for six hours under reduced pressure at 80° lost alcohol and left a residue that melted at 112". *Anal.* Subs., 0.2953: AgCl, 0.1555. Calcd. for $C_{10}H_8O_6NCl$: Cl, 12.98. Found: Cl, 13.03.

TABLE V

DERIVATIVES OF 2,5-DICHLOROVANILLIN

No.	Compound	Solvent	Crystal form	Yield, %

The compound just described was hydrolyzed by boiling with 10 *N* potassium hydroxide solution into 5,6-dichlorovanillin, which was obtained as the sparingly soluble potassium salt. This was decomposed by dilute sulfuric acid and the product crystallized from alcohol; m. p. 192°.

Anal. Subs., 0.1688: AgCl, 0.2196. Calcd for $C_8H_6O_3Cl_2$: Cl, 32.12. Found: Cl, 32.19.

Trichlorovanillin and Derivatives

2,5,6-Trichlorovanillin.—To a saturated chloroform solution of 3 g. of 2,6-dichlorovanillin, 4 cc. of sulfuryl chloride was added, the mixture protected from moisture of the air and allowed to stand for twenty-four hours. The solvent was allowed to evaporate at room temperature and the reddish residue was fractionally crystallized from dilute alcohol. Nearly colorless needles, m. p. 154°, were obtained; yield, 31%.[17]

Anal. Subs., 0.1612: AgCl, 0.2704. Calcd. for $C_8H_5O_3Cl_3$: Cl, 41.68. Found: Cl, 41.49.

2,6-Dichloro-5-bromovanillin.—The required amount of bromine was added to a warm acetic acid solution of 2,6-dichlorovanillin and sodium acetate, the mixture allowed to stand for fifteen minutes and then poured into water; yield, 96%. The product was dissolved in hot acetic acid, hot water was added until precipitation began, the mixture was heated until clear and then allowed to cool. Small colorless needles were formed; m. p. 167°.

Anal. Subs., 0.1715: AgX, 0.2713. Calcd. for $C_8H_5O_3Cl_2Br$: X, 50.33. Found: X, 50.29.

Trichlorovanillin was further characterized by the preparation of the following derivatives. The oxime was obtained in 94% yield by the usual method. Crystallization from alcohol gave colorless needles; m. p. 173°.

Anal. Subs., 0.1665: AgCl, 0.2654. Calcd. for $C_8H_6O_3NCl_3$: Cl, 39.37. Found: Cl, 39.43.

The semicarbazone was obtained in 92% yield. Treatment of its hot alcoholic solution with hot water until precipitation began and allowing to cool gave colorless needles; m. p. 219°.

Anal. Subs., 0.1480: AgCl, 0.2001. Calcd. for $C_9H_8O_3N_3Cl_3$: Cl, 34.07. Found: Cl, 33.45.

Summary and Conclusions

1. The list of possible chlorine substitution products of vanillin has been completed. Each has been characterized by the study of several derivatives.
2. In the reactions which involved the aldehyde radical, the presence of ortho substituents caused no noticeable hindrance.
3. When chlorine is allowed to react on a vanillin derivative it does not always enter the same position as does bromine under the same conditions, which shows that the position taken is, in part, dependent on the character of the entering substituent.
4. In no case was there obtained more than one of the stereoisomeric

---

[17] Unchanged starting material was recovered from the mother liquors.

oximes demanded by theory. The one obtained, probably the *anti* form, could not be transmuted by hydrogen chloride.

5. Further work is in progress in this Laboratory.

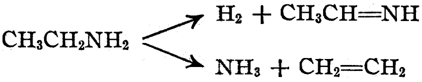
PYROLYSIS OF ALLYLANILINES

BY F. L. CARNAHAN[1] AND CHARLES D. HURD

RECEIVED SEPTEMBER 9, 1930 PUBLISHED NOVEMBER 5, 1930

Allylaniline sufficiently resembles ethylamine and allyl phenyl ether in structure so that its pyrolysis may be considered to have points of similarity with theirs, both of which have been previously investigated. Primary effects of dehydrogenation and of deammonation have been shown to be the case[2] with ethylamine

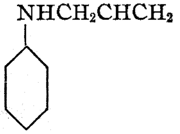


$$\begin{tikzcd} & H_2 + CH_3CH{=}NH \\ CH_3CH_2NH_2 \arrow[ur] \arrow[dr] & \\ & NH_3 + CH_2{=}CH_2 \end{tikzcd}$$

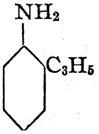
Most of the secondary reactions were traceable to the acetaldimide, chief of which was the further dehydrogenation into methyl cyanide or the demethanation into hydrogen cyanide.

For allylaniline to undergo the deammonation reaction the products would be aniline and allene. No allene was found in spite of careful search for it. The dehydrogenation reaction would give rise to acrolein-anil or its products of polymerization: $CH_2{=}CHCH_2NHC_6H_5 \longrightarrow H_2 + CH_2{=}CHCH{=}NC_6H_5$. Diallylaniline, $C_6H_5N(CH_2CH{=}CH_2)_2$, would give rise to acrolein-anil polymers by loss of propylene. Both of these reactions seem to occur. However, the fact that considerable aniline is formed during the pyrolysis of both mono- and di-allylaniline shows that this is not the exclusive feature.

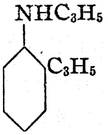
Allyl phenyl ether, on refluxing, has been shown to rearrange[3] into *o*-allylphenol. Similarly, N-allylaniline might be expected to change into o-allylaniline, and N,N-diallylaniline into either o-allylphenylallylamine or 2,6-diallylaniline. Inasmuch as pyrolysis of allyl phenyl ether gave rise



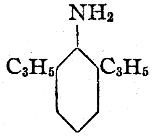
N-Allylaniline



o-Allylaniline



o-Allylphenyl-allylamine



2,6-Diallylaniline

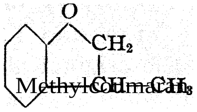
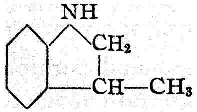
to a small yield of methylcoumaran in addition to the *o*-allylphenol, so it might be anticipated that N-allylaniline should give rise to methylindoline,



Methylcoumaran



Methylindoline

Preliminary study[4] of allyl- and diallylaniline indicated **a** pyrolysis on refluxing. The former changed partially into a primary amine, but it was not ascertained whether or not this was *o*-allylaniline. Similarly, the tertiary amine, diallylaniline, gave rise to both primary and secondary amines. Dains[5] found that the products obtained on heating allylaniline in a sealed tube at 250° for eight hours were unchanged amine, aniline, unsaturated gaseous hydrocarbons and a large amount of non-basic tarry material.

In this investigation it was established that the only primary amine formed from either allyl- or diallylaniline was aniline itself. It was further established that the secondary amine from diallylaniline was monoallylaniline and not o-allylphenylallylamine. Although diallylaniline is the ammono analog of allyl phenyl ether, and although both substances possess a similar instability, it is apparent that the final products of the reaction are not strictly comparable in the two cases; but this should not be interpreted to mean that no analogy exists. Diallyl-*p*-phenetidine, C_2H_5O-C_6H_4-$N(C_3H_5)_2$, was studied and its pyrolysis was found to be very similar to that of diallylaniline. Before discussing a mechanism of the pyrolysis, the general results will be outlined briefly.

General Discussion of Results

Propylene, in a fair state of purity, was liberated when either diallylaniline or diallyl-*p*-phenetidine was refluxed. It came more rapidly from the latter because of the higher reflux temperature (275°). Some diallylaniline was recoverable after two days of refluxing. Some allylaniline and larger amounts of aniline were isoluble. With diallylphenetidine, none was recoverable even when the reflux period had been shortened to two hours, nor was monoallylphenetidine found, but a large quantity of phenetidine was produced. In both cases over half of the original tertiary amine was changed into a non-volatile (at 23 mm. and 300°), brittle, black resin. The resin from diallylaniline possessed an average molecular weight of 783.

With monoallylaniline, the reflux temperature was too low for rapid pyrolysis. Accordingly, it was heated at 275° in a sealed tube. Aniline, gas and non-volatile tar were formed. When allylaniline vapor was

---

[4] H. Greengard and C. D. Hurd, unpublished results.

[5] Dains, Brewster, Blair and Thompson, THIS JOURNAL, 44, *2638* **(1922).**

passed through a pyrex tube at 600° at such a rate that a hot contact time of two and one-half minutes was maintained, a similar but more deep-seated pyrolysis occurred. A 14-g. sample gave nearly 5 g. of aniline, 2.3 g. of unidentified liquids, 0.5 g. of benzene, 2.3 g. of tar and 1.3 liters of gas (hydrogen, olefins and paraffins). None of the original allylaniline was recovered. A similar change occurred at 700° when the contact time was shortened to thirty-nine seconds. From a 50-g. sample the following substances were identified: 5.7 liters of gas, 4.5 g. of benzene, 19 g. of aniline, 1–2 g. of quinoline, 7.0 g. of other liquids and 8 g. of residue. The benzene which was produced in these high temperature experiments undoubtedly was formed by the splitting action of hydrogen on aniline (or aniline derivatives), an effect which has been previously established.[6]

The moles of the more important reaction products have been summarized in Table I.

TABLE I

MOLES OF REACTION PRODUCTS FORMED

Amine used	Moles taken	Moles converted into tar	Substances formed, moles Propylene	Aniline or phenetidine	Allylaniline	Benzene
Diallylaniline (reflux)	0.146	0.104	0 038	0.035	0.011	...
Diallyl-p-phenetidine (reflux)	.138	.080	.062	.091	...	...
Allylaniline (reflux)	.044	.029	...	.011	...	...
600°	.105	.017	...	.054	...	0.007
700"	.376	.060	...	.204	...	.06

A preliminary study of **acyl-allylanilines**, C_6H_5N (allyl) (acyl), wherein the acyl group was acetyl and *p*-toluenesulfonyl.—Allylacetanilide, b. p. 149° at 24 mm., was prepared in 71% yield by the reaction of allylaniline and acetyl chloride in absolute ether. About two-fifths of it was recovered after four and one-half hours' heating at 300°. The remaining three-fifths was changed into higher-boiling material. Only a little gas was liberated. With allyl-p-toluenesulfonanilide, the decomposition at 300° was complex. Hydrogen sulfide was evolved and resin formation took place. Only traces of primary amine derivatives were formed in either case.

Mechanism of Pyrolysis of Allylanilines.—Resin formation may be accounted for through the intermediate acrolein-anil by the equations

$$\text{Ar—NHC}_3\text{H}_5 \longrightarrow \text{H}_2 + \text{Ar—N=CH—CH=CH}_2$$
$$\text{Ar—N(C}_3\text{H}_5)_2 \longrightarrow \text{C}_3\text{H}_6 + \text{Ar—N=CH—CH=CH}_2$$

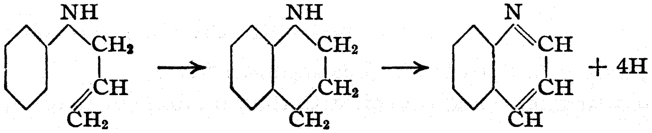
No doubt these reactions do occur, and the presence of hydrogen from allylaniline provides an explanation for the presence of aniline: $ArNHC_3H_5 + 2H \longrightarrow ArNH_2 + C_3H_6$. This is a reasonable equation for the 600 and 700° experiments, but a rather doubtful one for the others. However, aniline was formed generously in all cases. Furthermore, just as much aniline (and phenetidine) was formed when the diallyl derivatives

---

[6] Fischer and Schrader, *Brennstoff-Chem.*, 1, 4, 22 (1920).

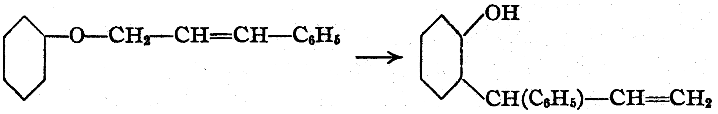
were heated as when monoallylaniline was taken, but the equation permits of no hydrogen formation with the diallyl derivatives. Aniline (or phenetidine) was not formed by direct cleavage, since allene was not formed.

Although allyl phenyl ether is known to pyrolyze into o-allylphenol, the ammono analogs in this case appear not to behave in a parallel manner. Thus, N-allylaniline does not pyrolyze into o-allylaniline. However, a carbon-to-carbon union at the ortho position was demonstrated in the 700° experiments with the isolation of quinoline. The following plan suggests itself to explain its presence

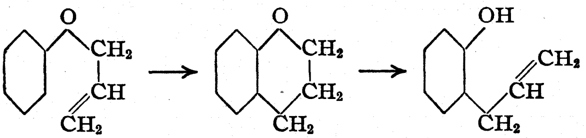


Such a series of reactions may seem to have little in common with the rearrangement  , which was discussed above.

However, it is important to note that it is the third carbon from the N which becomes attached to the ortho nuclear carbon. As Claisen[7] has demonstrated, such is also the case in allyl aryl ethers, as witnessed by the equation



The mechanism for such a rearrangement is speculative, but it is conceivable that it proceeds through a 6-membered oxygen ring. To illustrate with allyl phenyl ether



Quinoline, from allylaniline, may be explained in another fashion by assuming rearrangement to o-allylaniline, isomerization to 2-methylindoline, dehydrogenation to 2-methylindole, and rearrangement[8] to quinoline. Unidentified bases which may have contained tetrahydroquinoline, 2-methylindoline or 2-methylindole were produced in all experiments.

No single reaction seems adequate to explain the complex picture which this subject presents. It seems, however, that there are at least two major

---

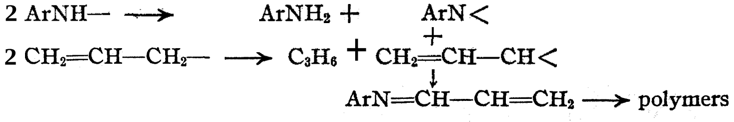
[7] Claisen and Tietze, *Ber.*, 58, 275 (1925).

[8] The rearrangement of 2-methylindole into quinoline by passing it through a hot tube has been reported by Pictet, *Ber.*, 38, 1949 (1905).

effects. One is the reaction of ring closure, giving bicyclic products. Fundamentally this seems related to the pyrolysis of allyl aryl ethers. The other effect is one which is caused by the loose type of union between the allyl radical and the nitrogen. It is convenient to picture this reaction as

$$\text{Ar—NH—C}_3\text{H}_5 \longrightarrow \text{ArNH—} + \text{—CH}_2\text{—CH=CH}_2$$

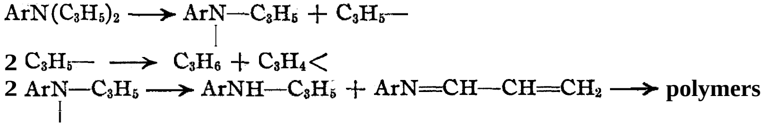
after which the radicals should disproportionate



$$\begin{array}{lll} 2\,\text{ArNH—} \longrightarrow & \text{ArNH}_2 + & \text{ArN<} \\ & & + \\ 2\,\text{CH}_2\text{=CH—CH}_2\text{—} \longrightarrow & \text{C}_3\text{H}_6 + & \text{CH}_2\text{=CH—CH<} \\ & & \downarrow \\ & & \text{ArN=CH—CH=CH}_2 \longrightarrow \text{polymers} \end{array}$$

Propylene, aniline and resins are thus accounted for.

A similar situation would prevail with diallylaniline or diallyl-*p*-phenetidine



$$\begin{array}{l} \text{ArN(C}_3\text{H}_5)_2 \longrightarrow \underset{|}{\text{ArN}}\text{—C}_3\text{H}_5 + \text{C}_3\text{H}_5\text{—} \\ 2\,\text{C}_3\text{H}_5\text{—} \longrightarrow \text{C}_3\text{H}_6 + \text{C}_3\text{H}_4\text{<} \\ 2\,\underset{|}{\text{ArN}}\text{—C}_3\text{H}_5 \longrightarrow \text{ArNH—C}_3\text{H}_5 + \text{ArN=CH—CH=CH}_2 \longrightarrow \text{polymers} \end{array}$$

This mechanism calls for allylaniline as an intermediate product. Some was isolated from diallylaniline, but for the most part it suffers further pyrolysis as outlined above.

The polymeric material with an average molecular weight of 783 may represent $(\text{C}_6\text{H}_5\text{N=CHCH=CH}_2)_6$, which has a molecular weight of 786. To ascertain whether the polymerization reaction was justified, acrolein and aniline were made to interact at 10°. A yellow resinous solid was formed which melted at about 76°. On heating, it changed into higher-melting resins which resembled those derived from the allylanilines. The reactivity of such anils is also evidenced in ethylidene-aniline, $\text{C}_6\text{H}_5\text{N=CHCH}_3$, which is known[9] to change into 1,3-dianilino-1-butene at 10°. The resins from the pyrolysis of diallylaniline were similar but not identical in appearance with the material from acrolein and aniline. This would be expected, however, in view of the presence of such radicals as C_3H_4, etc., with which the acrolein-anil could also unite.

Experimental Part

General Method of Investigation of Pyrolytic Products.—The mixtures obtained from the action of heat on allylanilines were subjected to fractional distillation first at atmospheric pressure and then under diminished pressure until only very high-boiling resinous material remained in the flask. The intermediate cuts in which were found the anilines were treated with *p*-toluenesulfonyl chloride in the presence of an excess of 10% potassium hydroxide solution. After standing for several hours the mix-

---

[9] Von Miller, Plochl and Eckstein, *Ber.*, 25, 2030 (1892).

the nearly colorless liquid was 239–240° at 746 mm,, 148° at 45 mm. and 123" at 18 mm. Its index of refraction, n_D^{23}, was 1.5556. It gave tests for only a trace of secondary amine and contained no primary amine.

Pyrolysis **by Refluxing.**—A 30-g. sample of diallylaniline was placed in a 100-cc. long-necked round-bottomed pyrex flask to which was sealed a piece of tubing 1 cm. in diameter and 60 cm. long to serve as an air condenser. A thermometer rested on the bottom of the flask and extended into the condenser. The flask was heated in a fused salt bath which was maintained at about 255". With a reflux maintained at about 25 cm. above the liquid level, the temperature fell from the initial value of 240° to 228.5' in forty-eight hours.

About one liter of gas was evolved. Analysis showed the presence of 0.5% of carbon dioxide, 86.1 propylene, 0.5 ethylene, 0.7 oxygen, 3.4 hydrogen, 1.0 carbon monoxide, 3.4 paraffins (n in C_nH_{2n+2} was 1.7) and 4.4% of nitrogen. The identification of the main portion of the gas as propylene rather than allene was made in another run (40 g.) in which the gas evolved was passed into a solution of 18 g. of dry bromine in 200 cc. of dry carbon tetrachloride. The material which remained after removal of excess bromine and solvent was distilled at 50 mm. The main fraction (4 g.) boiled at 68–70°. This boiling point is much lower than that of allene tetrabromide, which[11] is 115.5" at 9 mm. The index of refraction gave confirmatory evidence that it was propylene bromide. At 23.5" the value was 1.5178 as compared to the known value at 20° of 1.5182. Two or three drops of higher-boiling material had an index at 23° of 1.5420 and the same amount of residue in the flask had one of 1.5'720. The value for allene tetrabromide is 1.6200 at 20°. If the latter compound was not completely absent, it was certainly present in no more than traces.

After forty-eight hours' refluxing, the hot, sticky product was transferred as completely as possible to a Claisen flask equipped with a 20-cm. Vigreux column. The first fraction came over at 180–200° (atm. press.). Continuing at 23 mm., the next was collected from 100–123° and the third at 123°, constantly. The fractions weighed 2.8, 3.78 and 2.92 g., respectively. No more distillate could be obtained even when the flask was heated to 300° (23 mm.). While still hot, the residue was poured onto a watch glass. It solidified to form a brittle, black, resinous mass, weighing 18 g.

The three liquid fractions, with a total weight of 9.5 g., were separately treated with *p*-toluenesulfonyl chloride and alkali in the usual manner. The presence in them of 3.33 g. of aniline and 1.47 g. of allylaniline was established. The remainder was probably unchanged diallylaniline, to a certain extent. The identity of the derivatives with known samples was confirmed in each case.

Some work was done on the resinous material. About one-tenth of it was soluble in boiling 4 N hydrochloric acid. Neither the soluble nor the insoluble portion seemed to give quinones on oxidation with dichromate in dilute sulfuric acid solution. The molecular weight of the original resin in acetone was 783, an average of the values obtained from the following data.

Mol. wt. Subs., 2.1868 g.: vol. acetone taken, 26.0, 25.0, 26.5 cc.; *AT*, 0.255, 0.250, 0.235". Mol. wts.: found, 793, 777, 779.

Action of Acrolein on Aniline.—To a solution of 9.3 g. of aniline in 10 cc. of 95% alcohol and held at about 10° in an ice-bath, there was added slowly the theoretical amount (5.5 g.) of acrolein. The reaction was strongly exothermic, giving a slightly yellow, sticky mass. This was washed with petroleum ether, then dissolved in ether and precipitated from it by the addition of petroleum ether. The solvent was poured off. and as the solvent evaporated from the residue, the sticky mass gradually changed into

---

[11] Hurd, Meinert and Spence, THIS JOURNAL, 52, 1145 (1930).

a slightly yellow powder. It started to soften and become dark colored at 68°, and melted at about 76°. Some of this material was heated at 150' for ten minutes. After cooling and solidifying, it then melted at 87°. This resin resembled in appearance the one which was formed in the pyrolysis of diallylaniline.

Diallyl-*p*-phenetidine

Synthesis.—To 50 g. of p-phenetidine in a balloon flask equipped with an air condenser was added 45 g. of allyl bromide in small portions. After being heated for fifteeen minutes on a water-bath, the mixture was made alkaline and extracted with ether. The solvent was evaporated from the dried ether extract and to the residue was added another 45-g. portion of allyl bromide, The mixture was heated on a boiling water-bath for fifteen minutes and allowed to stand overnight. It was made alkaline and ether-extracted. The extract was dried over stick potassium hydroxide, the ether evaporated and the residue distilled from a modified Claisen flask at 23 mm. The distillate boiling at 162–170° was 60 g., or 76% of the caculated amount. Redistillation gave 50 g. of pure material boiling at 164–165°. Its density, d_4^{23}, was 0.9921, and its index of refraction, n_D^{22}, 1.5458.

Anal. (Kjeldahl). Subs., 0.3456, 0.3594: cc. of 0.1311 *N* HCl, 12.46, 12.80. Calcd. for $C_{14}H_{19}ON$: N, 6.45. Found: N, 6.62, 6.55.

Preparation of *p*-Toluenesulfone-*p*-phenetidide.—A mixture of 7.8 g. of *p*-phenetidine, 19 g. of *p*-toluenesulfonyl chloride and 100 cc. of 2 *N* potassium hydroxide was allowed to stand overnight and was worked up in the customary manner. The treatment with sodium ethoxide must not be omitted. Altogether, there was obtained 13.4 g. of product, an 81% yield. Crystallization from methanol, accompanied by treatment with bone black, gave beautiful colorless crystals, melting at 109° (110°, corr.).

Anal. Subs., 0.5244, 0.5381: cc. of 0.1311 *N* HCl, 13.20, 14.04. Calcd. for $C_{15}H_{17}O_3NS$: N, 4.81. Found: N, 4.63, 4.80.

Pyrolysis of Diallyl-*p*-phenetidine.—A 30-g. sample of diallyl-*p*-phenetidine was heated in an all-glass apparatus in a fused salt bath. It refluxed at 265° with the evolution in seventeen minutes of 350 cc. of gas. Analysis showed this to be 95% propylene, 0.4% ethylene, 1.3% oxygen and 3.3% nitrogen. The remaining gas was led into 200 cc. of carbon tetrachloride which contained 18 g. of bromine. Identification of the major portion as propylene and not allene was accomplished as outlined above for the gas from diallylaniline. Distillation of the bromide derivative at 25 mm. gave 1.5 g. at 48–50''; its index of refraction was 1.5180. Practically complete distillation of the material remaining in the flask gave 1.75 g. with an index of 1.5225. The value for propylene dibromide at 20° is 1.5182, while that for allene tetrabromide is 1.6200. Furthermore, the boiling point of the latter compound is 115.5° at 9 mm., which is much higher than the value of the material in question.

After forty-four hours of refluxing, the hot contents of the reaction vessel were transferred to a modified Claisen flask and distilled at 25 mm. In the range of 139–146° there was obtained 7.9 g. of *p*-phenetidine, identified as *p*-toluenesulfone-*p*-phenetidide in a yield equivalent to that which was obtained from a sample of the pure amine. The melting point was 109° and this was unchanged by admixture of known material. Additional proof of the identity of the material as p-phenetidine was secured by diazotization, replacement by a cyanide group, and hydrolysis of the latter to *p*-ethoxybenzoic acid, m. p. 197°. From 146–165° was obtained 1.5 g., containing 0.9 g. of p-phenetidine. The brittle black resin which remained as a distillation residue weighed 17 g.

In brief, 30 g. of diallyl-*p*-phenetidine on refluxing at 276–272'' for forty-four hours gave 8.8 g. of phenetidine, 1.35 g. of propylene (0.61 g. in 350 cc. of gas, and 0.74 g.

equivalent to 3.25 g. of the dibromide), 17 g. of resin, and 2.85 g. lost or unidentified. A weight of propylene that would be equivalent (2 moles) to the phenetidine formed would be 3.24 g. No monoallylphenetidine was found. Its stability at the reflux temperature of 275° is evidently less than that of allylaniline at 240°.

Pyrolysis. Two Hours of Reflux. —A 30-g. sample of diallyl-p-phenetidine on refluxing for two hours in an all-glass apparatus gave 10.6 g. of liquid products, 16.5 g. of resin and 2.65 g. of propylene. The phenetidine in the liquid products amounted to 8.07 g. These results are almost identical with those obtained with the forty-four hours reflux period. The greater recovery of propylene in this instance is due to the fact that the gas was collected as such and was not subjected to the unavoidable losses occasioned by its conversion into propylene dibromide.

Summary

The behavior of allylaniline, diallylaniline and diallyl-p-phenetidine at elevated temperatures has been studied. In general, the products are the parent primary amine, propylene and resinous material. Some quinoline was formed from allylaniline at 700°. Allene was not a product of the pyrolysis. Mechanisms have been suggested and discussed.

The following new compounds have been prepared and characterized: diallyl-p-phenetidine, allyl-*p*-toluenesulfonanilide and *p*-toluenesulfone-*p*-phenetidide.

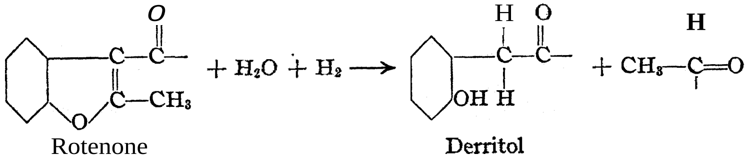
ROTENONE. X. CLEAVAGE OF DERRITOL AND ROTENOL

BY **L. E. SMITH** AND F. B. LAFORGE

RECEIVED SEPTEMBER 24, 1930 PUBLISHED NOVEMBER 5, 1930

When rotenone, $C_{23}H_{22}O_6$, is boiled with zinc dust and potassium hydroxide in alcoholic solution, two products are obtained: derritol, a yellow phenol formed with the loss of two carbon atoms, and a white compound, rotenol,[1] which contains two hydrogen atoms more than rotenone and which exhibits the properties of an alcohol.

Butenandt[1] has advanced several theories to account for the formation of derritol of which the following mechanism is an example



Rotenone Derritol

Rotenol is assumed by the same author to be formed by the reduction of the carbonyl group of rotenone to a secondary alcohol group.

In previous articles[2,3] we have reported that several compounds derived

---

[1] Butenandt. *Ann.*, 464, 253 (1928).

[2] La Forge and Smith, THIS JOURNAL, **52**, 1091 (1930).

[3] La Forge and Smith, *ibid.*, **52**, 3603 (1930).

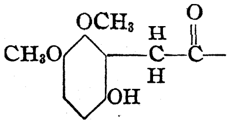
from dehydrorotenone are cleaved by hydrogen peroxide in alkaline solution to dibasic acids which contain the original two methoxy groups present in rotenone. Derric acid of formula $C_{12}H_{14}O_7$ was obtained from hydroxyrotenonic, as well as from dihydroxyrotenonic acids, while dehydrorotenonic acid gave the next lower homolog of derric acid, $C_{11}H_{12}O_7$, the latter acid being identical with the permanganate oxidation product of derric acid.

Both derritol and rotenol, as already reported,[4] yield acids on catalytic hydrogenation although in the case of derritol it is found convenient to methylate the phenol group in order to facilitate separation of the dihydroderritol and derritolic acid. In the case of rotenol the original double bond in the side chain of rotenone is also reduced during hydrogenation to the acid. The two resulting compounds, methylderritolic and dihydrorotenolic acids, are both well adapted to oxidation by the alkaline peroxide method and both yield interesting cleavage products.

Methylderritolic acid yields a monobasic trimethoxy acid of formula $C_{11}H_{14}O_5$ corresponding to a trimethoxyphenylacetic acid. Permanganate oxidation of this compound yields the next lower homolog, an acid of formula $C_{10}H_{12}O_5$, still containing the three methoxyl groups, and in all probability, a trimethoxybenzoic acid. Of the six theoretically possible compounds of this nature, four are known, but the properties of the compound obtained from derritol do not correspond to those of any of them. There remain the 2,3,5- and 2,3,6-trimethoxybenzoic acids of which the new compound most likely corresponds to the last-mentioned derivative. The choice between the two possibilities must be decided by synthesis of one or both of the missing members.

It follows from the facts so far established that the phenolic hydroxyl group in derritol arises from the indifferent oxygen atom in rotenone, that this group is attached to the same benzene nucleus as the methoxyl groups and that at least one carbon atom separates that nucleus from the carbon atom, probably the carbonyl group, at which cleavage takes place.

It seems probable therefore that derritol does in fact contain the grouping (A) as suggested by Butenandt.[1]



A

As mentioned above, dihydrorotenolic acid is easily cleaved by alkaline peroxide and in this case also a monocarboxylic acid is obtained in good yield.

The acid obtained from rotenol is represented by the formula $C_{12}H_{14}O_5$. It contains the original two methoxyl groups of rotenone, gives no test for a phenol and does not reduce Fehling's solution. The compound will be named netoric acid.

Oxidation of Methylderritolic Acid with Hydrogen Peroxide.—The procedure followed in carrying out this reaction was the same as that used for the preparation of derric

acid.[5] Two grams of methylderritolic acid[4] was dissolved in 25 cc. of 5% potassium hydroxide. The solution was warmed to 60° and 6 cc. of 30% hydrogen peroxide was added in small portions, after which the solution was boiled to remove any excess hydrogen peroxide. After cooling, the solution was made acid with dilute hydrochloric acid and extracted with ether. The ether solution was dried over anhydrous sodium sulfate and the ether evaporated. The residue crystallized at once. The oily by-products were removed by pressing the crystals between filter papers, after which the compound was recrystallized from water. The melting point was 93°; the yield, 0.7 g. Owing to the presence of water of crystallization, the substance was dried for analysis to constant weight at 110°.

Anal. Subs., 0.0740, 0.0772: CO_2, 0.1578, 0.1650; H_2O, 0.0411, 0.0423. Subs., 0.0218, 0.0143: AgI, 0.0676, 0.0455. Calcd. for $C_{11}H_{14}O_5$: C, 58.40; H, 6.15; $3CH_3O$: 41.4. Found: C, 58.16, 58.25; H, 6.16, 6.10; CH_3O, 40.96, 42.02. *Titration.* Subs., 0.0194: 0.905 cc. of $N/10$ KOH. Calcd. mol. wt.: 226. Found: 214.

Oxidation of Acid of Formula $C_{11}H_{14}O_5$ (Trimethoxyphenylacetic Acid).—Three-tenths of a gram of the acid was dissolved in 50 cc. of water containing an excess of potassium hydroxide and to the cold solution 0.45 g of potassium permanganate dissolved in 50 cc. of water was added in small portions. When the purple color had disappeared, the solution was warmed on the steam-bath and filtered. After evaporation to a small volume the solution was acidified and extracted with ether and the ether solution dried over anhydrous sodium sulfate. After removal of the solvent the residue was distilled in a high vacuum. The distillate crystallized at once and was recrystallized from carbon tetrachloride. The melting point was 78–80°; the yield. 0.14 g. For analysis the substance was dried to constant weight at 110".

Anal. Subs., 0.0737, 0.0766: CO_2, 0.1530, 0.1593; H_2O, 0.0404, 0.0434. Calcd. for $C_{10}H_{12}O_5$: C, 56.6; H, 5.66. Found: C, 56.62, 56.70; H, 6.09, 6.29. *Titration.* Subs., 0.0195: 1.76 cc. $N/20$ KOH. Calcd. mol. wt.: 212. Found: 221.

Amide.—One-half gram of the acid was dissolved in 12 cc. of dry benzene and 0.5 g of phosphorus pentachloride was added. The solution was gently boiled until all of the hydrochloric acid was removed, then cooled in an ice-bath and dry ammonia gas passed into the solution. Water was then added and the benzene boiled off. The amide crystallized from the aqueous solution and was recrystallized from the same solvent. The melting point was 173° and the yield, 0.35 g. The compound was analyzed for nitrogen by the micro Kjeldahl method.

Anal. Subs., 0.0171: 0.76 $N/10$ HCl. Calcd. for $C_{10}H_{13}O_4N$: N. 6.63. Found: N, 6.46.

Oxidation of Dihydrorotenolic Acid.—The procedure followed in this reaction was also the same as that used for the preparation of derric acid.[5] Two grams of dihydrorotenolic acid[4] was dissolved in 25 cc. of 5% potassium hydroxide, the solution warmed to 60° and 6 cc. of 30% hydrogen peroxide was added in small portions. With each addition of hydrogen peroxide the solution was stirred until the precipitate which formed was dissolved. When the solution began to effervesce the stirring was discontinued. The reaction mixture was then boiled to remove excess peroxide and the small amount of separated resinous material extracted with ether. The solution was then acidified with dilute hydrochloric acid and extracted with ether. After drying over anhydrous sodium sulfate the ether was removed, leaving a sirupy residue which soon crystallized. The adhering oil was removed by pressing between filter papers. The compound was then recrystallized from water. The substance contained crystal water, and for an-

Summary

Methylderritolic acid yields on alkaline peroxide oxidation a monocarboxylic acid of formula $C_{11}H_{14}O_5$ having the properties of a trimethoxyphenylacetic acid which yields the next lower homolog by permanganate oxidation. The new acid corresponds in its empirical formula to a trimethoxybenzoic acid but does not agree in its properties with any of the four known compounds of this type. It therefore probably corresponds to either the 2,3,5- or 2,3,6-derivative, both of which are unknown.

Dihydrorotenolic acid on peroxide oxidation yields a monocarboxylic acid of formula $C_{12}H_{14}O_5$ containing the two methoxyl groups of rotenol.

ON THE COURSE OF ADDITION OF SODIUM ENOL ALKYL MALONIC ESTERS TO ALPHA, BETA-UNSATURATED ESTERS

BY ARTHUR MICHAEL AND JOHN ROSS

RECEIVED OCTOBER 6, 1930 PUBLISHED NOVEMBER 5, 1930

In the first account of the addition of sodium enol malonic ester to esters of α,β-unsaturated acids[1] the reaction was expressed as though the parts of the addendum were Na and $-CH(COOEt)_2$

$$\begin{array}{lcl} \mathrm{RCH{=}CHCOOEt} & & \mathrm{RCHCHNaCOOEt} \\ + & \longrightarrow & | \\ \mathrm{NaCH(COOEt)_2} & & \mathrm{HC(COOEt)_2} \end{array}$$

In agreement with this view, the many cases of α,β-olefinic carboxylic esters that have since been examined by reaction with sodium enol malonic ester gave products that indicated that the malonic residue had united with the 8-carbon atom. After the enol structure was assigned *to* the sodium derivative of malonic ester[2] the above reaction continued to be written as though the sodium atom migrated in the reaction.[3] This mecha-

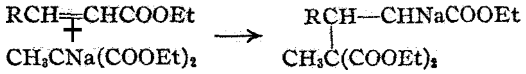
---

[1] Michael, J. *prakt.* Chem., 35, 349 (1887).

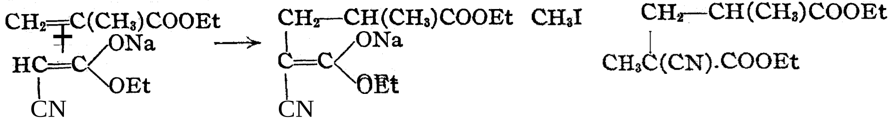
[2] Michael, *ibid.*, 37, 496 (1889).

[3] Although usually written as though the sodium atom becomes attached to the a-carbon atom of the unsaturated ester, attention had been called to the fact that the structure of such an addition compound would be unstable and would rearrange from the $-CHNaCOOEt$ to the $-CH{=}C(ONa)OEt$ form [Michael, Ber., 33, 3731 (1900)].

nism for the reaction received apparent support when it was shown that addition products could be obtained using sodium enol alkyl malonic esters in the place of sodium enol malonic ester.[4]

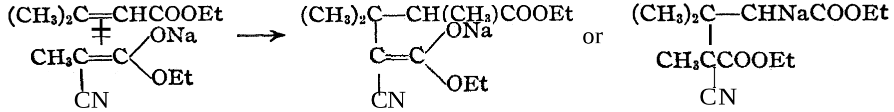


J. F. Thorpe[6] examined the reaction of the sodium derivatives of cyanacetic and of a-cyanopropionic esters and concluded that the above manner of expressing the addition of sodium enol malonic esters to α,β-unsaturated esters was erroneous. He showed that the addition of sodium enol cyanacetic ester to a-methylacrylic ester proceeded as follows, since upon treating with methyl iodide the addition compound gave α,γ-dimethyl-γ-cyano glutaric ester

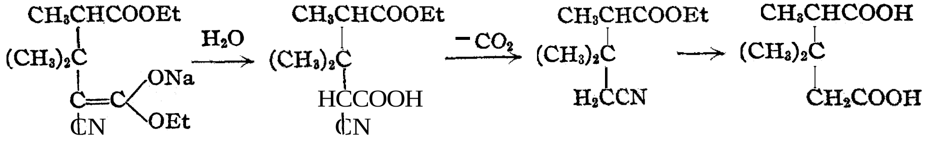


Thorpe regarded this as evidence that the sodium showed no tendency to leave the oxygen in the more acidic cyanacetic ester residue in order to add to the α-carbon atom attached to only one carbethoxyl group, and concluded that the reaction took place with migration of hydrogen but not of sodium.

In the addition of sodium enol a-cyanopropionic ester to β,β-dimethyl acrylic ester, the following possibilities were considered



The acid cyano ester obtained upon acidifying the product lost carbon dioxide upon distillation to give a cyano ester. This upon hydrolysis yielded α,β,β-trimethylglutaric acid and it was, therefore, concluded, that the methyl group had migrated to the a-carbon atom in the initial addition. These reactions were expressed as follows



Michael[6] examined the addition of sodium enol methylmalonic ester to crotonic ester and obtained an ester (a) which upon treatment with methyl

---

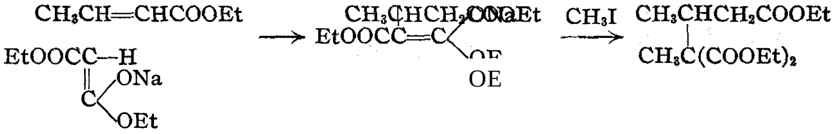
iodide gave a quantitative yield of a trimethylcarboxyglutaric ester. Methylation of the sodium derivative of 8-methyl-y-carboxyglutaricester (prepared by addition of sodium enol malonic ester to crotonic ester) gave a dimethyl y-carboxyglutaric ester (b), which had quite different properties from the isomeric ester (a). The ester (a) not only boiled 6° lower than the ester (b) but upon attempted methylation with sodium ethoxide and methyl iodide the ester (b) gave crotonic and dimethylmalonic esters. Evidently ester (a) forms a stable sodium derivative whereas ester (b) does not, but undergoes retrogression into crotonic and sodium enol methyl malonic esters.[7] From their methods of preparation the two esters should have been identical and Michael was unable to explain the appearance of different compounds. Thorpe's research appeared at about the same time but neither chemist was aware of the other's work.

In view of these anomalous results it was decided to reexamine the addition of sodium alkyl malonic esters to α,β-unsaturated esters and determine the constitution of the two isomeric esters (a) and (b). It was thought that this might lead to an explanation of the reactions by which they were formed.

When the product of addition of sodium enol malonic ester to crotonic ester is treated with methyl iodide, β,γ-dimethyl-γ-carboxyglutaric ester is formed



This is a proof that when sodium enol malonic ester is used in these addition reactions, then the sodium remains combined with the oxygen in the malonic residue. In other words, the addendum components are H and —C(COOEt)=C(ONa)OEt, a parallel mechanism shown by Thorpe to occur with sodium enol cyanacetic ester addition. It has also been shown that it is hydrogen that migrates in the reactions of sodium enol malonic, sodium enol alkyl malonic esters[8] and diethylaminocrotonic ester[9] toward phenyl isocyanate.

If the above conception of the mechanism of this reaction offers any parallel in the case of the addition of sodium enol alkyl malonic esters to such α,β-unsaturated esters, the course of the reaction would depend upon the chemical hindrance to separation of the components of the addendum, that is, upon the separation of the alkyl group from the directly attached carbon atom. This might be rendered possible by the positive character

---

[7] This was the first proof of the possible retrogression of these addition reactions; the subject was later more fully investigated by Ingold, *J. Chem. Soc.*, **119, 1976 (1921)**.

ture was acidified and from the precipitated material was separated the derivative of the primary amine by solution in boiling 10% alkali in the usual way. The alkali-insoluble material was treated with sodium ethoxide to convert any disulfonyl derivatives of primary amines to the monosulfonyl ones. The *p*-toluenesulfonyl derivatives were, in general, purified by crystallization from methanol and water. Filter charcoal was used if necessary. The yields obtained from known quantities of the amines concerned were considered in determining the composition of mixtures by this plan.

Allylaniline

Synthesis.—Allylaniline was prepared in yields of about 30% by the action of allyl bromide on sodium acetanilide. After subsequent hydrolysis, the product was purified by vacuum distillation. Its boiling point was 115° at 23 mm. and 218° at 745 mm. The material contained about 2% of aniline by analysis. It was not found practicable to form allylaniline by the action of equimolar quantities of aniline and allyl bromide as Schiff[10] recommended.

Pyrolysis at 275°.—A sample of material containing 12.15 g. of allylaniline and 0.35 g. of aniline was heated in a sealed tube at 275° for twelve hours. A small amount of inflammable gas was noticed when the tube was opened. Distillation at atmospheric pressure gave 2.5 g. at 186–206°, 3.0 g. at 206–220°, 2.5 g. at 220–223° and a residue of 3.9 g. of black, viscid tar. not volatile even under reduced pressure. The three fractions were treated separately with *p*-toluenesulfonyl chloride and excess alkali. The presence in them of 1.38 g. of aniline and 6.24 g. of allylaniline was established. The identity of the derivatives obtained was verified in each case by the melting point and a mixed melting point with authentic specimens. The aniline derivative melted at 103° and its melting point was not lowered by admixture of known *p*-toluenesulfonanilide. Allyl-p-toluenesulfonanilide melted at 69° and a mixed m. p. had the same value.

Pyrolysis at 600°.—Allylaniline was dropped very slowly into a 50-cc. distilling flask held at 270°. The vapor thus formed was conducted through a horizontal pyrex tube heated to 600° in a gas combustion furnace, The temperature, as indicated by a chromel–alumel thermocouple potentiometer set-up, did not vary from this temperature by more than three degrees. A bent piece of smaller tubing, sealed to the exit end of the reaction tube, extended into a 25-cc. distilling flask. The latter was cooled in an ice–salt bath. A U-tube, in series with the flask and held at the same temperature, collected nothing. The residual gas was collected over water in a 2.5-liter bottle.

A 14-g. sample of allylaniline was passed through the apparatus in three hundred and fifty minutes. The dimensions of the tube and the barometric pressure were such that the contact time in the hot zone was 154 seconds. The amount of liquid product was 10.1 g. The gas collected was about 1300 cc. (0°, 760 mm.). It gave on analysis in percentage by volume: propylene 28.1, ethylene 12.9, hydrogen 9.4, carbon monoxide 2.8, paraffins 36.2 (n in C_nH_{2n+2} was 1.68), nitrogen 11.6. As would be expected under these conditions, much of the propylene which was formed underwent pyrolysis. Considerable carbonization and the presence of hydrogen cyanide in the off-gases were indicative of secondary reactions. Hydrogen cyanide was tested for by passing the gas through water in a test-tube and converting it into Prussian blue. Thus, alkali was added, then ferrous and ferric ions. On boiling for a minute and then acidifying, the blue precipitate appeared.

---

[10] Schiff, Ann. *Supplement,* 3, 364 (1864).

The liquid product was fractionated. Below 105° was obtained 0.5 g., which was presumably benzene. At 105–190° but mostly at 180–186° was collected 4.25 g. of liquid, 3.44 g. of which was confirmed as aniline through p-toluenesulfonanilide. Three grams of distillate containing 1.53 g. of aniline was collected at 120–150° and 70 mm. Summarizing, a sample of material containing 13.61 g. of allylaniline and 0.39 g. of aniline gave 4.97 g. of aniline, about 0.5 g. of benzene, 2.35 g. of non-distillable tar, and 2.28 g. of unidentified liquids. The 1300 cc. of gas contained propylene and its decomposition products. No unchanged allylaniline was found.

Pyrolysis at 700°.—During sixty-four minutes a 50-g. sample of allylaniline was displaced by mercury from a graduated capsule into a vertical pyrex tube. This tube was heated to 700° in an electric furnace whose temperature was automatically controlled and recorded by a Leeds–Northrup potentiometer type recorder-controller. The dimensions of the hot part of the reaction tube were 90 × 2.1 cm. and the contact time was calculated to be thirty-nine seconds. A small tube sealed to the main reaction tube passed into a 100-cc. distilling flask which was surrounded by an ice–salt bath. The products which condensed in this flask weighed 44 g. A U-tube in series with it and also cooled by ice–salt collected nothing. The gases of the reaction, collected over water at 21° and 740 mm., had a volume of 6.5 liters. The corrected volume was 5.7 liters.

The liquid product was fractionally distilled. The first fraction was collected at 740 mm. between 80–150°, mostly below 120°. This material was identified as benzene by conversion into m-dinitrobenzene, m. p. 87°; mixed m. p. 89°. The distillation was continued at 24 mm. The greater part of an 80–90° fraction weighing 19.7 g. came over at 87–88". Of this, 15.7 g. was identified as aniline through conversion of a portion into p-toluenesulfonanilide. In the range of 90–200°, 11.5 g. of a deep yellow liquid was obtained; non-volatile residue, 8 g. Of the 11.5 g. of distillate, 3.4 g. was identified as aniline. Only a trace of secondary amine was present. The presence of 1–2 g. of quinoline in this fraction was established as follows. The tertiary amines in 2.27 g. of the distillate were separated, employing *p*-toluenesulfonyl chloride in the usual way. After steam distillation, ether extraction and evaporation of the ether, methyl iodide was added and the mixture allowed to stand for two to three hours. The solid obtained was crystallized from 3 cc. of absolute alcohol. The yellow crystals were pressed on a porous plate. They melted at 73°, the melting point of quinolinium methiodide. The mixed melting point with an authentic specimen was also 73°.

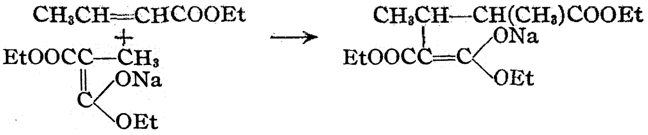
The analysis of the gas was as follows: CO_2, 0.7; unsatd. hydrocarbons soluble in 62.5% H_2SO_4, 1.3; propylene, 24.0; ethylene, 18.1; oxygen (from admixed air), 4.9; hydrogen, 15.9; CO, 0.6; residue of paraffins and nitrogen, 34.5.

Allyl-*p*-toluenesulfonanilide.—Allylaniline was treated with 1.5 equivalents of *p*-toluenesulfonyl chloride and 4–5 equivalents of 2 N potassium hydroxide. The mixture was allowed to stand overnight, acidified and worked up in the usual way. The yield was 75% and the melting point was 69°, or 69.3° corrected. An identical product was obtained in 89% yields by the action of an excess of allyl bromide on p-toluenesulfonanilide in *N* alkali solution. This method is preferable because of the difficulty in obtaining allylaniline. Unused p-toluenesulfonanilide was removed by solution in hot 2 *N* potassium hydroxide solution.

Anal. (Kjeldahl). Subs., 0.5155, 0.5437, 0.5329: cc. of 0.1311 N HCl, 13.68, 14.38. 14.00. Calcd. for $C_{16}H_{17}O_2NS$: N, 4.88. Found: N, 4.87, 4.83, 4.83.

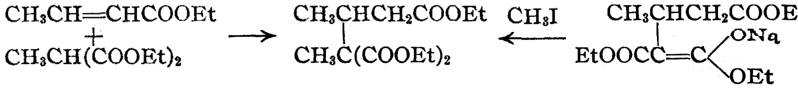
Diallylaniline

Preparation.—This was prepared in 68% yield by the action of allyl bromide on residues from the attempted direct preparation of allylaniline. The boiling point of of the alkyl group and the strong positive influence of the slightly neutralized sodium atom in loosening the affinity between the respective carbon atoms. The addendum to the ethylenic linkage would then be alkyl and —C(COOEt)=C(ONa)OEt. With sodium enol methylmalonic ester and crotonic ester the reaction would be as follows



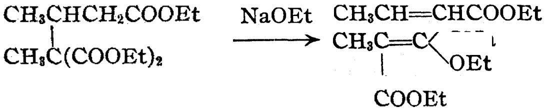
$$\begin{matrix} CH_3CH{=}CHCOOEt \\ + \\ EtOOCC{-}CH_3 \\ \| \\ C(ONa)OEt \end{matrix} \longrightarrow \begin{matrix} CH_3CH{-}CH(CH_3)COOEt \\ | \\ EtOOCC{=}C(ONa)OEt \end{matrix}$$

Upon examining the conditions of addition of methylmalonic to crotonic ester, it was found that the course of the reaction varied according to the amount of sodium ethoxide used. When the addition was carried out in the presence of a small quantity of sodium ethoxide, then the addendum functioned as H and —$C(CH_3)(COOEt)_2$. With one-sixth of a molecular equivalent of sodium ethoxide, almost the theoretical yield of β,γ-dimethyl-γ-carboxyglutaric ester was obtained. This ester is also 60% of the product of methylation of the sodium derivative of β-methyl-γ-carboxyglutaric ester with methyl iodide. These reactions may be represented thus



$$\begin{matrix} CH_3CH{=}CHCOOEt \\ + \\ CH_3CH(COOEt)_2 \end{matrix} \longrightarrow \begin{matrix} CH_3CHCH_2COOEt \\ | \\ CH_3C(COOEt)_2 \end{matrix} \xleftarrow{CH_3I} \begin{matrix} CH_3CHCH_2COOEt \\ | \\ EtOOCC{=}C(ONa)OEt \end{matrix}$$

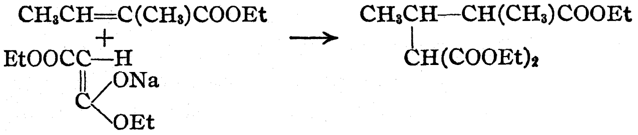
In each case the structure of the ester was proved by saponifying and isolating the β,γ-dimethyl-γ-carboxyglutaric acid, m. p. 167°. Furthermore, it was shown that β,γ-dimethyl-γ-carboxyglutaric ester would not form a sodium derivative. Upon attempted methylation by treatment in the cold with sodium ethoxide and methyl iodide, fission occurred into crotonic and sodium enol methylmalonic esters.



$$\begin{matrix} CH_3CHCH_2COOEt \\ | \\ CH_3C(COOEt)_2 \end{matrix} \xrightarrow{NaOEt} \begin{matrix} CH_3CH{=}CHCOOEt \\ CH_3C{=}C(OEt) \\ | \\ COOEt \end{matrix}$$

The sodium enol methyl malonic ester was converted by the methyl iodide into dimethylmalonic ester.

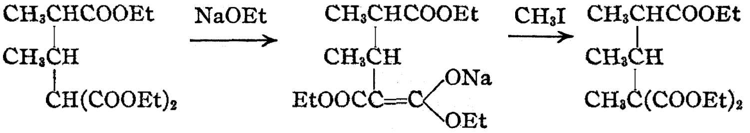
When methylmalonic ester and crotonic ester were condensed using a molecular equivalent of sodium ethoxide, no β,γ-dimethyl-γ-carboxyglutaric ester was formed. Instead, a 60% yield of α,β-dimethyl-γ-carboxyglutaric ester was obtained. Hence it is concluded that under these conditions the reaction takes place with migration of the methyl group. The direct proof of this migration of the methyl group was obtained by comparison of the α,β-dimethyl-γ-carboxyglutaric acid, m. p. 145°, obtained on saponification of the above ester, with the acid synthesized by the addition of sodium enol malonic ester to tiglic ester as follows.



$$\begin{array}{l}\mathrm{CH_3CH{=}C(CH_3)COOEt} \\ \quad + \\ \mathrm{EtOOCC{-}H} \\ \quad \| \\ \quad \mathrm{C}\begin{matrix}\mathrm{ONa} \\ \mathrm{OEt}\end{matrix}\end{array} \longrightarrow \begin{array}{l}\mathrm{CH_3CH{-}CH(CH_3)COOEt} \\ \quad | \\ \mathrm{CH(COOEt)_2}\end{array}$$

However, the yields are small by this method (about 15%). Blaise[10] prepared α,β-dimethyl-γ-cyanoglutaric ester by addition of sodium enol cyanacetic ester to tiglic ester and obtained a better yield (65%). He also obtained α,β-dimethyl-γ-carboxyglutaric acid from the above cyano ester, but described it as a thick sirup. Repeating his synthesis, a crystalline acid was obtained which was identical with the acid prepared by the other methods.

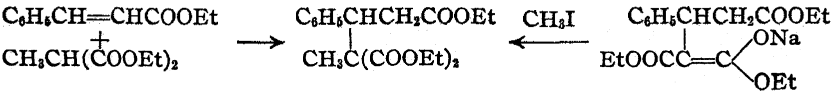
The α,β-dimethyl-γ-carboxyglutaric ester readily gave a sodium derivative which with methyl iodide gave the theoretical yield of α,β,γ-trimethyl-y-carboxyglutaric ester



$$\begin{array}{l}\mathrm{CH_3CHCOOEt} \\ \quad | \\ \mathrm{CH_3CH} \\ \quad | \\ \mathrm{CH(COOEt)_2}\end{array} \xrightarrow{\mathrm{NaOEt}} \begin{array}{l}\mathrm{CH_3CHCOOEt} \\ \quad | \\ \mathrm{CH_3CH} \\ \quad | \\ \mathrm{EtOOCC{=}C}\begin{matrix}\mathrm{ONa} \\ \mathrm{OEt}\end{matrix}\end{array} \xrightarrow{\mathrm{CH_3I}} \begin{array}{l}\mathrm{CH_3CHCOOEt} \\ \quad | \\ \mathrm{CH_3CH} \\ \quad | \\ \mathrm{CH_3C(COOEt)_2}\end{array}$$

When β,γ-dimethyl-γ-carboxyglutaric ester was treated with one molecular equivalent of sodium ethoxide, about half underwent retrogression into crotonic and methylmalonic esters. The remainder was converted into α,β-dimethyl-γ-carboxyglutaric ester, while a small amount (about 5%) of the ester was recovered unchanged. Since the addition is readily reversible, the change from β,γ-dimethyl-γ-carboxyglutaric ester to α,β-dimethyl-γ-carboxyglutaric ester undoubtedly went through this stage, the methyl migrating by virtue of the type of addition that occurs between the sodium enol methylmalonic and crotonic esters.

Parallel results were obtained in the addition of sodium enol methyl malonic ester to cinnamic ester. When the condensation was carried out using one-fifth of a molecular equivalent of sodium ethoxide, y-methyl-@-phenyl-γ-carboxyglutaric ester was produced, showing that the parts of the addendum under these conditions are H and $\mathrm{{-}C(CH_3)(COOEt)_2}$. The same ester was obtained by treatment of the sodium derivative of β-phenyl-γ-carboxyglutaric ester with methyl iodide



$$\begin{array}{l}\mathrm{C_6H_5CH{=}CHCOOEt} \\ \quad + \\ \mathrm{CH_3CH(COOEt)_2}\end{array} \longrightarrow \begin{array}{l}\mathrm{C_6H_5CHCH_2COOEt} \\ \quad | \\ \mathrm{CH_3C(COOEt)_2}\end{array} \xleftarrow{\mathrm{CH_3I}} \begin{array}{l}\mathrm{C_6H_5CHCH_2COOEt} \\ \quad | \\ \mathrm{EtOOCC{=}C}\begin{matrix}\mathrm{ONa} \\ \mathrm{OEt}\end{matrix}\end{array}$$

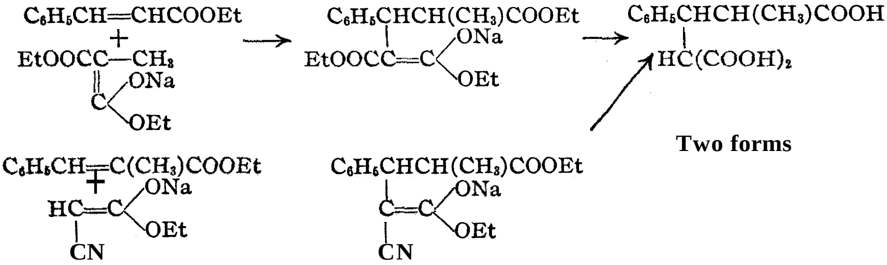
These esters were identified by the acids obtained from them upon saponification. Two apparently stereomeric forms of γ-methyl-β-phenyl-γ-carboxyglutaric acid were obtained, m. p. 148 and 188°, respectively. The

---

[10] Blaise, *Bull. soc. chim.*, [3] *29*, 332 (1903).

acid of m. p. 148° is a labile form and under certain conditions changes into the stable form, m. p. 188°. However, the acid of m. p. 148°, crystallized in large prisms, could be kept apparently for an indefinite period (a specimen over six months old shows no signs of change). Such isomerism in an acid of the glutaric series, asymmetric about one carbon atom only, is anomalous since a meso as well as a racemic form is not possible,

When methyl malonic ester was added to cinnamic ester, using one molecular equivalent of sodium ethoxide, the addition product consisted entirely of α-methyl-β-phenyl-γ-carboxyglutaric ester. Upon saponification and separation of the isomeric acids produced from this ester, two apparently stereomeric forms of **a-methyl-fl-phenyl-y-carboxyglutaric** acid were obtained. These were identified by direct comparison with the isomeric acids synthesized from the condensation product of sodium enol cyanacetic ester with α-methylcinnamic ester. The α-methyl-β-phenyl-γ-carboxyglutaric acid was obtained by hydrolysis of the cyano ester with caustic potash.



From these experiments it is apparent that sodium enol methylmalonic ester will suffer fission in the presence of an α,β-unsaturated ester so that the addendum to the ethylenic carbon atoms becomes CH_3 and $-C(COOEt)-$ $=C(ONa)OEt$. When small amounts of sodium ethoxide are used to bring about the addition of methylmalonic ester to unsaturated esters, an entirely different mechanism is involved and the sodium enol methylmalonic ester cannot be considered to react as such; it is even doubtful whether it is formed. The small amount of sodium methoxide merely serves as a catalyst in the same manner as certain nitrogen bases, *e.* g., piperidine, diethylamine,[11] used to produce similar additions of malonic to unsaturated esters.

A reacting system will proceed along the course whereby the maximum possible degradation of energy under the conditions of the experiment will be realized. This is illustrated by the conversion of maleic into fumaric acid by the catalytic action of a small amount of hydrobromic acid.[12] It may be assumed that a polymolecule of hydrobromic and maleic acid

---

[11] Knoevenagel and Mottek, *Ber.*, 37,4464 (1904).

[12] Michael, Am. Chem. *J.*, 39, 3 (1908).

is first formed, evidently possessing greater free chemical energy than maleic acid, which enables it upon decomposition to form fumaric acid with liberation of heat and hydrogen bromide. Such a transformation proceeds until almost all the maleic acid is converted into fumaric acid. Thus a far greater degradation of energy is realized in the formation of fumaric acid than would be achieved in the formation of a small amount of bromosuccinic acid. When a considerable quantity of hydrobromic acid reacts with maleic acid, a mixture of bromosuccinic with furnaric acid is obtained.

Similarly, small amounts of sodium ethoxide may form polymolecules of high free chemical energy content but low stability, with the alkyl malonic ester present. The maximum degradation of energy is accomplished by causing simple addition of the alkyl malonic ester to the unsaturated ester, rather than the formation of some sodium enol alkyl malonic ester and addition of this to the unsaturated ester with migration of alkyl group to form a small amount of the sodium enol derivative of the tricarboxylic ester.

However, when a molecular equivalent of sodium ethoxide is used, the neutralization of the sodium in the sodium enol alkyl malonic ester becomes the deciding energy factor upon the course of the reaction. This is realized by the migration of the alkyl radical and the consequent formation of a better neutralized sodium enol derivative.

As a consequence of the above results, it is very probable that the addition products obtained previously using sodium enol alkyl malonic esters are compounds in which the alkyl group has migrated from the malonic residue. Some of these compounds are under reexamination.

Experimental

β-Methyl-γ-carboxyglutaric ester was prepared by condensing sodium enol malonic ester with crotonic ester by Auwers.[13] A better yield was obtained by using a small amount of sodium ethoxide as condensing agent.

0.75 g. of sodium was dissolved in 10 cc. of absolute ethyl alcohol, 32 g. of malonic ester added and the mixture diluted with 300 cc. of dry ether; 23 g. of crotonic ester was added and the liquid refluxed for five hours on the water-bath. After cooling, a solution of 2 g. of acetic acid in 20 cc. of water was added with rapid shaking. The ethereal extract was washed with 10% sodium carbonate solution. The neutral ester had b. p. 144° (3 mm.); yield, 95%.

β-Methyl-γ-carboxyglutaric acid was obtained upon saponification of the above ester with 10% caustic soda. It crystallized in large prisms from a mixture of acetone and chloroform, m. p. 139°.

Anal. Calcd. for $C_7H_{10}O_6$: C, 44.21; H, 5.26. Found: C, 44.54; H, 5.36.

Methylation of **β-Methyl-γ-carboxyglutaric** Ester.—Two and three-tenths grams of sodium was pulverized and dissolved in 4.6 g. of ethyl alcohol in absolute ether solution by standing overnight;[14] 27.4 g. of β-methyl-γ-carboxyglutaric ester was added to the suspension of sodium ethoxide with cooling in ice and shaking. In a few minutes the

[13] Auwers, *Ber.*, 24, 2888 (1891); Michael. ibid., 33, 3748 (1900).

[14] Brühl, ibid., 37, 2067 (1904).

sodium ethoxide went into solution and 15 g. of methyl iodide was added. After standing for six hours in ice water, the product was worked up in the usual fashion; 28 g. of ester, b. p. 160° (9 mm.), was obtained, representing almost the theoretical yield of dimethyl-y-carboxyglutaric ester.

Anal. Calcd. for $C_{14}H_{24}O_6$: C, 58.33; H, 8.33. Found: C, 58.2; H, 8.5.

β,γ-Dimethyl-γ-carboxyglutaric acid was obtained upon saponification of the above ester with caustic soda. It crystallized from acetone-chloroform mixture in characteristic nodules, m. p. 167°. Thorpe and Young[15] prepared this acid by methylation of β-methyl-γ-cyanoglutaric ester and give the melting point as 165°.

Anal. Calcd. for $C_8H_{12}O_6$: C, 47.07; H, 5.88. Found: C, 47.05; H, 5.9.

This acid, m. p. 167°, formed approximately 65% of the acid material. From the mother liquor a quantity of a sirupy acid was obtained, probably α,β-dimethyl-γ-carboxyglutaric acid.

Attempted Methylation of β,γ-Dimethyl-γ-carboxyglutaric Ester.--One and one-tenth grams of sodium was converted into anhydrous sodium ethoxide, and 12 g. of β,γ-dimethyl-γ-carboxyglutaric ester was added to the ether suspension cooled in ice. Although shaken for thirty minutes, not all the sodium ethoxide dissolved; 7.5 g. of methyl iodide was added and in a few minutes sodium iodide separated. The mixture was permitted to stand for six hours at room temperature. The material was then worked up in the usual way and the neutral products on distillation gave the following two main fractions: b. p. 80–100° (12 mm.), 8.0 g. of crotonic ester, dimethylmalonic ester; b. p. 160–162° (10 mm.), 3.5 g. of unchanged ester. Upon saponification, the last fraction gave entirely β,γ-dimethyl-γ-carboxyglutaric acid, m. p. 167°, showing that the only change that took place was the fission of the main part of the ester into crotonic and sodium enol methylmalonic esters.

Addition of **Methylmalonic** Ester to **Crotonic** Ester.—The methylmalonic ester used in the following experiments was prepared by methylation of sodium enol malonic ester and was purified from malonic ester by shaking out the latter with 25% caustic potash in the cold.[16]

(a) Using a Small Amount (One-Sixth Molecule) of Sodium Ethoxide.—0.75 g. of sodium was dissolved in 10 cc. of ethyl alcohol, 35 g. of methylmalonic ester was added, followed by 23 g. of crotonic ester and 300 cc. of dry ether. The whole was refluxed for five hours, then cooled and 2 g. of acetic acid in 20 cc. of water added. The ethereal solution was washed with 10% sodium carbonate. A yield of 49 g. of ester, b. p. 155" (2 mm.), was obtained. Saponification of this ester gave a mixture of acids which consisted of approximately 90% β,γ-dimethyl-γ-carboxyglutaric acid, m. p. 167°, together with 10% of α,β-dimethyl-γ-carboxyglutaric acid.

(b) Using One Molecular Equivalent of Sodium Ethoxide.—Four and six-tenths g. of sodium was converted into anhydrous sodium ethoxide; 35 g. of methylmalonic ester was added to the ethereal suspension, followed by 23 g. of crotonic ester and 300 cc. of ether. The mixture was refluxed for five hours, cooled, poured into 100 cc. of water containing 12 g. of acetic acid and worked up in the usual manner. On distillation 20 g. of unchanged esters, b. p. 60–100° (12 mm.), was first obtained, followed by 32 g. of ester, b. p. 148–150° (3 mm.), which proved to be α,β-dimethyl-γ-carboxyglutaric ester; yield, 60%.

Anal. Calcd. for $C_{14}H_{24}O_6$: C, 58.33; H, 8.33. Found: C, 58.25; H, 8.4.

α,β-Dimethyl-γ-carboxyglutaric acid was obtained by saponification of the above

ester with caustic soda. It was obtained as a sirup which in a desiccator became a solid. This was broken up, rubbed with chloroform and recrystallized from a mixture of ether and ligroin, m. p. 145°.

Anal. Calcd. for $C_8H_{12}O_6$: C, **47.07; H, 5.88.** Found: **C, 47.13; H, 5.99.**

This acid was identified as α,β-dimethyl-γ-carboxyglutaric acid by mixed melting point with the acid prepared from the condensation product of sodium **enol** malonic ester with **tiglic** ester.

Upon distillation of this acid, m. p. 145°, a mixture of ***cis*** and ***trans*** **α,β-dimethyl**glutaric acids was produced. This was separated by conversion of the ***cis*** acid into the anhydride and thence into the imide by treatment with dry ammonia **gas** at 130°. The ***trans*** acid was extracted with sodium carbonate from the reaction mixture, leaving the pure imide, m. p. **113'.** Hydrolysis of the imide with caustic soda gave the ***cis*** **α,β-dimethylglutaric** acid, m. p. 87°. The ***trans*** acid was a liquid.[17]

Similarly. distillation of **β,γ-dimethyl-γ-carboxyglutaric** acid, m. p. 167°, gave ***cis*** and ***trans*** a,@-dimethylglutaricacids, which were separated through the imide. These were shown to be identical with the ***cis*** and ***trans*** **α,β-dimethylglutaric** acids obtained from α,β-dimethyl-γ-carboxyglutaric acid.

Methylation of α,β-Dimethyl-γ-carboxyglutaric Ester.—One and two-tenths grams of sodium was converted into anhydrous sodium ethoxide and **14.5** g. of **α,β-dimethyl-γ-carboxyglutaric** ester was added to the ether suspension, cooled in ice water. The sodium ethoxide readily dissolved, **8 g.** of methyl iodide was added and the mixture left to stand for six hours. The product was then worked up in the usual way; **14** g. of α,β,γ-trimethyl-γ-carboxyglutaric ester, b. p. 164° **(3** mm.), was obtained.

Anal. **Calcd. for** $C_{15}H_{26}O_6$: C, 59.6; H, 8.61. Found: C, 59.4; H, 8.6.

α,β,γ-Trimethyl-α-carboxyglutaric acid was obtained from the above ester by saponification with caustic soda. The acid was obtained as a sirup which could not be crystallized.

Anal. Calcd. for $C_9H_{14}O_6$: **C, 49.53; H, 6.45.** Found: **C, 49.83;** H, **6.52.**

Upon distillation the acid gave the ***cis*** and ***trans*** forms of **α,β,γ-trimethylglutaric** acid.

Action of Sodium Ethoxide upon **β,γ-Dimethyl-γ-carboxyglutaric** Ester.—Fourteen and five-tenths grams of the ester was refluxed for six hours with an ethereal suspension of sodium ethoxide prepared from 1.2 g. of sodium by Briihl's method. After **cooling,** the product was poured into a solution of 4 g. of acetic acid in water, and the mixture worked up in the usual manner; 7 g. of the neutral ester boiling below 150° **(15** mm.) consisted of crotonic and methylmalonic esters; **6** g. of ester boiled at 160–163° (15 mm.). This ester was saponified and found to consist mainly of **α,β-dimethyl-γ-**carboxyglutaric acid, m. p. **145°.** A small amount **(0.5 g.)** of **β,γ-dimethyl-γ-carboxy-**glutaric acid, m. p. 167°, separated from this material was formed from unchanged ester.

Addition of Malonic Ester to Tiglic Ester.—Twelve grams of malonic ester was added to sodium ethoxide prepared by **Brühl's** method from **1.8** g. of sodium; 9 g. of **tiglic** ester, b. p. 158° **(760** mm.), was added and the ethereal solutiop heated on a **water-**bath for five hours. Working up the products in the usual manner gave a yield of 3 g. of α,β-dimethyl-γ-carboxyglutaric ester, b. p. 150° (3 mm.).

Anal. Calcd. for $C_{14}H_{24}O_6$: **C, 58.33; H, 8.33.** Found: **C, 58.1; H, 8.4.**

α,β-Dimethyl-γ-carboxyglutaric acid was obtained from the above ester by saponification with caustic soda. It crystallized in well-defined prisms, m. p. **145'** with decomposition.

[17] Thorpe, J. Chem. *Soc.*, **83, 358 (1903).**

Anal. Calcd. for $C_8H_{12}O_6$: C, 47.07; H, 5.88. Found: C, 47.15; H, 5.8.

Larger quantities of this acid were prepared from the product of addition of sodium enol cyanacetic ester to tiglic ester.[18] The yield of α,β-dimethyl-γ-cyanoglutaric ester was 65% and it boiled at 143° (3 mm.). α,β-Dimethyl-γ-carboxyglutaric acid, obtained from the cyano ester by hydrolysis with caustic potash, was identical with the substance prepared by the other two methods.

α,β,γ-Trimethyl-γ-cyanoglutaric Ester.—Twelve grams of α,β-dimethyl-γ-cyanoglutaric ester was added to sodium ethoxide prepared from 1.2 g. of sodium and to the cooled ether solution 8 g. of methyl iodide was added, After standing for six hours. the mixture was worked up as usual. α,β,γ-Trimethyl-γ-cyanoglutaric ester distilled at 160° (2 mm.).

Anal. Calcd. for $C_{13}H_{21}O_4N$: C, 61.2; H, 8.24. Found: C, 60.9; H, 8.3.

α,β,γ-Trimethyl-γ-carboxyglutaric acid was obtained by hydrolysis of the above ester with a 20% caustic potash solution. The acid was obtained as a sirup.

Anal. Calcd. for $C_9H_{14}O_6$: C, 49.53; H, 6.45. Found: C, 49.6; H, 6.6.

F. E. Ray[19] prepared this acid from the ester obtained upon methylation of α,β-dimethyl-γ-cyanoglutaric ester, and described it as a solid. m. p. 144–145°. (It may be noted that 145° is the melting point of α,β-dimethyl-γ-carboxyglutaric acid.)

α,β,γ-Trimethylglutaric Acid.—α,β,γ-Trimethyl-γ-carboxyglutaric acid was heated at 160° in a distilling flask for thirty minutes, when the evolution of carbon dioxide ceased. The residue was then distilled, coming over at 170–180° (15 mm.) and partially solidifying in the receiver. This distillate was a mixture of *cis* and *trans* acids which were separated by the conversion of the *cis* form into the imide in the following way. The mixture, in a small distilling flask, was converted into the anhydride by several treatments with acetyl chloride. The acetic acid formed was removed under reduced pressure and dry ammonia gas passed through the sirupy mass at 130° for one hour. The cooled contents was dissolved in dilute hydrochloric acid. The acid solution was extracted with ether and the extract washed with aqueous sodium carbonate to remove the *trans* acid. Upon concentration of the ether solution the imide crystallized out.

α,β,γ-Trimethylglutarimide was recrystallized from a mixture of ether and ligroin, m. p. 90°.

Anal. Calcd. for $C_8H_{13}O_2N$: C, 61.94; H, 8.38. Found: C, 61.8; H, 8.2.

Cis-α,β,γ-trimethylglutaric acid was obtained from the α,β,γ-trimethylglutarimide by hydrolysis with 20% caustic soda. It crystallized from an ether and ligroin mixture in large prisms which, after the fourth crystallization, softened at 115° and melted at 125°.

Anal. Calcd. for $C_8H_{16}O_4$: C, 55.2; H, 8.06. Found: C, 55.6; H, 8.3.

Cis-α,β,γ-trimethylglutaric anhydride was a liquid. It was prepared from the above acid by treatment with acetyl chloride.

Trans-α,β,γ-trimethylglutaric acid was obtained by acidification of the sodium carbonate extract in the above separation from the *cis* imide. It remained a liquid and resisted all attempts to obtain a crystalline form.

Anal. Calcd. for $C_8H_{14}O_4$: C, 55.2; H, 8.04. Found: C, 55.0; H, 8.2.

F. E. Ray[19] described an α,β,γ-trimethylglutaric acid melting at 134°. He did not attempt to separate his product into the *cis* and *trans* forms, but obtained his acid by a series of crystallizations.

[18] Blaise, Bull. *soc. chim.*, [3]29, 332 (1903).

[19] Ray, This Journal, 50, 558 (1928).

β-Phenyl-γ-carboxyglutaric ester was prepared by addition of malonic ester to cinnamic ester using a small amount of sodium ethoxide; yield, 70%; b. p. 187° (4 mm.).[20]

β-Phenyl-γ-carboxyglutaric acid was obtained by saponification of the above ester with 10% caustic soda. This acid crystallizes from a mixture of chloroform and ligroin in fine needles, m. p. 137°.

Anal. Calcd. for $C_{12}H_{12}O_6$: C, 57.15; H, 4.76. Found: C, 56.9; H, 5.0.

Methylation of β-Phenyl-γ-carboxyglutaric Ester.—Thirty-four grams of the above ester was added to anhydrous sodium ethoxide prepared from 2.3 g. of sodium in ether; 15 g. of methyl iodide was added, the mixture allowed to stand in ice water for six hours, and the material worked up in the usual manner. On distillation of the neutral product, 17 g. boiled from 80–140° (3 mm.) and consisted of cinnamic and dimethylmalonic esters and 12 g. of γ-methyl-β-phenyl-γ-carboxyglutaric ester boiled at 194° (3 mm.).

And. Calcd. for $C_{19}H_{26}O_6$: C, 65.13; H, 7.43. Found: C, 65.0; H, 7.6.

γ-Methyl-β-phenyl-γ-carboxyglutaric acid was obtained from the above ester by saponification with caustic soda. On crystallization from a mixture of chloroform, acetone and ligroin, the acid first deposited fine needles which melted at 188° with decomposition.

And. Calcd. for $C_{13}H_{14}O_6$: C, 58.64; H, 5.26. Found: C, 58.4; H, 5.4.

The mother liquor then deposited a second acid crystallizing in large prisms, m. p., 148°.

Anal. Calcd. for $C_{13}H_{14}O_6$: C, 58.64; H, 5.26. Found: C, 58.3; H, 5.1.

These two acids are isomeric forms of γ-methyl-β-phenyl-γ-carboxyglutaric acid. The fine crystals of the acid, m. p. 148°, upon standing on a porous tile became converted into a form of m. p. 188° in the course of several hours. Large, well developed crystals of the low-melting form could be kept in a corked vessel for several months without change.

Carter and Lawrence[21] described γ-methyl-β-phenyl-γ-carboxyglutaric acid which they prepared by methylation of β-phenyl-γ-cyanoglutaric ester and saponification of the resulting γ-methyl-β-phenyl-γ-cyanoglutaric esters (which they obtained in two stereoisomeric forms) with caustic potash. They found that each of these stereoisomeric cyano esters gave the same γ-methyl-β-phenyl-γ-carboxyglutaric acid, m. p. 148'. Since they did not report obtaining any of the form of m. p. 188°, their synthesis was repeated. It was found that hydrolysis with alkali of each of the two **γ-methyl-β-phenyl-γ-cyanoglutaric** esters gave the acid of m. p. 148°, but this could be converted into the form of m. p. 188°.

Addition of Methylmalonic Ester to Cinnamic Ester

(a) Using a Small Amount of Sodium Ethoxide.—One-half gram of sodium was dissolved in the minimum of ethyl alcohol, 20 g. of methylmalonic ester added, then 200 cc. of dry ether and finally 20 g. of cinnamic ester. The mixture was refluxed on the water-bath for five hours, cooled and a solution of 2 g. of acetic acid in 20 cc. of water added. The product was worked up in the usual way; 16 g. of ester boiling at 80–140° (3 mm.) consisted of apparently unchanged esters; 20 g. boiling at 194–195° (3 mm.) proved to be **γ-methyl-β-phenyl-γ-carboxyglutaric** ester, since upon saponification it gave the corresponding acid.

---

[20] **Michael,** *J. prakt.* Chem. 35, 350 (1887).

[21] Carter and Lawrence, *Proc. Chem. Soc.*, **178 (1900).**

(b) Using One Molecular Equivalent of Sodium Ethoxide.—Twenty grams of methylmalonic ester was added to a suspension of sodium ethoxide prepared from 2.6 g. of sodium in dry ether; 20 g. of cinnamic ester was added and the mixture refluxed on the water-bath for six hours. After cooling, 7 g. of acetic acid in 50 cc. of water was added, and the ethereal extract worked up in the usual way. The neutral esters were fractionated and 16 g., b. p. 185–188° (3 mm.), was obtained.

Anal. Calcd. for $C_{19}H_{26}O_6$: C, 65.13; H, 7.43. Found: C, 64.9; H, 7.51.

α-Methyl-β-phenyl-γ-carboxyglutaric acids were obtained from the above ester upon saponification with caustic soda, thus proving its structure. The acid first deposited from solution in a mixture of chloroform, acetone and ligroin had a melting point of 171°. The mother liquor deposited a second acid, which crystallized in fine needles, m. p. 145°. These two acids, present in approximately equal amounts, were shown by analysis and mixed melting point to be identical with the corresponding acids synthesized from α-methylcinnamic ester.

Addition of Sodium Enol Cyanacetic Ester to α-Methylcinnamic Ester.—Three and six-tenths grams of sodium was dissolved in 50 cc. of alcohol and 17 g. of cyanacetic ester added, followed by 29 g. of a-methylcinnamic ester. The mixture was heated on the water-bath for twenty-four hours. After cooling, the product was poured into a solution of 10 g. of acetic acid in 200 g. of water, and the esters were extracted with ether. On fractionation of the neutral esters, 26 g. of α-methyl-β-phenyl-γ-cyanoglutaric ester, b. p. 185–187° (3 mm.), was obtained as a thick liquid.

Anal. Calcd. for $C_{17}H_{21}O_4N$: C, 67.33; H, 6.93. Found: C, 67.15; H, 7.1.

α-Methyl-β-phenyl-γ-carboxyglutaric acids were obtained by hydrolysis of the above ester with caustic potash. Upon fractional crystallization, the first acid was deposited as large prisms, m. p. 171°, with decomposition.

Anal. Calcd. for $C_{13}H_{14}O_6$: C, 58.49; H, 5.26. Found: C, 58.49; H, 5.5.

From the mother liquor a second acid was deposited as fine needles, m. p. 145° with decomposition.

Anal. Calcd. for $C_{13}H_{14}O_6$: C, 58.49; H, 5.26. Found: C, 68.30; H, 6.4.

Summary

1. It has been shown that the course of addition of methylmalonic ester to crotonic and cinnamic esters varies with the amount of sodium ethoxide used.

2. In the presence of small amounts of sodium ethoxide the addition proceeds with H and $—C(CH_3)(COOEt)_2$ as addendum components.

3. In the presence of a molecular equivalent of sodium ethoxide the addition proceeds with CH_3 and $—C(COOEt)=C(ONa)OEt$ as addendum components.

4. These results have rigorously proved the correctness of Thorpe's conclusions: that the addition of sodium enol cyanacetic ester to a-methylacrylic ester takes place with migration of the hydrogen atom and that the addition of sodium enol a-cyano propionic ester to β,β-dimethylacrylic ester takes place with migration of the methyl group.

5. The mechanism of these reactions is discussed and explanations of the results are suggested.

Cambridge, Massachusetts

NOTES

The Reduction of 1-Cystine to 1-Cysteine.—In a recent paper by Max Bergmann and Giorgios Michalis[1] a method is described for the catalytic hydrogenation of 1-cystine to 1-cysteine by means of "Palladium Mohr" and hydrogen. The authors also emphasized the possible importance of such a method for certain biological work in which metal-free cysteine preparations are desirable.[2] The use of dissolved metal salts for the reduction can be excluded with this method.

On the other hand Vincent du Vigneaud, L. F. Audrieth and H. S. Loring have presented a paper on "The Reduction of Cystine in Liquid Ammonia by Metallic Sodium" at the meeting of the Federation of the American Societies for Experimental Biology held at Chicago University on March 26, 1930. Without actually having heard this paper it is to be assumed from its title that it has anticipated the results obtained by the present author on the same subject, who also had found the system liquid ammonia–sodium to be a suitable reducing agent for 1-cystine. However, some sodium sulfide and alanine also were found to be formed in the course of the reaction.

Another reduction method for 1-cystine using aluminum amalgam as a reagent was simultaneously developed by the author and found to have some merits. This amalgam offers the possibility of reducing in aqueous solution, a minimum amount of dissolved metal salts being involved in the reaction due to the insolubility of the aluminum hydroxide formed. This and other advantages of the aluminum amalgam reduction process have been emphasized already several times before. An actual example was given in THIS JOURNAL in the reduction of phenylsulfonylchlorides to the corresponding mercaptans.[3]

A brief outline for the 1-cystine reduction, therefore, will be sufficient. 1-Cystine is dissolved in carbon dioxide-free water and 1–1.5 times its weight of aluminum amalgam[4] is added. The mixture is heated for approximately one hour. During this time the evolution of some hydrogen sulfide is noticed (hydrogen sulfide is also evolved in the course of the ordinary reduction using tin and hydrochloric acid; see Harrison, Ref. 2). The material is filtered with suction and washed with carbon dioxide-free water until the test with ferric chloride is negative. The filtrate and washings are combined, acidified with hydrochloric acid and evaporated to dryness in a vacuum at as low a temperature as possible. The crystalline

Chlor Phenol Red.—During the past summer this Laboratory had occasion to examine colorimetrically several commercial samples of this indicator from various sources. The wide variation in the color produced by the indicator in buffer solutions led to a careful examination of the samples.

Anal. Calcd. for dichlorophenolsulfonephthalein. $C_{19}H_{12}O_5SCl_2$: S, 7.58; Cl, 16.76. Found: Sample A, S, 6.76; Cl, 13.5; Sample B, S, 6.54; Cl, 16.00; Sample C, S, 7.14; Cl, 12.10; Sample D, S, 6.48; Cl, 8.46.

This indicator was first prepared by Cohen[1] by condensing *o*-chlorophenol with the crystalline anhydride of o-sulfobenzoic acid and subsequently crystallizing the crude product from glacial acetic acid.

The experience of this Laboratory has been that repeated crystallization from acetic acid will not give a pure product. By repeatedly dissolving the crude dye in hot water, acidifying with hydrochloric acid and concentrating on the water-bath to the point of crystallization, a product was obtained that gave the analysis: S, 7.60; Cl, 16.66.

This sample consisted of small, fine, greenish-brown crystals and gave an entirely different color in buffer solutions than samples heretofore examined. The alkaline color, besides being much more intense, contained more blue and less red than the commercial samples.

X-RAY INVESTIGATIONS ON RUBBER

Sir:

During some earlier x-ray investigations on crêpe rubber, it was observed that the originally translucent sample became more and more milky at the spot where the x-rays passed the material. The sample was the same as described in an earlier paper.[1] This rubber gave a distinct x-ray pattern during the first exposure, but, although the lines did not change their position, they became increasingly sharper with each exposure; simultaneously the opaqueness of the milky spot increased. The increase of sharpness of the originally broad lines represents, of course, increase in particle size; but evidently also the increasing cloudiness of the crepe rubber shows progressing crystallization

Another sample of the crepe rubber was placed in front of the window of the x-ray tube and again slowly the milky spot formed becoming eventually entirely opaque toward transmitted light. The spot obtained was sharply defined by the transmitted x-ray beam and showed no diffuseness at the circumference. After four years of storage, no further changes occurred in the sample. Upon slight warming the milky spot would melt away again.

An increase in the rate of crystallization of gutta-percha, but not of rubber, by means of ultraviolet light was observed by Kirchhof.[2]

Evidently the above sample of rubber behaves similarly under the influence of x-rays as does gutta-percha with ultraviolet light.

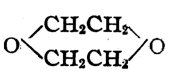
THE RAMAN SPECTRUM OF DIOXANE

Sir:

During the course of an investigation of the Raman spectrum of some synthetic resins, the solvent dioxane was used. As the spectrum of the latter has not been published previously, I wish to report here my findings.



Dioxane

An apparatus designed by Reynolds and Benford [*Review of Scientific* Instruments, 1, 413416 (1930)] was used, modified by having a chromium elliptical reflector instead of a silver one, and its major axis in a horizontal rather than a vertical plane. A mercury arc gave the exciting spectrum, exposures of about six hours being made.

THE PHOTOCHEMICAL POLYMERIZATION OF ACETYLENE

Sir:

It has been reported by several observers[1] that the polymerization of acetylene to a solid resembling cuprene is induced by either activated mercury atoms or by the direct absorption of ultraviolet light. A quantitative investigation of the photochemical reaction has been undertaken in the hope of throwing some light on the kinetics of the process and to determine whether there is any simple relation between the ***quantum yield*** and ***the ion pair yield*** of the analogous radiochemical reaction.[2]

The following are some of the more important results of this investigation. Using the complete radiation of a quartz mercury arc and a reaction vessel three centimeters deep, the reaction velocity was observed to be proportional to the pressure of acetylene as long as this pressure was not greater than 30 cm.; at higher pressures the velocity approached a constant value. It seems probable therefore that the rate of polymerization

is proportional to the intensity of the absorbed light but is otherwise independent of the acetylene pressure. Using the same light source, the temperature coefficient of the reaction was determined by comparing the rate at 12 and at 39°. The ten degree temperature coefficient, so determined, has a value of 1.25. It is quite possible that this observed value may be largely the temperature coefficient of the light absorption rather than that of the chemical reaction. Experiments performed with light filters indicate that light of wave length 2537 Å. and longer is not efficient in producing the reaction; this is probably due to the comparative transparency of acetylene in this region.

Several determinations of the quantum yield have been made. The light source used in these experiments was a mercury arc combined with a focal isolation apparatus, which excluded all radiation of wave length greater than 2537 Å. A weighted average of $M/h\nu$, for three separate determinations, is 7.4 ± 2.5. The uncertainty of this value is due to the precipitation of cuprene on the walls of the reaction cell, which limited the measurements to the first two millimeters' reduction in pressure. These experiments will be repeated with a more sensitive manometer in order to obtain a more accurate value for the quantum yield. Similar experiments with allene and the homologs of acetylene are now in progress. In all experiments a "hot" mercury arc was used, pressures were measured with a quartz spiral manometer and liquid-air traps and gold foil were used to prevent the access of mercury vapor to the reaction system.

NEW BOOKS

Gmelins Handbuch der anorganischen Chemie. (Gmelin's Handbook of Inorganic Chemistry.) Edited by R. J. MEYER. Eighth edition. Beryllium. System-number 26. Issued by the Deutsche Chemische Gesellschaft, Verlag Chemie G. m. b. H., Corneliusstrasse 3, Berlin W 10, Germany, 1930. xviii + 180 pp. 10 figs. 17 X 25 cm. Price, to subscribers, M. 23.50; singly, M. 30.

This volume covers the history of our knowledge of Beryllium, its occurrence, the preparation and properties of the free element and the preparation and properties of its compounds with elements having system-numbers smaller than 26, namely, the non-metals and the alkali metals. The literature has been covered to May 1, 1930.

The collaborators in the preparation of this volume were Martin Hosenfeld, Hellmut Fischer, Sibylle Cohn-Tolksdorf (atomic and optical properties) and Adrienne Eisner (the complex compounds).

This volume is yet another valuable addition to this useful reference work.

ARTHUR B. LAMB

Gmelins Handbuch der anorganischen Chemie. (Gmelin's Handbook of Inorganic Chemistry,) Edited by R. J. MEYER. Eighth edition. Cobalt. Part B. The Cobaltammines. System-number 58. Issued by the Deutsche Chemische Gesellschaft, Verlag Chemie G. m. b. H., Corneliusstrasse 3, Berlin W 10, Germany, 1930. xxv + 376 pp. 2 figs. 17 X 25 cm. Price, to subscribers, M. 45; singly, M. 58.

The great group of the Cobaltammines whose broad outlines were first discerned by our own Wolcott Gibbs and F. A. Genth and which S. M. Jorgensen so greatly enriched, has been of much importance in the development of chemical theory—particularly as a basis for Alfred Werner's revolutionary and far-reaching ideas.

The first and indeed only adequate encyclopedia of our experimental knowledge of this group has been the volume entitled "Kobaltiake" written by Paul Pfeiffer and published as a part of the seventh edition of Gmelins Handbuch. The present volume is a revision and extension of this earlier work. Its original 290 pages have grown to 376 pages in spite of the use of finer type and the exercise of the greatest conciseness. The literature has been covered to the end of 1929.

Dr. Olga Angern (with Professor Pfeiffer's counsel), Dr. Mark von Stackelberg and Dr. Emma Haller collaborated in the writing and preparation of this book. It, like its predecessor, will be invaluable to anyone engaged in a study of this interesting group.

ARTHUR B. LAMB

Oxidation–Reduction Potentials. By L. MICHAELIS, Member of the Rockefeller Institute for Medical Research. Translated from the German Manuscript by Louis B. Flexner. J. B. Lippincott Company, East Washington Square, Philadelphia. Pennsylvania, 1930. xii + 199 pp. 16 illustrations. 14 X 21 cm. Price, $3.00.

During the past few years the author of this monograph has played an active part in the potentiometric study of those oxidation–reduction systems which are of particular interest to the biologist, and he has "thought it timely and useful to venture to weigh the investigations so far made, to collect and to analyze their application to biological problems and to discuss the theoretical principles of oxidation–reduction potentials with the hope that future work by others as well as by himself might be facilitated." An introductory discussion of the energy changes which may occur in living organisms is followed by an exposition of the more important aspects of the physical chemistry of inorganic and organic oxidation–reduction systems. The remainder of the book is devoted to a description of the physiological applications which have been made of these principles, with particular emphasis on the puzzling system formed by cystine and cysteine, to our knowledge of which Michaelis and his associates have generously contributed.

Those who have felt the need of some assistance in the problem of rapidly instructing the uninitiate in this modern field of research will not find their desires very well fulfilled by the new book, for it is addressed primarily to the expert rather than to the beginner The treatment throughout is critical, and the author's comments and historical notes, however interesting, do not always add to the clarity of presentation. The coining of the new word "redox" for "oxidation–reduction" and the inclusion in the text of the symbols "Rep," "Ret," "Oxp" and "Oxt" add neither to the beauty of scientific language nor to the simplification of the subject,

Those who are engaged in research on oxidation–reduction potentials will find in Michaelis' monograph an interesting commentary on those phases of the general subject which he has selected for discussion. Few will fail to find both matters which are treated quite to their liking and ideas with which they definitely disagree. Since little agreement among the critics themselves is to be expected, it is clear that Michaelis has hesitated neither to raise plenty of debatable questions nor to indicate his own opinion. Theoretical views, indeed, are often advanced with a considerable degree of enthusiasm. In the treatment of the long-standing question of the mechanism of oxidation–reduction, for example, Michaelis is well aware that equilibrium data, which represent the only facts yet available, furnish no clue to the mechanism, and yet he finds the hypothesis of electron exchange so attractive that he applies it even to the oxidation of basic substances in neutral or acid medium. It is necessary in this case to assume the *acidic* dissociation of a strongly basic group as a primary step in the oxidation. A less ardent supporter of the electron hypothesis would concede that the Wieland mechanism gives a more reasonable interpretation of this particular type of reaction.

While the newer ideas advanced by the author afford stimulating reading, one feels that they are to be regarded as suggestions rather than as well-rounded theories, for they do not always appear to be complete. Thus in developing a theory of the relation between color and oxidation potential the author states that the oxidized forms of the dyestuffs are without exception colored and the reduced forms colorless. He apparently has overlooked the striking relationship between the pale yellow anthraquinones and the intensely colored anthrahydroquinone ions.

In a field of work which is in the course of active development and which still presents numerous important problems, it is of value from time to time to have a comprehensive statement of the views of anyone whose work stamps him as an authority. Michaelis' monograph will be accepted as exactly fulfilling this function.

LOUIS F. FIESER

Diatomaceous Earth. By ROBERT CALVERT, Chief Chemist, Van Schaack Bros. Chemical Works, Chicago, Illinois. Book Department, The Chemical Catalog Co., Inc., 419 Fourth Avenue, at 29th Street, New Pork, U. S. A, 1930. American Chemical Society Monograph Series, No. 52. 251 pp. 15.5 X 23.5 cm.

The author of this American Chemical Society Monograph intends it as "a description of the present day industry of diatomaceous earth, an interpretation of the literature in the light of experience, and an indication of needed discoveries yet to be made in a new and interesting field of research."

He begins by explaining the structure and composition of diatomaceous earth with numerous photomicrographs showing the exquisite and varied forms of the diatoms whose fossilized remains have accumulated in enormous deposits in earlier geologic periods. The available statistics on production and trade throughout the world are assembled, showing that the amount mined in the United States exceeds the total in all the rest of the world by a substantial margin. The more important deposits are briefly described. The mining of the earth and its preparation for the market are discussed in considerable detail. The physical properties are expounded with special emphasis on the high porosity with the resultant low apparent density, great power to absorb liquids and low heat conductivity. Most of the book is devoted to present-day uses of the earth, the chief of these being for the filtration of sugar solutions, and for the manufacture of diatomaceous brick for thermal insulation, and as an addition to concrete. The **use** of diatotnaceous earth in these and in many other industries is discussed thoroughly. There is also a chapter on thermal conductance and loss of heat through furnace walls, which gives the theory and mathematics of conductance and insulation.

The book is well planned and clearly written, and offers a comprehensive review of the diatomaceous earth industry.

GRINNELL JONES
DOROTHY M. BOLLINGER

Organisch-chemisches Praktikum. **(Manual of Organic Chemistry.) By Dr.** LUDWIG **ORTHNER, Lecturer at the Technical High School of Karlsruhe, and Dr.** LUDWIG REICHEL, **Assistant at the Technical High School of Karlsruhe. Verlag Chemie, G. m. b. H., Corneliusstrasse 3, Berlin W 10, Germany, 1929. xvi + 260 pp. 61 figs. 23.5 × 15.5 cm. Price, unbound, M. 9; bound, M. 10.**

This is an interesting, useful and well-written little handbook of organic preparations. The choice and spread of experiments is quite commendable. In keeping with the present trend of organic chemistry, there are a number of experiments dealing with natural products, with the synthesis of biologically important compounds, and with a few catalytic procedures. There are interspersed throughout the book, and particularly at the conclusion of each series of preparations dealing with a given type of compound, brief discussions of the fundamental chemistry of the series. That the authors have an appreciation of the physical chemistry viewpoint is also evident. The conventional chapter on analytical procedures differs uniquely from other texts of this character in that it describes the very useful and practical half-micro methods of H. ter Meulen and Heslinga. Taken as a whole, then, the book creates a decidedly favorable impression.

ARTHUR J. HILL

The Constitution of Sugars. By WALTER NORMAN HAWORTH, D.Sc., Ph.D., F.R.S., Professor of Chemistry and Director of the Department of Chemistry in the University of Birmingham. Longmans, Green and Company, 55 Fifth Avenue, New York City, 1929. vii + 100 pp. Illustrated. 15 × 24 cm. Price, $3.40.

This book gives a review of the more recent developments in the field of carbohydrate chemistry with which Professor Haworth's name is so closely linked.

The important part played by the ring configuration of sugars is being more and more recognized in biological, biochemical, physiological, botanical and industrial problems.

In the field relating to the structure of carbohydrates and polysaccharides, Professor Haworth's brilliant contributions are too well known to require note. Thanks to the masterly technique developed with the aid of his colleague, Dr. Hirst, assisted by a very able group of co-workers, it has been possible to establish the constitution of the majority of the sugars on a firm experimental basis and, while such views have not yet been accepted in their entirety in all quarters, it is, in the reviewer's opinion, merely a matter of a relatively short time before such will be the case.

The volume can be recommended most heartily to all students of carbohydrate and polysaccharide chemistry, as well as to all other students interested in obtaining a clear and accurate present-day picture of the structure of the products in this field.

HAROLD HIBBERT

Aluminiumchlorid in der organischen Chemie. (Aluminum Chloride in Organic Chemistry.) By GEORG KRÄNZLEIN, I. G. Farbenindustrie A.-G. Verlag Chemie G. m. b. H., Corneliusstrasse 3, Berlin W 10, Germany, 1930. 47 pp. 15.5 X 2.35 cm. Price, M, 3.

The recent developments in the commercial production of aluminum chloride and the publicity given them make this booklet unusually timely. It presents a survey of the organic chemical uses of aluminum chloride in eleven subdivisions: the Friedel–Crafts reaction with its ramifications, the Fries rearrangement, the Scholl reaction, dehydrogenations, addition reactions, condensation reactions with the elimination of water, halogenations, nitrations, polymerization and condensation reactions, splittings and rearrangements, and the cracking of hydrocarbons. The technical and industrial values of the various reactions are emphasized. The book work is well done and the numerous formulas make for a clearer and more ready understanding of the complicated polynuclear compounds frequently introduced, The brochure is up-to-date, containing, as it does, citations from the literature of 1929. The large number of footnote references, 179 being given, include several to patents. This little volume will be of interest to anyone who is concerned with the scope of the use of a reagent, aluminum chloride, which promises to be of increasing significance in organic chemistry.

G. ALBERT HILL

Thyroxine. By EDWARD C. KENDALL, M.S., Ph.D., D.Sc., the Mayo Foundation, Rochester, Minnesota. American Chemical Society Monograph Series. The Chemical Catalog Company, Inc., 419 Fourth Avenue, New York 1929. 265 pp. 39 figs. **15 X 23.5 cm. Price, $5.50.**

The interested public—and it is a large one—owes much to Dr. Kendall's reserve in the preparation of this admirable monograph on this active agent of the thyroid gland. As the author notes in his preface, the book was one of the first to be announced in the series in which it appears, but actually it is the forty-seventh of the monographs to reach the public. The great interest in all that pertains to the thyroid both from the purely scientific and from the clinical viewpoints has led to a large amount of highly important investigative work during the last few years. By his well considered delay, Dr. Kendall has been able to give us a conspectus of these recent additions to knowledge in the field.

The author's own contributions are of the greatest significance, and the early chapters of the book are devoted to a summary of them, prefaced by a brief historical sketch. As a chemist, the author emphasizes that aspect of the work in these earlier chapters, giving a critical review of the methods adopted for the isolation of thyroxin, the proof of its constitution, and a summary of its physical and chemical properties. This naturally leads to a discussion of the iodine content of the thyroid gland, the only portion of the body known certainly to contain this demonstrably essential element in detectable amounts.

The author next turns to clinical consideration of the thyroid gland and its functional and organic derangements. Certain phases of mineral and nitrogen metabolism, the nervous influence of the secretory activity of the gland, Reid Hunt's acetonitrile test, and the effects of changed function on the respiratory and carbohydrate metabolism are successively considered.

It is well recognized that the thyroid is one of the potent regulators of growth and development, and chapters are allotted both to the results of spontaneous failure on various living forms and also to the stimulating effects of thyroid substances on the metamorphosis of amphibian larvae. Other chapters dealing with pharmacological studies include the standardization of thyroid preparations and their physiological activity; in addition, certain clinical and pathological material is discussed. With its well-known profound effect upon respiratory metabolism in the living organism, space is devoted to a consideration of possible mechanisms through which the active agent, thyroxin, may influence biological oxidations. The book concludes with a well selected bibliography listing five hundred and forty-one titles and well compiled author and subject indices. The book as a whole is a most excellent piece of work. While the author states that he has approached the task from the standpoint of a chemist, he has presented the clinical aspects in a way to be of interest and information to the practitioner. The selections from the over-abundant literature have been most judicious, and an adherence to factual evidence is maintained throughout, the latter a pleasing and refreshing contrast to some of even the more recent of the literature of the ductless glands. Dr. Kendall is to be congratulated on the production of a most readable and significant treatise on a subject of wide general interest and import.

A. W. ROWE

Essences naturelles et parfums. (Natural Essences and Perfumes.) By RAYMOND DELANGE, Chief, Services Scientifiques des Fabriques de Laire. Librairie Armand Colin, 103 Boulevard Saint-Michel, Paris, 1930. 222 pp. 11 × 17 cm. Price, unbound, 10.50 fr.; bound, 12 fr.

While this little handbook does not pretend to compete with the larger works on essential oils and perfumes, it should prove very valuable to those who wish to acquire a general knowledge of the chemistry of the subject.

A chapter on odor and its relation to the properties and molecular structure of substances is useful and interesting.

Chapters on analysis of oils and on the chemistry of the constituents of essential oils will be of interest to the worker in the laboratory.

The chapter on definite odoriferous compounds, both natural and synthetic, contains much valuable information.

The information given is accurate and concise.

The author states that by reason of the plan of the work he describes only a few of the more characteristic essential oils. Fifteen such oils are included, besides certain natural resins and some animal products used in perfumery.

The work includes a bibliography with references in the text.

COLLOIDAL PLATINUM AND ITS BEHAVIOR AS A TYPICAL ACIDOID SOL

BY S. W. PENNYCUICK

RECEIVED APRIL 29, 1930 PUBLISHED DECEMBER 18, 1930

For some time the author has been engaged on a series of investigations upon the structure, stability and general reactions of colloidal platinum.[1] The advancement of the work has reached a stage where it has proved desirable to present the collective evidence concerning the behavior of colloidal platinum as an acidoid sol, and to discuss the surface actions and the coagulation process, in the light of the more recent work.

Apart from its general interest as a negative hydrophobic sol, colloidal platinum presents added features of importance. Its catalytic powers are well-known and, further, the question arises as to whether each platinum particle in the presence of oxygen (or of hydrogen) does not behave as a tiny oxygen (or hydrogen) electrode. Investigations at present in hand lead to the hope that the results will ultimately throw light on catalytic actions and on electrode phenomena.

The Arcing of Platinum Poles.—All platinum sols used by the author were prepared by the Bredig method, using chemically pure platinum poles and conductivity water of specific conductivity less than 0.6×10^{-6}. The arcing was carried out in a closed vessel into which any required gas could be introduced. The negative pole showed the characteristic disintegration crater, and hence the platinum leaves this pole, probably with a negative charge. Some of the atomized platinum condenses on the positive pole, which accordingly becomes elongated. The rest is dispersed into the solution, but only a fraction of this remains suspended as the colloid. Although the solution is kept continually circulating and at a temperature close to 0°, the tips of the poles become red hot and the action there is violent. Conditions are, therefore, suitable for the reaction of the atomized platinum with the water or with the oxygen due to the electrolytic decomposition of the water. In any case, Rocasolano[2] has found

---

[1] See *Australian* **J.** *Exp. Biol. Med. Science,* 4, 99 (1927); *J. Chem. Soc.,* 2600 (1927); 551, 2108 (1928); 618, 623 (1929); *Kolloid-Z.,* 49, 407 (1929).

[2] Rocasolano, "Colloid Chemistry (Alexander)," Vol. I, 1926, p. 678.

that only hydrogen gas is actually given off, and therefore the equivalent amount of oxygen has been taken up by the platinum. As finely divided platinum is relatively easily oxidized,[3] one may conclude that under the conditions cited the oxygen has been taken up to form definite oxidation products, such as oxides and oxy-acids.

The dissolved oxygen does not play a controlling part in the formation of these oxidation products, for if the preparation be carried out in the presence of nitrogen and the complete absence of oxygen[4] (or of air), a comparable sol is obtained. It is acidoid, it contains the same free strong platinic acid, but it is somewhat less stable (more readily coagulated on boiling) than the corresponding sol prepared in the presence of oxygen. Such sols will be referred to as platinum–nitrogen and platinum-oxygen sols, respectively. It will be convenient to point out here that the results obtained show that whilst the surface of the particles of the platinum–nitrogen sol contains some unoxidized platinum, the surface of the platinum–oxygen (or platinum–air) sol is wholly oxidized. If a stream of oxygen is passed into the former sol, sometime after preparation, its behavior is now comparable in every detail, with that of the platinum–oxygen sol. From these results one can assign the part played by the dissolved oxygen in the preparation of the latter sols.

The Free Electrolyte Produced by Arcing.—On dispersing from 100 to 150 mg. of platinum in a liter of water, the specific conductivity is of the order 6 to 8 X 10^{-6}, and this may be increased to 30 X 10^{-6} (or more) by boiling. From the weight of platinum present, and from the approximate radius of the particles (30 X 10^{-7} cm.), one may calculate that the molality of the dispersed platinum is of the order 10^{-10} M, and the specific conductivity due to the particles of the order 5×10^{-12}. This is, of course, immeasurably small. Now the total negative charge on the platinum is equal to the positive charge on the contra ions ("gegenionen"), and these as will be shown are hydrogen ions. In order that the conductivity of these ions should approach the average error shown in conductivity measurements (0.3 X 10^{-6}, corresponding to 0.000001 equivalent of hydrogen ion), it can be shown that each platinum particle must give rise to at least 10,000 "free" hydrogen ions. (By "free ions" are understood those which contribute the whole of their conductivity to the solution.) The evidence available leads us to believe that in no case does the number of free contra ions ever approach this value, and hence the conductivity of both the platinum particles and their hydrogen contra ions may be neglected. This conclusion is confirmed by the following experiment. When an acid such as hydrochloric or nitric is added to a pure platinum

---

[3] Wohler, *Z. anorg. Chem.*, 29, 1 (1901); 40, 423 (1904).

[4] The oxygen due to the electrolytic decomposition of the water cannot, of course, be excluded.

sol and to a strictly comparable sample of the intermicellar fluid, the conductivity-concentration curves exactly coincide, even when carried right past the coagulation point. Hence the removal of the platinum with its hydrogen ion partners causes no alteration in the conductivity. The whole of the measurable conductivity of a platinum sol may, therefore, be attributed to the free electrolyte produced during the arcing process. The intermicellar fluid (referred to above) can be isolated so as to retain this electrolyte by freezing and then thawing the sol. This treatment completely coagulates the platinum and leaves the clear intermicellar fluid.

Although the amount of dissolved electrolyte is too small for exact quantitative identification, titration with bases shows that it is a strong acid. From a knowledge of the oxidation products of platinum, the author concludes that this free strong acid is hexahydroxyplatinic acid ($H_2Pt(OH)_6$), or one of its dehydration products, *e. g.*, $H_2PtO(OH)_4$. The amount present is always small, and an average sol of specific conductivity 15×10^{-6} contains 0.00004 equivalent. It will be shown later that many acids, including the common inorganic acids, coagulate at a constant hydrogen-ion concentration, namely 0.0002 N. It therefore appears that this would also serve as an approximate limiting maximum for the concentration of the hexahydroxy acid, in the preparation of stable sols.

If platinum sols are filtered in order to remove the larger particles or the products of coagulation, the free acidity may become completely destroyed by the filter paper. The work of Kolthoff,[5] Rona and Michaelis,[6] and Mokruschin and Kryloff[7] on the action of filter paper on acids, shows either that the acid is "adsorbed," or that there is an interchange of cations. To retain an acidoid sol in the absolutely pure state, filtering must be avoided, and any flocculated products removed by centrifuging or simply allowing the sol to stand for some time.

Hexahydroxyplatinic Acid as the Stabilizing Ionogen at the Colloid Surface.—In the theory of colloid structure as developed by Duclaux,[8] Gouy,[9] Debye and Hückel,[10] McBain,[11] Bjerrum,[12] Pauli and Engel,[13] Pauli and Schmidt,[14] and others, the colloid particles are regarded as huge multivalent ions which owe their charges to the ionization of surface ion-

ogens. In many cases the surface ionogen has been identified.[15] With colloidal platinum, the following considerations leave no doubt that the active ionogen is the strong platinic acid, which has already been identified as $H_2Pt(OH)_6$[16] or one of its near relations.

(a) First there is the general evidence that colloidal platinum prepared in conductivity water forms a stable sol. The surface ionogen necessary for stability must therefore have been formed during the arcing process. This immediately suggests that the ionogen is identical with the free acid present in the sol, and that probably an equilibrium exists between the amount combined and the amount free.

(b) On aging or on boiling, the conductivity steadily increases. The statement[17] that "many metallic sols, *e. g.*, colloidal platinum, coagulate quickly upon warming," is not correct. Pure platinum sols when prepared as above, can be boiled for hours. The increase in conductivity is due to the liberation (or formation) of more free electrolyte. On freezing out the platinum from the boiled sols, it can be shown, by titration with bases, that the whole of the electrolyte present (including that newly formed) is the strong platinic acid. As there is a possibility that boiling may favor the production of further acid by oxidation, the boiling has also been carried out in the absence of oxygen and in the presence of nitrogen. Similar increases in conductivity were always obtained; hence it may be concluded that the colloid particles contain some platinic acid, which is gradually liberated on boiling or on aging.

(c) On the addition of neutral salts it can be shown that the increase in acidity up to (and past) the coagulation point, is due to the ionic exchange of hydrogen contra ions for cations of the added salt. This result, together with the foregoing, offers conclusive evidence that the contra ions are hydrogen ions, the surface ionogen is an acid and the sol is an acidoid.

(d) In the presence of added acid, experiments show that the decrease in the cataphoretic velocity (or in the ζ-potential) is a linear function of the square root of the acid concentration. In terms of the Debye–Hückel theory as applied to colloids,[10] this result directly indicates that the added acid simply depresses the ionization of the surface acid until the critical potential is reached and coagulation ensues. This, in conjunction with the fact that acids coagulate at a fixed P_H, affords further direct evidence that the platinum sol is acidoid.

The Amount of Surface Acid.—It has proved extremely difficult to obtain an approximate idea of the fraction of surface covered by the acid. Quantitative examination of the platinum particles is of little use,

for apart from the surface acid there appears to be a considerable amount of acid in the interior of the particle. Experiments with barium hydroxide indicate that a maximum of 25% of the surface is the hexahydroxy acid, but later work with other bases shows that this is far too high even as a guiding maximum. By calculating the amount of hydrogen ion displaced from the surface by barium ion in the presence of excess barium chloride, one obtains a maximum of 14% of surface acid. As in such cases hydrolytic cleavage is superimposed on the ionic replacement, the actual fraction is probably considerably less than this. Furthermore, the results indicate that in the pure sol an intimate relationship exists between the charge carried and the concentration of free hexahydroxy acid. A comparison of the free acid concentration and the ζ-potential, for a variety of pure sols, gave such irregular results as to suggest that the hexahydroxy acid is bound at the colloid surface only at active points, and that the latter vary with the age and the treatment of the sol. The percentage of surface acid, therefore, varies from sol to sol, and at present no reliable value can be given in any one case.

How is the Acid Held at the Surface?—There is nothing to be gained by laboring the different points of view as to whether the hexahydroxy acid is adsorbed or chemically combined at the surface. It must be pointed out, however, that explanations of surface action (adsorption) in terms of the single physical factor, surface energy, have proved notoriously infertile and incomplete. Ellis[18] and Powis[19] have demonstrated, in the case of oil emulsions, that the supposed intimate relation between adsorption, surface tension and electric charge, does not exist at all, whilst coagulation phenomena observed with oil drops, vanadium pentoxide and also with colloidal platinum, can be shown to have no connection with changes in interfacial tension. Furthermore, Laing, McBain and Harrison[20] have obtained results which appear to be quite contrary to the predictions of the Gibbs theorem.

The more useful interpretation that surface reactions take place through oriented and polar groups is to be preferred. Adsorption forces are then identified as those which produce chemical combination, any differences being only in degree. This is the point of view adopted by the writer, who considers that the anion of the hexahydroxy acid exists at the surface as part of the micelle structure, and the following evidence indicates that it is there combined with certain active molecules which are probably oxides. It has been pointed out that a platinum–nitrogen sol contains less surface oxide than a platinum–oxygen sol. The former is, moreover, less

---

[20] "Colloid Symposium Monograph," Chemical Catalog Co., Inc., New York, 1928, p. 631.

stable against boiling. If, however, it receives a stream of oxygen, its stability is now comparable with the platinum–oxygen sol. The stabilizing acid is therefore more strongly held, the more the surface is oxidized. Further, if hydrogen is passed into any sol, one would expect the surface oxides to be reduced, and in keeping, the sol immediately loses its acidoid properties; if oxygen is now re-introduced the acidoid properties are recovered. One therefore concludes that the hexahydroxy acid is only combined when there are surface oxides present.

The Nature of the Rest of the Surface.—As colloid reactions are fundamentally surface reactions, a knowledge of the nature of the surface is of primary importance. It has been shown that the hexahydroxyplatinic acid appears to be combined at the surface with oxides of platinum, and the evidence will now be briefly summarized which indicates that the rest of the surface is also some form of oxidized platinum.

Platinum sols can take up large amount of bivalent bases. Measurements show that these amounts are not only more than sufficient to neutralize the surface acid, but that they are approximately sufficient to cover the whole of the colloid surface with a unimolecular layer. If a stream of hydrogen is passed for a limited period into a pure sol, two results become evident, first, the acidoid properties immediately disappear, and, second, the sol cannot now take up any barium hydroxide at all. Under the action of the hydrogen the surface properties have thus become completely altered.[21] If a stream of oxygen be now passed, both the acidoid properties and the power of removing bases are restored, although both are somewhat weakened. The obvious explanation of these phenomena is that the particles of colloidal platinum, when in the presence of oxygen (or of air), are coated with some form of oxidized platinum which confers upon them their characteristic properties. The addition of hydrogen immediately reduces the surface oxides and hence destroys these properties. (The hydrogen also probably reduces some of the free hexahydroxy acid, but this action is relatively slow and is not allowed to become complete.) In keeping with the above it is found that a sol prepared and handled in the presence of nitrogen takes up less base than a normal sol, *i. e.*, one prepared in the presence of air. If, however, a stream of oxygen is passed into the former sol its power of removing bases is considerably increased. It therefore appears that the surface of the platinum–nitrogen sol contains some unoxidized platinum, which is turned into the oxide simply by passing oxygen.

The question might be raised as to whether the oxygen held at the surface is merely physically adsorbed and not chemically combined. This is really of secondary importance, the major point being that it is the surface

---

[21] The sols containing hydrogen, although no longer acidoid, are quite stable in the absence of air. Such sols are at present under investigation.

oxygen which confers the normal properties on colloidal platinum. However, the indications are that definite compounds are formed. Freundlich[22] quotes general evidence that "oxygen appears to be bound by platinum in the true chemical sense," *e.* g., platinum containing oxygen dissolves in acid in proportion to its oxygen content; the temperature coefficient of the fixation is positive, and oxygen cannot be pumped off at ordinary temperatures. These observations were made with platinum metal, and as it is well known that substances in a finely divided state, particularly when newly formed, are more reactive than when in the coarse state, the same general conclusions doubtless hold for the colloidal metal. In fact the author has shown that colloidal platinum particles, in the presence of air, take up 20 to 30 times as much barium hydroxide as an equal area of platinum gauze or foil. As it has been shown that bases are only taken up by the surface in the presence of oxygen, we must conclude that the colloid surface is far more reactive toward oxygen than the metal surface. Again the fact that ordinary platinum sols, when placed in a reflux condenser and in a stream of nitrogen, can be boiled for hours, is further evidence that the surface oxygen is particularly strongly held.

Reactions at the Surface of Colloidal Platinum.—The simplest formula for a platinum sol would be of the nature

$$[x\mathrm{Pt}\cdot y\mathrm{PtO_2}\cdot z\mathrm{Pt(OH)_6}]^{2z-}\ldots\ldots 2z\mathrm{H}^+$$

Here the Pt represents, very incompletely, the constitution of the interior of the particle, PtO_2 conveniently represents the surface oxide, and $H_2Pt(OH)_6$ the surface ionogen. From all points of view the formula is incomplete, but the representation of the surface is sufficiently accurate to serve as a basis for the discussion of surface reactions. In keeping with the Debye–Hückel theory of the colloid as a strong electrolyte,[10] the surface ionogen is shown as completely ionized. One might compare this formula, especially with regard to surface structure, with that proposed by Pauli[23] for silicic acid sols, namely

$$[x\mathrm{SiO_2} + n\mathrm{H_2O}\cdot y\mathrm{SiO_3H}]^{y-} + y\mathrm{H}^+$$

Reactions at the surface fall into three distinct classes, and these will be discussed separately.

First, there is the ionic replacement of the hydrogen contra ions by the cations of added electrolyte. Although the $H_2Pt(OH)_6$ in the above formula is represented as wholly ionized, the hydrogen ions form an ionic atmosphere around each particle, and only a small fraction can be regarded as actually "free." On the addition of any salt, *e.* g., barium chloride, some of the barium ions enter the ionic atmosphere, displacing the equivalent amount of "bound" hydrogen ion. This is the fundamental action leading up to coagulation and, in keeping, both the replacement and the coagula-

---

[22] Freundlich, Ref. 17, p. 153.

[23] See Pauli and Valkó, Ref. 15, p. 509.

tion depend upon the concentration, the valence and the specific properties of the cations concerned. This will be discussed in the section on "Coagulation;" it is sufficient to say here that in the case of colloidal platinum ionic replacement has been demonstrated with all types of salts.

Second, the surface oxide is an acidic oxide, and by combination with such added electrolytes as bases, etc., it may form either simple or complex salts. These-act as fresh surface ionogens, and cause an increase in the charge, greater stability and so on. These conclusions are based on considerable experimental evidence; for example, it may be shown with sodium hydroxide that a definite amount of base is removed by the colloid, and at the same time cataphoretic velocity of the particle, and the ζ-potential, are increased by more than 100 per cent. The combination of the base at the surface has thus produced fresh surface ionogens, and these are interpreted in the nature of salts. All bases act in a similar manner. Further, it may be shown that some few electrolytes, *e.* g., HCN, $K_4Fe(CN)_6$ and $K_2Pt(CN)_6$ are also removed by the colloid and at the same time cause an increase in the ζ-potential of the colloid particles, and hence a production of fresh surface ionogens. This reaction is interpreted as due to the formation of complex salts between the surface oxide and the added electrolyte, *e.* g., $[PtO_2\ldots CN]^- + H^+$, or $[PtO_2\ldots(CN)_6Pt]^= + 2K^+$. In keeping with the acid nature of the surface oxide, it is always a complex anion (never cation) which is formed, and this being bound at the surface increases the negative charge of the colloid. This also serves to explain the combination of the hexahydroxy acid itself at the surface, for as has already been pointed out this acid is bound only so long as there are platinum oxidation products there.

Third, we have the possibility of hydrolytic cleavage. One of the striking features of colloidal platinum is its great affinity for bases. As this is due to the acid nature of the surface, it follows that on the addition of a salt the ordinary partition effects would hold and the surface would claim its share of the base. Salts of weak acids, such as potassium acetate, contain a certain amount of free base by hydrolysis, and the results show that the platinum surface takes its share of this. Recent work, which will be published in detail elsewhere, shows that even with neutral salts the platinum surface takes a small but important fraction of base from the salt, leaving free acid behind.

The whole of the work carried out with colloidal platinum has not revealed the necessity for any further classification of surface reactions. All the so-called "adsorption" phenomena come under one of the above three headings. It is advisable to make this quite clear. It is generally accepted that adsorption compounds are Werner compounds, or at all events that they are essentially chemical at basis. Moreover, in the case of electrolytes (and electrolytes only are considered in this paper) the adsorption is polar. If the anion be oriented in toward the surface, the most probable and the most useful interpretation is the formation of a complex anion as described in the second case above. Now, the surface is essentially acidic, and whilst the formation of complex anions with the surface acid oxide (*e.* g., $[\mathrm{PtO_2}\ldots\mathrm{CN}]^- + \mathrm{K}^+$) is exceedingly probable, combination of the acidic oxide with cations (*e.* g., $[\mathrm{PtO_2}\ldots\mathrm{K}]^+ + \mathrm{CN}^-$) is exceedingly improbable. In keeping with this conclusion there is no experimental evidence that the distinctly acidoid sol, colloidal platinum, ever combines with a cation. Whenever cations are removed from solution and found at the surface, the action can always be traced either to ionic replacement or, to a lesser extent, to hydrolytic cleavage.

The reversal of sign experienced by colloidal platinum when ferric chloride or aluminum chloride is added, is generally interpreted as due to the adsorption of the cation at the surface. This explanation is not in keeping with the conclusions above, and in a paper which will appear shortly it will be shown that experiments with colloidal platinum demonstrate that the cation is not the reversing agent. Reversal is due to the reaction at the surface of the initial products of hydrolysis, probably the basic chloride, and the surface compound formed is of the nature  $\left[\mathrm{PtO_2}\genfrac{}{}{0pt}{}{\diagup\mathrm{OH}\diagdown}{\diagdown\mathrm{OH}\diagup}\mathrm{Fe}\right]^{++} + 2\mathrm{Cl}^-$. When excess of this is formed, the sol changes sign and becomes positive.

Coagulation

(a) Coagulation by Acids.—With acids such as hydrochloric, nitric, sulfuric and acetic, the evidence shows that there are no surface reactions beyond the attenuation of the hydrogen ionic atmosphere, due to the increase in the hydrogen-ion concentration of the solution. This is based largely upon three facts, (a) none of the added acid is taken up by the colloid, (b) the decrease in the ζ-potential is proportional to the square root of the acid concentration, and (c) acids coagulate at a fixed P_{H}.[24] With acids which react at the surface, e. g., hydrocyanic, the production of fresh ionogens exercises a stabilizing action which is opposed to the depression of the ionization due to the increase in the hydrogen-ion concentration of the solution. Such acids show a maximum in the ζ-concentration curve, and coagulate at a higher acidity depending on the extent of the surface action.

(b) Coagulation by Bases.—With univalent bases, *e. g.*, sodium hydroxide, the outstanding features are the rapid increase in the ζ-potential to a maximum, and the high coagulation concentration. These are obviously related and are due to the base reacting with the surface oxide to form fresh ionogens. The whole of the contra ions are univalent sodium

---

[24] See *J. Chem. Soc.*, 551 (1928).

ions, and the increased charge on the particles necessitates an abnormal increase in the sodium-ion concentration to produce coagulation (compare coagulation concentrations, NaOH = 0.02 *N*, NaCl = 0.003 *N*).

Bivalent bases, e. g., barium hydroxide, show some characteristic differences The amount of base removed is four to five times greater than in the case of univalent bases, the increase in the ζ-potential is very much less, whilst the coagulating concentration is very low. These differences are brought out in Fig. 1. It may be assumed that the barium hydroxide reacts at the surface in the same way as the sodium hydroxide, namely, to form surface salts of the nature $[PtO_2\ldots O]Ba$, but the very small increase in the ζ-potential, and likewise the low coagulation concentration of the barium ion, show that the surface ionization is relatively small. The well-known fact that the concentration of the coagulating ion decreases very rapidly with valence is beyond doubt intimately connected with the interionic attractive forces between the colloid ion and the coagulating contra ions. When the valence of the latter is high, the ionic atmosphere is more confined or attenuated, the colloid charge is low and the sol is less stable. Accordingly small increases in the concentration of the free higher-valenced cations are sufficient to depress the ζ-potential to the critical value.

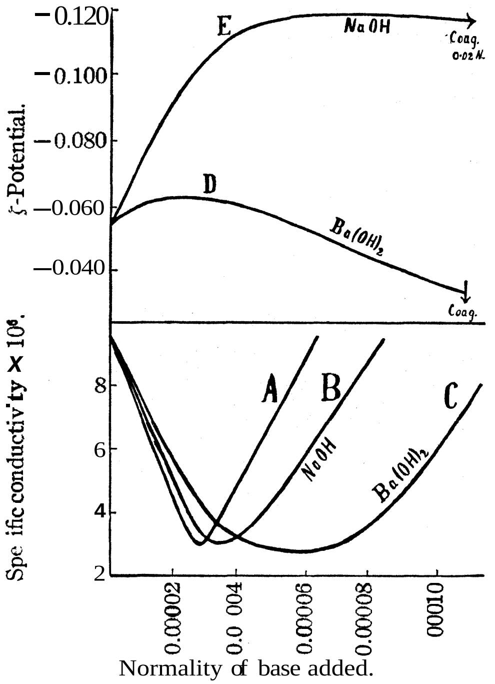

Fig. 1.—Curve A is the titration curve of the intermicellar fluid with NaOH and with $Ba(OH)_2$. Curve B is the titration curve of the platinum sol with NaOH. Curve C is the titration curve of the platinum sol with $Ba(OH)_2$. Curves D and E are the ζ-concentration curves for $Ba(OH)_2$ and NaOH, respectively (ζ-potential = cataphoretic velocity × 187.1).

(c) Coagulation by Salts.—On the addition of a salt, the first step, and the one which ultimately leads to coagulation, is the ionic replacement of the hydrogen contra ions by the cation of the added salt. This has been well illustrated in the case of barium chloride, as the following experiment shows. From a comparison of the curves obtained by following the conductivity changes on the addition of barium chloride to a platinum sol, and also to the intermicellar fluid, one may calculate the amount of hydrogen ion set free by exchange at any concentration of salt. With a sample of the same sol one may also follow the decrease in the ζ-potential for progressive additions of the same salt. By choosing convenient scales and plotting these changes on the one figure, it is found that the curves coincide (Fig. 2). Hence the changes due to ionic replacement agree step by step with those in the ζ-potential, It would thus appear that in such cases, the replacement of the hydrogen ion is the primary cause of the decrease in the ζ-potential and therefore in the stability of the colloid.

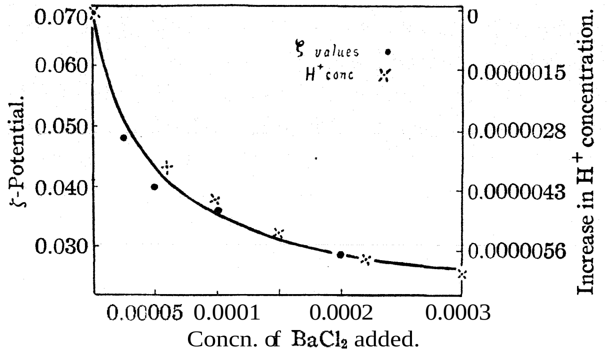

Fig. 2.

For many years it has been the practice to explain the coagulation of negative sols in terms of the "adsorption of the oppositely charged ion." It would now appear that for every oppositely charged ion "adsorbed," a surface contra ion is set free.[25] Hence the explanation in terms of the "adsorption of the oppositely charged ion"—an explanation which has been subject to rather loose usage—may be considered as having served its purpose. It should now be discarded and replaced by the more definite idea of ionic replacement.

Besides the usual replacement, some salts show appreciable formation of surface compounds or exhibit hydrolytic cleavage. The foregoing generalization may be extended to meet these cases. For example, with potassium cyanide, not only does the cyanide ion combine at the surface to form fresh ionogens but the potassium hydroxide of hydrolysis does likewise. Moreover, the extent of the combination increases with the concentration of potassium cyanide. Experiment shows that at low concentration this stabilizing action predominates and the charge increases, but at high concentration these are outweighed by the depression

---

Chem.*, *39*, 630 (1902); Pauli and Matula, *Kolloid-Z.*, 21, 49 (1917); Michaelis and Rona, *Biochem. Z.*, 97, 57 (1919); Pauli and Schmidt, *Z. physik. Chem.*, 126, 247 (1927); Rabinowitsch and Dorfmann. *ibid.*, 131, 313 (1928); Ganguli, *Phil.* Mag., [VII] 7,317 (1929).

of ionization due to the increase in concentration of the free potassium ions and this ultimately leads to coagulation.

The effect upon coagulation of changing the PH of an acidoid sol may now be generalized. If the sol be made more acid the colloid charge is depressed, and salt coagulation occurs at a lower concentration, whilst if the sol be made basic, fresh ionogens are formed and more salt is required to bring the ζ-potential to the critical coagulation value.

Action of Hydrocyanic Acid on Platinum Sols.—Hydrocyanic acid has an extremely important poisoning action on colloidal platinum, and although the investigations in this direction are incomplete, the results so far obtained may be presented here.

Experiments have been carried out to determine the effect on the cataphoretic velocity of increasing additions of hydrocyanic acid. For the purpose the Landsteiner–Pauli apparatus was used, with the intermicellar fluid as the overlying liquid. From the cataphoretic velocity, the ζ-potential is calculated by the usual formula.[26] The results are set out in Table I and shown by Curve A in Fig. 3. In contradistinction to the normal depression shown by hydrochloric and nitric acids, we find with hydrocyanic acid that there is an initial increase in the velocity of the particles, and a maximum at a concentration of approximately 0.0002 N. From the course of the curve it may be concluded that at low concentrations of hydrocyanic acid, the production of fresh surface ionogens and the consequent increase in charge predominate, whilst at higher concentrations the effect due to the depression of the surface ionization is the greater. We thus not only have a direct indication of the removal of hydrocyanic acid by the colloid surface, but we also have the interesting fact that the "poisoned" particle carries a bigger charge than normal. Now in the catalysis of hydrogen peroxide it is well known[27] that sodium hydroxide greatly increases the catalytic velocity, whilst the author has shown (see Fig. 1) that the same base causes an abnormal increase in the colloid charge. Other results agree in pointing to a relationship between the velocity of decomposition and charge carried. The nature of the interrelation is unknown, but the fact that hydrocyanic acid increases the charge

and at the same time poisons the catalyst, appears to the author to afford direct confirmation of the view that the poisoning is due to the combination of the hydrocyanic acid with catalytically active centers at the colloid surface.

Previous work with colloidal platinum has failed to give any information as to the amount of hydrocyanic acid combined with the surface. As the conductivity method has been used successfully by the author to measure small amounts of surface change, *e. g.*, ionic replacement, this sensitive method was applied to follow the changes in the platinum sol on the addition of hydrocyanic acid. For the purpose, samples of the very pure platinum sol and of the intermicellar fluid of exactly the same conductivity were placed in conductivity cells having suitable cell constants. Increasing amounts of hydrocyanic acid were added and the conductivity changes followed. The results are shown in Table II and by Curve B in Fig. 3. Bearing in mind that similar pairs of curves for hydrochloric and nitric acids showed exact correspondence, it was expected that the platinum sol curve, owing to the removal of hydrocyanic acid would

lie below that of the intermicellar fluid. The opposite was found to be the case, for the platinum sol curve always lay above that of the comparable solution. Hence at all concentrations the decrease in conductivity due to the removal of hydrocyanic acid is completely overshadowed by some action which increases the conductivity. Two explanations of the latter action suggest themselves.

First, although hydrocyanic acid is a weak electrolyte, its combination at the surface may, and probably does, result in the formation of complex ionogens which are strong and highly ionized.[28] The increase in conductivity could then be attributed to the ionization of these fresh surface ionogens. Now it has been shown that pure platinum sols, with a cataphoretic velocity of **33.8** X 10^{-5} cm. sec. volt cm., do not contribute any measurable fraction of the conductivity; it may safely be concluded that when the velocity is increased to 41 X 10^{-5} units, the conductivity due to the particles (and their contra ions) would still be of a negligible order of magnitude.

The second explanation, which is probably correct, is that when the hydrocyanic acid combines with the surface, some (or even the whole) of the surface hexahydroxyplatinic acid is displaced. Such replacement is not unusual[29] and is due to a difference in affinity of the surface for the substances concerned. The removal of the weakly ionized hydrocyanic acid from solution, and its replacement by the strong acid $H_2Pt(OH)_6$, serves to explain the increase in conductivity found. If we assume that the whole of the increase, namely, 2 gemmhos[30] at high concentration, is due solely to this effect, then calculation shows that for one liter of sol, 0.000007 equivalent of $H_2Pt(OH)_6$ is replaced. This approaches the total amount of the hexahydroxy acid held at the surface as given by the barium chloride figures, namely, 0.000011 equivalent. Making allowance for hydrolytic cleavage in the latter case, it would appear that at higher concentrations the hydrocyanic acid replaces the greater part (and maybe all) of the bound platinic acid. Such effects in the presence of other surface active substances, particularly sodium hydroxide, must not be overlooked.

Until further experimental evidence is at hand, it is not considered advisable to present any conclusions which may be drawn connecting these surface actions with the catalytic phenomena.

The author is indebted to the Trustees of the Endowment Fund of the Council for Scientific and Industrial Research of the Commonwealth of Australia for grants toward the purchase of platinum used in these investigations.

summary

The general behavior of colloidal platinum as a typical acidoid sol is discussed from the point of view of more recent work.

Experiments are quoted which show that the whole of the colloid surface appears to be coated with a layer of oxidized platinum. On passing hydrogen the oxide layer is reduced **and** the acidoid properties disappear. On repassing oxygen or air the acidoid properties are recovered.

The $H_2Pt(OH)_6$ combines with part of the surface oxide to form Werner compounds, which act as the stabilizing surface ionogens.

The rest of the oxidized surface remains uncombined, but exhibits the properties of an acid oxide.

All the reactions of colloidal platinum are intimately connected with the acidic nature of the surface. They may be divided into three classes: ionic replacement, complex or salt formation and hydrolytic cleavage.

The general action of acids, bases and salts is interpreted in terms of these three reactions.

It is shown that hydrocyanic acid increases the charge carried by the colloid particle, and at the same time appears to displace the surface hexahydroxyplatinic acid.

THE DENSITY OF WATER ADSORBED ON SILICA GEL[1]

BY DWIGHT T. EWING AND CHARLES H. SPURWAY

RECEIVED MAY 15, 1930 PUBLISHED DECEMBER 18, 1930

It is well known that water adsorbed on a surface of a solid has undergone a thermodynamic change in state and that it is held to the surface by a force of great magnitude which may be expressed in terms of pressure, compressibility, etc. Among the early investigators to advance this idea were Rose,[2] Jungh[3] and Parks.[4] That silica gel holds adsorbed water as if under a high pressure is also more recently confirmed by data on the heat of adsorption of water by Lamb and Coolidge,[5] and Patrick and Grimm.[6] The object of this investigation was to measure by a direct method the volume of water adsorbed on silica gel and to determine its density when present in small amounts.

Ikerman[7] and one of us have measured the adsorption of helium on an active silica gel and it was found that no appreciable quantity was adsorbed until the temperature was lowered to near that of liquid oxygen. It seemed advisable, therefore, to use this gas as a medium for determining the various volumes necessary in this investigation.

Experimental Procedure

Apparatus.—The design of the apparatus is similar to that heretofore used for adsorption experiments. All glass parts are of pyrex glass. The form of the gel bulb A (Fig. 1) permits heating the gel by means of a cylindrical, electrical heating unit placed on from the top, and which could be replaced bv a constant temperature bath as outlined in the illustration. B is a calibrated gas pipet used for measuring and admitting known volumes of helium to the gel bulb. Air pressure at G and suction at D permit rough adjustment of mercury levels in the apparatus for the several operations. Fine adjustments of mercury levels for the cathetometer readings were obtained by means of the short rubber tubing at J operated by means of a pinchcock. For more accurate readings, the calibration marks on the stem of the gas pipet and the gel bulb are vertical scratches, read from the lower points, instead of the ordinary cross-etchings. The water was admitted to the gel by means of the side tube E, which is shown as containing a glass capsule of water and a soft iron rod enclosed in glass.

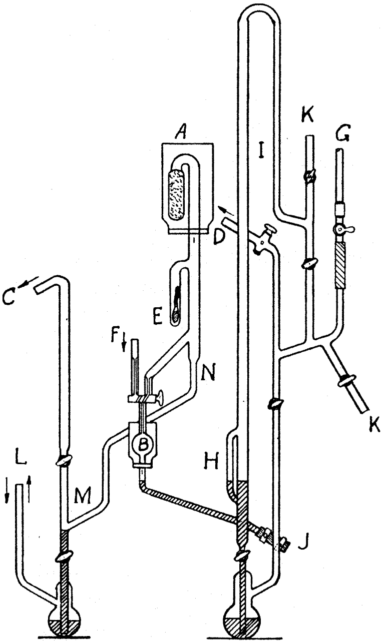

Fig. 1.—Adsorption apparatus.

Purification of the Helium.—The helium used in this work was furnished by the United States Bureau of Mines. As the experimental operations were conducted under conditions requiring adsorbable gases to be absent from the helium, it was necessary to purify the helium by removing these gases. The apparatus shown in Fig. 2 was designed for this purpose. A discussion of the operations performed in purifying the helium will also describe the uses of the different parts of the apparatus. After the apparatus was made ready for use, the "norite" charcoal bulbs O and P were heated to 500° by means of electrical heating units surrounding the bulbs, and the apparatus was evacuated through Q to activate the charcoal. The heating and evacuating occupied three periods of time of six hours each. After the minimum pressure was held for several hours, tube Q was sealed off, charcoal bulb O was surrounded with liquid air in a Dewar flask and when the temperature equilibrium was thought to have been attained, helium gas was allowed to flow slowly from the tank R through O to atmospheric pressure as was shown by the barometric gage S. Tube T was then sealed off, the liquid air was transferred to P and the helium was passed back and forth slowly through P seven times. The helium was finally stored in flask U and tube V sealed off. During all these operations mercury stood in tube F to the upper bend.

---

[7] Ikerman, Master of Science Thesis, Michigan State College, 1927.

Preparation of the Gel.—A sample of commercial Patrick's gel was passed over a 2-mm. round-hole screen and the particles held on the screen were carefully sorted. saving only the clear, uncontaminated particles. The dark-colored, opalescent and chalky particles were discarded. After sorting the gel, it was carefully dusted by rolling it on a piece of black velvet cloth.

Filling the Wafer Capsule.—Especially purified water was used from which the air and other gases had been removed by heating and evacuating. A piece of glass tubing of suitable size was drawn to a capillary in the middle section and weighed. The capsule end was then filled nearly full with the water and evacuated for several minutes to the vapor pressure of water at the operating temperature. Maintaining the pressure, the top was sealed off at the capillary, the whole reweighed and the weight of the water determined.

Temperature Control of Constant Temperature Bath.—This temperature control was effected by means of a 25-watt electric light bulb, operating against a stream of cool air bubbled through the water of the bath to obtain circulation of the water, and connected through a relay to a thermo-regulator set to maintain a temperature of 25.020 ± 0.004° as measured by a Beckmann thermometer.

Barometer.—The atmospheric pressure readings were obtained from a barometer made from heat-treated evacuated pyrex tubing and filled with purified and evacuated mercury. Filling the tube with mercury was accomplished by breaking off the lower end of the evacuated tube under the mercury. After continuing the evacuation for some time to the lowest pressure obtainable and with further heat treatment of the upper end of the tube, the barometer was sealed off from the apparatus and attached to the apparatus rack near the manometer.

Pressure Readings.—All of the pressure readings were made with a cathetometer calibrated to read to 0.05 mm. The mercury column of the manometer was always forced upward to the mark, and the mercury columns of both the manometer and barometer were carefully equilibrated before reading them.

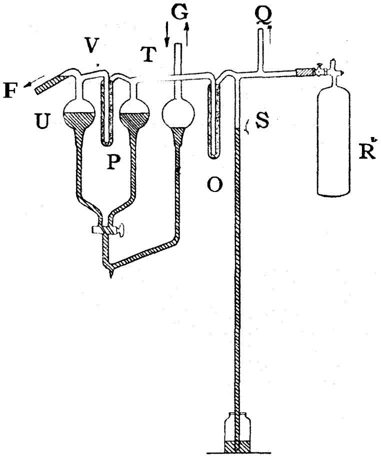

Fig. 2.—Apparatus for purification of helium.

Operation of Apparatus.—The minimum pressure obtained in the cool apparatus, and for all of the determinations requiring low pressure, was of the order 1 by 10^{-5} mm.

The silica gel, prepared as previously described, was admitted to the gel bulb through the bulb stem before sealing to the apparatus. After sealing the gel bulb containing the gel to the apparatus, the gel was heated to 250" and evacuated for several hours, the water tube E not being attached to the apparatus. When a satisfactory low pressure was obtained, the mercury trap M was closed and the mercury raised to N. Helium was then drawn from the storage flask into the gas pipet B and the volume measured in cc. at 25.02° and 760 mm. The helium was then admitted to the gel bulb, pressure readings were taken on it at certain intervals of time, and the volume not occupied by dry gel was determined under equilibrium conditions after several days. This volume subtracted from the volume of the gel bulb, determined by helium in the same manner, gives the volume of the dry gel. In the next step the mercury was drawn out of the manometer, and the water tube E, containing a known weight of water, was attached to the gel bulb stem below the calibration mark. Heat was again applied to the gel (250°), the gel evacuated to low pressure to remove the helium previously used, and the mercury elevated to fill the manometer up to the water tube inlet. The water capsule was then broken by raising the iron weight by means of an electromagnet and releasing it to fall on the capillary end of the water capsule. On breaking the water capsule, the water vapor was drawn rapidly into the gel, requiring about two hours for the largest quantity of water used (2.5667 g.) to disappear from the water tube, but the gel was allowed to stand for one day before further operations, in order to attain better equilibrium conditions. After sealing off the water tube close to the gel bulb stem, another volume of helium was then admitted to the gel bulb and the volume not occupied by gel and water was determined. From these results the volume and density of water adsorbed on the gel were calculated. The weight of the dry, evacuated gel was determined by sealing off the gel bulb under low pressure and making the requisite weighings.

Discussion

The accuracy of the results depends on the correlation of equilibrium conditions of the several pressure determinations. In order to meet these conditions as nearly as possible, the pressure readings were taken until the daily change in pressure was small, in most cases 0.05 mm.

An interesting phenomenon was observed when the largest quantity of water was admitted to the gel. Immediately on breaking the water capsule, the water vapor was drawn into the gel with sufficient force to raise the iron weight (9.245 g.) and hold it against the top of the water tube until the water was nearly all in the gel. In some cases the water froze in the water tube. On adsorbing the first quantity of water vapor, the gel became warm at the top and the heat, passing downward through the gel, could be traced with the hand. Only a few minutes were required for the heat to become distributed throughout the gel. From this heat effect it is concluded that the water vapor was evenly distributed over the gel surface.

There is a close correlation between the density values for the 1.6867 g. and 0.6357 g. of adsorbed water, indicating one phase of water on the gel. The density value for the smallest quantity of water used is somewhat lower, probably because of the greater experimental error due to the small volume. The mean density values for the two larger quantities of adsorbed water are less than the density of liquid water at the operating temperature, indicating the presence of three water phases: compressed water, liquid water and water vapor. This water vapor, however, exerts only a low vapor pressure; hence, all three forms of water are held on the gel under pressure. A sudden break occurs in the mean density curve (Fig. 3) at a point near the value for 1.6867 g. of adsorbed water.

No measurable vapor pressure was shown on the manometer by the three smallest quantities of adsorbed water, but the two larger quantities gave a vapor pressure of 4 mm. each. The calculated volume of water vapor in the gel bulb corresponding to this pressure, however, was not significant in these determinations. These vapor pressure measurements show that the vapor pressure of the adsorbed water is very low.

By a calculation based upon the volume of the adsorbed water in the runs where the silica gel contained 1.6867 g. or 0.6357 g. of water, and a correlation of Bridgman's compressibility data ("International Critical Tables," Vol. III, p. 40), it is shown that in these cases the pressure on the adsorbed water is of the magnitude of 750 atmospheres.

TABLE IV

ERRORS

Mean density	0.5408	0.8305	1.0285	1.0270	(1.0195)
Exptl. errors	* .0005	± .0017	±0.0031	±0.0083	±0.0129
He ads. errors	− .0027	− .0065	− .0099	− .0099	− .0102

The greatest probable error in these determinations was in reading the barometer and manometer and was calculated to be ±0.025 mm. on each reading or ±0.05 mm. on both in case the error was positive on one reading and negative on the other. Applying this error to the data, the values given as experimental errors in Table IV were obtained. The possible error due to the absorption of helium in the water was calculated from the data of Lannung[8] assuming that the water adsorbed on the silica gel absorbed helium to the same extent as does liquid water. This assumption is improbable, however, especially where the water is held under great pressure.

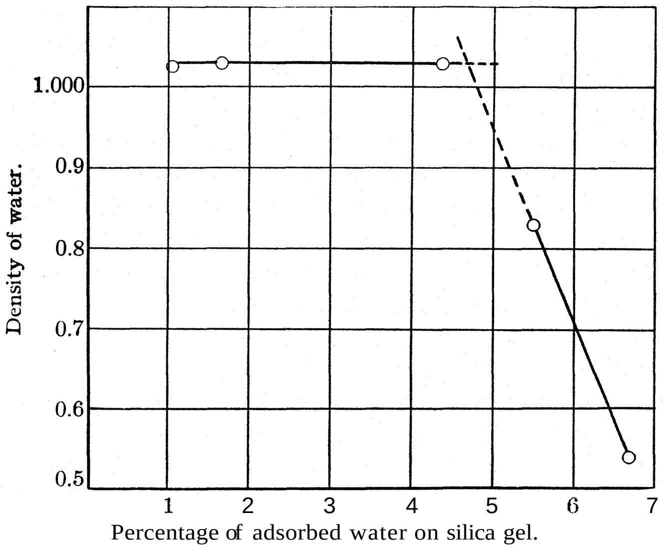

Fig. 3.—Mean density curve.

A noticeable drift occurs in the pressure readings with time (Table I), varying from 0.05 mm. with 1.6867 g. of water on the gel to 1.05 mm. both with dry gel and 0.6357 g. of adsorbed water. As this drift also occurs with helium only in the gel bulb, it must be due chiefly to adsorption of helium on the inner walls of the gel bulb or absorption of helium in the

---

[8] Lannung. THIS JOURNAL, 52, 68–80 (1930).

mercury exposed to the helium. Provided this drift was caused by adsorption of helium on the gel bulb only, it should be nearly the same in all cases as the gel bulb was heated and evacuated each time before admitting the helium. The differences in this drift may be caused partly by mercury surfaces in the manometer containing more or less absorbed helium when exposed to the helium in the gel bulb. In the three determinations of volume of dry gel made before the admissions of 1.6867 g., 0.6357 g. and 0.4017 g. of water, the variations from the mean were only +3 and —4 parts in 17,676, although the drifts in the pressure readings were 1.05 mm., 0.25 mm. and 0.85 mm., respectively. The computations were made, therefore, on the basis of the volumes determined directly with helium, using the lowest pressure readings, and considering that a stable pressure equilibrium was reached in each case.

Summary

Values were obtained for the density of water adsorbed on silica gel by volume measurements using a gas dilatometer with helium as the inactive gas. For small quantities of water up to 4.36% these measurements showed that the density of water adsorbed on silica gel at 25.02° is greater than the density of liquid water at the same temperature.

THE THERMODYNAMIC PROPERTIES OF MOLTEN SOLUTIONS OF LEAD CHLORIDE IN LEAD BROMIDE

BY E. J. SALSTROM AND J. H. HILDEBRAND

RECEIVED JUNE 11, 1930 PUBLISHED DECEMBER 18, 1930

The investigation described in this paper represents a continuation of the plan begun several years ago in this Laboratory by Hildebrand and Ruhle[1] of studying the thermodynamic properties of fused salt solutions. There were two disturbing factors involved in that investigation, first, the system studied, solutions of lead chloride with potassium chloride, was somewhat complex, as indicated by the existence of several solid compounds; second, the chlorine electrode was produced by polarization, a procedure that did not guarantee its reversibility. In the present investigation a system has been selected, lead bromide with lead chloride, which, according to Monkmeyer,[2] shows no evidence of compound formation in the solid state. The freezing point varies linearly with the composition, indicating a continuous series of solid solutions. The second complication mentioned above has been avoided by our success in constructing a reversible bromine electrode suitable for use under these conditions.

---

[1] Hildebrand and Ruhle, THIS JOURNAL, 49, 722 (1927).

[2] K. Monkmeyer, *Neues Jahrbuch.* 22, 1 (1906).

Further interest attaches to this system because Professor W. C. Bray[3] made a suggestion in 1908 that the freezing points of this system should offer an opportunity to determine the extent of ionization. Unfortunately the existence of solid solutions invalidates any simple conclusion from the freezing points and makes desirable the use of some other measure of partial molal free energy. Since the completion of our investigation there have appeared measurements of the partial vapor pressures of this system carried out by Jellinek and Bolubowski.[4] These will be referred to later.

Experimental Part

A. Materials and Apparatus.—The lead chloride was from commercial sources of high purity. The lead bromide was prepared by precipitation from ammonium bromide and lead acetate solutions in **0.001** N hydrobromic acid. The precipitate was washed repeatedly by decantation with a dilute solution of the acid, and dried by suction on a filter. It was then boiled in the acid solution, cooled, washed again by decantation, dried by suction and twice again subjected to this procedure. Tests then showed it to be free from ammonium salts. It was finally dried in a furnace at 130° for over twelve hours. Hydrogen bromide gas was prepared directly from its elements by passing hydrogen and bromine over a heated catalyst of platinized asbestos. The hydrogen used was especially prepared in this Laboratory by the electrolysis of water. It was freed from oxygen by passing it over a hot nickel catalyst, and from water by passing, first, through a sulfuric acid drying tower, and finally over phosphorus pentoxide. The bromine used in the preparation of hydrogen bromide was freed from chlorine and water by standing over powdered anhydrous calcium bromide and then twice distilled from calcium bromide. The bromine used for the electrode in the cell was generated by electrolysis of molten lead bromide. The hydrogen chloride gas was produced by dropping concentrated sulfuric acid on pure concentrated hydrochloric acid, and was dried by bubbling through a tower containing concentrated sulfuric acid. The molten lead used as an electrode was prepared by electrolysis of pure molten lead bromide.

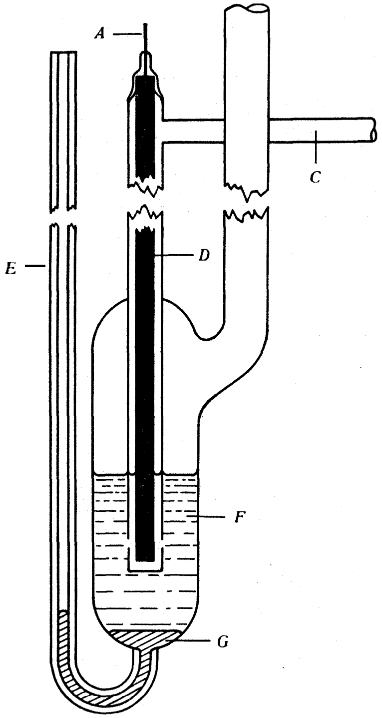

Fig. 1.—Cell container.

The cell containers were made of pyrex glass of cylindrical form, **2–3** cm. in diameter and about **30** cm. long, as shown in Fig. **1**. Tungsten wires with copper leads were

---

Jellinek and Bolubowski, *Z. physik. Chem.,* Abt. A, **147,461 (1930).**

sealed into the tube, E, so as to make contact with the molten lead, G. The positive electrode, D, was a graphite rod 6–10 mm. in diameter, its size depending on the number of heat treatments it had undergone. These rods were sealed into the cells by means of platinum wire leads, A. Tube C served as an inlet for bromine vapor. The large open tube was first used as an opening for charging the cell with salt and metal, after which it was sealed onto a bromine trap, to serve as an exit for bromine. The bromine generator, made of pyrex glass and having positive and negative poles, respectively, of graphite and tungsten wire, was larger than this cell, but similar in construction.

The thermostat consisted of a large electrical resistance pot furnace of high heat capacity and well insulated. The thermostat bath was a mixture of molten lead and tin. An efficient mechanical stirrer kept the bath at a uniform temperature. The pot and stirring fan were of cast iron, and were protected from the solvent action of the bath by several coats of "Insa-lute" cement.

The temperature was measured by two platinum–platinum-rhodium thermocouples, standardized by the U. S. Bureau of Standards. During the course of the investigation the thermocouples were repeatedly checked against each other and were found accurate to within 0.5°. All electromotive force measurements were made on a Leeds–Northrup type K potentiometer.

B. Method of Procedure.—The graphite rods used as electrodes in the cell and generator were first treated for about twenty-four hours with bromine gas under several atmospheres' pressure at 600°. They were then heated in the oxygen flame to a bright yellow heat until no more fumes were evolved, and allowed to cool in an atmosphere of bromine. These rods were used over and over again, but with each new cell or generator the glowing and cooling process was repeated. The only observed difference between graphite rods thus treated and those untreated was that in the former case equilibrium was reached in from one to two hours, while otherwise eighteen to twenty hours were required.

The generator was charged with pure lead bromide and placed in a small cylindrical electrical resistance furnace kept at about 450°. The cells were first charged with pure lead in sufficient amounts to cover completely the sealed-in tungsten wires. Weighed amounts of lead chloride and lead bromide were then added, and the cell was lowered into the thermostat bath and sealed in series with the bromine generator. All connections were of glass only. Stopcocks, where they could not be dispensed with, were lubricated with concentrated sulfuric acid, since bromine attacked the various greases tried, causing them to harden. No openings to the air were permitted except in the bromine exit tube, where a trap of liquid bromine was inserted.

The lead bromide in the generator, and also in the cell, when it contained lead bromide only, was freed from moisture, oxides and hydrolysis products occasioned by the filling and sealing up process by bubbling dry hydrogen bromide gas through the melt for an hour and forty minutes. Without such treatment, the fluctuations in e. m. f. were quite marked. Equilibrium was reached in from one to two hours. Prior to taking each reading, the thermostat was kept constant within one or two degrees for sufficient time to insure constant e. m. f. Each cell was in this way measured at twenty- or thirty-degree intervals over the whole temperature range several times. Ascending and descending series were in complete agreement.

The cells containing solutions of lead bromide and lead chloride were cleaned out with hydrogen chloride gas instead of with hydrogen bromide, since the reaction

$$PbCl_2 + 2HBr = PbBr_2 + 2HCl$$

was found experimentally to proceed almost quantitatively as written.

Using the free energy of formation of lead bromide given in this paper, the free energy value of lead chloride, given by Wachter and Hildebrand in a paper shortly to appear as −**58,720** cal., and the free energy equations for the formation of hydrogen chloride and hydrogen bromide gas

$$\text{for HCl, } \Delta F = -21{,}870 + 0.45\,T\ln T - 0.000025\,T^2 - 5.31\,T$$
$$\text{for HBr, } \Delta F = -11{,}970 + 0.45\,T\ln T - 0.000025\,T^2 - 5.74\,T$$

as given by Lewis and Randall,[5] we have calculated the free energy change of this reaction to be −**8050** cal. at 500°. That the reverse reaction is negligible in effect was proved by passing hydrogen chloride gas through the cell for thirty minutes, then measuring the e. m. f. over a range of temperatures, again passing in hydrogen chloride for thirty minutes and again determining the e. m. f.–temperature curve. No difference was observed in the two sets of readings.

To test the effect of polarization on the e. m. f. of the pure lead bromide, the cell was electrolyzed by a current of **0.1** to **0.15** ampere for one hour without shutting off the bromine stream from the generator. After such polarization, no change in the readings of the cell was observed. However, when an electrolyzing current of *2* to **3** amperes was used, the e. m. f. immediately after electrolysis was from two to three centivolts higher, thus being more in accord with the results of Lorenz and Czepinski,[6] obtained by a polarization method.

The cells used involved a thermoelectric effect. To correct for this, cells were made up, identical with those used with molten salts with the exception that the contact between tungsten and graphite was in this case made by a platinum wire instead of molten salts. The e. m. f. of these cells, placed in the thermostat in the same position as the other cells, was measured over a temperature range, using two types of graphite rods, some treated as previously described, and others untreated. These gave identical and very reproducible e. m. f.'s.

Since it was hoped that lattice energy considerations would prove useful in interpreting the experimental results, density determinations were made by a pycnometer method, using pyrex bulbs of about 15-cc. capacity and having a capillary stem of **3** mm. The problem of filling these bulbs with the molten salts made a smaller capillary impracticable. The data of Peters and Cragoe[7] indicate that the coefficient of expansion for pyrex glass can be satisfactorily applied up to a temperature of 500°.

Experimental Results

Measurements for this system are given in Table I and plotted in Fig. **2.**

			.450 G	584.0	1.0308

Three cells were run for pure lead bromide, cell **A** containing a graphite electrode treated as above described and cells B and C with untreated graphite rods. Each was run over the whole temperature range of 450 to 580°. In no case was a deviation from a straight line observed in excess of 0.5 millivolt, and the average deviation was less than 0.2 millivolt. The cells containing solutions of lead bromide with lead chloride were found to give equally accurate and reproducible results. The cells containing pure lead bromide yield the relation that $\Delta F = -69270 + 28t$ over the range studied.

The values of Lorenz and Czepinski for the e. m. f. of pure lead bromide obtained by polarization deviate from their smoothed out curve by as much as 5 to 6 millivolts. The curve chosen by them to smooth out their results is about 0.024 volt higher than ours at 450° and 0.030 volt higher at 550°. However, since they carried out their experiments in open vessels and, as far as we can determine, made no effort to eliminate impurities due to oxidation and hydrolysis, we can readily understand why their figures should differ considerably from those herein given.

To determine whether we were actually dealing with a reversible electromotive force, and one which is in accord with the assumed cell reaction, we studied the effect of pressure changes on the e. m. f. of the cell. The bromine passing through the cell was allowed to escape against a reduced external pressure. Table II gives the results. It will be seen that the observed e. m. f.s agree to 0.2 millivolt or better with those calculated by the aid of the usual formula. We may therefore claim a high degree of accuracy for this electrode.

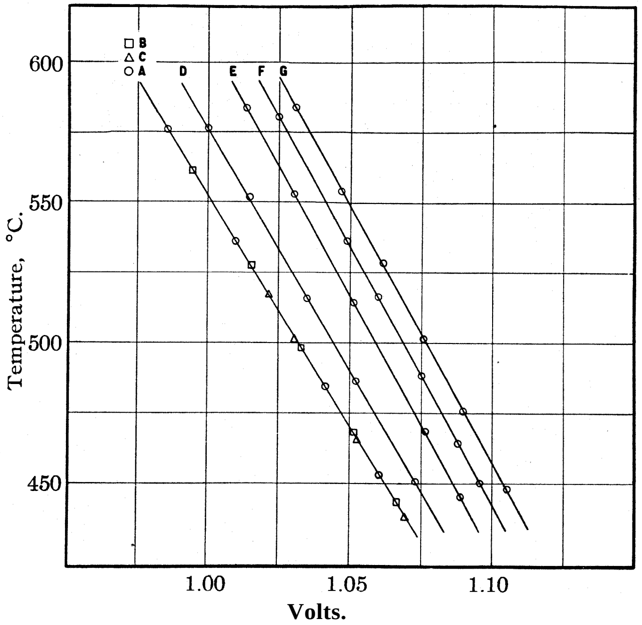

Fig. 2.—Temperature, e. m. f. and composition relations of the cells Pb/$PbBr_2$, $PbCl_2$/Br_2. Mole fraction of lead bromide in A, B and C is 1.000, D is 0.800, E is 0.600, F is 0.500 and *G* is 0.450.

TABLE II

THE EFFECT OF PRESSURE UPON THE BROMINE ELECTRODE IN THE LEAD BROMIDE CELL

Pressure, cm. of mercury	74.96	60.04	43.80	55.21	60.8
Temperature, °C.	443.3	438.6	442.3	443.3	441.7
E **(obs.)**	1.0671	1.0634	1.0511	1.0576	1.0609
E **(calcd.)**	1.0671	1.0632	1.0510	1.0576	1.0611

It was found that when the concentration of lead chloride in the molten solution reached a mole fraction of 0.6, the reaction

$$PbCl_2 + Br_2 = PbBr_2 + Cl_2$$

first became noticeable by a gradual falling off in the e. m. f. of the cell if observed over a period of twenty-four hours. Subtracting the free energy of formation of lead chloride from its elements, —58,720 cal. at 500°, from that for the formation of lead bromide from its elements herein given, we arrive at +11,090 cal. as the free energy change of this reaction when each substance is at unit activity. Using this value and assuming that the activities of the salts are proportional to their mole fractions, we have calculated the partial pressure of chlorine at 0.6 mole fraction lead chloride to be less than 0.002 atmosphere at equilibrium. This small pressure might be considered negligible were it not for the fact that chlorine is constantly being swept out as fast as formed by the bromine stream passing through the cell. That the above reaction does not occur appreciably at lower concentrations of lead chloride is shown by the fact that no falling off in the e. m. f. with time is discernible, even though allowed to run for several days. In view of the above considerations, we do not give any measurements upon cells containing lead chloride above 0.55 mole fraction.

In order to determine how the molal volumes of the solutions vary in going from pure lead bromide to pure lead chloride, density determinations were made of the pure salts and solutions of them. The results are given in Table III. The density value given for lead chloride in Table III at 500' was obtained by extrapolation of the molal volumes–composition curve, since the salt freezes at 501°. Extrapolating the density values obtained by Lorenz, Frei and Jabs,[8] we obtain 4.897 for lead chloride at 507° and 5.45 for lead bromide at 500° compared to our measured values of 4.879 and 5.4735, respectively. Since we have extrapolated the values of these investigators below the region for which they were given as valid, the agreement is quite satisfactory.

TABLE III

RELATIONS BETWEEN COMPOSITION, DENSITY AND MOLAL VOLUMES OF LEAD BROMIDE–LEAD CHLORIDE SOLUTIONS AT 500°

Mole fraction lead bromide	1.000	0.800	0.600	0.500	0.450	0.200	0.000
Density of soln.	5.4735	5.381	5.2537	5.2013	5.1219	5.027	4.887 (extrapolated)
Obs. volume of 1 mole of soln. in *cc.*	67.05	64.86	63.01	61.92	61.335	58.70	56.75 (extrapolated)
Calcd. on basis of additivity	67.05	64.97	62.91	61.88	61.34	58.79	56.75

Discussion of Results

To show the effects of both temperature and composition upon the thermodynamic properties of the salt solution we have proceeded as follows. The plot shown in Fig. 2 was made upon a large scale and the values of the e. m. f., E, determined for each solution at the temperatures 450, 500 and 550'. Using then the relation $\Delta F_1 = -23{,}070\ NE$, where N is the number of equivalents per mole, here 2, we calculate ΔF_1, the free energy of formation of lead bromide in calories, from molten lead and bromine vapor at 1 atmosphere. This varies with the mole fraction of $PbBr_2$, N_1, and we will write ΔF_1° to denote pure lead bromide. The partial

---

[8] Lorenz, Frei and Jabs, *Phil. Trans. Royal Society,* 7,468 (1908).

molal free energy of lead bromide in a solution, $\bar{F}_1$, is then $\bar{F}_1 = \Delta F_1 - \Delta F_1^\circ$. The entropy of formation, ΔS_1, is given in calories per degree by $\Delta S_1 = 23{,}070\ N\ dE/dT$, and the partial molal entropy $\bar{S}_1 = \Delta S_1 - \Delta S_1^\circ$. The heat of formation is $\Delta H_1 = \Delta F_1 + T\Delta S_1$ and the partial molal heat $\bar{H}_1 = \Delta H_1 - \Delta H_1^\circ$. The activity of lead bromide in its solutions, a_1, taking pure lead bromide as the standard state, is calculated by the relation $\bar{F}_1 = RT \ln a_1$. By dividing the activity by the mole fraction of lead bromide, the activity coefficient, γ, is obtained.

The values so calculated are given in Table IV, and in Fig. 3 are shown, in Curve A, the values of $-\bar{F}_1$ at 500° plotted against log $(1/N_1)$, where N_1 is the mole fraction of lead bromide. In order to see how these values agree with simple assumptions regarding ionization, we will assume, first, that both salts are un-ionized, and that the activity of lead bromide is proportional to its mole fraction. This gives curve B, Fig. 3, much lower than the observed. This corresponds to a negative deviation from Raoult's law, *i. e.*, the activity is less than the simple mole fraction. This can be seen quite clearly by comparing the values of a_1 in the table with the corresponding values of N_1. This result does not accord with the measurements of Jellinek and Bolubowski,[4] who found Raoult's law obeyed by the vapor pressures at temperatures from 660 to 780°. We are at a loss to explain the discrepancy, as neither the difference in the temperature range nor departure of the vapors from the gas laws would seem to be sufficient to account for it.

TABLE IV

ENERGY RELATIONS OF LEAD BROMIDE, WHEN DILUTED WITH LEAD CHLORIDE

550°, γ	1.000	.845	.713	.652	.576

If we assume, second, that both salts are completely ionized, but that the partial substitution of bromide by chloride ion can be made without changing any of the interionic forces (an assumption which is obviously incorrect) then, if we take n_1 moles of $PbBr_2$ to n_2 moles of $PbCl_2$, we get $n_1 + n_2$ moles of Pb^{++}, 2 n_1 moles of Br^- and 2 n_2 moles of Cl^-. The activity of Pb^{++} would then be constant, unity; the activity of Br^- would be $n_1/(n_1 + n_2)$, the activity of $PbBr_2$ the former times the square of the latter, or N_1^2. This makes $-\bar{F}_1$ calculated upon this assumption, curve C in Fig. 3, just twice what it is on the former assumption. This agrees better with the observed values but is too high. We have, therefore, two alternatives, either to assume partial ionization, or, what is obviously preferable, to attempt to take into account the change in the interionic forces due to the substitution of the smaller chloride ion for the larger bromide ion. This we will postpone to a later communication where we will treat at the same time data obtained for other systems.

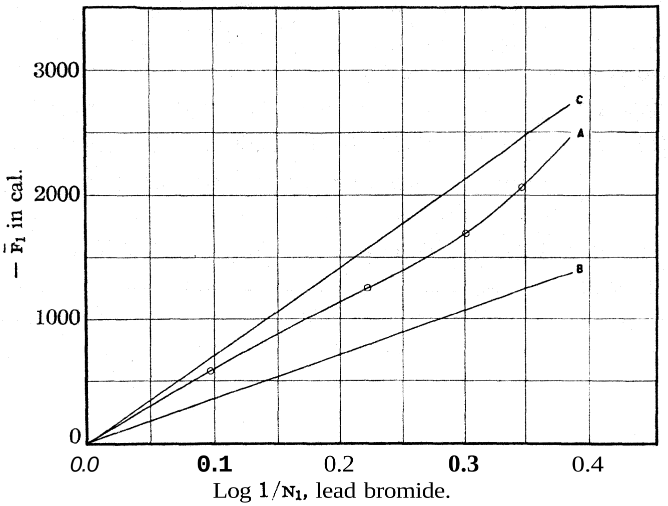

Fig. 3.—Change in free energy of lead bromide at 500° upon dilution with lead chloride: A, observed; B, calculated, no ionization; C, calculated, complete ionization.

Summary

1. A reversible and reproducible bromine electrode has been applied to the study of molten salts and their solutions.

2. Density determinations have been made on lead bromide and lead chloride and solutions of these at 500°. The molal volumes of these solutions have been found to be additive within the limits of experimental error.

3. The energy changes of molten lead bromide upon dilution with lead

chloride have been determined at mole fractions of lead chloride varying from 0 to 0.55, between the temperatures of 440 and 585'.

4. The free energy of formation of pure molten lead bromide was found to be $-69270 + 28t$ between $t = 450°$ and $t = 580'$.

5. The results have been discussed on the basis of simple assumptions regarding ionization, without taking into account the changes in interionic forces.

THE THERMODYNAMIC PROPERTIES OF MOLTEN SOLUTIONS OF LITHIUM BROMIDE IN SILVER BROMIDE

BY **E. J. SALSTROM** AND J. H. HILDEBRAND

RECEIVED JUNE 11, 1930 PUBLISHED DECEMBER 18, 1930

The work described in this paper is a continuation of the general program mentioned in the preceding article of collecting data necessary for a general study of molten salt solutions. Solutions of lithium bromide in silver bromide seem well suited to this investigation because their freezing point curves, investigated by Sandoninni and Scarpa,[1] show no evidence of complex salt formation which might add difficulty to any interpretation of the results. This is likewise true of silver bromide diluted with sodium bromide and with potassium bromide. A study of these latter two systems is now in progress in this Laboratory and when completed will furnish information on the influence of the size of the cation of the diluting salt upon the activity of the solvent.

Experimental Part

The silver bromide was prepared by precipitation from a solution of silver nitrate by ammonium bromide. It was washed repeatedly by decantation with a hot 0.001 N hydrobromic acid solution until freed from ammonium salts, then dried by suction on a filter, and finally in an oven at 130" for at least twelve hours. The lithium bromide was of high purity from commercial sources. It was freed from moisture by fusing the salt and bubbling dry hydrogen bromide gas through the melt for two hours. It was subsequently kept in a glass-stoppered bottle in a desiccator over anhydrous calcium chloride. The hydrogen bromide gas and the bromine used for the electrode in the cell were prepared as described in the preceding paper.

With the following exceptions, the apparatus and experimental procedure involved in the study of this system were essentially the same as those described for the lead bromide–lead chloride system. A pure silver

[1] **Sandoninni and Scarpa, *Atti.* accad. *Lincei,* 22, II, 517 (1913).**

wire inserted through the glass tube E, shown in Fig. 1 in the preceding article, served as the negative electrode. The amounts of lithium bromide added to the cells were but roughly weighed. Air and hydrolysis products were removed as before with a stream of dry hydrogen bromide gas continued in this case for at least two hours. After the run, the entire content of each cell was accurately weighed and dissolved in potassium cyanide solution. Measured portions were analyzed electrolytically.

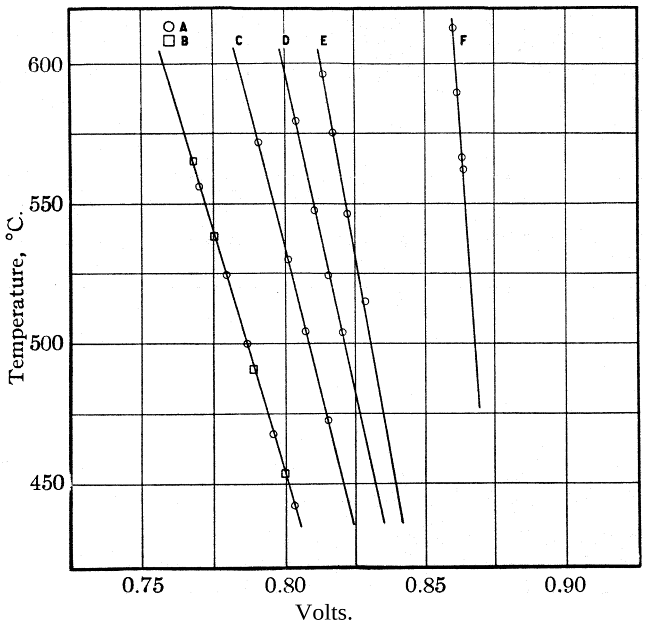

Fig. 1.—Temperature, e. m. f. and composition relations of the cells Ag/AgBr, LiBr/Br_2. Mole fraction of silver bromide in A and B is 1.0000, C is 0.5937, D is 0.4086, E is 0.2548 and F is 0.1100.

Since the cathode in these cells consisted of solid silver, the effect of any possible strains affecting its activity was investigated by polarizing the cell with 0.1 ampere for half an hour. The subsequent e. m. f. was identical with the previous one, hence at these high temperatures any strains such as are often found at room temperatures are negligible. The thermo-electric effect was measured as before, using in this case silver wire and graphite joined by a short platinum wire.

Measurements for this system are given in Table I and plotted in Fig. 1. The extreme deviation of the observed values from the straight lines drawn through them in Fig. 1 is 0.4 millivolt, and the average deviation is less than 0.15 millivolt.

Values for the e. m. f. of pure silver bromide have been obtained by

TABLE I

Lorenz[2] by a polarization method where the molten salts were not protected from the air, nor, as far as we can determine, were any efforts made to remove oxidation and hydrolysis products. Their results deviate from a straight line by as much as 4 and 5 millivolts. The results chosen by this investigator to smooth out his results are at 450° about 8 millivolts higher than those observed by us, while at 550° they are 6 millivolts lower. Hence, while Lorenz's values are in fair agreement with those herein given, the slope of his curve is very different. Due to the higher melting point of lithium bromide, namely 556°, cells containing high mole fractions of this salt could be run only over a more limited range of temperatures. The experimental results were found to be reproducible within 0.5 millivolt.

The effect of a variable bromine pressure on the e. m. f. of the pure silver bromide cell was again studied. The excellent agreement between the observed and calculated results is shown in Table II.

TABLE II

EFFECT OF PRESSURE ON THE BROMINE ELECTRODE IN THE SILVER BROMIDE CELL

Pressure, cm.	75.66	60.15	44.36	60.36	75.64
Temperature, °C.	456.6	457.2	458.7	458.7	458.7
E (obs.), volt	0.7985	0.7912	0.7814	0.7909	0.7980
E (calcd.), volt	.7985	.7912	.7812	.7909	.7980

In order to determine the volume changes involved in mixing molten silver bromide and lithium bromide, density determinations were made

---

[2] Lorenz, "Die Elektrolyse geschmolzener Salze," Dritter Teil, p. 30, "Elektromotorische Kräfte," Knappe, Halle a.S., 1906.

upon a solution containing a half mole fraction of each. The method consisted of weighing a previously standardized quartz cylinder filled with tungsten, first in air and then at various temperatures while suspended in the solution. The measurements are shown in Table III.

TABLE III

DENSITY OF 0.5 MOLE FRACTION LiBr IN AgBr

Temp., °C.	517.4	527.6	533.4	545.6	550.0	555 2
Density	4.051	4.041	4.036	4.026	4.022 (extrapolated)	4.017

Using the density values for silver bromide obtained by Lorenz and Höchberg[3] and for lithium bromide obtained by Brunner,[4] we have shown the densities and molal volumes at 550° in Table IV. The change in volume upon mixing is thus seen to be very slight.

TABLE IV

DENSITIES AND MOLAL VOLUMES OF SILVER BROMIDE AND LITHIUM BROMIDE AND THEIR SOLUTION AT 550°

Composition	Density	Molal volume in cc.
AgBr	5.457	34.40
0.5 mole fraction LiBr in AgBr	4.022	34.15 (34.27 on basis of additivity)
LiBr	2.545	34.15

Discussion of Results

The data for this system have been treated in a manner similar to that described in the preceding paper on the lead bromide–lead chloride system. The results are given in Table V and $-\bar{F}_1$ plotted against log $(1/N_1)$ in curve A, Fig. 2, where N_1 is the mole fraction of silver bromide. If we attempt to calculate $\bar{F}_1$ from N_1 as before, we find that both assumption of no ionization and of complete ionization lead to the same result, $a_1 = N_1$. This gives curve B, Fig. 2, much higher than the observed.

TABLE V

In other words, there is a strong positive deviation of the activity from Raoult's law, since a_1 is greater than N_1. It therefore seems that, as with the lead bromide–lead chloride system, the change in interionic forces due to substitution of the smaller lithium ion for the silver ion should be considered. This attempt we will again postpone for a future communication when investigations now in progress will permit a more general treatment.

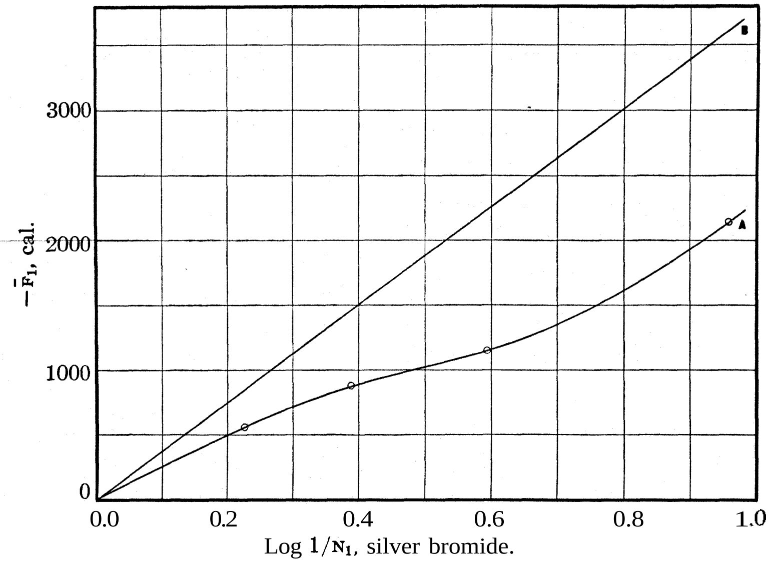

Fig. 2.—Change in free energy of silver bromide at 550° upon dilution with lithium bromide: A, observed; B, calculated.

Summary

1. The energy changes of molten silver bromide upon dilution with lithium bromide have been determined at mole fractions of lithium bromide varying from 0 to 0.89 between the temperatures of 450 to 600°.

2. The free energy of formation of pure molten silver bromide was found to be given by the equation $\Delta F_0 = -21{,}510 + 6.7\,t$ between 440 and 575°.

3. Density determinations of 0.6 mole fraction lithium bromide in silver bromide were made between 517 and 555° and may be expressed by the equation $d^t = 4.504 - 0.000877\ t$.

4. The results have been discussed on the basis of simple assumptions as to ionization, but without taking into account any changes in interionic forces upon dilution.

THERMODYNAMIC PROPERTIES OF SOLUTIONS OF MOLTEN LEAD CHLORIDE AND ZINC CHLORIDE

BY A. WACHTER AND J. H. HILDEBRAND

RECEIVED JUNE 11, 1930 PUBLISHED DECEMBER 18, 1930

The following investigation represents a contribution to the program begun by Hildebrand and Ruhle[1] of gathering data upon free energy of dilution of molten salt solutions. The system selected, solutions of lead and zinc chlorides, seemed to be simpler than many others, for the freezing point–composition diagram, obtained by Herrmann,[2] shows no evidence of solid compounds. As in the research of Hildebrand and Ruhle, we started with measurements of the e. m. f. of the cell Pb (liq.) | $PbCl_2$ (liq.) | Cl_2 (gas), but instead of producing the chlorine electrode by polarization, as in the earlier work, and as was done by Lorenz[3] and co-workers for a number of molten chlorides, we succeeded in getting a reversible chlorine electrode, reproducible over a range of pressure and temperature. The lead chloride was then diluted with zinc chloride and the free energy of the dilution determined from the change of e. m. f. of the cell, a procedure which avoids the uncertainty of a liquid junction.

A similar study of certain bromide systems by Salstrom and Hildebrand[4] was carried out approximately at the same time as this one, and the procedure was developed more or less in common. We will therefore avoid needless repetition by referring the reader to the description already given and state here only the features peculiar to this research.

The chlorine, the lead and zinc and their chlorides were from commercial sources of high purity, analyses of which were furnished, and were considered by us to be free from impurities that could affect the e. m. f. Substitution of chlorine generated by electrolysis of pure fused lead chloride made no appreciable difference in the results. The most serious im-

purity to be avoided was water; hence not only was the chlorine carefully dried in a tower containing glass beads wet with sulfuric acid, but the lead and zinc chlorides were fused in dry hydrogen chloride gas before weighing and introduction into the cell, and the cell itself, after being made up, was treated with dry hydrogen chloride bubbled up through the molten salt for about an hour.

Reproducible values for the cells were reached after chlorine had been bubbled through them for from twelve to twenty-four hours. After that they responded very quickly to temperature changes with no evidence of hysteresis. The effect of changing the pressure of the chlorine was studied using five different pressures from 76 to 105 cm. The changes in e. m. f. so produced agreed within 0.3 millivolt with those calculated by aid of the usual formula. Electrolysis of the cells at 0.25 ampere for two hours caused no change in e. m. f., although a current of 3 amperes decreased the e. m. f. by several millivolts.

Since the theoretical treatment of our results will ultimately require a knowledge of the interionic distances, we considered it desirable to measure the densities of the two pure chlorides as well as their 50 molal per cent. solution. This was done by weighing a tungsten-weighted pyrex bulb in air, in water and in fused salt, correcting for the expansion of the bulb. The bulb was sharply tapped after each reading to remove any adherent bubbles of gas. The densities observed are given in Table I.

TABLE I

DENSITIES OF LIQUID LEAD AND ZINC CHLORIDES

100% $PbCl_2$		49.8% $PbCl_2$, 50.2% $ZnCl_2$		100% $ZnCl_2$	
t, °C.	Density	t, °C.	Density	t, °C.	Density
545.3	4.872	552.5	3.703	550.7	2.401
537.2	4.886	545.4	3.709	549.3	2.401
535.5	4.886	535.2	3.717	524.5	2.413
526.7	4.902	510.2	3.733	509.3	2.420
514.4	4.924			503.2	2.422
502.1	4.944			493.7	2.427
				485.7	2.431

The observed values yield the following equations: for the density of lead chloride: $d^t = 4.947 - 0.00164\ (t - 500)$; for the density of zinc chloride, $d^t = 2.424 - 0.00046\ (t - 500)$. Lorenz, Frei and Jabs,[5] using a platinum cube, obtained a density of 4.907 for pure lead chloride at 500°, differing from ours by 0.04 g. per cc. The molal volumes of lead and zinc chlorides at 500° are, respectively, 56.22 cc. and 55.82 cc., nearly identical. A 50 mole per cent. solution at this temperature has a molal volume of 55.31 cc., which is 0.7 cc. less than additive.

The results of the e. m. f. measurements are given in Table II and plotted in Fig. 1. The values for pure lead chloride represent three dif-

ferent cells, indicated in the figure by points of different styles. No systematic differences between these cells could be detected. The points for each composition, although recorded in the table in order of increasing temperature, were not obtained in this order, but some were approached from above and some from below. The average deviation of our points from the straight line of the plot is less than 0.5 mv.

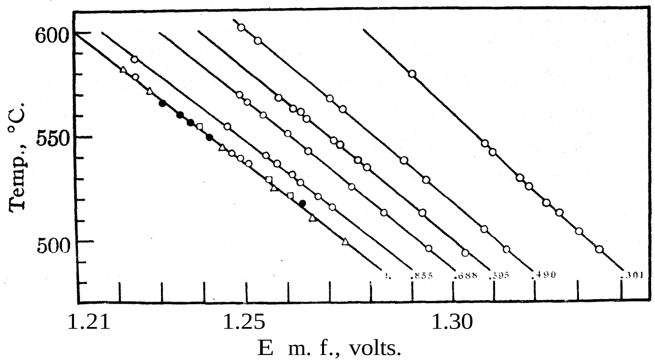

Fig. 1.—Temperature variation of e. m. f. of cells containing different mole fractions of lead chloride–zinc chloride solutions. Different symbols represent different cells at mole fraction 1.

In order to be sure that there was no danger of the lead electrode replacing zinc, we measured the e. m. f. of the cell Zn (liq.) | $ZnCl_2$ (liq.) | Cl_2.

The results are given in Table III. They show the e. m. f. to be sufficiently large to indicate that such displacement would not be a disturbing factor.

Our results for the pure chlorides can be compared with those obtained by previous workers. Lorenz and Czepinski,[6] using a polarized electrode and taking no special precautions to exclude oxygen or moisture, obtained very fluctuating values, about 30 mv. less than ours for lead chloride and 60 mv. less for zinc chloride. Lorenz and Weber,[7] excluding air obtained values for lead chloride about 15 mv. less than ours, and Hildebrand and Ruhle,[1] taking proper precautions but using a polarized electrode, found values close to ours at 500° but falling off considerably at higher temperatures, 13 mv. at 600°. Recently Lorenz and Velde,[8] employing a procedure essentially the same as ours except that their preliminary treatment involved electrolysis of the cells for eight days at 0.25 ampere, obtained figures for lead chloride agreeing with ours to within 4 mv. For zinc chloride their values are 10 mv. less at 500° but in good agreement at 600°.

Since our main interest lies in the relation of free energy to composition at constant temperature, we obtained from Fig. 1, plotted on a large scale, the intersections at the round temperatures 500 and 600°, getting the values of e. m. f., E, given in Table IV, together with the values of dE/dT at the different compositions. The temperature coefficients fall off almost linearly with N_1 except for the most dilute cell, in which case it is considerably smaller. Since such a difference can hardly be real, it seems to us that the figures for this composition, $N_1 = 0.301$, are probably less accurate than the others.

Table IV also contains the values of the entropy, ΔS_1, and free energy of formation, ΔF_1, of lead chloride, its partial molal free energy or free energy of dilution, $\bar{F}_1$, its activity, a_1 and its activity coefficient, a_1/N_1. All of these have been calculated from the observed data by the usual formulas. We have also calculated the molal heat of formation, getting $\Delta H_1 = -81{,}100$ cal. for the pure liquid; this varies scarcely at all with changing temperature or upon dilution with zinc chloride.

The values for zinc chloride in Table III yield in a similar manner $E = 1.5725 - 0.000695(t - 500)$ for the e. m. f. between 500 and 600°, also, at 500°, $\Delta F_2 = -72{,}550$ cal. and $\Delta H_2 = -97{,}300$ cal.

$-\Delta F_1$, cal.	58,750	59,050	59,550	59,950	60,450	61,450
$-\bar{F}_1$, cal.	0	300	800	1200	1700	2700
a_1	1.000	0.820	0.595	0.455	0.330	0.175
a_1/N_1	1 000	0 930	0 865	0.770	0.675	0.575
			600°			
E, volts	12105	1.2185	1.2310	1.2405	1.2520	1.2800
$-\Delta F_1$, cal.	55,850	56,200	56,800	57,250	57,750	59,050
$-\bar{F}_1$, cal.	0	350	950	1400	1900	3200
a_1	1.000	0.835	0.580	0.445	0.335	0.155
a_1/N_1	1.000	0.945	0.840	0.750	0.685	0.515

The general nature of the results is most clearly indicated by the values of a_1/N_1, which are less than unity in the solutions, corresponding to negative deviations from Raoult's law, as found by Salstrom and Hildebrand[4] for the solutions of lead chloride with lead bromide. We find in this case, however, that the simple assumption of complete ionization of both salts, with no change in interionic forces, does not account for the direction of the deviation. Since the dilution with zinc chloride would, if both salts were completely ionized, make no change in the proportion of chloride ion, the only effect would be due to the substitution of lead ion by zinc ion, reducing the activity of the former and hence of the lead chloride, in proportion to N_1, the same as for the case of no ionization.

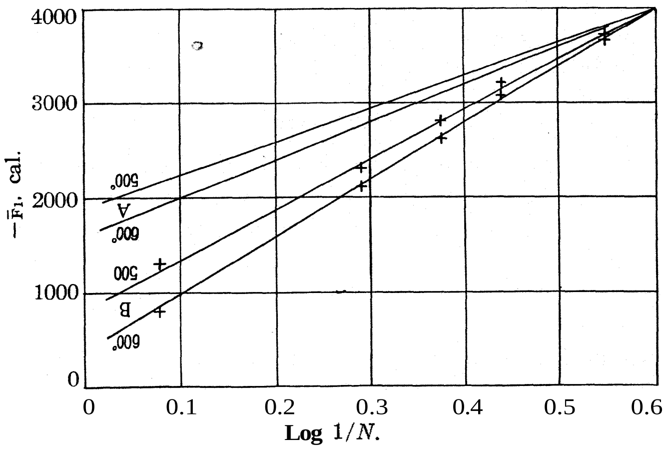

Fig. 2.—Variation of free energy of dilution with composition.

That a mere change in the interionic forces of a completely ionized mixture of these salts could affect the activities of the ions would seem plausible only in view of the contraction on mixing amounting to a little over one per cent., as shown by our density determinations. We will postpone till later any attempt to calculate the magnitude of this effect.

The deviation of the experimental results from the previous assumptions leading to $a_1 = N_1$ is illustrated graphically in Fig. 2, where $-\bar{F}_1$ is plotted against log $(1/N_1)$ for 500 and 600°. In view of the equation $\bar{F}_1 = RT \ln a_1$, this method of plotting yields the straight lines, A, when $a_1 = N_1$. As a matter of fact the empirical relation $\bar{F}_1 = 1.5\ RT \ln N_1$, given by the curves B, reproduces the experimental values very well.

An explanation of the deviations from $a_1 = N_1$ might be sought in a difference of dissociation between the two salts. Support for this view is lent by the fact that the electrical conductivity of zinc chloride at 500° is only one-sixteenth that of lead chloride, 0.084 mhos as compared with 1.33 mhos. Zinc chloride shows further evidence of low polarity in its low melting and boiling points and in its considerable solubility in various organic solvents. However, the most obvious difficulty in the way of an explanation along this line lies in the fact that we would not expect zinc chloride to have so much effect in small concentrations, but rather that curves B would begin tangent to curves A when N_1 is unity.

We will postpone a more searching treatment of this system till we have at hand data now being obtained for other systems, when we expect to make a comprehensive study of the whole subject.

Summary

1. The free energy of the formation of liquid lead and zinc chlorides has been measured between 500 and 600° by measuring the e. m. f. of reversible cells with metal and chlorine electrodes and fused salt electrolytes.

2. The e. m. f. of the Pb | $PbCl_2$ | Cl_2 in this range is given in volts by $1.2730 - 0.000625\ (t - 500)$, that of the corresponding zinc cell by $1.5725 - 0.000695\ (t - 500)$.

3. Dilution of the lead chloride by zinc chloride yields values for e. m. f. from which have been calculated the free energy of dilution and the activity over a range of composition from 30 to 100 mole per cent. of lead chloride.

4. It is pointed out that neither the assumption of no ionization or of complete ionization of both salts accounts for the observed values. Assuming the lead chloride to be ionized and the zinc chloride unionized accounts for the results only partially.

5. The densities of the pure salts and their 50 mole per cent. mixture have been measured in order to furnish information regarding interionic distances as a guide to a future theoretical treatment. The density of

lead chloride is given by 4.947 − 0.00164 (t − 500), that of zinc chloride by 2.424 − 0.00046 (t − 500).

AN ATTEMPT TO MEASURE THE VELOCITY OF DISSOCIATION OF NITROGEN TETROXIDE BY THE METHOD OF SOUND WAVES

BY GEORGE B. KISTIAKOWSKY AND WILLIAM T. RICHARDS

RECEIVED JULY 5, 1930 PUBLISHED DECEMBER 18, 1930

For some years it has been apparent that sound waves offer an opportunity to investigate the velocity of dissociation of rapidly dissociating gases. The argument was at first[1] purely qualitative, it being supposed that when the compressions and rarefactions in the sound waves succeeded each other with sufficient rapidity the dissociating gas would no longer be able to attain equilibrium. An increased velocity of sound with increasing frequency was therefore to be expected when a certain critical region of frequency had been reached. Einstein gave this conception greater precision in a well-known paper[2] relating the velocity constant of the reaction to the increase in velocity of sound with increasing frequency. Since the velocity constants of rapid reactions are of the utmost importance for the kinetic interpretation of reaction velocities, Einstein's theory was soon tested, first by Selle[3] and later by Grüneisen and Goens.[4] Nitrogen tetroxide, which dissociates considerably in a convenient temperature range, was the object of study of both of these investigations. The work of Grüneisen and Goens was of an extremely scholarly character, the velocity of sound being measured by the resonance tube method to frequencies of 15,600 cycles per second from 10 to 35° and from 760 to 265 mm. pressure. The velocity being independent of frequency to a few tenths of a per cent. over this range, these authors estimated that the velocity constant of the reaction must exceed 10,000, a conclusion with which this communication is in entire accord. More recently Olson and Teeter[5] in a brief note, report an increase of velocity at 50 kilocycles. Their results have not been confirmed by this investigation. Their published data are limited, and no critique of their conclusion can be attempted here. It seems possible that they have underestimated their systematic error, a point of unusual importance in the calculation of the velocity constant.

The discovery by Pierce[6] of the magneto-striction oscillator made easily available a far wider range of conditions, and suggested a reexamination of nitrogen tetroxide. The negative result obtained from this study was not to be expected, and leads to certain theoretical conclusions.

Experimental Procedure

The apparatus employed was necessarily rather complex, and in the interests of space conservation no attempt will be made to describe it completely. It naturally falls into two main divisions, the electrical circuit, which generated the sound waves, detected their nodal points in the gas-filled tube, and measured their frequencies, and the glass apparatus which generated and purified nitrogen tetroxide, maintained its temperature, and measured its pressure during the progress of the experiment. It will be convenient to describe the two separately.

The magneto-striction oscillators employed followed closely the design of Pierce[6] and drove one of three one-inch nichrome rods. The frequencies of these were approximately 10, 41.5 and 80 k. c. respectively. At the termination of an experiment with a given frequency the rod which had been used was heterodyned against another rod and the resulting beat note analyzed on a bridge closely resembling that recommended by Pierce. The variable inductance and capacity in this bridge were Leeds and Northrup calibrated precision instruments and gave the frequency of the heterodyne note to better than twenty cycles. Appropriate corrections for the temperature of the rods were, of course, applied. The rods were finally compared, by means of an intermediate heterodyne nichrome rod of about 45 k. c., with a calibrated quartz crystal of 47.45 k. c. (temperature coefficient 0.47 cycle per degree centigrade). The frequencies of the nichrome rods used during the experiments were therefore known with an estimated error of 20 cycles, or, respectively, 0.2, 0.05 and 0.03% for the 10, 41.5 and 80 k. c. rods. The greatest error in this determination was in the calibration of the capacities and inductance of the frequency bridge, and was largely eliminated by making many readings with a wide range of capacities and inductance and averaging. A characteristic series of such measurements follows.

TABLE I

TYPICAL FREQUENCY DIFFERENCES AS READ FROM CAPACITY BRIDGE

Difference in frequency in cycles per second between fourth harmonic of 10 k. c rod (at 25°) and 41.5 k. c. rod at 20.7°.

Corr. to 25° = 1969

Of the glass apparatus only one piece, the observation tube, merits a detailed description. Since nitrogen tetroxide is a highly corrosive gas it was necessary that this tube be constructed as far as possible of materials exceedingly resistant to oxidizing action. Glass and nichrome satisfy this condition and, as a glance at Fig. 1 will show, no other materials were found necessary with the exception of a single small and well-protected cement joint. In Fig. 1, A represents the one-inch nichrome rod balanced on a

[6] G. W. Pierce, Proc. *Am. Acad. Sci.*, **63**, 1 (1928). Mr. W. J. Cahill, whose work under Professor Pierce demonstrated the precision of measurements made with 2.54-cm. magnetostriction rods in 2.54-cm. tubes, acted as advisor in the very early stages of this investigation.

small asbestos support B, and fitting as tightly as possible without cramping its oscillations the long straight uniform glass tube which constituted the observation chamber. The driving coils for this rod were slipped over the outside of the tube, and were interchangeable with a magnetizing coil which made it possible to polarize the rod and change its position without opening the sealed tube at C. At the conclusion of any experiment the tube was blown open at C, another rod substituted for A, and the tube resealed, thus making a removable joint with possible leakage, oxidizable grease, etc., entirely unnecessary. The gas space through which sound waves were transmitted is represented by the region D. E is a piston of glass tubing which fitted snugly the main tube, and had a polished reflecting face carefully adjusted normal to the walls of the latter. Scrupulous plane-parallelism between this reflecting surface and the end of the nichrome rod is, of course, necessary to secure accurate measurements of the half-wave length of sound. The piston was sealed at F to two lengths of glass rod which extended parallel through the distance of motion of the piston, and terminated in a nichrome nut G which was sealed to them by glass-covered tungsten wires. A loop of glass-supported nichrome rod H shaped to receive the parallel glass rods served to prevent irregularities in the orientation of the polished piston face E by providing a rigid guide for the motion of the parallel glass rods. Motion of the piston was obtained by means of a nichrome screw which passed through G, and out of the tube through the asbestos–graphite packing I. A knurled handle, J, was rigidly attached to the screw. The side-tube K, which served to introduce the gas to be observed, is shown sealed as during the progress of an experiment. At L was a quartz spiral manometer which was attached to the apparatus throughout the experiments. and served to measure the pressures of gas in the tube to ±1 mm.

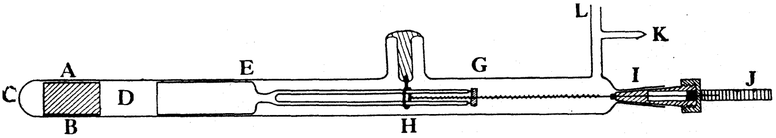

Fig. 1.—Glass chamber for measuring the velocity of sound in a corrosive gas.

Nitrogen tetroxide was prepared in the usual manner by heating lead nitrate in a stream of oxygen. The gas was repeatedly dried by passing through phosphoric anhydride tubes, and finally subjected to a vacuum distillation, being condensed at the temperature of solid carbon dioxide to rid it of any adsorbed or included permanent gases. It was then allowed to evaporate into the already evacuated apparatus and the purification, pumping, etc., systems were sealed off, leaving the apparatus essentially as illustrated in Fig. 1.

During an experiment the apparatus, with the exception of the quartz manometer, was covered with an air thermostat which maintained 25.0 ± 0.1°. The position of the piston was ascertained through a plate glass window by a cathetometer mounted scrupulously parallel to the axis of the piston. This gave complete independence of irregularities in the construction of the screw, and defined the position of the piston to 0.1 mm. The pressure and temperature of the gas were read at the start and finish of the experiments, and at such intermediate points as seemed advisable. Experiments with air were made with dry, carbon dioxide-free air. Experiments with nitrogen tetroxide were begun at atmospheric pressure, and the pressure progressively diminished by condensing out portions of the gas in small tubes at K (Fig. 1), which were then sealed off. This served the further useful purpose of indicating the presence of nitric oxide by the bluish color of the condensate, and of permanent gases by the slowness of the process of condensation. If either was found present in appreciable quantity the experiment was discontinued and the result discarded.

The half wave length of sound was determined as the difference between the position of the piston at two resonance points. The resonance points were determined by a milliammeter in the plate circuit of the amplifier of the oscillating circuit, the reflection of sound from the piston at the resonance point greatly increasing the plate current. By suitable adjustment almost any desired magnitude of deflection could be obtained. The resonance points were uniformly sharp and evenly spaced over the entire range of the piston stroke (some 200 mm.) at pressures down to 300 mm. At 140 mm. the enormous increase of absorption made it impossible to examine more than some twenty or thirty half wave lengths. Since the regularity of spacing of the resonance peaks is a matter of some importance for the interpretation of the results, one series of typical measurements on nitrogen tetroxide is given in Table II.

TABLE II

CATHETOMETER READINGS AND HALF WAVE LENGTH VALUES IN N_2O_4

41,633 cycles per second, 277 mm., and 25.0". Cathetometer readings made every 10 half wave lengths.

Mm.	670.1	646.6	623.3	599.9	576.5	553.1	529.6	506.1	482.6
Difference	23.5	23.3	23.4	23.4	23.4	23.5	23.5	23.5	

After condensing a portion of gas and re-evaporating, the last reading, 80 half wave lengths from first, was 482.7 mm. Velocity of sound $= 4.163 \times 10^4 (670.1 - 482.7) (2/80) = 195.2$ meters per sec.

Experimental Results

The results of all measurements may be summarized in a series of almost self-explanatory tables.

TABLE III

VELOCITY OF SOUND IN AIR AT 25.0° AND VARIOUS FREQUENCIES AND PRESSURES

Frequency	Pressure	Number of nodes	Velocity
9,916	730	8	345.6
41,633	758	40	346.5
41,633	152	40	346.5
80,350	760	110	345.5
80,350	147	20	346.1

In Table III, as in all subsequent tables, frequency is quoted in cycles per second, pressure in mm. of mercury, and velocity in meters per second. The number of nodes, or half-wave lengths, measured is also quoted, since this plays an obviously important part in estimating the relative accuracy of each particular measurement. The average value obtained from these figures is 346.0 meters per second and when reduced[7] to 0° becomes 331.2 meters per second, a satisfactory agreement with the most probable absolute value of 331.6 meters per second.

Tables IV, V and VI give similar data for nitrogen tetroxide at different frequencies, and, in addition, an arbitrary number which designates the sample of gas which filled the tube in each particular determination. The temperature coefficient, used for covering temperature variations of 0.1°,

7	485	109	189.4
12	333	128	193.5
7	304	193	195 3

The results given in Tables IV to VI have been represented as points in Fig. 2. The solid curve drawn through them defines the velocity of sound at all pressures considered to better than 0.5%, since the largest single deviation does not exceed this value. The figure demonstrates conclusively that, within this limit, there is no systematic change of velocity with frequency between 10 and 80 k. c., since the distribution of points about the solid curve appears perfectly random. It also should be noted that points measured by Griineisen and Goens show satisfactory agreement with the solid curve, especially since the pressure determinations for these points with the exception of the 760 mm. value depend on the vapor pressure data of nitrogen tetroxide[8] and hence may be considerably in error.

Several details call for brief comment. In the first place, it was most unfortunate that measurements could not be obtained at 140 mm. with the 80 k. c. oscillator, since this would have doubled the significance of the negative result reported. This was, of course, repeatedly attempted but, because of the difficulty of supporting adequately the very short rod for

[8] F. E. C. Scheffer and J. P. Treub, *Z. physik. Chem.*, 81, 308 (1912)

optimum oscillation conditions, because at such low pressures exceedingly little energy enters the gas from the vibrating metal, and because absorption was most pronounced, every attempt to measure velocities at this **frequency** below 300 mm. met with failure.

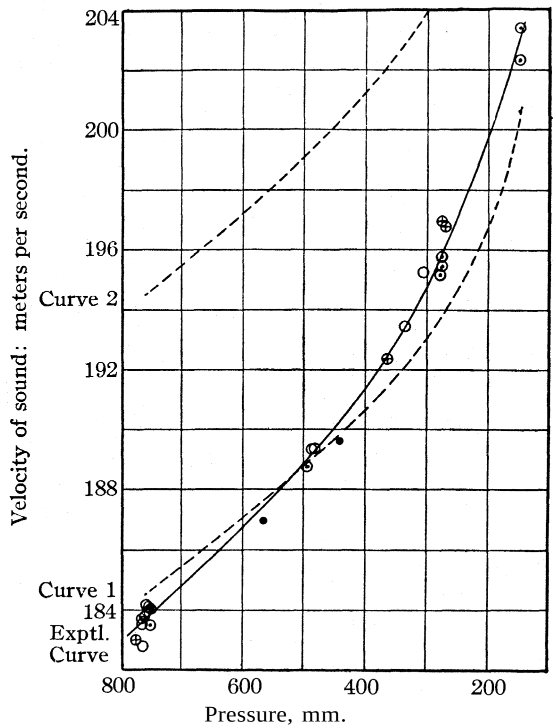

Fig. 2.—The velocity of sound in nitrogen tetroxide at 25° and various pressures: ⊕ represents 10 k. *c.* observations; ⊙, 41.5 k. c. observations; O, 80 k. *c.* observations, and ● the summarized observations of Grüneisen and Goens; Curve 1 represents the theoretical velocity according to Einstein for ω = o. Curve *2* for w = m.

Again, although the accuracy of any determination could have been increased by measuring a larger number of half-wave lengths, it was found unnecessary to do so. An examination of a relatively small number of nodes was sufficient to fix the velocity of sound in any particular determination to about 0.05% and errors in other parts of the procedure produced greater deviations than this. Each determination was carried out by running the piston along the tube from a position as near as possible to the vibrating rod to the end of its stroke, the spacing and number of the peaks being noted. A considerable quantity of the gas was then condensed out at K

(Fig. 1) and reëvaporated, and the peak nearest the end stroke of the piston redetermined. It was always found to check the previous value within 0.2 mm., which was the accuracy of determining a single resonance peak.

The greatest source of error was evidently small, almost undetectable traces of permament gases and nitric oxide, since variations of as much as 0.5% were observed between velocities measured with different fillings of the apparatus, No method of purification or evacuation was found completely to obviate these.

Theoretical Discussion

The Einstein theory permits the calculation of the velocity of sound in a dissociating gas at zero frequency, at infinite frequency and at intermediate frequency provided the absorption coefficient is sufficiently small. For zero frequency the expression is

$$V_{\omega = 0} = \sqrt{\frac{P}{\rho}\left(1 + \frac{A}{B}\right)} \tag{1}$$

for infinite frequency

$$V_{\omega = \infty} = \sqrt{\frac{P}{\rho}\left(1 + \frac{R}{\bar{c}_v}\right)} \tag{2}$$

and for intermediate frequencies

$$V_{\text{intermed.}} = \sqrt{\frac{P}{\rho}\left(1 + \frac{K^2AB + R\bar{c}_v\omega^2}{K^2B^2 + \bar{c}_v^2\omega^2}\right)} \tag{3}$$

where V represents the velocity of sound, ω the circular frequency, P the pressure, ρ the density, R the molecular gas constant, $\bar{c}_v$ the averaged specific heat at constant volume, K the velocity constant of dissociation, and A and B are abbreviation constants defined by

$$A = \left(2\frac{D}{T} - \bar{c}_v\right)\frac{n_1}{n_1 + n_2} + R\left(1 - 4\frac{n_1}{n_2}\right)$$

$$B = \frac{D^2}{RT^2}\frac{n_1}{n_1 + n_2} + \bar{c}_v\left(1 - 4\frac{n_1}{n_2}\right)$$

D being the heat of dissociation, T the temperature and n_1, n_2 the molecular numbers of nitrogen tetroxide and nitrogen dioxide, respectively.

For this calculation, therefore, a knowledge of the equilibrium constant of nitrogen tetroxide and its heat of dissociation, and of the specific heats of nitrogen dioxide and nitrogen tetroxide is necessary. The first two quantities were obtained from the work of Bodenstein,[9] the value of K being 0.1455 and of D 12,940 cal. at 25°. The specific heats of the gases have not been measured, and must be calculated on the basis of certain assumptions. It has therefore been assumed that c_v of nitrogen dioxide equals that of carbon dioxide, nitrous oxide, etc., namely, 6.8 cal., whereas that of nitrogen tetroxide is larger by 6/2 R calories, and hence becomes 12.75 cal. While no strong arguments for these values may be advanced,

---

[9] M. Bodenstein, *Z. physik. Chem.*, **100**, 68 **(1922).**

they are reasonable approximations, and even if considerably in error the validity of the calculation would be little affected.

Using these values the pressure–velocity curves indicated by dotted lines 1 and 2 in Fig. 2 are obtained for Equations 1 and 2, respectively. It will be noted that dotted curve 2, which indicates the maximum effect possible, lies far above the observed values. Dotted curve 1 agrees better with the experiments here reported, but does not coincide within the limit of experimental error. This is not surprising, since the calculated velocity is highly sensitive to the values chosen for the dissociation data, as is strikingly illustrated by the fact that Grüneisen and Goens, using less accurate values for these quantities, obtain a calculated value for the velocity at 760 mm. which is almost 2% higher than that given on dotted curve 1.

Grüneisen and Goens, using Equation 3, and taking into account their probable experimental error, have estimated that at 25° the reaction velocity constant must be larger than 10^4. On the basis of the present communication this lower limit must be raised. It may safely be assumed that the probable error of the sound velocity measurements here reported does not exceed the maximum deviation, 0.5%, and hence the minimum velocity constants compatible with the 41.5 k. c. and 80 k. c. measurements are 2.6×10^4 and 5×10^4, respectively, since at these two frequencies agreement is obtained within the allowed error with determinations at lower frequencies.

It is of some interest to compare the lower limit of the velocity constant thus determined with the upper limit of the reaction velocity as deduced, on some assumption concerning the reaction mechanism, from the kinetic theory. It is most plausible to assume that the dissociation process belongs to the so-called "quasi-unimolecular" reaction type,[10] that, in other words, the activation of a nitrogen tetroxide molecule on collision is followed either by its decomposition or by its deactivation on another collision. Since, for the present purpose, only the upper limit of the reaction velocity is of interest, only the case need be considered where the mean life of the activated nitrogen tetroxide molecules is short compared with the time between inelastic collisions, and hence the rate of decomposition is essentially equal to the rate of activation. It will further be expedient to assign to the heat of activation its lowest possible value, the heat of reaction. Unfortunately, the cross sections of the nitrogen dioxide and nitrogen tetroxide molecules, which must be used to calculate the total number of kinetic collisions Z, are unknown and experimentally inaccessible. It is, therefore, necessary to assume cross sections for these molecules, and the values of $d_{NO_2} = d_{CO_2} = 4.2 \times 10^{-8}$ cm. and $d_{N_2O_4} = \sqrt[3]{2d^3_{NO_2}} = 5.3 \times 10^{-8}$ have been chosen as being least likely to be in error.

Granting these assumptions which, although not wholly defensible, can

---

[10] Lindemann, *Trans. Faraday Soc.*, 17, 598 (1922).

hardly yield too low a value for the maximum dissociation velocity which is kinetically possible, the computation is easily made. The data employed may be either the measurements made at 150 mm. and 41.5 k. c. or 250 mm. and 80 k. c. since the result obtained will be approximately the same for the two. It follows from ordinary kinetic considerations that, if only two degrees of freedom of the molecule participate, the velocity of decomposition at 150 mm. and 25° will be

$$-\frac{dn_1}{dt} = Ze^{-D/RT} = 2.6 \times 10^{27} \times 2.7 \times 10^{-10} = 7 \times 10^{17} \text{ molecules per cc. per sec.}$$

t referring, of course, to time, and the other symbols having the significance defined above. From the minimum value of the velocity constant K determined by experiment at 41.5 k. c. and 150 mm. (2.6×10^4), it is evident that the rate of decomposition must be greater than $Kn_1 = 5.5 \times 10^{22}$ molecules per cc. per second, a number far greater than that calculated above. It is necessary, therefore, to assume, as has been done by Polanyi, Hinshelwood, and others for several reactions, that more than two degrees of freedom participate in the activation process. Since the total number of internal degrees of freedom of the nitrogen tetroxide molecule is twelve, the maximum possible rate of activation and reaction is given[11] approximately by

$$-\frac{dn_1}{dt} = Ze^{-D/RT}\frac{(D/RT)^{11}}{11!} = 1.1 \times 10^{25} \text{ moles per cc. per sec.}$$

this value is not greatly in excess of the experimental value, which indicates that the activation of nitrogen tetroxide must involve a large number of degrees of freedom, and hence be very similar in character to the decomposition of nitrogen pentoxide.

A comparison may also be made between the rate of association of nitrogen dioxide molecules—which, in the case under consideration, must be larger than 1.1×10^{23} molecules per cc. per sec.—and the number of triple collisions. The second quantity is easily estimated, using the approximation that the number of triple collisions is related to the number of all collisions as the molecular diameter to the mean free path, and may thus be assigned the value 2×10^{24}.

As a result of this calculation it may be stated with some confidence that the maximum theoretical velocity of decomposition and the number of triple collisions have values close to that calculated from the minimum velocity constant defined experimentally. The discrepancy between the two is sufficiently small to suggest at first sight the desirability of performing further measurements at higher frequencies and lower pressures in an attempt to discover whether or not the kinetic theory of reaction velocity may be applied to the process with ordinary molecular dimensions, or

---

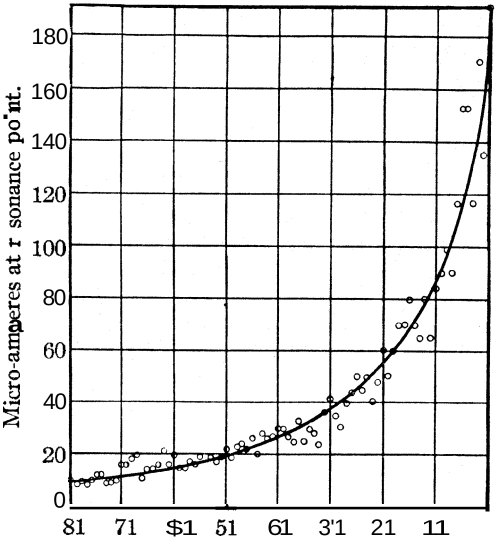
[11] K. F. Herzfeld "Kinetische Theorie der Wärme" Braunschweig. 1925.

whether larger effective cross sections must be postulated. More critically examined, such an extension of these measurements appears much less promising, owing to the greatly increased absorption of sound in nitrogen tetroxide at low pressures.

A few rough determinations of the absorption of sound were made in the course of the experimental work described above by noting the magnitude of change in plate current at succeeding nodal points. It cannot, of course, be claimed that this is a method of precision, but since no data of the kind have been published for nitrogen tetroxide, and since an assumption concerning absorption appears in the theory of Einstein, a brief summary of these observations will be set down here. Figure **3** represents a typical series of measurements, in this case those corresponding to the determination reported in detail in Table II. A line drawn through these points has a clearly exponential form, which may be expressed approximately by the empirical equation

$$I = I_0 e^{-hN}$$

where I and I_0 represent intensities, h an absorption coefficient and N the number of half wave lengths between I_0 and I. The values for h best fitting the curves at various pressures are given in Table VII.



Distance from rod in half wave lengths.

Fig. 3.—Absorption of sound in nitrogen tetroxide as illustrated by diminution in plate current at resonance points with increasing distance of reflector from vibrating rod. 41.5 k. c., 25.0°, 277 mm.

TABLE VII

ABSORPTION COEFFICIENTS IN NITROGEN TETROXIDE AT VARIOUS PRESSURES AND FREQUENCIES

Mm. pressure	760	400	150
10 k. c.	...	0.06	0.24
41.5 k. c.	0.02	.06	...
80 k. c.	.03	.05	0.20

It appears, therefore, that in nitrogen tetroxide the absorption of sound increases extremely rapidly below 400 mm. pressure, although, as is to be expected if the dissociation is far more rapid than the frequency, it is not noticeably dependent on frequency. similar measurements with air showed no significant change in h with pressure. The bearing of Table VII on further experiment is immediately apparent. Not only does the increased absorption at lower pressures very greatly diminish the accuracy of experiments by decreasing the number of half wave lengths which may be examined, but below 140 mm. the absorption becomes so great that it is likely that Einstein's reasoning would no longer apply. At increased frequencies it seems highly probable that absorption would set in at higher pressures, since Pierce[6] observed at 200 k. c. in carbon dioxide, a similar but non-dissociating gas, an absorption about a hundred times as great as that in air.

Measurements of this character are nevertheless being undertaken by one of us. It seems further advisable to investigate other dissociating gases and vapors in less accessible regions of temperature, for it is by no means certain that the behavior of nitrogen tetroxide is typical of all such dissociation processes.

Summary

1. The velocity of sound at 25° in nitrogen tetroxide has been investigated from 10 to 80 k. c., and from 760 to 140 mm., and has been found to be independent of frequency.
2. It has been calculated that the minimum velocity constant defined by these experiments is not far from the maximum possible velocity constant deduced from the kinetic theory of gases.
3. The bearing of this conclusion on the kinetic theory of reaction velocity is discussed.

PARAMAGNETISM INDEPENDENT OF THE TEMPERATURE AND THE EXISTENCE OF ELECTRONIC ISOMERS IN POLYATOMIC IONS

BY SIMON FREED AND CHARLES KASPER

RECEIVED JULY 15, 1930 PUBLISHED DECEMBER 18, 1930

It has been almost universally believed that the phenomenon of paramagnetism owes its origin to the motion of the unbalanced electrons in the stationary states of molecules. Employing the model of such molecular magnets Langevin[1] was very successful in accounting for the magnetic behavior of many substances, not only in the gaseous state where interaction between the molecules is slight, but also in the crystalline state and in solution. He was led to Curie's law, which states that the paramagnetic susceptibility is inversely proportional to the absolute temperature. Many substances, however, display a somewhat more com-

---

[1] Langevin, *Ann. chim. phys.*, [8] **5**, 70 (1905).

plicated behavior and require an arbitrary constant to describe their deviation from Curie's law.[2]

A number of substances have been found to have susceptibility quite independent of the temperature. Their paramagnetic susceptibility is small, usually of the same order of magnitude as the diamagnetic susceptibility. Indeed, such constant susceptibility may well be a general phenomenon experimentally inseparable from the diamagnetic susceptibility, since the latter is also independent of the temperature and in paramagnetic substances it may constitute part of the deviations from Curie's law. Only one type of substance exhibiting constant paramagnetism has been investigated here. It consists of a molecular ion in which a metallic constituent is surrounded with just the number of electrons which suggest a very balanced and symmetrical arrangement. One would, of course, expect such an ion to be diamagnetic. It was the aim in this investigation to observe by precise measurements to what degree the paramagnetism of such ions was independent of the temperature and to correlate their magnetism with the results of the quantum mechanics.

Previous **Work** and its Relation to the Present Investigation.—Manganese in permanganate ion, MnO_4^-, is in its maximum valence of +7, and it would normally be expected to resemble argon and be diamagnetic, since the latter has all its electrons mutually balanced.[3] Ishiwara[4] measured the specific susceptibility of potassium permanganate over a range of temperatures and found it to be 0.179 at 103°K., 0.175 at 294°K., 0.175 at 368°K. and 0.179 at 435°K.

Similarly, chromium in dichromate ion, $Cr_2O_7^{=}$, is in its maximum valence of +6. The susceptibility of this ion was found to be constant by Weiss and Collet[5] in solution from 14 to 50° within 1×10^{-6}, and by Collet[6] in the solid state from 12 to 90° to within 0.1×10^{-6}.

There are analogous ions such as UO_2^{++}, $WO_4^{=}$, VO_3^-, etc., which one would predict to behave similarly.

There is another type of ion manifesting constant paramagnetism,

---

[2] A generalized Curie's law known as Weiss' law, $X(T + \Delta) = C$, is often obeyed; X is susceptibility, T, absolute temperature, Δ an empirical constant and C is Curie's constant.

[3] Kossel, *Ann. Physik*, 49,229 (1916), first observed that the paramagnetic susceptibility of many ions depends only on the number of unbalanced electrons in the valence shell. For example, bivalent vanadium, V^{++}, has three unbalanced electrons and it has three Bohr magnetons (Freed, THIS JOURNAL, 49, 2456 (1927)), VO^+ (V^{+++}) has two unbalanced electrons and it has two Bohr magnetons. VO^{++} (V^{++++}) has one unbalanced electron, as potassium has, and it possesses one Bohr magneton. VO_3^- (V^{5+}) has no unbalanced electrons, like argon, and hence would presumably be diamagnetic.

[6] Collet, *ibid.*, 181, 1057 (1925).

which has some resemblance to the ions just mentioned, namely, the cobaltammines[6] and similar complex ions, and the ferrocyanide ion. The number of electrons surrounding cobalt in the cobaltammines is 36. The same number surrounds iron in ferrocyanide ion. Argon has the same number of electrons[7] and these, of course, balance completely and form a diamagnetic system.

Experimental Method

It was found that the method of Freed[8] for measuring susceptibilities at low temperatures would justify the use of a more sensitive balance than the one he employed. In the present work the apparatus was equipped with a Sartorius micro-balance having a capacity of 20 g. and a sensitivity under ideal conditions of ±0.001 mg. Under the conditions of the experimentation a sensitivity of about ±0.007 mg. was reached but the reproducibility was reduced to ±0.01 mg. or ±0.02 mg. by the fluctuations in the current exciting the magnet.

In short, the method consists in employing the use of the Gouy method at low temperatures in such a way that the tube containing the substance to be measured is in a regular stream of hydrogen at known temperatures. The hydrogen is cooled by liquid air, for example, boiling under atmospheric pressure, or to obtain lower temperatures, under reduced pressure. The stream of hydrogen gas is not connected with the vacuum pump and the tube swings just as freely at all temperatures as if it were suspended in air under atmospheric pressure. The balance can thus be manipulated as under normal conditions.

Materials and Experimental Results.—The chemical substances which were utilized in this work were analyzed for iron by the sensitive thiocyanate method and also for any other paramagnetic impurities that were likely to be present. Most careful attention was given to the possible presence of the metals of the ions in less than their maximum valence, for example U^{4+} in UO_2^{++}, Cr^{+++} in $Cr_2O_7^{=}$, etc. These are all paramagnetic and their undetected presence in appreciable concentration would have been disastrous. For this purpose, we observed colorimetrically the effect of adding permanganate solution drop by drop. This procedure was impossible in the case of dichromate due to its intense color. To avoid this, recrystallized potassium dichromate of great purity was measured magnetically and its susceptibility was found to increase slightly as the temperature was reduced. The same material was then recrystallized in the cold, that is by pumping off the water from a saturated solution at room temperature and distilling it into a liquid–air trap. The resulting dichromate crystals showed no temperature coefficient in the

---

[8] Freed, THIS JOURNAL, 52, 2702 (1930).

susceptibility. Perhaps it may be stated that the original paramagnetic contamination was so small that it would not have been detected by the previous investigators.

The susceptibility of uranyl ion decreased at first as the temperature was lowered, but increased again at lower temperatures. However, when the presence of iron was corrected for, the susceptibility continued to decrease steadily. If other undetected paramagnetic impurities had been present, the true susceptibility of UO_2^{++} would be decreasing more rapidly with decreasing temperature than appeared to be the case.

The sodium tungstate, $Na_2WO_4 \cdot 2H_2O$, was exceptionally free of impurities. It was recrystallized once.

The computation of the partial molal susceptibilities was made by assuming that the susceptibilities of the constituents were additive.

TABLE I

THE SUSCEPTIBILITIES OF UO_2^{++}

Temp., °K.	$\chi^a_{\text{gr. } UO_2SO_4 \cdot 3H_2O}$	$\chi^b_{\text{mole } UO_2^{++}}$
293.2	−0.0232	57.03
116.3	− .0212	56.28
90.8	− .0203	55.98
69.8	− .0228	53.97

[a] Uncorrected for ferric ion present. [b] Corrected for iron (2×10^{-6} g. per g. salt).

The second column is the susceptibility per gram of the salt $UO_2SO_4 \cdot 3H_2O$, which is effectually the difference between the susceptibilities of the paramagnetic and diamagnetic constituents. The partial molal susceptibility of UO_2^{++} can be ascertained with a greater percentage accuracy than this difference is known, provided the magnitudes of the diamagnetic susceptibilities are assumed to be without appreciable error. Such an assumption is justified, perhaps, in the case of liquid water. (The susceptibility of ice is a trifle less but is not known with the same accuracy.) 12.96×10^{-6} per mole was taken as its susceptibility. However, the molal susceptibility of $SO_4^{=}$ is only very approximate and should be redetermined. The value of -37.00×10^{-6} per mole was arbitrarily adopted for it. This value is correct to within about 3%. We cannot then insist upon the absolute magnitudes in the third column. The variation with the temperature is known with far greater accuracy than the values of the susceptibilities themselves. It was, of course, these variations with which this research was primarily concerned. The reproducibility in the measurements was such that a change in the susceptibility per gram of 0.0005×10^{-6} could be definitely established. Such a sensitivity corresponds to a change of 0.06×10^{-6} per mole.

Greater precision than this in terms of actual effects on the balance was obtained in the measurements of sodium tungstate. However, the pull was so great, about 10 mg. (it was only from 0.8 mg. to 1.7 mg. with $UO_2SO_4 \cdot 3H_2O$), that slight fluctuations in the current brought the reproducibility to ±0.02 mg. The susceptibility was measured at 296.5°K., 115.2°K. and 86.4°K. and was found to be constant. Of a total of thirty-six points only two deviated from the smooth curve of pulls against amperes by 0.03 mg. and one by 0.04 mg. The susceptibility per gram of the salt was found to be -0.1958×10^{-6} and the *susceptibility per mole of* $WO_4^=$ becomes $+5.93 \times 10^{-6}$. A change of 0.0005×10^{-6} per gram or 0.08×10^{-6} per mole would have been observed easily. The value of -10.4×10^{-6} was taken as the susceptibility of one mole of Na^+.[9]

Finer reproducibility was attained with $Cr_2O_7^=$. The purified potassium dichromate was measured at 293.6°K., 169.9°K., 114.0°K. and 84.3°K. and found to be constant. The measured values fell upon a smooth curve within ±0.01 mg. Of the thirty-six points only one deviated by more than this, and it deviated by 0.03 mg.

Another series of determinations was made to obtain the absolute susceptibility. It was suspected that the balance might have been jarred slightly since the previous calibration had been made. However, this series agreed with the first within 0.02 mg. The susceptibility per gram was found to be $+0.0962 \times 10^{-6}$. Employing the value of -16.9×10^{-6} as the molal susceptibility of K^+[9], the *susceptibility of one mole of* $Cr_2O_7^=$ *is* 62.1×10^{-6}. A change of 0.1×10^{-6} per mole would have been observable.

Discussion of Results

The existence of fluorescence from uranyl ion, UO_2^{++}, shows clearly the existence of an unusual freedom from interaction with external systems. Otherwise, the high density of matter in thermal agitation in the crystal would have quenched the fluorescence. The independence of the dichromate ions from one another is further confirmed in the identical susceptibility which dichromate ion has in solution and in the solid state. In the same way, the sharpness of the absorption bands of the permanganate ion, MnO_4^-,[10] indicates that its least stable electrons, that is, those to which one may assign the optical and paramagnetic properties of MnO_4^-, are shielded from external forces.

To a considerable degree of approximation, then, the least stable electrons of the ions we have been discussing may be regarded as localized near the metallic kernel of the ion and shielded from the external fields of the neighboring ions by the atmosphere of electronically saturated oxygen atoms (or ammonia, etc., in the cobaltammines or cyanide in the cyanides, etc.). Such a configuration immediately suggests the atomic

---

[9] Ikenmeyer, *Ann. Physik*, [5] 1,169 (1929).

[10] Hagenbach and Percy. *Helv. Chim. Acta*, 5, 454 (1922).

ions of the rare earths whose kernels contain the unbalanced electrons. These, too, are shielded from external forces by electronically saturated shells, that is, by electronic shells which are completely filled.

The ions of the rare earths conform very closely in their magnetic behavior[11,8] with that expected from independent ions. Indeed, their magnetic susceptibilities can be calculated accurately from considerations employed in the quantum theory of atoms (atomic ions.) Correspondingly we shall attempt to correlate the magnetic properties of the molecular ions, such as UO_2^{++}, $WO_4^{=}$, $Cr_2O_7^{=}$, MnO_4^{-}, etc., with the quantum theory of molecules.

Van Vleck[12] in a series of important papers on susceptibility from the point of view of the quantum mechanics arrived at the following formula

$$\chi = \frac{N}{3kT}\,\frac{\Sigma_{\sigma jm,\,j'm'}\,|\,M(\sigma jm;\ \sigma j'm')\,|^2\,e^{-W(\sigma j)/kT}}{\Sigma_{\sigma jm}\,e^{-W(\sigma j)/kT}} \tag{1}$$

$$+\,\frac{--\cdot}{3h}\,\frac{\Sigma_{\sigma jm,\,\sigma'j'm'\,(\sigma \neq \sigma')}\,\frac{|\,M(\sigma jm;\ \sigma'j'm')\,|^2}{\nu(\sigma;\ \sigma')}\,e^{-W(\sigma j)/kT}}{\Sigma_{\sigma jm}\,e^{-W(\sigma j)/kT}} \tag{2}$$

$$-\,\frac{Ne^2}{6mc^2}\,\Sigma r^2 \tag{3}$$

where χ is the susceptibility per mole, k is Boltzmann's constant, T is the absolute temperature, σjm are indices or quantum numbers of the molecule in a stationary energy state, a is an index corresponding to quantum numbers whose change is associated with an energy W (a), large compared with kT (in the present case we may identify it with electronic quantum numbers), j corresponds to quantum numbers whose change implies energies small compared to kT (in this case the rotational quantum number, m, corresponds to quantum numbers whose change is associated with energies small compared with kT, in this case, magnetic quantum numbers), v (a; a') is the absorption frequency corresponding to a transition from the state a to a' (it is practically equal to v $(\sigma jm;\ j'm'$—, since the change in a is associated with a greater energy difference than is brought about by the change in the other quantum numbers), e/m is the charge divided by the mass of the electron, N is Avogadro's number, h is Planck's constant, c is the velocity of light and Σr^2 is the average of the square of the radii of the electronic orbits summed over all the electrons.

$|\,M(\sigma jm;\ \sigma j'm')\,|^2$ is the square of the absolute magnitude of the magnetic moment generated by the electrons in the stationary electronic state of the molecule. (If the molecule is symmetrical as one would believe MnO_4^{-}, UO_2^{++} to be, an axis of symmetry exists with respect to which the angular momentum of the system may be resolved. $\Sigma_{j'm}\,|\,M(\sigma jm;$

---

[11] Hund, Z. *Physik*, 33,855 (1926).

[12] Van Vleck, (a) *Phys. Rev.*, 29,727 *(1927);* (b) 30, 31 (1927); (c) 31, 587 (1928).

$\sigma j'm')\,|^2$ can be visualized as the square of the magnetic moment parallel to this axis and $\Sigma\sigma j'm'(\sigma \neq \sigma')\ |\,M(\sigma jm;\ \sigma'j'm')\,|^2$ as the square of the magnetic moment perpendicular to this axis.) $\Sigma\sigma'j'm'(\sigma \neq \sigma')\ |\,M(\sigma jm;\ \sigma'j'm')\,|^2$ is the square of a sort of average magnetic moment associated with the transition $\nu(\sigma;\ \sigma')$.

$M(\sigma jm;\ \sigma'j'm')$ can be identified according to Van Vleck[13] and others as resulting from the fluctuation in angular momentum between the nuclei and the electrons. On the average the angular momentum in a stationary state of such ions as UO_2^{++} and $WO_4^{=}$ (doubtless having $^1\Sigma$ levels for their basic electronic states) is zero but instantaneously the square of the angular momentum (or magnetic moment) is not zero. The susceptibility arising from the magnetic moments of the stationary states would naturally be affected by the thermal agitation which counteracts the alignment induced by the magnetic field. Hence its susceptibility would show a dependence upon the temperature. The moment associated with a fluctuation which occurs with the frequency $\nu(\sigma;\ \sigma')$, which is very rapid as compared with thermal collisions, would of course not reflect its effect on the susceptibility as a function of the temperature. In line (2) we do not find T as a factor in the denominator. The Boltzmann factor contains the temperature, but its influence is inappreciable when the frequency is high. This term then becomes practically a constant. In fact, Van Vleck shows that when energy changes associated with j and m are small compared to energy changes associated with a, then form (2) reduces to

$$\frac{2N}{3h}\Sigma\sigma(\sigma \neq \sigma')\,\frac{|\,M(\sigma;\ \sigma')\,|^2}{v(\sigma;\ \sigma')} \tag{2a}$$

which is independent of the temperature. Line (3) comprises the diamagnetic contributions to the susceptibility. This results, of course, from the moment induced by the magnetic field and is not present in its absence.

As we have observed in the introduction, the ions we have been discussing have their net electronic moments equal to zero and hence would normally be diamagnetic. The first term in the summation on line (1) is then zero. Since the measured susceptibilities are practically independent of the temperature, the other terms of this summation are small, not because the moments in the activated states are zero (such a possibility is only very slight), but because the number present in those states is small. This number is, of course, regulated by the Boltzmann factor, which is small when the energy of activation, the frequency of transition, is large. The form of the term shows that the contribution of these activated molecules to the susceptibility would tend to have but a small temperature coefficient over a restricted temperature range. For example, the number present in the activated states increases with the tem-

---

[13] Ref. 12c. p. 606.

perature, but on the other hand their susceptibility decreases. The bulk of the constant susceptibility arises from the second line, the so-called fluctuation term.

Since neither the frequency of transition in these ions nor the magnetic moments in their activated states are yet known, we must speak only in more or less qualitative terms. The results show that UO_2^{++} becomes less paramagnetic as the temperature is reduced (any paramagnetic impurity would introduce an opposite trend). The small variation over so considerable a temperature range indicates that the fluctuation term is the predominant one, that the electronic frequency probably lies in the infra-red and that the number in the activated level increases more than linearly with the temperature.

The constancy in the paramagnetism of $WO_4^=$ implies that the frequency of transition to the first electronic level (possessing a magnetic moment) is probably higher than that of UO_2^{++}. It follows that the contribution of the "parallel" (or temperature) component is small and also that the fluctuation term is small since the same high frequency occurs in its denominator. The actual magnitude of the susceptibility of $WO_4^=$ is really small. $WO_4^=$ is colorless and it is conceivable that the first electronic activation lies in the ultraviolet. Indeed, it may possibly lie in the continuum of dissociation.

$Cr_2O_7^=$ also possesses a paramagnetism independent of the temperature. The same reasoning applies to dichromate as to tungstate. If the first electronic activation corresponds to light in the visible, the frequency would be more than high enough to account for the lack of a temperature coefficient in its susceptibility.

MnO_4^- measured by Ishiwara[4] is the only ion of this type other than UO_2^{++} whose susceptibility is known to decrease with the temperature. At the lowest temperature, however, he found it to increase again. This is exactly the same behavior that UO_2^{++} apparently followed before its susceptibility was corrected for the presence of ferric ion. It appears very probable indeed that Ishiwara's potassium permanganate was slightly decomposed (by light, perhaps, or by some contact with organic matter, to which potassium permanganate is extremely sensitive), and as a result the paramagnetic manganese dioxide is present. Even a minute contamination becomes significant at the lower temperatures as its susceptibility is constantly increasing. If this slight impurity be discounted, the conclusion is reached that the susceptibility of MnO_4^- decreases steadily with the temperature just as UO_2^{++} was found to do, and the influences discussed in the case of UO_2^{++} apply here also.

In this discussion it has been assumed that the frequency $\nu(\sigma;\ \sigma')$ in the denominator of the fluctuation term does not vary with the temperature. This constancy is definitely not fulfilled in solids, as variations have been observed in the line spectra of the rare earths.[14] However, the magnitude of the change is small. The fact that both $WO_4^=$ and $Cr_2O_7^=$ display a susceptibility independent of the temperature indicates that the influence in ions of this nature is inappreciable.

Summary

The degree of dependence of the susceptibilities of UO_2^{++}, $WO_4^=$ and $Cr_2O_7^=$ on the temperature has been accurately studied from room temperature to that of liquid air.

The susceptibility of UO_2^{++} was found to decrease slightly and uniformly as the temperature was reduced. It is pointed out from the work of Ishiwara[4] that MnO_4^- behaves very probably in the same way.

$WO_4^=$ and $Cr_2O_7^=$ showed no variation in their susceptibilities within the experimental error. The latter ranged from 0.06×10^{-6} to 0.1×10^{-6} per mole or about 0.0005×10^{-6} per gram.

Various properties of these ions are taken as evidence that the ions are of such a nature as to permit the application of the modern theories of magnetism.

The constant paramagnetism of these ions[15] is related to the results of Van Vleck derived from the quantum mechanics. As a consequence, the existence of electronic isomers in these molecular (polyatomic) ions is recognized.

From this point of view, constant paramagnetism is a general phenomenon and is associated with the existence of activated electronic energy levels in molecules (or their ions) in the solid state and in solution as well as in the gaseous state.

BERKELEY, CALIFORNIA

---

[14] Freed and Spedding, Phys. Rev., 34, 945 (1929).

[15] It is very probable that the constant paramagnetism exhibited by some solids cannot be approached in this manner. Their molecules cannot be regarded as isolated with sufficient approximation, and interactions characteristic of the crystal come into play. Magnetic oxides like CuO probably would be in this category. One would scarcely expect their partial molal susceptibility in solution in some diamagnetic medium to have the same value as in the pure solid. Such an identity in the susceptibilities actually exists among the ions we are studying. The constant paramagnetism exhibited by metals seems to have found a satisfactory explanation on the assumption of an electron gas in the metal obeying the Fermi–Dirac statistics; Pauli, *Z. Physik*, **41**, 81 (1927).

THE VAPOR PRESSURES OF SELENIUM TETRACHLORIDE. THE EXISTENCE OF SELENIUM DICHLORIDE

BY DON M. YOST AND CHARLES E. KIRCHER

RECEIVED JULY 30, 1930 PUBLISHED DECEMBER 18, 1930

Introduction

The former studies of the physical properties of selenium tetrachloride have been restricted to vapor density measurements and to the determination of its heat of formation from the elements. There is considerable lack of agreement between the results of the measurements of the vapor density made by different investigators, although in all cases the evidence for dissociation is fairly conclusive. Ramsay and Evans,[1] as a result of measurements by the method of Victor Meyer, give the degree of dissociation as zero at 200°, 0.19 at 210°, and 0.65 at 350°, while Clausnizer[2] finds complete dissociation at the temperature (not given) at which he worked, the vapor density being just one-half that calculated from the formula $SeCl_4$.

The recently published results of the very interesting experiments made by Simons[3] show definitely that the vapor density of selenium tetrachloride is one-half that to be expected from the formula over the temperature range from 200 to 600° and at atmospheric pressure.

The present investigation was undertaken to determine the extent and nature of this reported dissociation.

Experimental Method and Procedure

Owing to the corrosive action of selenium tetrachloride it was necessary to carry out the necessary pressure measurements in an all-glass apparatus. For this purpose the substance was placed in a cylindrical pyrex bulb at one end of which was sealed a so-called click-gage[4] also of pyrex. The gage was enclosed in and sealed to another glass tube, the latter being connected to the barometer used for measuring the pressures necessary to cause the gage to click. The whole assembly, reaction bulb and gage, being of one piece was placed in an electric furnace. The furnace was equipped with a copper core and auxiliary end coils for maintaining a

[3] Simons, THIS JOURNAL, 52, 3483 (1930). This article appeared after the present work was completed. The present results, in so far as they are concerned with the vapor density, are in complete agreement with those of Simons. The temperature range over which selenium dichloride exists is shown by our results to be different than that suggested by him, his conclusions being based solely on observations of color changes.

[4] Daniels, Mathews and Williams, "Experimental Physical Chemistry," McGraw-Hill Book Co., Inc., New York, 1929.

uniform temperature in the central region and a slightly higher one at the end near which the bulb of the gage rested. It was thus possible to maintain the temperature of the reaction bulb constant, while that of the gage was kept slightly higher to prevent any condensation of solid material on it.

The temperature range investigated lay between room temperature and 230°. It was accordingly necessary first to investigate the characteristics of pyrex click-gages over this range. Small but definite changes in the pressure differences necessary to cause clicking were found at the higher temperatures, and, in fact, some gages ceased to operate after having reached the highest temperature. The gage eventually used suffered no great changes in its click constants even after repeated heating and cooling, the variations amounting on the average to about 2 mm. of mercury.

In making the measurements the temperature of the furnace was raised or lowered to some definite value and held there until the pressure remained constant. That equilibrium had been reached was established by varying the temperature above and below the selected one until the pressure changes responded to such variations. Equilibrium was approached from temperatures considerably above and below those at which measurements were made.

For the purpose of making vapor-density measurements the initial quantity of solid selenium tetrachloride taken was such that at the higher temperatures it would be completely vaporized. Moreover, after complete vaporization, the manner in which the pressures increased with increase in temperature was observed in order to determine the extent of any dissociation of the vapor itself. Thus it was found possible to make measurements of the vapor pressures, the vapor density and the degree of dissociation by a rather simple experimental device.

The accidental errors involved in the values given for the pressures consist of those arising from measurements of the temperature and pressure and do not exceed 3%. The absolute errors due to small losses of selenium tetrachloride during preparation, changes in the volume of the bulb and gage as a result of sealing it, and to the already mentioned variations of the click constant of the gage, do not exceed 2%, and most of this is to be ascribed to the two former causes. The accuracy of the vapor pressure measurements is probably greater than that of the vapor density.

Preparation of Materials

Great care was taken in the preparation of the selenium tetrachloride. The selenium itself was first purified by dissolving the C. P. material in concentrated nitric acid, filtering, evaporating almost to dryness, dissolving in concentrated hydrochloric acid and then precipitating with sulfur dioxide. The precipitate was washed repeatedly with cold water, and then with boiling water. This process[6] yields selenium free from

---

[6] A. A. Noyes and W. C. Bray, "Qualitative Analysis for the Rare Elements," The Macmillan Company, New York, 1927, p. 381; Keller, THIS JOURNAL, 19, 771 (1897).

tellurium and was applied twice. The material so obtained was again dissolved in concentrated nitric acid, the solution evaporated almost to dryness, diluted to 400 cc. with water, filtered, and then treated with hydrazine hydrochloride. The resulting precipitate was thoroughly washed as before and finally dried and melted, and the melt poured into cold water in such a way that small spheres with diameters of 2 mm. and smaller were formed. This material was then dried.

To prepare the tetrachloride a weighed amount (about 0.0200 g.) of selenium was placed in a small glass tube one end of which was drawn down to a long thin capillary. the other end being then sealed to a drying tube containing anhydrous barium perchlorate. After displacing the air with carbon dioxide, chlorine was passed through the apparatus for some time, the vigor of the resulting reaction being diminished at the beginning by cooling the tube with a small lump of ice. When the reaction was almost complete it was necessary to heat the tube gently with the flame of a match in order to obtain complete conversion. Following this treatment the excess of chlorine was displaced with carbon dioxide. The tip of the capillary was then sealed, the whole assembly evacuated, and finally the tube containing the selenium tetrachloride sealed off. The material was almost white and was free from the lower chlorides. The tube containing the final product was placed in the reaction bulb, the bulb and gage were thoroughly evacuated, heat being applied to the bulb to drive out any adsorbed water, and finally the reaction bulb was sealed. The tube containing the tetrachloride was broken by shaking the reaction bulb.

The vapor of selenium tetrachloride has an intense orange color and at pressures of about one-fifth atmosphere a few diffuse absorption bands in the green region were observed.

For the experiments in which an excess of chlorine was present the procedure was as follows. A weighed amount of selenium in a small evacuated tube was placed in the reaction bulb and the latter carefully dried by heating and passing a stream of dried air through it. Dried chlorine was next passed through the bulb until the air had been swept out, after which the bulb was closed by sealing it, and the tube containing the selenium broken as before. The chlorine remaining was that in excess of the amount necessary to convert the selenium to the tetrachloride and was determined in advance by the amount of selenium taken.

Experimental Results and Discussion

TABLE I

VAPOR PRESSURES OF SOLID SELENIUM TETRACHLORIDE

Temperature, °C.	Pressure, mm.	Temperature, °C.	Pressure, mm.
109	11.3	157	157.8
120	23.9	161	203.4
129.5	40.0	163.6	235.8
131	42.6	170.5	310.6
140	65.5	171	317.7
149	111.1	175.5	389.6
150	117.4	180.5	482.0

In Table I are presented the final values for the vapor pressures of selenium tetrachloride. In Table II are given the values of the pressures after all the solid had been converted to the vapor, together with the pressures calculated on the assumption that the vapor consists of $SeCl_4$. All pressures are expressed in millimeters of mercury.

TABLE II

RESULTS OF PRESSURE–TEMPERATURE' EXPERIMENTS ON THE VAPOR FROM SELENIUM TETRACHLORIDE

Volume of reaction bulb and gage, 27.3 cc.
Wt. of selenium taken to prepare $SeCl_4$, 0.0188 g.
Wt. of Se calculated from gas law, assuming complete dissociation, 0.0185 g.
Wt. of Se calculated from slope of P–T curve, assuming complete dissociation, 0.0188 g.

Temp., °C.	Press. (obsd.), mm.	Pressure (calcd.) for normal $SeCl_4$ vapor, mm.	Ratio of obsd. to calcd. press.
189.2	489.6	250.7	1.95
191.5	495.3	251.9	1.97
199	502.2	256.0	1.96
199.5	502.6	256.2	1.96
208	612.1	260.9	1.96
209.5	513.4	261.7	1.96
215	520.1	264.7	1.96
223	526.6	269.0	1.96
226	533.5	270.6	1.96

The observed pressures given in Table II are, within the limits of the experimental errors involved, twice those calculated on the assumption that the vapor consists of $SeCl_4$. Moreover, the vapor obeys the simple gas law over the range where no solid is present. It may be concluded, therefore, that the selenium tetrachloride is, at these temperatures, completely dissociated in such a way that one molecule of it gives rise to two.

The vapor pressures of the solid increase very rapidly with the temperature. It was found that over the range of temperatures where the solid phase was present, the graph of $\log_{10}P_0$ plotted against the reciprocal of the absolute temperatures was a straight line. This fact indicates that the tetrachloride vapor is completely dissociated even at the lowest temperatures investigated.

There are three possible reactions that would be in accord with the results found experimentally, *viz.*

$$SeCl_4\ (s) = Se\ (s) + 2Cl_2\ (g) \tag{1}$$
$$2SeCl_4\ (s) = Se_2Cl_2\ (g) + 3Cl_2\ (g) \tag{2}$$
$$SeCl_4\ (s) = SeCl_2\ (g) + Cl_2\ (g) \tag{3}$$

Inasmuch as no solid or molten selenium (m. p. 217°) could be observed either in the vapor pressure experiments or in separate experiments devised to determine whether it were ever present, it is concluded that Reaction 1 does not occur.

If Reaction 2 or 3 takes place, chlorine should have a marked effect upon the vapor pressure of the solid. This was found by experiment to be the case. Indeed, it was found possible to establish that Reaction 3 is the correct one. If P_0 is the vapor pressure of the solid at a given temperature in the absence of excess of chlorine, and if complete dissociation takes place, then the equilibrium constants for Reactions 2 and 3 at the temperature in question are given by

$$K = \frac{27}{256} P_0^4 \quad (4) \qquad \text{and} \qquad K = \frac{1}{4} P_0^2 \qquad (5)$$

If excess of chlorine is present at the pressure p and if the total pressure is p_0, then for Reactions 2 and 3, respectively

$$P_0^4 = \frac{1}{27}(p_0 - p)(3p_0 + p)^3 \qquad (6)$$

$$P_0^2 = (p_0 - p)(p_0 + p) \qquad (7)$$

Applying Equations 6 and 7 to the results of the experiments in which excess of chlorine is present, the vapor pressure of the solid in the absence of excess of chlorine may be calculated. In Table III are given the results of such experiments together with the calculated and observed values of P_0. All pressures are expressed in mm. of mercury.

TABLE III

RESULTS OF EXPERIMENTS ON THE EFFECT OF CHLORINE ON THE VAPOR PRESSURE OF SELENIUM TETRACHLORIDE

Temp., °C.	Total press., mm.	Press. excess chlorine, mm.	P_0 (obs.) of $SeCl_4$, mm.	P_0 (calcd.) Eq. 7, mm.	P_0 (calcd.) Eq. 6, mm.
146	365.5	346.0	95.9	117.8	215.8
151	374.6	350.0	123.2	133.5	232.4
156	395.7	354.0	157.4	176.8	274.2
161	413.9	358.0	203.4	207.9	303.4
166	449.7	362.0	252.4	267.3	357.6
171	489.0	366.0	317.7	324.3	409.3
176	548.9	370.0	396.5	405 6	483.0

The results show that chlorine does have an effect on the vapor pressure of the tetrachloride, and that its magnitude corresponds to that demanded by Reaction 3, as may be seen by comparing the last three columns of Table III. It is, therefore, concluded that over the range of temperatures investigated the vapor phase consists of selenium dichloride and chlorine.

Thermochemical Results

The vapor pressures of selenium tetrachloride in equilibrium with the solid may be represented by the following formula[6]

$$\log_{10} P = -\frac{0.05223 \times 73{,}990}{T} + 11.2040$$

where P is expressed in millimeters of mercury and T is the absolute temperature.

The value of the heat of Reaction 3 is then

$$SeCl_4\,(s) = SeCl_2\,(g) + Cl_2\,(g) \quad \Delta H = 35{,}380 \text{ cal.}$$

---

[6] The formula is set up so as to conform with the usage adopted by the "International Critical Tables."

Thomsen[7] gives the heat of formation of selenium tetrachloride as 46,156 cal. Combining this with the above we find

$$Se\ (s) + Cl_2\ (g) = SeCl_2\ (g) \quad \Delta H = -10{,}780\ \text{cal.}$$

It may be remarked that, if Reaction 1 or 2 be assumed as true, the calculated values for the heats of formation of $SeCl_4$ or Se_2Cl_2 differ greatly from the experimentally found values of Thomsen.

Stability of Selenium Dichloride

Attempts made heretofore to prepare selenium dichloride from equivalent amounts of the two elements have always met with failure, the resulting product consisting of a mixture of the solid tetrachloride and liquid monochloride. In analogy with sulfur and tellurium, the dichloride of selenium would be expected to exist, and its tendency to decompose with the formation of the tetrachloride and monochloride under normal conditions has doubtless prevented its previous detection. From the results of the investigation described in this paper the vapor form appears to be fairly stable. It is also possible that the vapor above liquid selenium monochloride consists, in part, at least, of the dichloride, since a considerable residue of elementary selenium always results after distillation. Moreover, the reported vapor density measurements on the monochloride show that there is no increase in the number of molecules on evaporation, even though a residue of elementary selenium is left behind. These facts would be in agreement with the assumption that the vapor consists of the dichloride.

Summary

The vapor pressures of selenium tetrachloride have been measured both in the presence and absence of excess of chlorine. From these results and the results of vapor density measurements it has been shown that over the range of temperatures from 109 to 226° the vapor consists entirely of selenium dichloride and chlorine.

The vapor pressures of the solid may be computed from the following formula where P is expressed in millimeters of mercury and T is the absolute temperature.

$$\log_{10} P = -\frac{0.05223 \times 73.990}{T} + 11.2040$$

The heat change accompanying the decomposition of solid selenium tetrachloride into the gaseous dichloride and chlorine is $\Delta H = 35{,}380$ cal. The heat of formation of gaseous selenium dichloride was found to be $\Delta H = -10{,}780$ cal.

I. THE SPECIFIC HEATS OF THALLIUM, CALCIUM AND MAGNESIUM MEASURED TO 10° ABSOLUTE

II. THE ENTROPY AND CHEMICAL CONSTANTS OF MAGNESIUM FROM SPECTROSCOPIC DATA

BY K. CLUSIUS AND J. V. VAUGHEN

RECEIVED AUGUST 1, 1930 PUBLISHED DECEMBER 18, 1930

This paper presents the results of the measurement of specific heats from 10 to 200° absolute, of thallium, calcium and magnesium. The specific heats of these metals have indeed been measured in the low-temperature range, yet in no case have they been measured to a sufficiently low temperature to permit a safe extrapolation to the absolute zero, which is necessary in the calculation of the entropy. Because of the peculiarity of the entropy function, the chief interest in these measurements has been in the region under 80°A. The apparatus, however, was capable of rendering exact results even at a temperature as high as 250°A.

Of special interest is a comparison between the entropy values obtained from calorimetric and from spectroscopic data, respectively. In order to make such a comparison, it is necessary to calculate the entropy of the substance as a gas, which requires the values for the heat of vaporization, and for the specific heats at higher temperatures. The heat of vaporization may be calculated from the vapor pressure curve. At the present time, recent measurements of these quantities make it possible to calculate the entropy of magnesium vapor.

Experimental Details

The experimental method used is essentially that of the vacuum calorimeter, in which the material whose specific heat is to be measured served as the calorimeter. The apparatus pictured in Fig. 1 was made for a previous investigation[1] and is capable of reaching a temperature of 9.4°A. The bulbs A and B are made of thin glass, bulb B having a *double-walled construction.* The space formed in the double bulb B serves to hold liquid hydrogen, which is condensed by applying several atmospheres' pressure and cooling the outer bulb A with boiling hydrogen. The heat transfer is effected by 2–5-mm. pressure of pure helium in the space between the two bulbs. All other gases are ineffective for this purpose because they are either condensed or are strongly adsorbed at these low temperatures, so that rapid removal by pumping is impossible.[2] When the space between A and B is evacuated by means of a mercury diffusion pump, the inner parts of the apparatus are thermally well insulated. Then if vacuum from a Gaede steel mercury pump and a heavy-duty oil pump in series is applied to the condensed hydrogen so that it boils under 1 mm. pressure, the temperature of the hydrogen decreases rapidly to about 9.4°A.

The block of material to be investigated (K) is suspended freely in a protecting

mantle of copper, which has a block of lead in the upper end to increase its heat capacity. The cable, containing the wires which carry the heating current and the connections to the resistance thermometer, is made of four silk-covered copper wires 0.1 mm. in diameter. The cable, after being wound with thread, was boiled in a mixture of beeswax and resin. No disturbing gases are evolved under vacuum from a cable prepared in this way. To prevent any heat conduction to the block from the outside by the copper wires, the cable is connected thermally with the protecting mantle by imbedding it in a trough of Wood's metal.

In the block of metal a thread-like groove of suitable pitch and depth was cut to accommodate a 0.03 mm. constantan wire having a resistance of 500–800 ohms. Over this winding of the heating element was wrapped a layer of thin tissue paper, which served to insulate the constantan from the next winding of 0.05 mm. lead wire, which formed the resistance thermometer. To give good thermal contact between the block and the two windings, a small amount of lacquer was used. The quantity of lacquer, lead, constantan and paper was determined by weight and considered in the calculation of the specific heat of the metal.

Before undertaking this investigation, the qualifications of the lead resistance thermometer were again carefully determined[3] by comparing its resistance with that of a pure platinum wire between 20 and 80° absolute. The measured resistance of the platinum wire was recalculated by Henning's formula[4] to the exact temperature values given by K. Onnes and Tuyn.[5] The agreement between the lead and platinum thermometers is completely satisfactory considering the difficulty of calibration in this low temperature range.

The completely wound and lacquered block of metal was heated for several hours at 150° in order to harden the lacquer and to age the lead wire, which is necessary for a reproducible resistance value at 0.0°. As can be seen from the following table, a satisfactory behavior of the thermometer was obtained in every case. It was calibrated in the range of liquid air by means of an oxygen vapor-pressure thermometer, and in the range of liquid hydrogen by the boiling point of the latter substance in the chamber of bulb B under a known pressure. The deviations from the normal wire table were limited (maximum 0.1°A.) and were taken into account by means of the Nernst α-rule.[6]

[5] Onnes and Tuyn, *Comm. Leiden Suppl.*, 58 (1926).

[6] Nernst, Ann. *phys.*, 36, 432 (1911).

Date	Resistance at 0.0°	Sample
4-27-29	200.3 ohms Used at 90°A. 200.3 ohms	Thallium II

The determination of the energy supplied to the sample consisted in measuring the voltage, the resistance of the circuit, and the time of current flow A standardized stop watch was used in an apparatus which made or broke the circuit precisely as the watch was started or stopped. A storage battery of large capacity was used as a source of current. The circuit included a precision resistance box, the potential across the terminals of which was kept constant by balancing it against that of a standard cell. A second standard cell was at times substituted to serve as a check. The e. m. f. of the cell was taken as **1.0185** volts at 20° and a difference between the two cells greater than **0.0002** volt was never detected. The current flow was regulated by means of two parallel sliding resistances, one of which had ten times the resistance of the other. This regulation was not difficult because of the limited change in resistance of the constantan wire due to temperature changes. Before and after each individual heating, the resistance of the constantan wire was determined with an accuracy of 0.1% by means of a precision bridge. The same bridge was used to measure the resistance of the lead wire thermometer. The value, **4.1842** watt seconds = **1** calorie, as given by Jaeger and Steinwehr,[7] was used in the calculation of the heat quantities.

The various sources of error in these measurements are as follows.

(1) Measurement of the Temperature Rise in an Individual Experiment.—The rate at which the temperature increases, due to heat leaks, during the intervals before and after the energy input, was uniform and could be measured accurately even at the lowest temperature. Until after the heat capacity of the sample reached 0.4 calorie, the temperature was read every fifteen seconds. Later readings were taken every thirty seconds.

(2) Error in Determining the Energy Input.—The energy introduced into the sample may be regarded as being correct to within 0.3% for the shorter heating intervals (five to ten seconds), and within 0.03% for the longer intervals (thirty to one hundred twenty seconds).

(3) Error in the Correction for the Accessory Material.—The corrections for the various foreign materials such as the lead wire, constantan wire, thread and lacquer, are as follows.

A = percentage of the total heat capacity due to foreign materials
B = percentage error due to foreign materials

		10°A.	20°A.	80°A.	200°A.
Magnesium	A	39	16	2	2.2
	B	2	0.8	0.1	0.1
Calcium	A	15	5	2	2.5
	B	0.75	0.25	0.1	0.1
Thallium	A	1	.6	1.4	2.2
	B	0.06	.03	0.07	0.1

---

[7] Jaeger and Steinwehr, Ber. Sitzungsberichte, **424 (1915).**

(4) Errors in the Measurement of Temperature.—Taking into account the slight error due to the temperature measurement, the total error in the results for calcium at the lowest temperatures probably does not exceed 1.5%. At 20°A. this error amounts to 0.8%, and at 80°A. it is probably within 0.3%. These errors are somewhat lower for the thallium measurements, and are slightly larger for those of magnesium because of the larger error due to corrections for the foreign materials present in the latter sample.

Source of Materials. -The magnesium was presented to us as a very pure sample by Dr. Grützner of the I. G. Farbenindustrie. The analysis of the material is as follows:

Element	Si	Al	Fe	Mn	Cu	Zn	Total
Percentage	0.02	0.06	0.018	0.035	..	..	0.133

The sample of magnesium was turned to a cylindrical block 17 mm. in diameter and 83 mm. long weighing 31.959 g. Considering an atomic weight of 24.32 for magnesium, the block contained 1.316 mole.

The calcium block was of similar dimensions and was turned out of a sample of the purest commercial metal. Traces of iron, silicon, nitrogen and calcium chloride were found by the analysis. The block weighed 28.617 g., corresponding to 0.7139 mole at an atomic weight of 40.07.

Two thallium samples coming from different sources were used in these measurements. No difference in the specific heat curves for these two samples could be detected, which is worthy of mention because our measurements differ from those to be found in the literature. One sample was made by the reduction of pure thallium oxide with charcoal powder in a stream of hydrogen. The other sample came from Kahlbaum, and contained only traces of iron and aluminum according to the analysis furnished. Later, however, the presence of lead was discovered, yet the presence of this element in such limited quantities can hardly have affected the calculation of the specific heat because the atomic weights as well as the characteristic temperature of thallium and lead are similar. In consideration of the appreciably smaller heat conductivity of thallium, blocks of only 12 mm. in diameter and 64 mm. and 47.5 mm., respectively, in length were used. The first sample weighed 84.943 g. (0.4158 mole) and the second 63.671 g. (0.3115 mole), using an atomic weight of 204.39.

Results

The results of these measurements are assembled in Table I, which contains the absolute temperature and the directly measured C_p values. To picture the completeness of the results, the Debye characteristic temperature Θ has been calculated, which required the value of C_v. This value was obtained from the approximate equation[8]

$$C_p - C_v = AC_p^2T$$

In order to use this equation, the value of $C_p - C_v$ must be known exactly for at least one temperature, and since the equation

$$C_p - C_v = T\frac{\alpha^2 V_0^2}{XV}$$

requires data which are not known for calcium and magnesium, the following simplification according to Mie and Grüneisen was used

$$\frac{C_p}{C_v} \simeq 1 + 2.0\ \alpha\ T$$

This equation gives results correct to within 10% for monatomic substances, and the correction here is only about 1.5–2.5% of the C_p value.

The following values were obtained

$$A_{\mathrm{Tl}} = 2.85 \times 10^{-5}$$
$$A_{\mathrm{Ca}} = 2.42 \times 10^{-5}$$
$$A_{\mathrm{Mg}} = 2.61 \times 10^{-5}$$

The 8-values were calculated for values of C_v under 5 calories. Because of the form of the Debye curve, and the increasing errors in C_p and $C_p - C_v$, a further comparison is uncertain.

Figure 2 presents the curves of the data. The results of earlier investigations are also entered,[9] which in the case of thallium are too low, and with calcium and magnesium are too high, when compared with our data. With samples of thallium from different sources, however, we obtained the same values. The difference between the measurements with calcium and magnesium as recorded here, and those reported by earlier investigators,

which also differ among themselves, is surely not due to the use of impure samples.

In the case of thallium, direct reproduction of the specific heat values is possible from 17°A. on, by using 0 = 94° in the Debye function. Below this temperature, the 0 value decreases to about 84°, indicating a deceleration of the atomic vibrations. Lead, which is so similar to thallium as regards its elastic constants, its density and its melting point, possesses this characteristic also. With lead, between 20 and 80°A., the specific heat is given correctly by *a* Debye function with a Θ of 88,[10] but at lower temperatures 0 = 85.[11] Keesom and van den Ende,[12] in reporting earlier experiments,[13] mention that at liquid helium temperatures no further variation from the 0-value, determined at 10°A., is apparent.

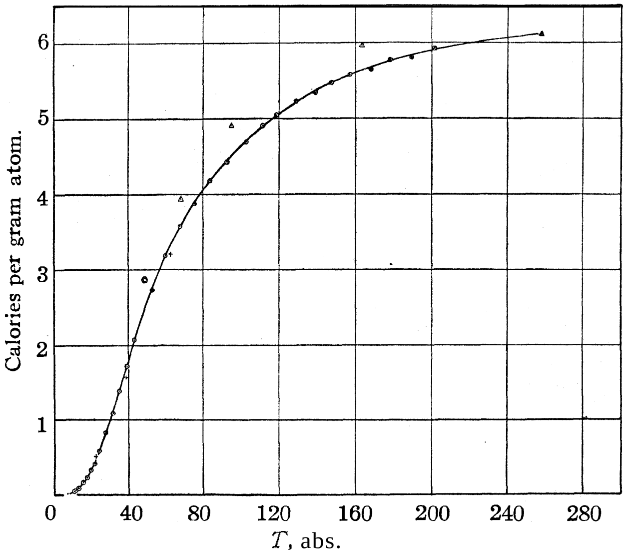

Fig. 3.—Calcium: ◎, Dewar, average; △, **Eastman** and Rodebush; +, **Günther**; ○, Clusius and Vaughen.

In all probability thallium behaves in a similar manner, and an extrapolation of the specific heat curve to the absolute zero (using a Θ value of 84) for the calculation of the absolute entropy, seems justifiable without introducing a large error.

In the measurements with calcium, special care was used in obtaining a high vacuum. Only after several days of continuous pumping did the hydrogen evolution from the calcium block cease. The 0 value of calcium

exhibits the comparatively moderate slope of about 6%, **and** therefore belongs to the class of elements whose specific heats are reproduced approximately by the Debye function.[14] Especially noteworthy is the fact that the Θ-value approaches a constant of about 219 at low temperatures, indicating that the T^3 rule of Debye is probably valid. In fact, the data for C_p, calculated from the equation

$$C_p \simeq C_v = 4.41 \times 10^{-5}\, T^3$$

agree remarkably well with the directly measured values of C_p below a C_p value of 0.3 calorie. It appears that the extrapolation to the absolute zero can be performed with safety.

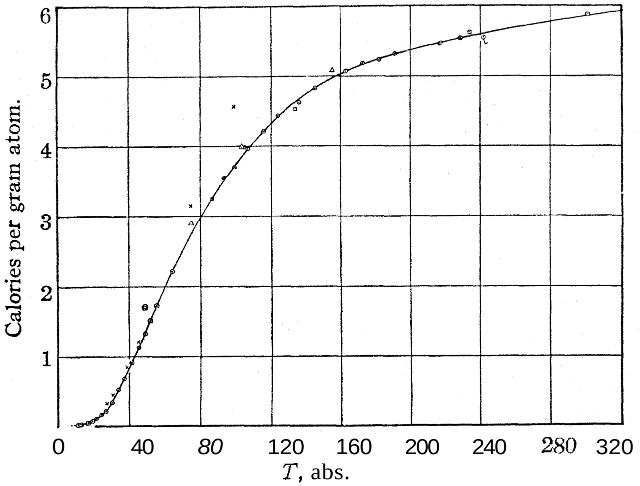

Fig. 4.—Magnesium: ◉, Dewar, average; ⊡, Ewald, average; Q, Schinipf, average; **A,** Eastman and Rodebush; ×, Nernst and Schwers; ⊙, Clusius and Vaughen.

With magnesium, on the other hand, the 0-values increase with decreasing temperature, and above 30°A. a 0-value of 322 reproduces a fairly satisfactory atomic heat value. Even when it is considered that the difficulties of measurement at the low temperatures (due to the extremely small heat capacity of the substance) strongly magnify the possibilities of error, the reality of the effect remains indeed unquestionable. At the lowest temperatures, the points on the curve due to separate series of measurements lie very close together, indicating very good reproducibility. If any appreciable experimental error were present, too high a specific heat value would probably be obtained. A more rapid decrease of the specific heat **curve** than is to be expected from the T^3 law has been noted only in

---

[14] Compare the assembly of Professor Eucken in "Handbuch der Experimental Physik," Vol. VIII, p. 245.

the case of copper and tungsten.[15] With copper at 14.51°A., a specific heat of 0.0396 cal. was determined, whereas the calculated value is 0.044 cal. The specific heat of tungsten decreases even more suddenly. The variations with magnesium are of the same order of magnitude. An explanation of this behavior, which might indicate a failure of the fundamental T^3 law, is not at present available.

For the calculation of the entropy under standard conditions, the curves were extrapolated to 298.1°A., by making use of the existing data (see Fig. 2). The following values for the integral $S_0 (S_0 = \int C_p \, \mathrm{d}t/T)$ were obtained.

	Calculated	Lewis and Randall[16]
Thallium S_0	= 15.51	14.6
Calcium S_0	= 9.72	10.64
Magnesium S_0	= 7.76	**8.3**

VAPOR PRESSURE CONSTANTS OF MAGNESIUM

The existing data for magnesium are sufficient to permit the calculation of the vapor pressure constants. The general vapor pressure curve for this element, whose vapor is probably monatomic, is as follows:[17]

$$\log p = -\frac{L_0}{4.573T} + \frac{5}{2}\log T - \frac{1}{4.573}\int_0^T \frac{\mathrm{d}T}{T^2}\int C_{p\text{cond.}}\,\mathrm{d}T + J_p \qquad (1)$$

where p is the saturation pressure at the temperature T, L_0 is the heat of vaporization at the absolute zero, $C_{p\text{cond.}}$ is the specific heat of the condensate, and J_p is the vapor pressure constant. The required values are calculated as follows.

The heat of vaporization at absolute zero may be calculated from the data of Hartmann and Schneider.[18] Since these values were obtained by the boiling method, in which the zone of condensation is located by determining the region of constant temperature, their results may be considered to be free from systematic errors. From the slope of their vapor pressure curve, these authors obtain a value of the heat of vaporization of $L_T = 32{,}800$ calories at an average temperature of 1100°A. Using for the triple point 924°A.,[19] the following is obtained as the heat of vaporization at the absolute zero

$$\bar{L}_T = L_0 + \int_0^T C_{p\text{gas}} \cdot \mathrm{d}T - \int_0^T T\, C_{p\text{cond.}}\,\mathrm{d}T - L_e \qquad (2)$$

$$L_0 = L_T + L_e + \int_0^T C_{p\text{cond.}}\,\mathrm{d}T - 5/2\,RT$$

where L_e is the heat of fusion **(1130 calories)**,[20] C_p is the specific heat of the condensate, which we have supplied for low temperatures, and **for** values above room temperature those reported by Eastman, **Williams** and Young[z1] have been used. The results of these authors are given correctly enough between **300** and 900°A. by the equation $C_p = 2.62 \times 10^{-3} T + 5.27$. The specific heat of the liquid has been taken as 7 **calo**rie~ .Then

$$L_0 = 32800 4 1130 + 7365 - 5965 = 35330 \text{ cal.} \qquad (2a)$$

The logarithm of the triple point vapor pressure is **−0.339** when the value of the saturation pressure at 1163°A. is taken as 84 mm. of mercury according to Hartmann and Schneider

$$\log p_2 - \log p_1 = \frac{L_T}{4.573}\left(\frac{1}{T_1} - \frac{1}{T_2}\right) \qquad (3)$$

The evaluation of the double integral of Equation 1 is easiest in this case by the transformation

$$\int_0^T \frac{\mathrm{d}T}{T^2}\int_0^T C_p\,\mathrm{d}T = \int_0^T \frac{C_p}{T}\,\mathrm{d}T - \frac{1}{T}\int_0^T C_p\,\mathrm{d}T \qquad (4)$$

The entropy at 298°A. is known as 7.76. The remainder of the equation follows

$$S_{298}^{924} = \int_{298}^{924} 2.62 \times 10^{-3}\,\mathrm{d}T + \int_{298}^{924} \frac{5.27}{T}\,\mathrm{d}T = 7.63$$

The value of the second integral in Equation 4 appears as 5455 calories from the calculation of Lo; therefore the second member of the above equation becomes 5.89. The double integral is then

$$\int_0^T \frac{\mathrm{d}T}{T^2}\int_0^T C_p\,\mathrm{d}T = 7.76 + 7.63 - 5.89 = 9.50$$

Combining the various values in the vapor pressure formula

$$j_p = \frac{35330}{4.573 \times 927} - 2.5 \times 2.967 + \frac{9.50}{4.573} + 0.339$$

$$j_{p\,\mathrm{mm.}} = 3\ 324$$

Calculating the pressure in atmospheres

$$j_{p\,\mathrm{atm}} = 3.324 - \log 760 = 0.443 \pm 0.1$$

The limit of error which has been given is a result of the uncertainty of the energy content of the condensate.

From statistical considerations, the chemical constant value for jk **is**[a3]

$$jk = -1.587 + 1.5 \log M + \log g$$

where M is the atomic weight of the gas, and g is the degree of freedom of the atom in a magnetic field, its quantum weight. For magnesium in particular $g = 1$, and $jk = 0.493$.

In order to compare the entropy of magnesium vapor, as calculated from these experimental data, with the theoretical value under standard conditions, the data must be rearranged somewhat. Let one mole of magnesium vaporize at 298°A. From Equation 2 the heat of vaporization is

$$L_{298} = 35330 + 298 \times 2.5 \times R - 1155$$
$$= 35655 \text{ calories}$$

if the value 1155 cal. is assigned to the energy content of the condensate (from the specific heat measurements). The entropy increase in vaporizing under equilibrium pressure is $35655/298 = 119.65$ cal. per degree. The equilibrium pressure is obtained from Equations 1 and 4 and from the value of jp.

$$\log p_{298} = \frac{-35330}{4.573 \times 298} + \frac{5}{2}\log 298 - \left(7.76 - \frac{1155}{298}\right)\frac{1}{4.573} + 0.443$$
$$= -25.92_5 + 6.18_6 - 0.84_8 + 0.44_3 = 20.14_4$$

This value corresponds to a vapor pressure of 0.717×10^{-21} atmospheres. In compressing this vapor to atmospheric pressure, the following entropy change takes place

$$AS = -4.573 \times 20.144 = -92.12 \text{ cal. per degree}$$

The entropy of magnesium vapor at 25° is empirically

$$S^{\circ}_{\mathrm{Mg}} = 7.76 + 119.65 - 92.12 = 35.2_9 \text{ cal. per degree}$$

We obtain from the theoretical equation

$$S^{\circ}_{\mathrm{Mg}} \text{ theor.} = 4.573\,ja + 6.699 \times 2.5 \times R = 35.5_2 \text{ cal. per degree}$$

Considering the tendency for double molecule formation, the agreement is satisfactory.

The data necessary for a similar comparison of the spectroscopic and calorimetric values in the cases of calcium and thallium are not at present available. These two metals have transition points somewhere above room temperature that have not been investigated thoroughly. In this Institute, however, experiments are in progress to supply the necessary data.

Many thanks are due Professor Eucken for the use of the property of the Institute, and for his interest and suggestions in the completion of this investigation.

Summary

1. An apparatus is described which was used in measuring specific heats from 10 to 200°A.

2. The specific heats of thallium, calcium and magnesium have been measured from 10 to 200°A. The Debye function has been discussed in the light of these experimental data.

3. The vapor pressure constant of magnesium has been determined as 0.443 ± 0.1 and is found to agree very well with the statistically calculated

value **0.493.** The entropy of monatomic magnesium vapor at atmospheric pressure and 25° has been determined empirically at 35.29 units, while the theoretical value is 35.5_1.

THE INFLUENCE OF THE PERIOD OF HEATING UPON THE BOILING POINT OF CERTAIN LIQUIDS USED IN EBULLIOSCOPY, WITH A NOTE ON TESTING THE PURITY OF VOLATILE LIQUIDS BY ISOTHERMAL DISTILLATION[1]

BY SYDNEY L. WRIGHT, JR., AND ALAN W. C. MENZIES

RECEIVED AUGUST 4, 1930 PUBLISHED DECEMBER 18, 1930

This paper describes a series of experiments designed to determine as accurately as possible whether the boiling point of a liquid is dependent upon the liquid's previous thermal history, *i. e.*, whether a liquid which has been boiling for several hours, boils at exactly the same temperature as one recently elevated from a lower temperature. It is obvious, as pointed out by Smits and others, that in associated liquids there might be a delay in attaining the degree of association appropriate to the higher temperature. This would usually result in a slightly higher boiling point at the beginning of ebullition than would be observed several hours later. For purposes of investigation two associated liquids, bromine and acetic acid, and two supposedly non-associated liquids, benzene and carbon tetrachloride, were used.

We also briefly refer to a method of testing the purity of volatile liquids, far more sensitive than the ordinary methods of boiling point and distillation range.

This study was prompted by experiments reported by H. B. Baker,[2] who believed that they demonstrate a delay in the attainment of internal equilibrium in the case of bromine and acetic acid. These observations, if confirmed, might serve to explain several difficulties previously encountered in ebullioscopic work, such as (1) the frequently mentioned necessity of allowing an astonishingly long period of time for the pure solvent to attain a constant boiling point in Beckmann's ebullioscopic method of determining molecular weights,[3] (2) the classical controversy[4]

as to the equivalence of the static and dynamic methods of vapor pressure determination, (3) the frequency with which it is found that the most satisfactory vapor pressure curve of a liquid shows a temperature at 760 mm. pressure not identical with the best observed boiling point determinations. Raikes and Bowen[5] pertinently remark that this discloses a "situation which can be cleared up only by further research."

Experimental Method

The method in brief consisted of a differential reading between two isoteniscopes,[6] one containing a portion of the liquid which had been held near the boiling point for several hours, the other containing a portion recently rapidly elevated to the same temperature by insertion in the bath. Isoteniscopes, being compact in form, can be used in a bath designed for more adequate stirring than can be supplied for long barometer tubes. This, with the fact that the liquid under consideration is used as a manometric fluid instead of the denser mercury, and that the readings are differential and not absolute in nature, allows a far greater sensitivity[7] than that attained by Baker. The observations were continued until the liquids were more similar in thermal history. A difference in vapor pressure observed at first and not disappearing within a reasonable time must be due not to difference in thermal history but to some of the other factors discussed later.

Apparatus.—The isoteniscopes were constructed of pyrex glass, the bulb of 35-cc. capacity, being sealed to thick-walled tubing of 2 mm. bore which formed the left side of the manometer. The right side was of 10-mm. tubing in which, above the level of the bath, were blown four elongated bulbs to serve as the inner tube of a condenser 27 cm. long. Near the end it was bent at a slightly acute angle to prevent possible contamination from the rubber connections. Each isoteniscope was connected through a short piece of rubber tubing to a tube containing calcium chloride, thence through a long flexible tubing to a 1-liter flask which served as a reservoir to stabilize the pressure and facilitate delicate adjustment. Mercury manometers connected with these flasks were a convenience in manipulation. By means of glass and rubber tubing fitted with suitable clamps, it was possible to establish pressure equality between them, and to adjust both or either of them to any desired pressure not greater than atmospheric The arrangement is shown diagrammatically in Fig. 1.

The bath consisted of a 3-liter beaker filled with glycerin and stirred by a six-bladed glass stirrer electrically propelled. Adjacent were two heating units and the expansion bulb of the thermostat. Near the front of the bath was a bakelite millimeter scale supported vertically. The scale was 120 mm. long and the markings were about 5 cm. wide, so that when the isoteniscopes were in position, the bulbs hung over the top of the scale near the center of the bath, while the manometers, side by side in front of the scale, could be read almost simultaneously. Except for windows at the front and back,

[7] The sensitivity is illustrated in the last column of Table I, which shows the temperature change corresponding to a pressure change of 1 mm.

the beaker was insulated with cotton wool. A lamp behind the bath furnished illumination. The heating units and the thermostatic control were so connected with rheostats that the difference between the current intensities during the "on" and the "off" periods could be reduced to a minimum at the time of reading, thus diminishing the "pumping" effect referred to later.

Procedure.—Except in the case of bromine (*q. v.*) the liquid was taken up in a dried pipet and 5 cc. placed in each of the thoroughly cleaned and dried isoteniscopes, which were immediately connected to the vacuum system. The permanent gases were removed as far as possible by repeatedly boiling out near room temperature. With water running through the condensers, the isoteniscope was evacuated to a pressure corresponding to the vapor pressure a few degrees above room temperatnre. A small flame was then applied intermittently to the bottom of the bulb. The vapor passed through the manometric portion of the isoteniscope carrying the dissolved gases with it and, condensing, formed a trap which prevented their readmission. By allowing the bulb to cool, the greater part of the liquid was returned to it, leaving sufficient in the manometer to form a trap. When this had been repeated several times with each isoteniscope, comparison in the bath at room temperature showed that their vapor pressures agreed within the experimental error and further boiling out caused no change. After the final comparison, isoteniscope A was removed from the bath and by closing clamp 1 was cut off from the rest of the system. The heat was then turned on and the pressure over the liquid in B allowed to increase as the vapor pressure rose. When the pressure had increased to within a few centimeters of 76, the thermostat was set to hold the bath at the corresponding temperature. The isoteniscopes were allowed to stand thus, A at room temperature, B near the boiling point, for about four hours. The position of the manometric liquid was watched during that time and any necessary adjustments made to prevent the entrance of air into the bulbs. Near the end of this period the pressure on B was reduced slightly so that bubbles of vapor passed through the confining liquid and condensed, thus eventually evaporating all the liquid from the bulb. Meanwhile, by slightly warming A, the liquid in that isoteniscope also was condensed in the wide arm of the manometer. At this point clamp 2 was closed, the connecting tubes evacuated and clamp 1 opened, allowing the pressure on A to be altered without affecting B. Isoteniscope A was then placed in the hot bath and by means of clamp 3 the pressure was increased as rapidly as possible without forcing any liquid into the bulb. When the behavior of the liquid in A indicated that temperature equilibrium was near attainment, clamp 2 was opened, thus assuring the identity of the external pressure on the two isoteniscopes. As rapidly as possible the greater part of the liquid in both isoteniscopes was returned to the bulbs and comparative vapor pressure readings taken. Agitation of the liquid in the bulbs hastened temperature equilibrium. When A was inserted without the precautions noted above, the sudden inflow of heat from the large surface of the

bulb caused instant and complete evaporation, with considerable loss of liquid. This procedure, by reducing the heating surface, allowed the increase of pressure to keep pace with the speed of heating.

The constant "pumping" movement of the manometric liquid due to small fluctuations of bath temperature was reduced as much as possible by proper rheostat adjustment. To minimize the error from this source the reading was made as far as possible at the time of momentary rest between rise and fall of temperature, the pressure being so adjusted that at that instant the menisci in **A** were level. The pressure difference was then read on the manometer of B. When the liquid in the wide arm of B was higher than in the capillary, it indicated that the vapor pressure of **A** was less than that of B. Such readings were recorded as negative. Readings were made at frequent intervals until they became constant, and then occasionally for a longer period.

Isothermal Distillation.—When the readings were completed, it was found advisable to test the purity of the liquids by isothermal distillation. The deficiency of this method as a means of measuring or even detecting impurities has recently been discussed by Washburn.[8] The data forming the basis of his discussion are, however, limited to the difference between the vapor pressure of the liquid with an infinitely large and an infinitely small vapor phase. The method here described, in that it furnishes a few intermediate points, is more promising and was found useful in testing at least the relative purity of the two samples.

The fractionation was generally carried out immediately after the completion of the main experiment, when both samples of liquid were already at the boiling point and supposedly free of permanent gas. By closing clamp 1, and reducing the pressure, bubbles of vapor could be made to pass through the manometer of B and, condensing, increase the volume of the manometric fluid. The speed of this evaporation could be controlled by the amount of change of pressure. By continuous agitation of the liquid in the bulb, and slow rate of evaporation, the condition is approached where the condensing vapor is of the composition in equilibrium with the liquid. At any point the distillation could be interrupted, temperature equilibrium reestablished and the change of vapor pressure in B observed by comparison with A. At the same time, the volume of the liquid in the manometer (previously calibrated against the millimeter scale) was read. Thus, by a series of observations, there could be plotted against the percentage of the original amount of liquid in the bulb, the corresponding reduction in vapor pressure. The points obtained are shown in Fig. 2, in which the lowering is expressed as percentage of saturation vapor pressure which in all cases was close to 760 mm. The points for a sample of acetic acid less pure than that used are included for comparison, as is also a line showing the points to be expected by a liquid containing one mole of a non-volatile solute in 9999 moles of solvent. Where the impurity is volatile, the theoretical curve will vary with each pair of substances according to the behavior of their partial vapor pressures. It may be seen

at a glance, however, that the benzene and bromine used in these experiments are of a higher order of purity than the acetic acid.

The most striking feature of this method of isothermal distillation is its sensitivity. Constancy of boiling point, a generally accepted criterion of purity, is crude in comparison, far the acetic acid used, which distilled completely within a range of 0.02°, was found, on isothermal distillation, to show vapor pressure changes up to 58 mm. of acetic acid (used as manometric liquid) in the course of the fractionation.[9] This acid had been subjected to fractional crystallization twelve times, until the melting point became constant within 0.02°, and was then distilled twice, all but a negligible residue coming over within a range of 0.02°, m. p. 16.6°, b. p. 117.8°.[10] These figures are in agreement with the best observations in the literature. In this case, therefore, fractionation as here carried out furnished the only evidence of the impurity undoubtedly present.[11] Im-

[9] Fifty-eight mm. acetic acid; density 0.94 ≡ 4.0-mm. mercury, density 13.6 ≡ 0.53% of 760 (Fig. 2).

[10] The thermometers used for testing the purity of liquids were compared with a standard thermometer, whose certified accuracy was 0.1°. The constancy of the readings could be estimated more closely as the thermometers were graduated in 0.2". Unless otherwise stated, boiling point observations are corrected to 760 mm. pressure.

[11] Lack of this evidence was undoubtedly the cause of the difficulties encountered by Meyer and Jaeger, *Ber.*, 36, 1555 (1903), and Kahlbaum, *ibid.*, 16, 2479 (1883), in working with acetic acid.

purities, therefore, too small in amount to be detected by ordinary means are capable of causing appreciable error in vapor pressure measurements where the circumstances are favorable to fractionation.

Errors.—Fractionation as a source of error in our results is eliminated by the expedient of evaporating all the liquid from the bulbs of both isoteniscopes immediately before the comparison is made. The liquid on condensing is thoroughly and automatically mixed by bubbles of vapor passing upward through it. On returning the liquid to the bulbs, one is then certain that the vapor pressures observed are those of the whole mixed portions of liquid. Error from parallax was negligible, because it was suffered alike by each limb of the confining liquid within the isoteniscopes; this was tested also by the very close agreement of two isoteniscopes in the bath under like conditions.

The most important single source of error remaining was the constant movement of the manometric liquid in the isoteniscopes. In Table I, Col. 5, is shown the amount of movement that would be caused by a variation of 1° in the bath temperature.

TABLE I

COLLECTED USEFUL DATA

Liquid	Temp. expt., °C.	Density at the b. p., g. per cc.	Factor, mm. liquid to mm. Hg	At normal boiling point p in mm. liquid	
				dp/dt, mm. liq.	dt/dp liq., °C.
Acetic acid	117.5	0.94	0.069	346	0.0029
Bromine	58.8	2.98	.219	115	.0087
Carbon tetrachloride	75.0	1.48	.109	213	.0047
Benzene	78.4	0.81	.060	392	.0026

Actually, by adjustment of the rheostat and making the reading in the manner described, the error of reading the pressure difference at the boiling points was probably not greater than ±1 mm. At room temperature these fluctuations were entirely absent. Temperature variation was significant only on account of this "pumping" effect. The actual temperature of the bath was of importance secondary to that of its constancy of temperature. Traces of impurity, if present in both samples in the same amount, produce no appreciable effect on the differential vapor pressure readings. Minute differences in the amount of impurity in the samples contained in the two isoteniscopes, however, produce considerable effect. Except in the case of bromine there was a possibility of absorption of moisture in transferring the liquids to the isoteniscopes. A greater source of error was the possible presence of permanent gases, even after boiling out and comparing the isoteniscopes at room temperature. Any traces of gas dissolved in the liquid or adsorbed on the inner walls of the isoteniscopes would tend to enter the vapor phase during the heating. Any such accumulation in B would be removed when it was boiled out just before the insertion of A, but in A the heating was of necessity deferred until the readings were to be made and the accumulating gas would cause a gradual increase in the apparent vapor pressure of A as compared to B. This was an error of the second order in all experiments but benzene (a), which was continued for ten hours. In this case a gradual increase of pressure amounting to 0.1 mm. of mercury was noted. Though nearly within the experimental error from other sources, it appeared to be quite definite, and could be accounted for by the liberation of only 0.004 cc. of permanent gas.

Results

Detailed experimental data are reported in only one instance for purpose of illustration. The results for all liquids are summarized in Table III. Information not readily tabulated is given under the heading of each liquid. The observations of pressure difference are given to the nearest 0.5 mm., as in some cases, notably those of bromine and carbon tetrachloride, this refinement of measurement has probably some significance, due to a diminished amount of pumping. The time required to heat the bath to the boiling point of the liquid varied from fifteen minutes in the case of bromine to eighty minutes in the case of acetic acid. The period of heating was not considered to have started until the boiling point was attained.

Acetic Acid.—The purity of this material has been discussed. Experimental details are shown in Table II. The pressure difference observed indicated that the more recently heated portion possessed a vapor pressure 0.17 mm. of mercury lower than that heated for about five hours. This is in the direction suggested by Baker's results, but there was no change in this difference over a period of four hours, at which time the thermal history of the two samples was more nearly similar.

Bromine.—This was prepared from recrystallized potassium bromide and purified by the method of Robinson and Briscoe.[12] It was then dried in contact with fused calcium bromide prepared from a portion of the pure bromine. The isoteniscopes were in this case sealed to the drying tube,

---

[12] **Robinson and Briscoe, J. *Chem. Soc.*, 127, 142 (1925).**

after which the system was evacuated and allowed to stand for a week. Finally 5 cc. of bromine was distilled into each isoteniscope, which was then sealed off, the tip being later broken after connection to the vacuum system. The desirability of this method of treatment is reflected in the results. The bromine used had not been elevated above room temperature for three months previous to the experiment; vapor pressure 760.5 mm. at 58.8". Isothermal distillation indicated a very high order of purity. There was no difference observed between the pressures of the two samples and no change in this condition over a period of four hours.

Carbon Tetrachloride.—The original liquid boiled at 76.6° within a range of 0.05°. The middle portion was retained and kept for eighteen months in contact with metallic calcium. This was an early experiment, completed before the disturbing effect of fractionation had been observed. In this case, instead of evaporating all the liquid from both bulbs immediately before making the comparison, B was not allowed to boil out, while A of necessity boiled out completely on immersion. No test of purity by isothermal distillation was made.

Benzene.—A high quality commercial product was shaken successively with sulfuric acid, sodium hydroxide and water, and dried over fused calcium chloride. On distillation it boiled at 80.1°. It then stood for twenty-two months at room temperature, for twenty months in contact with metallic calcium and for two months with sodium. Experiment (a) showed a higher vapor pressure in the more recently heated portion, amounting approximately to 0.3 mm. of mercury. The experiment was

TABLE III

SUMMARY OF EXPERIMENTAL WORK

1 Liquid	Acetic acid	Bromine	CCl_4	Benzene	
				(a)	(b)
2 Time liquid in A had remained at room temp., months	2.5	3	18	22	22
3 Time liquid had been held at the boiling point, hours	4.8	4.0	4.5	4.5	19.1
4 Time required for A to attain temp. equilibrium with bath, minutes	12–18	5	6	5	5
5 Duration of expt. after insertion of A, hours	4.2	3.4	0.5	10.0	0.3
6 Av. press. diff. for 15 minutes, mm. liquid first	−2 5	0.0	−1.0	+4.1	+0.8
7 Av. press. diff. for later observations, mm. liquid	−2.3	+0.1	−1.0	+5.8	+0.5
8 Change of press. diff. between 6 and 7, mm. Hg	+0 014	+0.022	0.000	+0.102	−0.018
9 Change in b. p. indicated by 8 in °C	0.0006	0.0009	0.0000	0.0043	0.0008

continued for ten hours, the difference increasing to 0.4 mm. As it was suspected that the original vapor pressure difference was caused by an impurity, both portions of the benzene were subjected to isothermal distillation. The sample contained in isoteniscope B showed good agreement with the other results for benzene, while that in A showed distinctly greater impurity (probably permanent gas). In order to see if this difference disappeared with equally pure samples, experiment (b) was performed. In this experiment the difference in vapor pressure amounted to only 0.06 mm. of mercury, and isothermal distillation showed almost identical curves for the samples in the two isoteniscopes.

Discussion

The following four points (Table III) are most pertinent to the question of whether the phenomenon reported by Baker has any influence on ebullioscopic determinations.

(1) All liquids had been standing at room temperature for a considerable time before being used, thus assuring attainment of the equilibrium for that temperature.

(2) Except in the case of acetic acid, the isoteniscope which had been plunged into the hot bath gained the temperature of the bath in six minutes or less.

(3) The difference in pressure observed varies in direction, suggesting that it is fortuitous. In benzene (a) the difference was accounted for by an impurity found in one of the isoteniscopes. In acetic acid the difference would amount to only 0.007" difference in boiling point. The striking contrast of this result with Baker's is shown in Table IV.

TABLE IV

COMPARISON OF RESULTS WITH ACETIC ACID

Temp. of ohsn., °C.	Pressure difference Mm.	Pressure difference In percentage of satn., press., %	Corresponding temp diff., °C.	Observer
20	2	17	3	Baku
117.5	0.17	0.002	0.007	Wright and Menzies

(4) In all cases but benzene (a) there was no perceptible change in the pressure difference produced by continued comparison over a period of time. The case of benzene (a) has been accounted for by a gradual accumulation of permanent gas.

Summary

To determine whether the boiling point of a liquid is altered by prolonged heating at the boiling point, an apparatus was constructed which allows a direct differential vapor pressure measurement to be made upon two samples of a liquid, one sample having been kept at the boiling point for several hours, the other elevated to the boiling point from room tern-

perature immediately before making the observation. Isothermal distillation within the apparatus furnishes a very sensitive test for the purity of the liquid. As the result of observations made on acetic acid, bromine, benzene and carbon tetrachloride, it may be concluded that the vapor pressure of a sample of liquid rapidly elevated to the boiling point is identical with that which it exerts after remaining for several hours at the boiling point. Delay in attaining internal equilibrium is therefore not a factor of influence in the measurement of boiling point or vapor pressure of these liquids, and observations may be made as soon as temperature equilibrium is established.

THE KINETICS OF THE POLYMERIZATION OF VINYL ACETATE

BY HOWARD W. STARKWEATHER AND GUY B. TAYLOR

RECEIVED AUGUST 7, 1930 PUBLISHED DECEMBER 18, 1930

Vinyl acetate forms high polymers on heating alone or in solution, with or without a catalyst.[1] The present investigation indicates that the probable mechanism of the process from monomer to polymer is a type of chain reaction.

The rate of polymerization was observed by measuring the contraction in volume. A linear relation was established between percentage contraction on the original volume of the monomer and the degree of polymerization by density measurements and by evaporating mixtures of monomer and polymers to constant weight, the polymers being nonvolatile.

Apparatus

Dilatometers similar to those used in measuring the thermal expansion of liquids were constructed, consisting of bulbs of 18 mm. tubing and approximately 20 cc. capacity, sealed to straight tubes 4–7 mm. in diameter. The straight tubes were graduated in per cent. Those made from the smaller tubing could be read to 0.02% and the larger one to 0.05%. The thermostats for heating the dilatometers consisted of three large tubes equipped with condensers and filled with boiling benzene, water and toluene. The temperatures of the different baths at the position of the dilatometer bulbs as determined by calibrated thermometers were 82, 101 and 111".

---

[1] H. Staudiger, K. Frey and W. Starck, *Ber.*, 60, 1782–92 (1927); Whitby, McNally and Galley, *Trans. Roy. Soc. Can.*, 22, 27–32 (1928). There are also numerous patents on the subject.

Experimental Procedure

The vinyl acetate was distilled, using an ordinary condenser, so that it was exposed to the air. It was kept in a clean tin can to protect it from the light. In some of the measurements the acetate was distilled in vacuum directly into the dilatometer in the all-glass apparatus shown in Fig. 1. The acetate was placed in B and cooled with solid carbon dioxide while the whole apparatus was exhausted with an oil pump. After sealing at E, C was cooled with liquid air or solid carbon dioxide and B allowed to reach room temperature. After collecting a light fraction in C, B was again cooled and D sealed. By a similar procedure another fraction was collected in the dilatometer A, rejecting the heavy fraction left in B. The dilatometer was then sealed off at F.

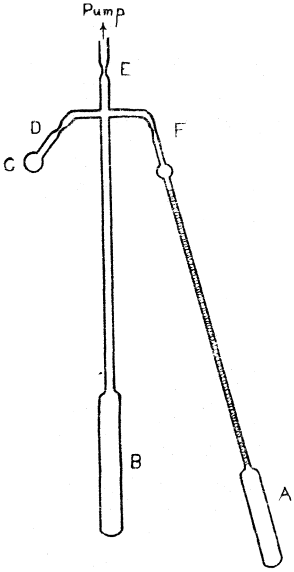

Fig. 1.

In experiments with air-distilled vinyl acetate, alone or in toluene solution, air was pumped out of the diiatometer after cooliig the acetate to −78°. Since the measurements were made at temperatures above the boiling point of the acetate, it was necessary to use a closed system. In preparing toluene solutions definite volumes of vinyl acetate were run from pipets into weighed 100 cc. graduated flasks. They were then filled up to the mark with toluene at 22°. Within the limits of accuracy of this work, no appreciable change in volume was found upon mixing vinyl acetate and toluene.

After a dilatometer had been filled and sealed it was placed in a water-bath at 22° and allowed to stand until the meniscus position was constant. The dilatometer was then placed in the boiling liquid (water, benzene or toluene) bath and the liquid level was read at frequent intervals. In the absence of an added catalyst the level usually rose for the first three to six minutes and then gradually fell. When a catalyst was present the level frequently started to fall by the end of one or two minutes, and the maximum reading was calculated from the reading at 22° and from the expansion as determined in the absence of the catalyst. The dilatometers in most cases were allowed to stay in the bath until no further contraction took place; this required from one to nine days.

Experimental Results

According to Staudinger and others,[1] when vinyl acetate polymerizes it does not yield a single chemical individual but a mixture of polymeric homologous compounds. Our experimental method is justified only if the average density of the mixed polymers is the same throughout the course of the reaction. It is not necessary to treat the reaction product as a chemical individual because we are concerned only with the rate of disappearance of the monomer. Whether the actual densities of all the polymers are nearly the same is not so important in establishing the kinetics of the process as are the differences in density between the monomer and the mixed polymers.

In this study the assumption has been made that all the polymers are non-volatile. In a number of cases, after measuring contractions in the dilatometer, the contents were evaporated to constant weight. Most of the toluene and monomer (b. p. about 60°) were allowed to evaporate at room temperature, and then the sample was kept in a vacuum oven at 65° until it reached constant weight. This required from one to two weeks. The results are given in Table I. Column 4 is calculated from Columns 2 and 3, and Column 6 from Columns 4 and 5. From the table it will be seen that percentage non-volatile (*i. e.*, polymers) is approximately proportional to contraction under widely varying initial concentrations. The experimental error in data of this kind is necessarily high for obvious reasons, but there is no definite trend in the values for percentage polymerization *versus* percentage contraction, so that the average may be accepted.

Table I

Relation between Volatility and Contraction

1	2	3	4	5	6

[a] Reaction catalyzed with benzoyl peroxide.

From this average, 3.65%, the contraction corresponding to complete polymerization is 27.4%. From density measurements of monomer and polymer at 101°, the calculated contraction is 26.8%, in fair agreement with the above figure of 27.4%. Since determinations of density could be made much more accurately than of non-volatile matter, contractions used in interpreting the data were calculated from them at all three temperatures. Table II gives the measured densities and the contraction calculated from the densities for complete polymerization. As an example of the calculation: 100 g. containing 61.6 g. monomer, at 82°, occupies 100/0.834 = 120 cc., the monomer 61.6/0.85 = 72.5 cc., the polymer 61.6/1.142 = 53.9 cc. The contraction is (72.5 − 53.9)/120 = 15.5%.

Table III summarizes some of the data obtained. The time in minutes

is given for each 10% reaction. Results obtained with pure vacuum-distilled vinyl acetate were easily reproducible, but those with the air-distilled material varied appreciably. The reaction with the pure acetate was allowed to proceed at all three temperatures until no more contraction in volume occurred. The densities of the three products thus obtained were determined by weighing in water and air at room temperature and found to be 1.190 ± 0.002. The uniformity in density indicates the same mixture of reaction products at all three temperatures.

The rate of polymerization of pure vacuum-distilled vinyl acetate approximately follows the law for a unimolecular reaction. Table IV gives the complete data for the run at 101°. The constant, k, was calculated from the formula

$$k = \frac{1}{t} \ln \frac{c}{c - x}$$

where c is the contraction for complete polymerization and x the contraction at time t.

[a] At 22° before placing in boiling water jacket. [b] Taken as zero time in computing velocity constant.

Undiluted vinyl acetate gives a fair unimolecular constant in all cases over the entire range. The temperature coefficient for 10° is 2.7 and the heat of activation 25,000 calories, which is the same order of magnitude as for other high-polymer reactions given by Kienle.[2] In toluene solutions the computed values for k fall rapidly with time. For example, take the case of the 80% solution at 101°, the constants figured for each 10% reaction up to 50% are 81, 66, 55, 44, 37 $\times 10^{-4}$. The values of k given in Table III for the toluene solutions are figured for the first 10% reaction, merely as an index of relative speeds at the start.

The effect of benzoyl peroxide upon the rate of polymerization of the 20% solution of vinyl acetate in toluene at 101° is shown in Fig. 2. The rate curves between 190 and 1200 minutes are omitted from the figure. After 1200 minutes, Samples II and III were cooled and more of the peroxide was added. After being replaced in the boiling water-bath, the polymerization rates increased sharply, as shown by the curves. The 1% additional benzoyl peroxide added to Sample II after 1200 minutes gave a curve practically identical in slope with that obtained with Sample V, which contained 1% of the peroxide at the start. In the first 1200 minutes Sample III, containing ten times as much catalyst as Sample II, polymerized only half again as much, and Sample V with 50 times

---

[2] R. H. Kienle, *Ind. Eng. Chem.*, 22, 590-594 (1930).

something over twice as much. The curves show, in general, that a given amount of catalyst causes the same degree of polymerization, whether added all at once or in portions at successive time intervals.

In no case did the reaction in toluene solutions go to completion although in some experiments the heating was continued for nine days. It is perhaps significant that in the uncatalyzed reactions the polymerization of 40, 60 and 80% solutions apparently stopped when they contained approximately 2.0 moles of monomer per liter, while the polymerization of the 20% solution appeared to stop when it contained 1.5 moles of monomer per liter.

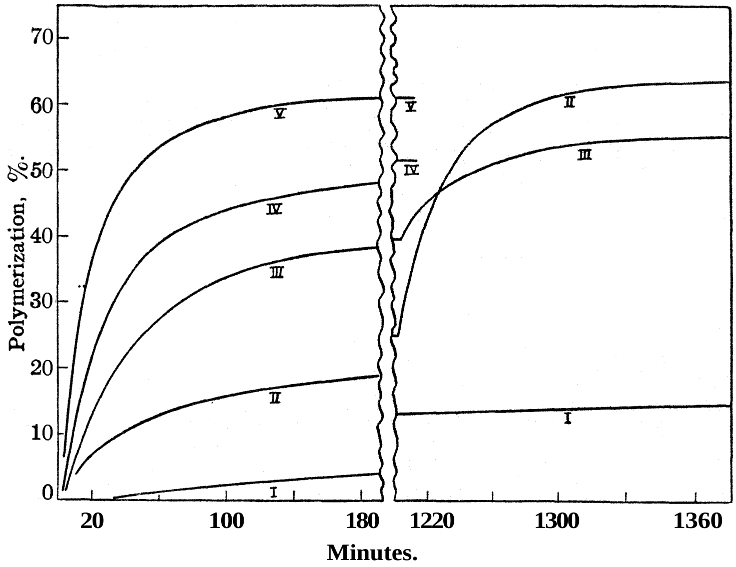

Fig. 2.—Polymerization of 20% vinyl acetate in toluene (101°). Percentage of benzoyl peroxide: I. 0.00; II, 0.02 and 1.0; III, 0.2 and 0.2; IV, 0.4; V, 1.0.

There are negative as well as positive catalysts for this polymerization. A sample of air-distilled vinyl acetate containing 1% of sulfur was heated for twenty hours in boiling water with no detectable contraction in volume. If no sulfur had been added, polymerization would have been essentially complete. This effect of sulfur had been determined previously by Blaikie.[3]

Discussion of Results

It seems likely that we are dealing with a chain reaction of some kind. The reaction involves the combination of many molecules to form a polymer and yet it follows the unimolecular reaction rate law. The explana-

[3] Blaikie, Canadian Patent 282,860 (1928).

tion is probably similar to that put forward by Christiansen and Kramers[4] to explain a simpler type of pseudo-unimolecular reaction. In this theory an activated molecule is formed for every one that reacts.

Benzoyl peroxide acts as a trigger catalyst in starting reaction chains and is itself destroyed in the process, since chemical tests always showed its absence when the catalyzed reaction stopped. Anti-catalysts, like sulfur, interrupt the reaction chains. The inhibition of the reaction by toluene may be explained on the basis that activated molecules give up their energy to the toluene molecules before they can combine with other vinyl acetate molecules. In other words, the toluene has the same effect in breaking reaction chains that walls exhibit in some homogeneous gas reactions.

Summary

The polymerization of pure vinyl acetate is shown to follow the unimolecular rate law. In toluene solution the rate of reaction is retarded. The kinetics of the polymerization are explained on the basis of a chain reaction. Benzoyl peroxide acts as a trigger catalyst by initiating reaction chains. Sulfur inhibits the reaction.

[COMMUNICATION NO. 439 FROM THE KODAK RESEARCH LABORATORIES]

THE VACUUM FRACTIONATION OF PHLEGMATIC LIQUIDS

BY K. HICKMAN AND W. WEYERTS

RECEIVED AUGUST 7, 1930 PUBLISHED DECEMBER 18, 1930

In the course of some work on heavy oils the need has been encountered for an adjective which will convey the sense of "difficultly volatile" or "high boiling." Instead of inventing a word we have prepared to adapt a word which is already well known and, therefore, nearly self-explanatory. Such a word is "phlegmatic." Derived from the Greek φλεγματικός, the original suggestion of "fieryness" has given place to the well-accepted sense of sluggishness, apathy or resistance to disturbance. Phlegmatic seems a particularly suitable word to denote high-boiling properties, and it is the adjective which will be used throughout this paper.

Many separations of phlegmatic liquids by fractional distillation could be performed more efficiently or more conveniently[1] at very low pressures if it were not for the uncertainty concerning the real pressure in the distilling

[4] Christiansen and Kramers, *Z. physik.* Chem., **104, 451 (1923).** See also Hinshelwood, "Kinetics of Chemical Change in Gaseous Systems," Clarendon Press, Oxford, 1929, Chapters V and VI.

[1] Bumping vanishes entirely at pressures below 1 mm.

apparatus. Where simple distillation is concerned, without reference to the temperature at which it occurs, high vacuum can be employed.[2] Where the temperature–pressure relation is important, as it is in fractionation, or in determining the purity of a distillate, or in identifying a material by its boiling point, then relatively poor vacua have hitherto been compulsory. It is safe to say that any boiling point recorded in the literature from ordinary distillations at 10 mm. is probably inaccurate by 1°, and boiling points expressed at lower pressures are completely unreliable.

This unreliability is due chiefly to the lack of uniformity of pressures in the distillation apparatus. In using gaseous systems at atmospheric pressure it is usually assumed that the pressures are identical at all parts of the apparatus; a gage attached at any part will give information relating to the whole. Where the internal conditions are dynamic rather than static, owing to a flow of gases from one portion to another, the pressures no longer are equal in all parts, a difference of a millimeter or so arising in the effort necessary to move the gases. The difference may be less than one-tenth of one per cent. of the total pressure, and is usually neglected. Under high vacuum conditions a difference of one millimeter may cause a difference of a thousand magnitudes in the density of gases in various parts of the system. Measurements of vapor tension taken at an appreciable distance from the thermometer region may be entirely untrustworthy.

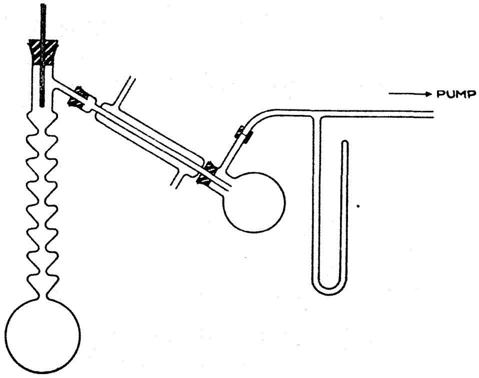

Fig. 1.

A full discussion of the factors contributing to false pressure readings has been given in a previous paper.[2] It will be more useful now to recall the phenomena which usually occur during the low pressure distillation of an organic liquid in the conventional distilling flask and condensing arrangements. In Fig. 1 a flask with rectifying column is shown connected by a side tube with a water-cooled condenser, *a* receiver, a manometer and an exhaust pump; a thermometer projects into the rectifying column to just below the exit tube.

We will place in the flask some comparatively phlegmatic liquid and commence distilling at a reduced pressure. **A** good material to distil would be butyl benzoate. With the pressure at 60 mm., vapor would pass over excellently at 170°. At 20 mm. the thermometer would register 132'; at 10 mm. 117°; at 5 mm. 104'; at 3 mm. 97°; at 1 mm. 92° and at

---

[2] Hickman *and Sanford, J. Phys. Chem.*, **34, 637 (1930).**

0.0 mm. 90°. Now it is apparent that if the temperature–pressure relation which subsists from 60 to 10 mm. still holds, as we have every confidence that it does, the temperature at 0.0 mm. pressure should be about absolute zero. The usual mercury manometer cannot be read with the naked eye below 0.1 mm., but even at this pressure the boiling point of butyl benzoate should be less than 50°. Furthermore, the discrepancy in boiling point is not constant. If, with the manometer still reading substantially zero, the heat is increased under the distilling flask, the mercury in the thermometer may rise 5 or 10°; if the heat input is decreased, it will fall.

The temperature measurements, within limits, are beyond reproach, but the pressure measurements are faulty. If the thermometer registers 60°, the pressure of a saturated vapor of butyl benzoate around the thermometer bulb must be about 1 mm. This vapor then passes into the condenser and turns into liquid in equilibrium with a vapor at such negligibly small pressure that for our present purposes it is zero. More vapor from the flask continues to flow into this empty space, and the temperature at the thermometer of 60" is a measure of the pressure (1 mm.) which is necessary to force the quantity of vapor which survives each moment, into the passage from the flask, through the side tube and into the condenser. Supply more heat at the flask, and the pressure must rise to drive over the larger quantity of vapor.

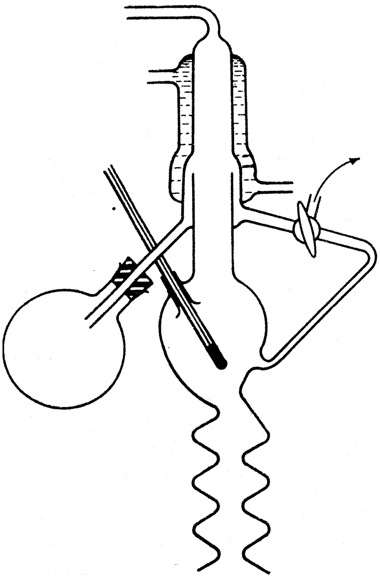

Fig. 2.

Many partial remedies will occur to the reader but drastic alterations to the equipment are required for a complete cure.

Two conditions should be satisfied if the data are to be recorded correctly. The thermometer should be placed in an expansion of the column where the vapor has a relatively small velocity, and the manometer should operate directly from the wall of this expansion. No passage filled with gas can communicate the pressure with an outside gageunless this passage and the pressure recording mechanism at the end of it are kept at the same temperature as the bulb.

It is simpler, therefore, to use a small portion of the condensate as it flows down the walls of the bulb as a manometric fluid and to provide a glass tube and recording scale at a convenient point on the bulb. The pressure side, however, is only one-half of a manometer, and it is necessary to produce a substantially perfect vacuum at the other end.[3] This would mean, since the filling is to be of the material distilled, that the high vacuum must be applied whenever wanted, presumably by a separate pump. The complication can be avoided by forming the condenser into a simple condensation pump, so that the vapor under treatment produces its own reference vacuum. We have given a still head (Fig. 2) modeled in this manner prolonged trial in the laboratory and have found that with liquids of the class for which it was intended the head never failed to yield a better reference vacuum than could be communicated through the three-way stopcock from a separate pump.

The differing capillary actions at the ends of the self-contained manometer require that the zero point be found empirically by momentarily relieving the vacuum so that the liquid may equalize in the two limbs. The liquid in the automanometer requires scavenging frequently if the condensate varies in volatility or density as distillation proceeds.

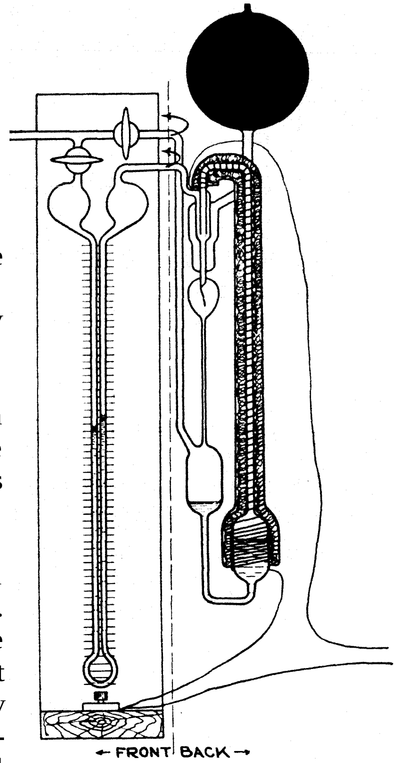

Fig. 3.

The still head can act as a diffusion pump only if the pressure at the exit tube to the exhaust pump is considerably less than the pressure of vapor in the thermometer cavity and thus at the male jet. It is therefore quite essential to have a sensitive manometer in the exhaust line. A McLeod gage and possibly a Pirani gage could be used, but we favor a direct reading liquid manometer. The mercury manometer is unreliable because of difficulty of reading minute changes in level and because of the doubt which must always exist as to the perfection of the reference vacuum in the closed limb. We have devised a butyl phthalate filled manometer which, although of somewhat complicated design, is simple and entirely reliable in use. It is illustrated in Fig. 3 and is described in an appendix to this paper.

[3] If the temperature of the liquid in the vacuum end is 80° less than at the pressure end, the vapor pressure will generally have decreased a thousand times and may be neglected. In chemical vacuum work it is a useful rule that any liquid which is under distillation may itself be used cold as a manometric fluid, as a joint seal and as a film to prevent the escape of volatile matter from the inside of rubber pressure tube and from corks. We repeatedly perform distillations in special apparatus at 0.1 micron using matured rubber stoppers and rubber tubes soaked in the phlegmatic liquid under treatment.

The condensation still of Fig. 2 will only accommodate vapor pressures up to 1 mm. and liquids to be condensed at 10 and 20 mm. will not generally survive on the high vacuum side of the jet unless the condenser is maintained many degrees below zero centigrade. It then becomes convenient to operate with a positive air pressure in the system and attach an external phthalate manometer to the free arm at the three-way stopcock of Fig. 2. The pressure difference between the thermometer cavity and the condenser is then added to the pressure registered by the external manometer and the sum is the pressure at which the liquid is condensing.

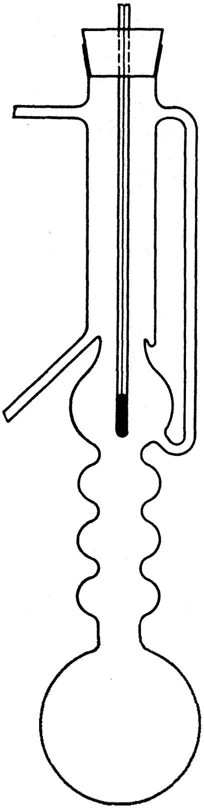

Fig. 4.

A very convenient unit for the accurate distillation of small samples ranging from 5 to 100 g. is that shown in Fig. 4. The thermometer bulb hangs in the largest cavity of the dephlegmating column and a side manometer tube passes from the lower region of the cavity to the top of the condensing chamber. The latter may be water cooled, but it is generally sufficient to employ the draught from a small fan. The condensate collects in the annulus and flows out of the delivery tube to the left. The correct boiling point at regions of rapid change of boiling point can be secured by preventing the distillate from escaping. It then collects in the annulus and flows back down the column. When the boiling point has been secured the side tube is unclipped and collection of the distillate resumed. Care must be taken that the cool distillate does not run down the thermometer bulb from the annulus. The pressure in the thermometer cavity is, of course, the sum of the pressure in an external manometer and in the automanometer.

The measurement of pressure by an external manometer becomes more and more accurate as the cavity housing the thermometer and the passage therefrom to the condenser become larger. We thought, at one time, that the automanometer construction could be abandoned in lieu of another suitable design. It was soon found that very large openings allowed the vapor–air junction to oscillate in position, at one moment leaving the thermometer uncovered, at another heating the stem many centimeters up. The apparent boiling point would fluctuate correspondingly. It was preferable to confine the vapors in the cavity and allow them to issue into the vacuum system under a small positive pressure. The vacuum system **then** became a comparatively inexhaustible reservoir waiting to receive products of decomposition or traces of volatile solvents. **A** much smaller vacuum bottle could be used in series with the **pump** to steady the pressure.

It may be inquired which of the columns described is the most useful. Our first choice would be the device pictured in Fig. 3. It may be noted that the point of novelty on which this paper is based is the application of a side tube near the thermometer region of any distilling flask. If the glass blowing difficulties are found insurmountable, quite good work can be done with the simple set-up pictured in Fig. 5.

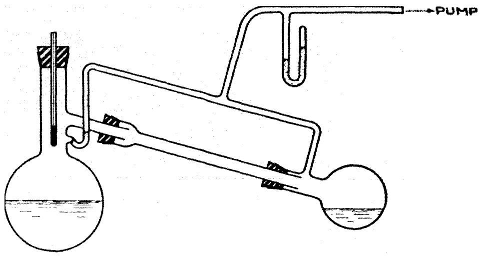

Fig. 5.

Experimental

Distillations were performed in flasks of the type shown in Fig. 1. Two flasks were used, one with a side arm of usual bore, and one with a side arm of as large diameter as the neck of the flask itself. Butyl benzoate was employed as the liquid, and was boiled by an electric heater at three different wattage inputs. The boiling points at each apparent pressure, as registered by an external manometer, are recorded in Table I. The real boiling points corresponding to the recorded pressure are included for comparison and all the data are summarized in Figs. 6 to 8. It will be noticed

[a] An interval of ten to fifteen minutes was allowed after each adjustment of heat input to allow a steady distillation rate to be reached. In the case marked with the a readings were taken after a few minutes only. Their divergence from the other series shows how sensitive to external conditions are these low-pressure distillations.

that the true boiling point of **131.5** at **20** mm. was disturbed by less than a degree at reasonable rates of distillation. A maximum discrepancy of a degree and a half occurred at 10 mm. pressure but the errors became serious at **5** mm. The large side arm flask gave an average inaccuracy of 5° at **3** mm., and the readings were valueless below this pressure. The narrow arm flask failed substantially at 5 mm.

As a second exercise, a sample of commercial a-chloronaphthalene was distilled in the still of Fig. **3.** The sum of the pressures in the external manometer and the automanometer was kept at **10** mm. This ensured a pressure of exactly 10 mm. in the thermometer cavity.

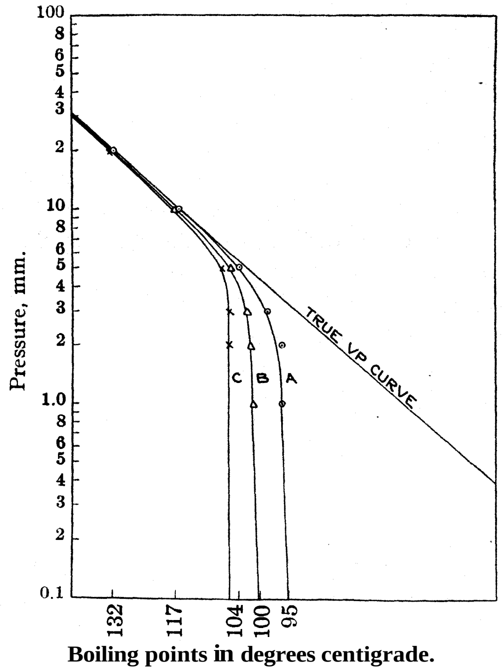

Fig. 6.—*n*-Butyl benzoate, Type of still, Fig. 1, small side arm. A, 40 watts; B, 50 watts; C, 60 watts.

The variation of temperature with the progress of distillation is shown in Fig. 9. It will be noticed that the points fall very smoothly on the curve drawn through them, indicating that little difficulty was encountered in obtaining true readings. The steep rise at the end of distillation is significant. The rise had to be accompanied with a corresponding increase of heat input to keep the pressure constant in the automanometer. Had the distillation been performed in an ordinary flask the real great rise in boiling point of the later fractions would have yielded a small apparent rise and the rate of distillation would have diminished until the pressure in the thermometer region had fallen sufficiently to convey the more phlegmatic vapor over with the same heat content. No indication of this would have been visible at the external manometer.

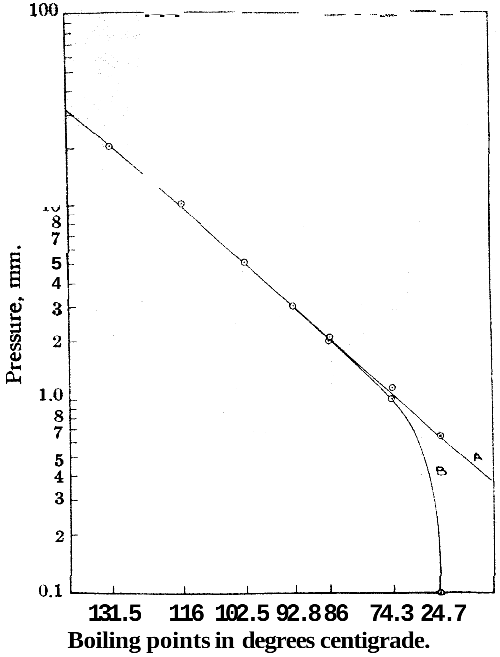

Fig. 7.—*n*-Butyl benzoate. Type of still, Fig. 2, condensation pump. Curve A, pressure read from external manometer plus pressure in automanometer, giving true pressure–temperature relation. Curve B, external manometer readings, yielding false pressure–temperature relation.

TABLE II

EXPERIMENTAL DATA

True pressure = sum of external manometer readings + automanometer readings	External manometer readings	Automanometer readings, corrected to mm.	Temperature, °C.

The composition of the distillate was fairly constant from 20 cc. to 40 cc., and as a further exercise the material was returned to the flask and distillation recommenced until 30 cc. had passed over. A by-pass tube was then inserted so that distillation could proceed cyclically, the material condensing being allowed to flow back into the still. The variation of boiling point with alteration of pressure was then examined and the data recorded in Table II. Figure 10 shows the correct and incorrect pressure–temperature curves drawn from these data. The bent, incorrect curve is the one which would ordinarily have been obtained if the automanometer device had not been employed to correct the pressures read by the external manometer.

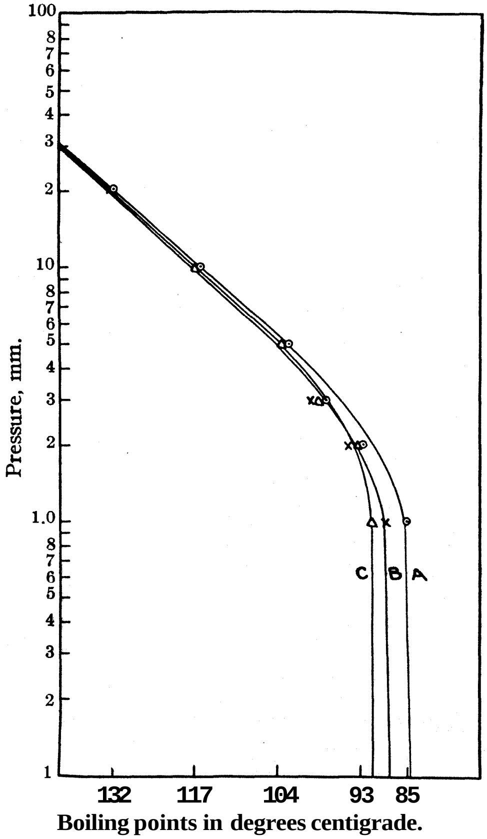

Fig. 8.—n-Butyl benzoate. Type of still, Fig. 1, large side arm. Curve A, 40 watts; B, 50 watts; C, 60 watts.

It would be impressive to perform a separation of two liquids under vacuum in an ordinary distilling flask and then show the improved result by using our special apparatus, but after the ample proof of discrepancy which we have already given such a course seems hardly worth while. Instead, a separation of two liquids, butyl benzoate and ethyl phthalate mixed in equal proportions, has been made in a flask with a *wide* side tube (Fig. 1, and Table I, subdivision 2), and this separation has been compared with that obtained with the condensation still of Fig. 2. The wide side tube still was operated with 0.1 mm. pressure in the condenser first at constant voltage input (Curve A, Fig. 11), and then at an attempted constant distillation rate (Curve B), but no steady thermometer readings could be obtained. An absolutely constant distillation rate was difficult to secure, and the slightest variation altered the thermometer readings by many degrees. The false maximum at 80 cc. is due to this cause. At 10 mm. (Curve C) better results were obtained. The excellent separations secured at 0.65 mm. and at 10 mm. in the condensation still are shown in Fig. 12. The temperatures are as concordant at a fraction of a millimeter as at 10 mm. The operator would have no difficulty in deciding where to make cuts or what the exact temperature–pressure relation was at each cut.

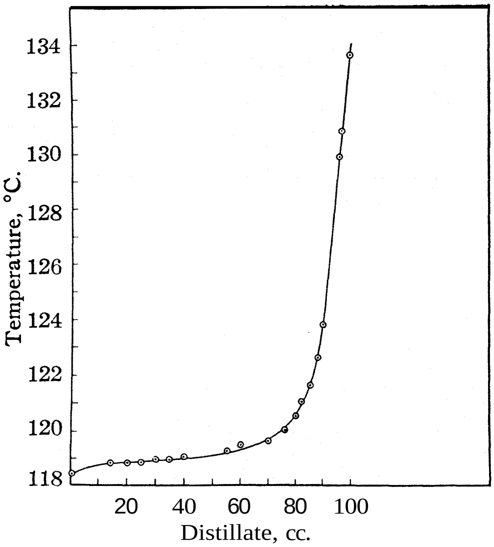

Fig. 9.—α-Chloronaphthalene, 10 mm. of mercury.

As a final exercise, about fifteen organic liquids were distilled which had boiling points ranging from 60 to 200° at less than 20 mm. pressure. The samples showed boiling points which were, in general, considerably lower than those stated in the literature.

Further Considerations.—The fall of pressure existing at the jet is not the only pressure difference within the still during distillation. At each constriction in the dephlegmating column there is a readily measurable drop in pressure which may give useful information. The early experimental column of the type shown in Fig. 2 had six manometers and corresponding thermometers inserted, but was later abandoned in favor of a distillation unit with only three thermometers: One in the liquid in the boiling flask, one in the lowest bulb of the column, and the third in the top bulb before the condensation head. Differences in reading between the bottom and middle thermometer indicated the purity of the liquid, while the top and middle thermometers coupled with manometer readings gave, when plotted with pressures against inverse of temperature, a good indication of the slope of the vapor-pressure curve for each fraction.

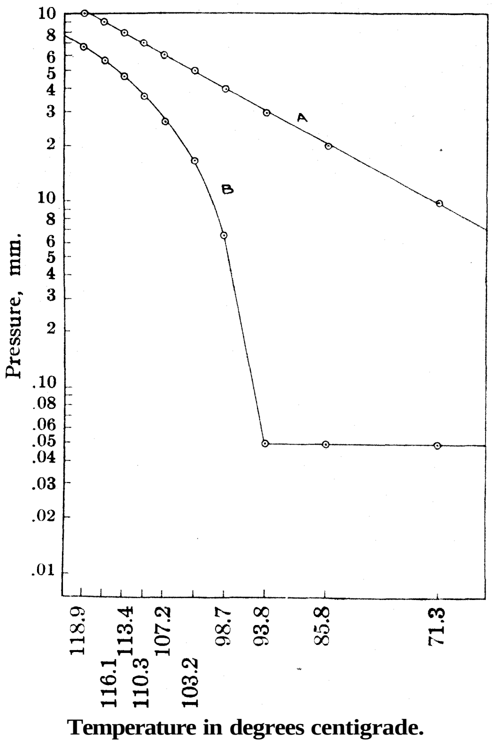

Fig. 10.—A, true temperature–pressure relation obtained by plotting the true pressures (sum of external manometer readings and automanometer readings) against the reciprocals of the absolute temperature. B, false temperature–pressure relation obtained by plotting the apparent pressures (external manometer readings) against the reciprocals of the absolute temperatures.

In the general reaction Aa + Bb = AB + ab where AB is a much larger molecule than ab, it is unlikely that either Aa, Bb or ab, will have the same slope of vapor pressure curve as AB, which will often be steeper, showing a greater depression of vapor pressure as the temperature falls. It is therefore an advantage to have a sheet of graph paper at hand while distilling, and plot the two or three pressure–temperature points for each fraction. The divergence in slope of the connecting lines will show whether a better separation is likely to occur when the pressure is raised or when it is lowered. Often the separation is better at the lowest pressures.

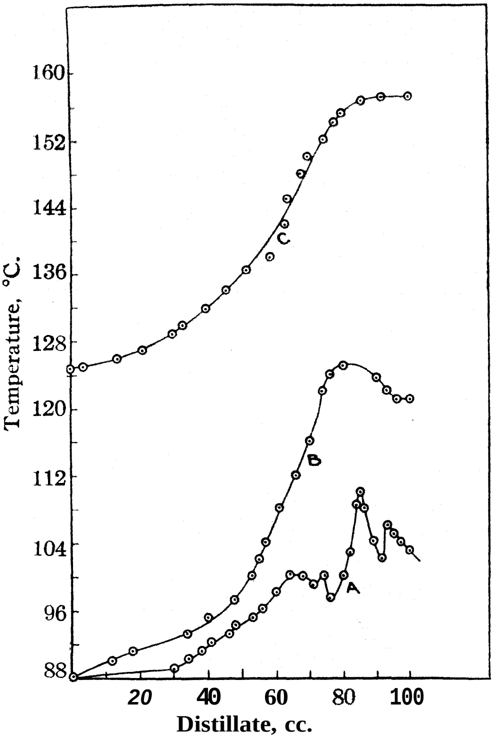

Fig. 11.—Mixture of *N* butyl benzoate + ethyl phthalate, type of still, Fig. 1, large side arm. A, at 0.1 mm. Hg heat input was held constant throughout; B, at 0.1 mm. Hg heat input variable, distillation rate constant; C, at 10 mm. Hg heat input was held constant throughout.

The purification of commercial butyl phthalate is a case in point. The likely impurities are butyl alcohol, butyric acid, phthalic anhydride and butylphthalic acid. At pressures above 20 mm a constant-boiling mixture distils, which, although it contains over 90% of butyl phthalate. is useless for vacuum pump purposes. When the distillation is performed at

0.64 mm. the butyl alcohol and butyric acid are sucked into the pump, the phthalic anhydride, which now boils at a lower temperature than the phthalate, deposits in a crystalline mass in the condenser, from which position it may be washed down with the first runnings of phthalate. A large middle fraction of pure butyl phthalate comes over, leaving a residue of butyl phthalate and butylphthalic acid which could be worked up under a lower pressure were it not that the crude phthalate is less expensive than the labor involved.

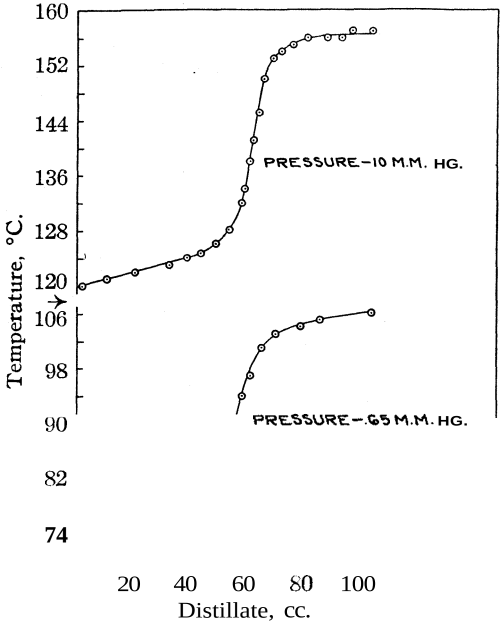

Fig. 12.—Mixture of n-butyl benzoate and ethyl phthalate, type of still, Fig. 3.

The statement that the phthalate was distilled at 0.64 mm. is derived from a knowledge that the specific gravity of *n*-dibutyl phthalate is 1.014 at 25° and that the column in the manometer attached to the thermometer cavity was 8.5 mm. high, whence

$$\frac{1.014 \times 8.5}{13.5} = 0.64 \text{ mm.}$$

A convenient way to describe the boiling point of any pure liquid would be in terms of the vapor pressure needed to support a unit height of a column of its own substance. Thus, butyl phthalate boils at 138° at a pressure supporting a column 8.5 mm. high of liquid butyl phthalate. We can denote this pressure by some convenient term, such as auto-pressure, and use the abbreviation A. P. Butyl phthalate boils at 138° at 0.64

mm., or 138° at 8.5 mm. **A. P.** Such a system of nomenclature would allow the pressure of any homogeneously boiling liquid to be described in conveniently-sized length units which are repeatable by anyone else without reference to tables. For conversion to the common mercury pressure scale, it is necessary to know the specific gravity of the liquid. Part of any pure preparation may be reserved for such a determination. A convenient means for securing approximate information of sufficient accuracy for the work is shown in Fig. **13.** Distilled water and the liquid are placed, one in each cup, and slight suction applied by the rubber ball. The liquid rises to a characteristic height which may be compared with the height of the water column. The menisci at the lower ends of the U-tubes compensate for surface tension errors.

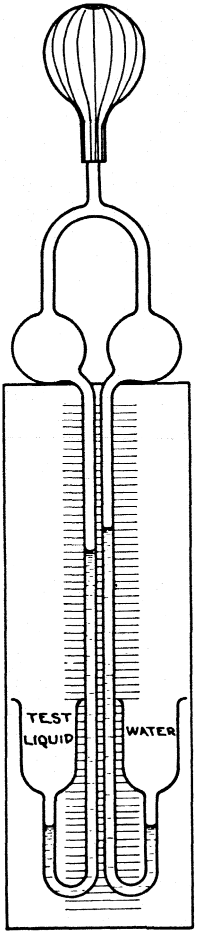

Fig. 13.

We have encountered an interesting source of error. As the liquids become very pure the surface tension alters and the liquid may cease to wet glass. Certain samples of benzyl phthalate appeared to suffer a sudden diminution of vapor tension. The liquid receded in the manometer and the meniscus flattened, occasionally becoming convex like mercury. Touching the tube with a lighted match caused the liquid to flow evenly and resume its normal position. It is necessary to be sure that the liquid under treatment thoroughly wets the manometer. It may be useful to recapitulate the factors which contribute to securing correct boiling points. They are: **(1)** a dephlegmating column between flask and thermometer to remove superheated vapors; (2) a cavity or expansion in the column where the thermometer bulb is situated; **(3)** a limited opening between the thermometer cavity and the condenser; (4) a manometer situated on the side of the thermometer cavity and operated by the condensate; (5) a sensitive external manometer.

Summary

It has been shown that the usual distillation apparatus does not give true boiling points at low pressures.

Apparatus has been described which enables true boiling points to be secured.

A number of distillation experiments under vacuum have been described. A system of nomenclature for high boiling liquids has been suggested.

APPENDIX

A DIRECT READING OIL MANOMETER

Referring to Fig. **3,** a simple U-tube is protected with splash bulbs at either end and is connected on the left-hand measuring side through a well-ground stopcock to the vacuum line. The other limb, in which a comparatively perfect reference vacuum is to be maintained, is connected with a miniature butyl phthalate condensation pump. The jets of this pump are only three or four millimeters in diameter and are surrounded by a cooling jacket communicating with a relatively large bulb painted black and situated above the main structure. The jacket is just completely filled with alcohol, the bulb is evacuated of all but the saturated vapor above the liquid and is then sealed off in the blow pipe flame. Hot vapors condensing at the jet cause the alcohol to boil at slightly above room temperature and send vapors into the flask, where they condense and return as liquid. The large surface of the bulb then becomes available for radiating the heat passing through the small surface of the pump. The jets are supplied with phthalate vapor through an electrically warmed and lagged tube from a boiling bulb some distance below. The condensate with entrained gases falls down a narrow tube having a preliminary dropping device which forms a secondary Sprengel backing pump. The gases are discharged into a storage bulb which connects by way of a second stopcock with the vacuum line. On commencing to use the manometer, the entrance tube is fastened to the pump, both stopcocks are opened, and the liquid in manometer and boiling bulb are thoroughly degassed. Presently, the condensation pump starts operating and the column in the reference limb rises a little, indicating that a good vacuum has been secured. The alcohol boils merrily into the black radiator bulb. The stopcocks are now closed, and the gage transferred to its place of operation. The left-hand stopcock is opened and the gage becomes available for readings. It is always shut off under vacuum The reference side storage bulb should be re-evacuated every few days of continued use.

THE DECOMPOSITION OF CITRIC ACID BY SULFURIC ACID

BY EDWIN O. WIIG[1]

RECEIVED AUGUST 11, 1930 PUBLISHED DECEMBER 18, 1930

The effect of inhibitors on the decomposition of certain organic acids by sulfuric acid has been explained on the basis of the theory of negative catalysis proposed by Taylor,[2] who concluded from Lichty's study[3] of the retarding influence of water on the velocity of decomposition of oxalic acid that inhibitors functioned as negative catalysts by reducing, through molecular compound formation, the active mass of one or both of the reactants. Taylor's theory has been substantiated more or less by experimental investigations of the rate of decomposition of formic, malic, *o*-benzoylbenzoic and triphenylacetic acids in sulfuric acid by Schierz,[4] Whitford,[5] Gleason and Dougherty[6] and Dittmar,[7] respectively. However, the results obtained in these studies are not always in agreement with what might be expected on the basis of the theory. A study of the effect of inhibitors on the decomposition of citric acid by sulfuric acid was undertaken in the hope of clearing away some of the present inconsistencies and for the purpose of testing still further the theory of negative catalysis involved in these reactions.

The reaction between citric acid and sulfuric acid first was studied about 1839 by Robiquet,[8] who observed that on heating the two a gas was evolved which at first consisted of carbon monoxide and later of a mixture of that gas with carbon dioxide. Various workers investigated the reaction without throwing any light on it until, in 1884, it was finally explained by von Pechmann.[9] Sulfuric acid decomposes citric acid into carbon monoxide, water and acetone-dicarboxylic acid according to the equation

$$(CH_2COOH)_2C(OH)COOH \longrightarrow CO + H_2O + (CH_2COOH)_2CO$$

Acetone-dicarboxylic acid, which was isolated by von Pechmann, decomposes rather readily into acetone and carbon dioxide, so that its detection had escaped earlier investigators. Fortunately, the velocity of decomposition of acetone-dicarboxylic acid in sulfuric acid at the temperatures employed in the present research is extremely small compared to the rate at which citric acid decomposes. It was necessary to correct for the

carbon dioxide evolved from acetone-dicarboxylic acid in only three slow decompositions at 35°.

Experimental Part

Preparation and Purification of **Materials.**—U. S. P. citric acid was recrystallized from water three times and dried over calcium chloride in a desiccator. The resulting hydrated citric acid crystals melted at 153–154°, which agrees very well with the value of 153° given by Meyer.[10]

Four lots of sulfuric acid corresponding to 100.00, 100.44, 100.50 and 100.52% were used. These acids were prepared by mixing C. P. 95–96% sulfuric acid with Baker and Adamson's reagent 30% fuming sulfuric acid, and subsequently analyzed, using due precautions to prevent the loss of sulfur trioxide or the absorption of moisture, by titration with standard alkali and by precipitation as barium sulfate. Samples of the lot which analyzed 100.00% H_2SO_4 were found to have a melting point of 10.40°, which is in good agreement with the values obtained by previous investigators.[11] The acids containing excess sulfur trioxide were mixed with the calculated amount of 95.44% acid required to give exactly 100% sulfuric acid and the melting point of the resulting mixtures was found to be 10.42". Moreover, when used for the determination of the velocity constant at a particular concentration of acid, the various lots of acid gave concordant results. Sulfuric acid of any desired concentration between 95.44 and 100.52% was prepared by mixing the calculated quantities of the dilute and fuming acids. These acids were run out of burets filled by an all-glass siphoning system from ground glass-stoppered storage bottles. To replace the acid withdrawn, air was admitted into the storage bottles by aspiration through two bubbling bottles containing 100% sulfuric acid.

Apparatus and Method of Procedure.—The velocity of decomposition of citric acid in sulfuric acid was determined by observing the volume of carbon monoxide evolved at various times during an experiment. The reaction was carried out in 50-cc. round-bottomed pyrex flasks supported in a shaking device similar to that designed by Walton.[12] The agitator was so arranged that the flasks were immersed completely in a thermostat whose temperature was regulated to within ±0.02°. The thermometer employed was calibrated against a Bureau of Standards and a P. T. R. thermometer. Supersaturation of the reaction mixture with carbon monoxide was prevented by adding short pieces of glass rod to the flasks. Capillary tubing conducted the gas evolved to water-jacketed burets which were maintained at the same temperature as the thermostat.

The dilute and concentrated acids (total volume, 20 cc.) were run from their respective burets into the reaction flasks while the flasks were stoppered onto the buret; the pressure in the flasks was first slightly reduced so as to permit flow of the acid. The citric acid, contained in a glass capsule supported in the neck of the flask, could be dropped into the sulfuric acid when the latter had come to the temperature of the thermostat. In the preliminary experiments solid citric acid was used but the velocity constants obtained were not concordant, varying with the size of the citric acid particles and the volume of solvent. This difficulty was finally overcome by using a concentrated solution of citric acid in water (58.43% acid and 41.57% water). From 0.25 to 0.50 cc. of this solution (molality of citric acid in sulfuric acid = 0.027 to 0.052) was accurately measured out into the capsules from an arbitrarily calibrated microburet. Concordant results were then readily obtained. By varying the experimental procedure it was shown that the heat evolved on adding the aqueous solution of citric acid to the

sulfuric acid had no effect on the reaction velocity. Later a solution of citric acid in approximately 80% sulfuric acid was used in order to eliminate any possibility of citric acid crystallizing before dissolving in the reaction mixture. Obviously, the water thus added with the citric acid was always included in calculating the strength of the sulfuric acid.

Results

Completeness and Order of Reaction.—In the preparation of acetonedicarboxylic acid by the decomposition of citric acid in fuming sulfuric acid yields of 92–97% have been reported.[13] The decompositions effected in this research always gave the theoretical yield of carbon monoxide within the limits of experimental error, except that in solutions containing more than about 0.5% sulfur trioxide the reaction is only about 80% complete. For example, four experiments at 25° in 96.46% H_2SO_4 gave an average of 46.65 cc. of carbon monoxide compared with the theoretical yield of 46.60 cc., while from four samples at 15° in 97.34% H_2SO_4 was evolved an average of 41.63 cc. compared with 41.70 cc. for quantitative decomposition. At the end of the experiments the sulfuric acid was nearly always colorless, indicating the absence of side reactions due to oxidation.

The decomposition of citric acid, although undoubtedly involving reaction with sulfuric acid, follows the unimolecular law. This was indicated by the "constancy" of the velocity constants obtained at various times in any one experiment as illustrated by the data given in Table I. That the velocity constants were independent of the rate of shaking was demonstrated by the use of four shaking speeds.

TABLE I

A TYPICAL EXPERIMENT

t	x	$a - x$	$k \times 10^3$
2	7.8	34.6	102
4	14.2	28.2	102
6	19.2	23.2	100
8	23.4	19.0	100
10	26.8	15.6	100
12	29.4	13.0	99
14	31.7	10.7	98
16	33.4	9.0	97
22	37.3	5.1	96

At 50% decomposition $k \times 10^3 = 100$

The values of k in the above table were calculated by means of the equation for a unimolecular reaction

$$k = \frac{2.303}{t} \log \frac{a}{a - x}$$

---

[13] "Organic Syntheses," John Wiley and Sons, Inc., New York, 1925, Vol. V, p. 5

Volumes of carbon monoxide were substituted for concentrations of citric acid and the time t is in minutes. The concentration of water has been expressed in molality, *i. e.*, the number of moles of solute per 1000 g. of solvent.

It will be observed that the velocity constants in Table I fall off slightly. This is due to the water formed during the reaction, for at higher concentrations of sulfuric acid, where the reaction is much more sensitive to small amounts of water, the velocity constants decreased still more, while in more dilute solutions the values of k scarcely changed at all. The third product of the decomposition, acetone-dicarboxylic acid, may also contribute to the falling velocity constant. The addition of 0.047 molality acetone-dicarboxylic acid (equivalent to that formed during an experiment) to a reaction mixture containing 1.04 molality water changed $k \times 10^3$ from 78.2 to 65.3 at 25°, whereas an equal quantity of water would decrease $k \times 10^3$ to 67.7. Thus this acid appears to be fully as strong an inhibitor as water.

Independence of the velocity constant of the initial concentration of the reactant is another criterion of a unimolecular reaction. In 98.16% H_2SO_4 at 25° the average values of $k \times 10^3$ obtained with initial concentrations of citric acid of 0.051 and 0.027 molality were 77.2 and 80.5, respectively. The difference is small and almost within the limits of experimental error. The reaction is also apparently homogeneous since the addition of 5 g. of clean, dry sand to the reaction mixture had no effect.

The Effect of Water on the Reaction Rate.—In the hope of determining the mechanism of the inhibition by water and other substances, a

study was made of the influence of water on the velocity of decomposition. The data obtained are summarized in Tables II, III and IV, and are represented graphically in Fig. 1. Each value of the velocity constant is the average of those obtained at 50% decomposition in from three to twelve experiments.

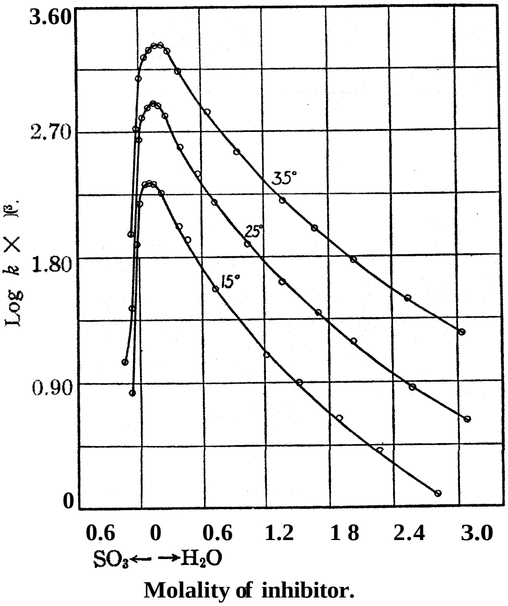

Fig. 1.—Effect of sulfur trioxide and of water on the reaction rate.

From the data it can readily be seen that small amounts of water in excess of a certain minimum concentration have a very marked retarding effect on the reaction rate, the relative effect decreasing as the concentration of water increases. Similar results have been obtained by previous investigators, particularly Lichty, who found the decomposition of oxalic acid to be even more sensitive to water.

The curves for the reaction rate at various concentrations of water at 15. 25 and 35° (Fig. 1) exhibit a maximum at molalities of about 0.10, 0.14 and 0.20, respectively. This entirely unexpected result has not been observed with the other acids that have been studied and was at first rejected as being due to the measurement of the rate of solution of citric acid in sulfuric acid instead of the rate of reaction. The work was repeated using, instead of a water solution of citric acid, an 80% sulfuric acid solution in which the decomposition at ordinary temperature is negligible. On dropping the capsule containing 0.7 cc. of this solution into 20 cc. of approximately 100% sulfuric acid there can be no crystallization or precipitation of the citric acid since the solubility[14] of citric acid in aqueous solutions of sulfuric acid reaches a minimum at approximately 60% acid and then increases with increase in sulfuric acid content. It was thought that possibly the maximum really corresponded to 100% sulfuric acid and that the analysis of the acid was incorrect, but a careful rechecking of the analysis gave the same result as found originally. Furthermore, the melting point of a sulfuric acid mixture made up exactly as in carrying out a decomposition in 100% sulfuric acid, except for the replacement of the aqueous citric acid solution by a carefully weighed equivalent amount of water, was 10.42°, corresponding to the melting point of 100% acid. In addition the velocity of decomposition of oxalic acid at 25° was measured in a 100% sulfuric acid solution made by mixing the calculated amounts of 100.50% and 95.44% acids. Since oxalic acid yields equal volumes of carbon monoxide and carbon dioxide, the gases were collected over a saturated magnesium sulfate solution which had been saturated with carbon dioxide at 25°. The average of three experiments gave $k \times 10^3 = 18.0$ at 50% decomposition. By interpolation the data of Lichty[15] give **17.4** and 12.0 for $k \times 10^3$ at 50% decomposition in 100% and 99.99% sulfuric acids, respectively. Thus the acid mixtures used in these experiments were in error, on the basis of Lichty's acids, by less than 0.01% sulfuric acid, which is much less than the error involved in analysis.

It was observed that the inhibiting effect of water might be decreased by the addition of another substance. At 25° in the presence of 0.56 molality water $k \times 10^3$ is 248. When only 0.032 molality anhydrous oxalic acid was added to such a mixture, $k \times 10^3$ became 260. Possibly the oxalic acid removes some of the water through hydrate formation.

The Effect of Sulfur Trioxide on the Reaction Rate.—Since Lichty[15] observed that the decomposition of oxalic acid proceeded more rapidly in a solution containing 1% excess sulfur trioxide than in 100% sulfuric acid, while Whitford[11] found that 1% free sulfur trioxide had no effect on the velocity of decomposition of malic acid and 12.5% decreased the rate to about 60% of that observed in 100% sulfuric acid, it was important to determine the effect of the free oxide in the case of citric acid. The data obtained are given in Table V and shown graphically in Fig. 1

as a continuation of the curves for the effect of water. The marked inhibiting effect of sulfur trioxide, even greater than water, was rather unexpected but it fits in very well with the finding of the maximum discussed in the preceding section.

The Effect of Temperature on the Reaction Rate.—Schierz and Dittmar indicate that the temperature coefficients for the decomposition of formic and triphenylacetic acids change very irregularly with the concentration of the sulfuric acid. To show that these apparent irregularities are probably due to experimental error the temperature coefficients for the decomposition of citric acid have been calculated. The curves in Fig. 1 were plotted on a much larger scale and the value of the temperature coefficient at various molalities of water was readily obtained from the distance between two curves. From the integrated form

$$E = \frac{1.98\, T_2 \times T_1 \times 2.303 \log k_2/k_1}{T_2 - T_1}$$

of the Arrhenius equation expressing the relation between the absolute temperature and the reaction velocity constant, k, the "critical increment" or "energy of activation," E (in calories), was calculated. The results are shown in Table VI, where each value of the temperature coefficient is the average of those obtained from three separate sets of curves.

TABLE VI

TEMPERATURE COEFFICIENTS OF THE WATER INHIBITED REACTION

Molality of water	Temperature coefficient k_{25}/k_{15}	 k_{35}/k_{25}	"E" in calories 15–25'	 25–35'
0.4	3.92	3.53	23200	22900
.6	4.09	3.70	23900	23800
.8	4.29	3.70	24800	23800
1.0	4.30	3.76	24800	24100
1.2	4.31	3.81	24800	24300
1.4	4.27	3.86	24700	24600
1.6	4.29	3.92	24800	24800
2.0	4.32	3.92	24900	24800
2.2	4.31	4.03	24800	25300
2.4	4.29	4.09	24800	25600
2.6	4.34	4.13	24900	25800
2.8	4.41	4.12	25200	25700

A study of the table reveals the fact that for the same temperature interval the temperature coefficient increases as the amount of water increases, although several values are slightly less than that at the preceding smaller molality of water. These differences, however, are comparatively small and well within the limits of experimental error. Furthermore, it is very difficult to draw a smooth curve that will average the errors in all the experimental points. The large irregularities observed by the other investigators do not manifest themselves in this investigation; in fact, when the temperature coefficients for the decomposition of triphenylacetic acid are calculated as above from Dittmar's data, the same rather regular increase in temperature coefficient with increase of water is obtained. The value of the critical increment, theoretically, is practically a constant quantity for a given reaction and it is interesting to note that there is fairly good agreement between the two values of the activation energy at a given concentration of water.

Discussion

The decomposition of citric acid, as with the other organic acids investigated, is probably best explained by the assumption of an unstable sulfuric acid–citric acid complex. From a study of the solubility of citric acid in various concentrations of aqueous sulfuric acid, Knox and Richards[14] concluded that the two acids form a molecular compound. That the compound is sufficiently stable so that indications of its presence may be obtained might seem to be an argument against its playing a role in the decomposition of citric acid. However, in the aqueous solutions employed, the unstable citric acid–sulfuric acid complex is stabilized by water, which is a powerful inhibitor of the decomposition, possibly through hydration, of which the solubility measurements give no indication.

Whitford and Dittmar have pointed out that the velocity of decomposition in sulfuric acid of the organic acids already investigated is apparently related to the strength of the acid as measured by its acid dissociation constant. On this basis the rate of reaction in the case of citric acid should be less than for malic acid, whereas experimentally a considerably higher value is found. This would indicate that there are other factors besides acid strength to be taken into consideration.

Since in 100% sulfuric acid there undoubtedly exists the equilibrium[16] represented by the equation $H_2SO_4 \quad H_2O + SO_3$, and since sulfur trioxide was found to be a more powerful inhibiting agent than water, an explanation readily suggests itself for the maximum in the curves showing the effect of water. As successively smaller amounts of water are used the reaction mixture approaches 100% sulfuric acid and the velocity of decomposition increases until a point is reached at which there is sufficient dissociation of the sulfuric acid into sulfur trioxide so that the accelerating effect produced by decreasing the water content is more than offset by the stronger inhibiting influence of the sulfur trioxide, and the reaction rate decreases. In agreement with this explanation, the maximum in the curves in Fig. 1 is shifted in the proper direction by an increase in temperature.

The action of the inhibitors may be explained on the basis of Taylor's theory[2] of negative catalysis in which it is postulated that the added substance decreases the concentration of the active mass of one or more of

[16] Christiansen, *J. Phys. Chem*, **28**, 145 (1924); *Trans. Faraday Soc.*, **24**, 596 (1928)

the reactants through compound formation. In the present case water and sulfur trioxide would be assumed to form molecular complexes with either sulfuric acid or citric acid, or with both. Such compounds are, of course, well known.

The mechanism of inhibition in the decomposition of organic acids by sulfuric acid will be discussed in detail in a later paper.

The author takes great pleasure in acknowledging his indebtedness to Professor Hugh S. Taylor for his kindly interest in the problem and to Princeton University for supplying adequate facilities for its prosecution.

Summary

The decomposition of citric acid by sulfuric acid has been found to be quantitative and to follow the unimolecular reaction law.

Small amounts of water and of sulfur trioxide both have a pronounced inhibiting influence on the velocity of decomposition.

As the concentration of sulfuric acid was increased, the reaction rate increased until a maximum, varying with temperature, was reached; further removal of water decreased the rate. No such maximum has previously been reported.

For a ten degree rise of temperature the temperature coefficient is approximately 4, and it increases fairly regularly as the water content of the sulfuric acid is increased.

The decomposition is assumed to proceed through the formation of an unstable citric acid–sulfuric acid molecular complex. Inhibition by water and sulfur trioxide may be accounted for on the basis of Taylor's theory of negative catalysis.

THE EFFECT OF SULFUR TRIOXIDE ON THE DECOMPOSITION OF OXALIC ACID BY SULFURIC ACID

BY EDWIN O. WIIG[1]

RECEIVED AUGUST 11, 1930 PUBLISHED DECEMBER 18, 1930

The effect of water, and certain other substances, on the decomposition of oxalic, formic, malic, o-benzoylbenzoic, triphenylacetic and citric acids[2] by sulfuric acid is to inhibit to a marked degree the velocity of reaction. This would indicate that the reaction mechanisms are analogous. There is one notable exception, however, in the similarity of the inhibiting effects of added materials. Lichty[2b] observed, qualitatively,

that 1% of sulfur trioxide greatly increased the velocity of decomposition of oxalic acid whereas Whitford[2d] found 1% of sulfur trioxide to have no effect, while 12.5% decreased the reaction rate in the case of malic acid to about 60% of that observed in 100% sulfuric acid. In the decomposition of citric acid[zg] sulfur trioxide has a very marked inhibiting influence, much greater than water. It was pertinent, therefore, for the theories of negative catalysis involved in these reactions to determine quantitatively the effect of sulfur trioxide on the rate of decomposition of oxalic acid.

Apparatus and Materials

The velocity of decomposition of oxalic acid was followed by observing the volume of gas (carbon monoxide and dioxide) evolved at various times during an experiment. The apparatus and procedure employed were the same as in the previous investigation.[2g] The sulfuric acid mixtures were made up as before, except that those marked "approximate" in the data were prepared by mixing the calculated weights of 30% fuming and c. p. 96% acids. These mixtures may be in error by as much as 2% sulfur trioxide but are sufficiently accurate to indicate the trend of the velocity constants with change in acid concentration. The oxalic acid (Kahlbaum's "zur Analyse") was dissolved in 95% sulfuric acid, in which the decomposition is negligible, and 0.7 cc. of this solution used in an experiment. Where necessary the water thus added was taken into consideration in calculating the final sulfuric acid concentration.

Results

As Lichty has shown that the decomposition of oxalic acid follows the unimolecular law, the velocity constants were calculated by the usual equation. The data obtained at 15 and 25° are given in Table I, where

TABLE I

EFFECT OF SULFUR TRIOXIDE ON THE VELOCITY OF DECOMPOSITION OF OXALIC ACID BY SULFURIC ACID

each value is the average of $k \times 10^3$ at 50% decomposition obtained in three or four experiments. In 100% sulfuric acid $k \times 10^3$ is 18.0, which agrees very well with the value of 17.4 obtained by interpolation from Lichty's data. The results given in the table, together with the data of Lichty, are represented graphically in Fig. 1. For comparison part of the analogous curve for citric acid has been reproduced in the figure.

It will be observed that the rate of decomposition of oxalic acid in sulfuric acid increases with increase in sulfur trioxide until a maximum is reached in about 14% fuming acid, after which the rate falls off slightly. As the velocity of decomposition is extremely rapid at 25° ($t_{1/2}$ is of the order of one-third minute at 14% SO_3), a series of experiments was performed at 15° to confirm the maximum observed at 25°.

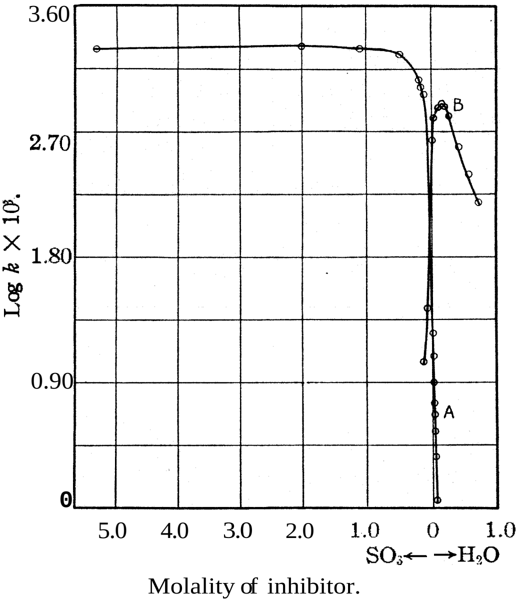

Fig. 1.—Effect of sulfur trioxide and of water on the reaction rates of oxalic and citric acids. A—oxalic; B—citric.

Discussion

The results obtained for the effect of sulfur trioxide on the decomposition of oxalic acid by sulfuric acid appear to conform with the analogous effects in the case of citric and malic acids. From the figure it may be seen that water has an extremely large inhibiting influence on the decomposition of oxalic acid while sulfur trioxide is a very weak inhibitor, as shown by the slight falling off in the velocity at a molality of 5.3. The increase in the reaction rate on increasing the sulfur trioxide molality from 0 to 2.0 may be attributed to a decrease in concentration of minute amounts of water formed by the thermal dissociation of sulfuric acid (H_2SO_4 $H_2O + SO_3$) rather than to an accelerating effect of sulfur trioxide. The slope of the curve for the effect of water on the oxalic acid decomposition would indicate the plausibility of such an assumption. An analogous explanation was given to account for the maximum in the citric acid curve. Christiansen[3] has previously pointed out that displacement of the equilibrium H_2SO_4 $SO_3 + H_2O$ may determine the rate at which oxalic acid decomposes, but he also sug-

---

[3] Christiansen, J. *Phys. Chem.*, 28,145 (1924); *Trans. Faraday Soc.*, 24,596 (1928).

gests that the reaction actually measured may be between oxalic acid and SO_3 or some other "sulfuric acid" which is less hydrated than H_2SO_4.

If the equilibrium constant at 25° for the reaction H_2SO_4 H_2O + SO_3 were known, the concentration of water and of sulfur trioxide inhibiting, respectively, the oxalic and citric acid reactions in 100% sulfuric acid could be calculated. Fortunately there are sufficient data available in the literature so that such a calculation may be made.

Bodenstein and Katajama[4] have studied the thermal dissociation of sulfuric acid in the gas phase. From the empirical equation which they give for the variation of the equilibrium constant with temperature, K_c (in moles/liter) may be calculated for the constant boiling acid (317°).[5] Since the vapor and liquid of a constant boiling mixture have the same composition and since the liquid analyzes 98.54% H_2SO_4, the concentration of sulfur trioxide, water and sulfuric acid in the gas phase may be obtained. The same ratio must hold for the liquid, from which the composition of the mixture, expressed in molalities, is calculated to be $H_2O = 3.976$, $SO_3 = 2.815$, $H_2SO_4 = 10.20$. These data readily give K, expressed in molalities, for the liquid at 317'.

The equilibrium constant at 25° may now be calculated by means of the equation of the reaction isochore[6] $d \ln K/dT =$ AH/RT^2. To make use of the integrated form of this equation, it is necessary to know the heat of reaction and the specific heats of the substances involved over the temperature range 25–317°. From heats of formation,[7] the heat absorbed by the reaction $H_2SO_4(l) \longrightarrow H_2O(l) + SO_3(l)$ is found to be 20,290 calories at 18°. The known specific heats[S] (in joules/gram) are $H_2O(l) = 4.18–4.35$ from 20 to 300° and $H_2SO_4(l) = 1.42 + 0.0016t$ from 10 to 45°. The specific heat of $SO_3(l)$ was estimated to be about 1.40 from analogy with SO2 (= 1.37–1.43 from 20 to 40°) and from the similarity in specific heats of $H_2SO_4(l)$ and $H_2S_2O_7(l)$ (=1.4 at 35°). The values for the specific heats used in the calculations are $H_2O(l) = 4.18$, $H_2SO_4(l) = 1.45$, $SO_3(l) = 1.4$; these values are probably sufficiently accurate. At 25° the value $1.09 \text{ X } 10^{-8}$ was found for K. This gives for the water and sulfur trioxide concentrations[9]

[7] "International Critical Tables," Vol. V, pp. 176–178.

[8] "International Critical Tables," Vol. V, pp. 106, 113, 114.

[9] The calculation is, of course, only approximate since it has been tacitly assumed that the molecular species in the gas and liquid phases of the constant-boiling mixture are the same and that 100% sulfuric acid at 25° is not polymerized. If these factors could be taken into consideration, smaller values for the concentrations of sulfur trioxide and of water in 100% sulfuric acid would be obtained. The indicated concentrations are therefore maxima but they show very well the tremendous influence of minute amounts of inhibitors.

in 100% sulfuric acid a molality of 3.3×10^{-4}, which corresponds to 0.0026% SO_3 and 0.0006% H_2O. The concentrations of the stronger of the two inhibitors at the maxima of the two curves must be still smaller. By extrapolating the curve for the effect of water on the citric acid reaction rate to zero water, $k \times 10^3$ is found to be about 1800. Thus 0.0026% SO_3 decreases $k \times 10^3$ from 1800 to 440 in the case of citric acid. On the assumption that sulfur trioxide is not an accelerator for the oxalic acid reaction but that water is the inhibitor, a concentration of 0.0006% water reduces $k \times 10^3$ from about 2000 to 18.

It is interesting to note that the maxima in the two curves correspond to a minimum and a maximum in electrical conductance. The maximum in the citric acid curve is at about 0.25% water while Knietsch[10] and Kohlrausch[11] found a maximum in electrical resistance for aqueous resistance for aqueous sulfuric acid solutions at 0.05–0.10 and 0.25–0.26% water, respectively. Similarly in fuming acids Knietsch found a minimum in electrical resistance at 14–16.7% sulfur trioxide whereas oxalic acid decomposes most rapidly at about 14% sulfur trioxide.

Inhibition in the decomposition of organic acids by sulfuric acid is best explained by Taylor's theory[12] of negative catalysis. The experimental results for the effect of sulfur trioxide on the oxalic, malic and citric acid reactions are shown by the present work to be in accord with that theory. A discussion of the application of Taylor's theory of negative catalysis to these reactions will be given in another paper.

The writer wishes to express his gratitude to Professor Hugh S. Taylor for his interest in the progress of the work.

Summary

The rate of decomposition of oxalic acid has been studied in sulfuric acid mixtures containing from 0 to 30% free sulfur trioxide. The maximum velocity is obtained at about 14% sulfur trioxide (2.0 molality).

The data have been interpreted to indicate that sulfur trioxide is not a positive catalyst for the reaction but merely decreases the concentration of water, which is a very powerful inhibitor, the sulfur trioxide in this case being a relatively weak inhibitor.

INHIBITION IN THE DECOMPOSITION OF ORGANIC ACIDS BY SULFURIC ACID

BY EDWIN O. WIIG[1]

RECEIVED AUGUST 11, 1930 PUBLISHED DECEMBER 18, 1930

The most outstanding group of negative catalytic reactions in homogeneous solution to which Taylor's theory of negative catalysis appears to apply is probably that which deals with the decomposition of organic acids by sulfuric acid. The results of the first intensive study of inhibition in these reactions were published by Bredig and Lichty in 1906. Within the past few years, principally through the efforts of Professor Walton and his students at Wisconsin, several other reactions of this type have been investigated. There are now data available for the effect of inhibitors on the velocity of decomposition of six organic acids in sulfuric acid. In addition to the well-known investigation of Bredig and Lichty[2] on the decomposition of oxalic acid, studies have been made of the reaction of sulfuric acid with formic,[3] malic,[4] *o*-benzoylbenzoic,[5] triphenylacetic[6] and citric[7] acids. In addition, the influence of inhibitors on the temperature coefficient of the malic acid[8] reaction and the effect of sulfur trioxide on the decomposition of oxalic acid[9] have been measured. In view of the increasing interest in inhibited reactions in general, the data covering the decomposition of organic acids in sulfuric acid have been deemed sufficient to warrant an analysis of the experimental results, together with a discussion of the application, of Taylor's theory[10] of negative catalysis.

The decompositions mentioned above all follow the unimolecular reaction law in spite of the fact that sulfuric acid would seem to be one of the reactants. This may be due to the large excess of sulfuric acid always employed, since under such conditions the change in its concentration in a single experiment would be negligible. On the other hand, the reaction may be a true unimolecular decomposition if we consider that the reaction whose velocity is actually measured is the decomposition of a sulfuric acid–organic acid complex. The velocity constants obtained are not,

however, always constant but often decrease considerably. As the reaction being studied always produces water or other inhibitors, a falling velocity constant is to be expected. The magnitude of the decrease in the velocity constant depends on the extent to which the substance formed inhibits. Thus, in the decomposition of oxalic acid[2] in 100% sulfuric acid at 25°, $k \times 10^3$ decreases from 21.5 to 11.9 during a single experiment. This is in agreement with the observation that water is an extremely powerful inhibitor of the reaction. In contrast with this, water is a comparatively weak inhibitor for the condensation of o-benzoylbenzoic acid and, as might be predicted, the water formed during the reaction does not cause a measurable decrease in the velocity constant. Furthermore, where a reaction displays sensitiveness to the small quantity of water formed during the experiment, this sensitiveness vanishes in the more dilute sulfuric acid solutions used.

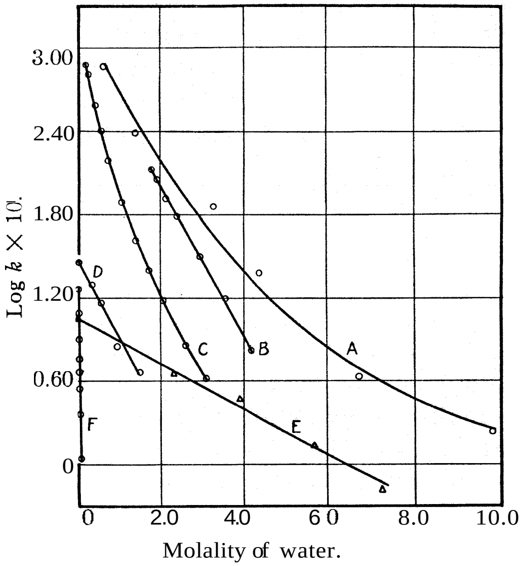

Fig. 1.—Effect of water on the reaction rates of (A) formic, (B) triphenylacetic, (C) citric, (D) malic, (E) *o*-benzoylbenzoic and (F) oxalic acids. A, C, F at 25°; B at 12°; D at 30"; E at 75°.

Inhibition by Water.—The effect of water on the velocity of decomposition of the six acids investigated has been determined over wide concentrations and at temperatures varying from 12 to 98°. In Fig. 1 there is presented one curve for each acid showing the influence of water on the reaction velocity at 25° or as near thereto as the data permit. The values used in plotting the curves are those given in the original papers except in the case of formic and o-benzoylbenzoic acids. For the former the velocity constants of Schierz[3] were multiplied by 2.303 to obtain the ordinary velocity constant, but, for the latter acid, velocity constants are given at only one concentration of sulfuric acid. Fortunately, Gleason and Dougherty[5] have presented their experimental data in the form of a curve showing the percentage of o-benzoylbenzoic acid decomposed at four hours as a function of the sulfuric acid concentration. By substituting in the usual equation for a unimolecular reaction $a = 1$, $t = 240$ and $x =$ the fraction of o-benzoylbenzoic acid condensed, we obtain one value of the velocity constant for each concentration of sulfuric acid. In view of the small inhibiting effect of water in this reaction, one value is sufficiently accurate for purposes of comparison.

From the figure it may be seen that in all six cases the effect of water is an exponential function of the concentration. Gleason and Dougherty[5] concluded that for o-benzoylbenzoic acid the retarding action of added water is in direct proportion to the amount added, and that it would appear that the o-benzoylbenzoic acid condensation differs fundamentally from reactions of the oxalic acid type. However, the curve for *o*-benzoylbenzoic acid in Fig. 1 indicates that the velocity constant is a logarithmic function of the added water and consequently this decomposition is similar to the others. Although these reactions are all of the same type, they differ in sensitivity to inhibition by water. The influence of water, as measured by the slope of the curves, is greatest in the decomposition of oxalic acid and least for o-benzoylbenzoic acid. At small concentrations of water the relative effect is nearly the same for the other four acids. The strength of the acids, as measured by the ordinary acid dissociation constants, decreases in the order oxalic, citric, malic, o-benzoylbenzoic, formic, triphenylacetic. Thus it may be seen that there is apparently no relationship between the strength of the acid undergoing decomposition and the retarding action of water. However, there may be some question as to whether it is justifiable to carry over into sulfuric acid, for purposes of comparison, dissociation constants that were determined with water as the solvent.[11]

Inhibition by Sulfur Trioxide.—The influence of sulfur trioxide on the rate of decomposition has been studied for only three of the six acids under consideration. For a number of years there was an apparent inconsistency in the results obtained with this substance. Bredig and Lichty[2] found qualitatively that 1% SO_3 accelerated the decomposition of oxalic acid to such an extent that it could not be measured by the method they employed. Whitford,[4] working with malic acid, found 1% SO_3 to have no effect while 12.5% decreased the reaction rate. Recently the effect of sulfur trioxide has been determined in the case of citric[7] and oxalic[8] acids and now the results appear entirely concordant. Figure 2 shows graphically the experimental results that have been obtained.

It will readily be seen that the three curves conform in shape to a curve with a maximum. The position of the maximum and the slopes of the curve on either side of the maximum depend wholly on the relative inhibiting powers of water and of sulfur trioxide. The relative retarding effects may be summarized as in Table I.

Since there exists in sulfuric acid the equilibrium $H_2SO_4 \quad H_2O + SO_3$ and since the ratio of the relative inhibiting powers of water and of sulfur trioxide may have any value whatever, the maximum reaction ve-

locity may occur anywhere within a concentration range determined by the equilibrium. It may be predicted that when formic, triphenylacetir and *o*-benzoylbenzoic acids are studied over sufficiently great concentrations of water and of sulfur trioxide in sulfuric acid, a maximum analogous to those in Fig. 2 will be found in each case.

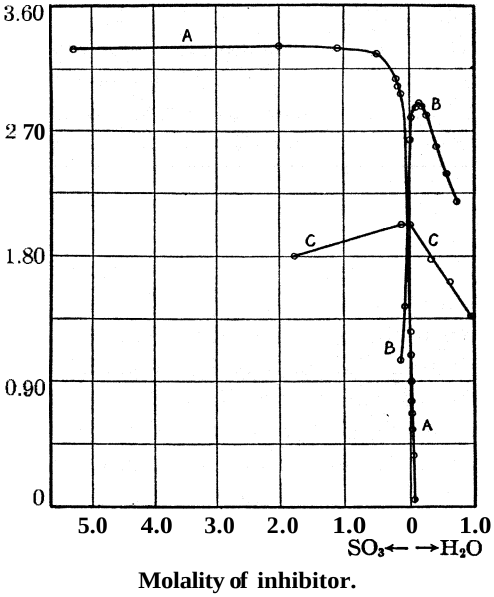

Fig. 2.—Effect of sulfur trioxide and of water on the reaction rates of (A) oxalic, (B) citric and (C) malic acids. A, B at 25°; C at 40°.

Relative Rates of Decomposition.—-Attempts have been made to find some relationship between the velocity of decomposition of the organic acids and their strength. For the acids studied up to 1925 Whitford[4] gives the following table, where the velocity constant is for the reaction in 0.562 molality of water at 50°.

Dittmar[6] added triphenylacetic acid to this list since he found that it decomposes more rapidly than formic acid and is the weakest acid of the four. Also, Dittmar points out that the reaction velocities increase in the order of decreasing heats of activation as calculated from temperature coefficients by means of the Arrhenius equation. An inspection of the curves in Figs. 1 and 2 shows that such comparisons no longer hold when all the data now available are considered. The decomposition velocities vary so greatly with the concentration of water and of sulfur

TABLE II

RELATION OF ACIDITY TO REACTION VELOCITY

Acid	Dissociation constant	Velocity constant
Oxalic	3.8×10^{-2}	0.515
Malic	4.0×10^{-4}	158.5
Formic	2.1×10^{-4}	Reaction immeasurably fast

trioxide that the organic acids might be arranged in several orders of increasing reaction rates.

The original comparison of Whitford was based on Kendall's rule[12] that the tendency toward molecular compound formation between sulfuric acid and an organic acid varies with the acidity of the second acid. The decomposition of the organic acids which have been investigated is supposed to proceed by way of an unstable sulfuric acid–organic acid complex, so that Kendall's rule should apply here *provided* the mere tendency toward compound formation can be assumed to govern the velocity of reaction. We have just seen, however, that reaction velocity comparisons cannot be made (unless an extrapolated value for each acid in the total absence of inhibitors can be obtained). Furthermore, Kendall's rule is at the best qualitative. For example, Hoogewerf and van Dorp[13] isolated an addition compound of sulfuric acid with mesaconic acid ($K_A \times 10^4 = 8$), whereas Kendall and Carpenter[12] obtained no indication by the freezing point method of similar compound formation between sulfuric acid and α-chlorocrotonic acid ($K_A \times 10^4 = 7.2$). The structure of the organic acid, the presence of various groupings, steric hindrance, etc., may play a not inconsiderable role in molecular compound formation. In addition, as already mentioned, acid dissociation constants determined in water solution may not furnish a proper basis of comparison when the medium is sulfuric acid. It is not surprising, therefore, to find that there is no apparent relation between velocity of decomposition and the ordinary acid dissociation constant of the organic acids. Furthermore, no such relationship would be expected since the rate of decomposition of the organic acid-sulfuric acid complex would depend on its instability rather than the rate or extent of its formation.

The Effect of Miscellaneous Inhibitors.—The retarding influence of numerous substances other than water and sulfur trioxide has been studied. Whitford[4] and Dittmar[6] found, in agreement with Kendall's rule for compound formation, that sodium and potassium sulfates were stronger inhibitors than water for the decomposition of malic and triphenylacetic acids. However, in the case of oxalic acid, Bredig and Lichty[2] found that water was a slightly better inhibitor than potassium sulfate. Dittmar's data covering the effect of a large number of inhibitors on the velocity of decomposition of malic and triphenylacetic acids show analogous differences very convincingly. For example, ethyl alcohol is a better inhibitor than crotonic acid in the decomposition of triphenylacetic acid but the reverse is true in the case of malic acid. A similar relationship holds for the following pairs of inhibitors: phenol–*p*-cresol, ethyl alcohol–*o*-toluic acid, coumarin–o-toluic acid, benzophenone–o-toluic acid.

---

[12] Kendall and Carpenter, THIS JOURNAL, 36, 2506 (1914).

[13] Hoogewerf and van Dorp, *Rec. trav. chim.*, **18**, 211 (1899).

These results are not unexpected when we recall the wide variation in the relative effects of water and of sulfur trioxide on the decomposition of oxalic, malic and citric acids. If the action of an inhibitor depended solely on compound formation with sulfuric acid, then the same relative effects on the velocity of decomposition of the organic acids by sulfuric acid should be obtained. Since the experimental results show such marked differences in inhibiting power, it must be concluded that it is not sufficient to consider only the tendency toward compound formation with sulfuric acid in seeking for a mechanism of inhibition. In this connection Dittmar[5] points out that although phosphoric acid is an inhibitor for the decomposition of malic and triphenylacetic acids, no molecular compound of phosphoric and sulfuric acids has been shown to exist. On the other hand, Walton and Kepfer[14] have found, from solubility measurements, that phosphoric acid forms a molecular complex with malic acid. Dittmar concludes, therefore, that inhibition may be more satisfactorily explained by compound formation between malic acid and the inhibitor.

The Effect of Temperature.—Determinations of temperature coefficients have been made for the six organic acids whose decompositions have been studied but many of the values vary so much that they are not of much use for purposes of comparison. The chance for error is so large in these sulfuric acid systems that only by making careful measurements at a large number of sulfuric acid concentrations at two or more temperatures can dependable values of the temperature coefficient be obtained. In this way the experimental errors may be averaged, but in much of the data given in the literature this has not been taken into consideration. However, it may be stated that, in general, the addition of an inhibitor increases the temperature coefficient, and increase in concentration of the inhibitor increases the temperature coefficient. Where there are exceptions to these statements, and there are several, more data are usually needed before a definite decision may be made.

Dittmar[5] has determined the temperature coefficients for the decomposition of malic acid by sulfuric acid in the presence of a large number of inhibitors and finds that, in general, the temperature coefficient is greater than that for 100% sulfuric acid. Also, in the majority of the experiments the temperature coefficients increase with increase in inhibitor concentration. This last generalization holds very well for citric acid[7] also, where the data for the effect of water are sufficiently complete so that the trend of the temperature coefficient may be seen. The results are thus in general agreement with Dhar's[15] statement that a negative catalyst increases the temperature coefficient of a reaction. In the event

---

[14] Walton and Kepfer, J. *Phys. Chem.*, 34, 543 (1930).

[15] Dhar, *ibid.*, 28, 951 (1924).

that these reactions follow a chain mechanism, the agreement with Dahr's rule may be only fortuitous, since at present the temperature coefficient of a chain reaction has no theoretical significance.

Mechanisms

Of the Decomposition.—It is rather generally agreed that the decomposition of oxalic, formic, malic, triphenylacetic, o-benzoylbenzoic and citric acids is brought about by the formation of an unstable sulfuric acid–organic acid complex (oxonium compound) which subsequently breaks up into the reaction products and sulfuric acid. The process may be represented by the equations

$$\text{Organic Acid} + H_2SO_4 \rightleftharpoons \text{Organic Acid}\cdot H_2SO_4 \quad (1)$$

$$\text{Organic Acid}\cdot H_2SO_4 \longrightarrow \text{Products of decomposition} + H_2SO_4 \quad (2)$$

The experimentally determined velocity would be that of the second reaction, which is dependent on the concentration of the molecular complex. Thus, it is evident that these reactions are not to be considered as simple dehydrations. This is convincingly shown by the fact that the decomposition of triphenylacetic acid by sulfuric acid involves no water at all, the products being triphenylcarbinol and carbon monoxide.

There is also the possibility that the formation of the simple organic acid–sulfuric acid complex is not in itself sufficient for decomposition, especially in view of the fact that evidence for the existence of these compounds has been obtained in the case of oxalic, citric and malic acids from solubility data. It may he that addition of another molecule of sulfuric acid at a second point in the organic acid (which is possible since the acids all contain two or more oxygen atoms) is required to produce sufficient strain to cause a rupture of the atomic linkages. This process would also give a unimolecular reaction. The effect of inhibitors would be the same in the two cases. However, this mechanism really has nothing to recommend it as being better than the simpler one given first. Moreover, the data which indicate compound formation of oxalic,[16] malic[8] and citric[16] acids with sulfuric acid have been obtained in aqueous solutions where it is quite possible that these molecular compounds are also combined with water, a possibility of which the method employed can give no evidence.

Of Inhibition.—The retardation of the velocity of decomposition of organic acids in sulfuric acid by the addition of a third substance may best be explained by what has come to be known as Taylor's theory[10] of negative catalysis. The Titoff concept, according to which a negative catalyst acts by suppression of a positive catalyst, certainly does not hold for these reactions, especially when one considers the positions of the maxima in the curves for citric, malic and oxalic acids in Fig. 2. Like-

---

[16] Knox and Richards, *J. Chem. Soc.*, 115,508 (1919)

wise, as pointed out by Christiansen[17] for the decomposition of oxalic acid in sulfuric acid, the chain reaction theory does not appear to be applicable to these inhibited decompositions, though there is no direct experimental evidence on which to base such a conclusion. That chain reactions may occur in solution is shown by the work of Bäckström[18] and of Alyea and Bäckström[19] on the oxidation of sodium sulfite solutions. The reaction between mercuric chloride and the oxalate ion in aqueous solution also appears to be a chain reaction.[20] It is not impossible, therefore, that the decomposition of organic acids in sulfuric acid may be chain reactions.

Deactivation by mere collision of the inhibitor with organic acid–sulfuric acid complexes which have acquired sufficient energy to undergo reaction also seems to be out of the question. In this case inhibition would depend only on the number of free molecules of the negative catalyst. At a given concentration of inhibitor, then, approximately the same relative decrease in the velocity of decomposition should be observed for all the acids whereas the actual effect. vary greatly. This difficulty might be obviated by assuming a specific deactivating effect for each molecular complex, but then we really approach momentary compound formation instead of mere physical impact.

The mechanism of negative catalysis proposed by Taylor[m] is the direct opposite of that for positive catalysis in homogeneous reactions in solution where the reaction proceeds more readily by way of the intermediate compound, In negative catalysis the intermediate compound diverts one or more of the reactants from the main reaction, thus decreasing the active concentration of the reactants and slowing down the reaction velocity. According to the theory the function of inhibitors must be, in the present case, to bring about a decrease in the concentration of the unstable critical complex-organic acid·H_2SO_4. The concentration of the unstable complex is determined by the equilibrium represented in Equation 1. Consequently, its concentration may be reduced by a decrease in the concentration of (1) H_2SO_4, through the formation of H_2SO_4·Inhibitor, and (2) the organic acid, through the formation of Organic Acid·Inhibitor. A third possibility is that the active concentration of the complex, Organic Acid·H_2SO_4, may also be lowered by reaction of the addition compound itself with the inhibitor. It is evident then that inhibition may be brought about by any one, or various combinations, of the above three possibilities. However, by a consideration of the experimental data some of these mechanisms would seem to be eliminated.

(a) Inhibition Due only to H_2SO_4 + Inhibitor $H_2SO_4 \cdot$Inhibitor.—That this possibility must be discarded has already been shown by the discussion in the section dealing with the effects of miscellaneous inhibitors. In case of inhibition by sulfur trioxide, for example, if compound formation with sulfuric acid were the only factor, then the effects with oxalic, malic and citric acids should be similar. Experimentally it is found that for the decomposition of citric acid sulfur trioxide is a very strong inhibitor, in the malic acid reaction a fair inhibitor, and for the oxalic acid decomposition an extremely weak inhibitor only after the concentration exceeds 14% SO_3.

(b) Inhibition Due only to Organic Acid + Inhibitor Organic Acid·Inhibitor.—The same sort of argument that was used to eliminate the preceding mechanism would appear to apply here. Kendall's rule for compound formation seems to work fairly well for hydrates of the acids but the inhibiting effect of water does not vary with the strength of the organic acid, as has previously been indicated. Similarly the very diverse effects of sulfur trioxide on the oxalic, malic and citric acid reactions seem to preclude the possibility that compound formation between the inhibitor and the organic acid determines completely the retarding action. Furthermore, Dittmar[5] found that o-toluic acid is a better inhibitor for the malic acid reaction than phosphoric acid, which has been shown to form a compound with malic acid, whereas compound formation between malic and o-toluic acids is scarcely to be expected since they are of nearly the same acid strength ($K_A \times 10^4$ is 4.0 and 1.25, respectively). While it would seem that compound formation between the organic acid and the inhibitor cannot be the only factor governing inhibition, still it must be admitted that there are weaknesses inherent in the reasons just advanced. Part of the argument depends on the use of the ordinary dissociation constants of the acids but the comparisons are made for sulfuric acid as the solvent, instead of water. Again, the effect of an inhibitor, o-toluic acid for example, in 100% sulfuric acid might be to change the H_2SO_4 $H_2O + SO_3$ equilibrium (by combination with either of the products). Then inhibition by o-toluic acid might be due to compound formation between water (or sulfur trioxide) and malic acid rather than between *o*-toluic and malic acids as we have supposed. However, the mechanism being discussed would seem to be eliminated definitely by the consideration, in the next section, of the extremely small concentrations of negative catalysts necessary for inhibition to manifest itself.

(c) Inhibition Due to Reaction of the Inhibitor with the Organic Acid·Sulfuric Acid Complex.—This postulate is so flexible that no experimental evidence may be adduced against it. If it be assumed that reaction of the negative catalyst with the fugitive complex is highly specific, then this mechanism must be in agreement with the observed effects for all the negative catalysts. Since the acid properties of the two acids in the oxonium addition compound are very probably altered, the assumption of specific inhibitor effects is reasonable.

There are several experimental facts that would seem to be in accord with this mechanism. The concentration of the critical complex must, of course, be very small, so that inhibition by very minute amounts of negative catalysts should be possible. Such inhibition is indicated in the case of oxalic and citric acids. It will be recalled that for citric acid[7] the maximum reaction velocity at 25° occurs at 0.14 molality of water (0.25%). The decrease in the velocity of decomposition at concentrations of water less than 0.14 molality was attributed to the presence of sulfur trioxide formed as a result of the reaction $H_2SO_4 \quad H_2O + SO_3$. The concentration of sulfur trioxide in 99.75% sulfuric acid must be vanishingly small since calculations[9] indicate that its concentration in 100% sulfuric acid is at the most of the order of 3×10^{-4} molality. An entirely analogous explanation holds for the finding of the maximum reaction velocity for oxalic acid[S] at a molality of sulfur trioxide of about 2.0. If inhibition is due to compound formation with the sulfuric acid or the organic acid, or even both, it is difficult to see how a concentration of inhibitor of the order of 10^{-4} molality can influence the concentration of the organic acid-sulfuric acid complex simply by diverting an extremely minute amount of sulfuric acid or organic acid from the main reaction. Even in higher concentrations of water, say **3.0** molality, the concentration of free water, resulting from the equilibrium $H_2SO_4 + H_2O \leftharpoondown H_2SO_4 \cdot H_2O$, must be small, so that inhibition by reaction of this free water with the fugitive complex would not be sufficient to bring the reaction to a full stop.

We may, of course, have all three inhibiting mechanisms operative at the same time, especially in the more concentrated inhibitor solutions. It would appear from the foregoing discussion, however, that the negative catalytic action must be due principally to reaction of the inhibitor with the intermediate compound through which the decomposition proceeds. The only weakness in this mechanism is that its great flexibility makes it very difficult to devise experimental tests.

In view of the present lack of any positive evidence for the existence of reaction chains in the decomposition of organic acids in sulfuric acid, it would seem that Taylor's theory of negative catalysis offers the only satisfactory explanation for the effect of inhibitors on these reactions. It is well to bear in mind, however, that no definite decision with respect to the applicability of the chain reaction theory can be made until more data are available.

In conclusion, the author wishes to acknowledge his indebtedness to Professor Hugh S. Taylor for valuable suggestions and criticisms.

DETERMINATION OF MAGNESIUM WITH 8-HYDROXYQUINOLINE – GRAVIMETRICALLY, VOLUMETRICALLY AND COLORIMETRICALLY

BY W. A. HOUGH AND J. B. FICKLEN

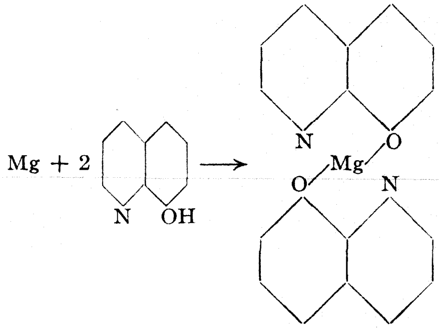
RECEIVED AUGUST 16, 1930 PUBLISHED DECEMBER 18, 1930

In an attempt to develop a quick method for the determination of magnesium in dilute solutions, particularly in boiler feed water analyses, the quantitative reaction which takes place in alkaline solution between the magnesium ion and a molar equivalent of 8-hydroxyquinoline with the formation of a light green precipitate was used.

Strebinger and Reif filtered off this salt through a Pregl filter tube, dried it at 105° for twenty minutes, and weighed it as $Mg(C_9H_6ON)_2 2H_2O$.[1]

The following methods diverge from that of Strebinger and Reif beyond the point where the green magnesium salt of 8-hydroxyquinoline is precipitated.

The reaction which takes place between the magnesium ion and 8-hydroxyquinoline is as follows



One part by weight of magnesium reacts with 11.9 parts by weight of 8-hydroxyquinoline.

An accurate standard solution of a magnesium salt which contained 0.1 gram of magnesium per liter was prepared.

The solution of 8-hydroxyquinoline was prepared by dissolving 0.5 g. in 100 cc. of alcohol and diluting to 1 liter. The solution obtained is of a bright yellow color.[2]

I. Gravimetric Method (**N. B.** Calcium must first be precipitated as oxalate and filtered off).—Take a sample containing at least 0.001 g. of magnesium and bring this sample to a volume of from 50 to 150 cc. Make ammoniacal with 20 cc. of ammonia reagent. Heat to 70° and add 100

---

[1] Strebinger and Reif, *Chemical Abstracts*, 24, 2397 (1930).

[2] Allen, "Commercial *Organic Analysis*," Vol. *V*, p. 657.

cc. of a solution of 8-hydroxyquinoline containing 0.5 of this salt per liter. If the amount of magnesium present exceeds 0.004 g., add a larger amount of 8-hydroxyquinoline solution for completeness of precipitation, and, if necessary, add more 8-hydroxyquinoline. An excess of 8-hydroxyquinoline is made evident by the yellow color in the filtrate. Wash the precipitate with a weak solution of ammonium hydroxide, ignite strongly for thirty minutes in a porcelain crucible, and weigh as magnesium oxide.

Various amounts of the standard magnesium solution from 10 cc. (0.0010 g.) to 75 cc. (0.0075 g.) were run as above, and the actual results varied slightly from the theoretical. On the higher ranges the agreement was highly satisfactory. On the lower ranges the slight inaccuracies were due to the limitations inherent in the gravimetric method—such as error in weighing and taring, loss through slight solubility of the salt, loss through escape during ignition, and possible variance in the tare of filter paper ash.

Amounts of magnesium less than 0.0010 g. are not determined to good advantage gravimetrically, on account of the magnification of the above mentioned errors in consequence of the small quantity of magnesium present.

The table shows how results obtained compared with the theoretical.

TABLE I

COMPARISON OF RESULTS

Mg taken, mg.........	1.0	1.5	2.0	2.5	3.0	3.5	4.0	4.5	5.0	7.5	10.0
Mg found, mg.........	1.1	1.7	2.3	2.7	3.1	3.3	3.9	4.3	5.0	7.5	9.9

Magnesium taken as solution containing 0.1 mg. per cc.

II. Volumetric Methods.—Reagents: Solution of potassium permanganate, 4.17 g. per liter; N sulfuric acid. Precipitate the magnesium salt as described above, and wash with ammonium hydroxide. Dissolve the precipitate in 100 cc. of hot N sulfuric acid by immersing filter paper and precipitate in the acid and stirring. Titrate against the potassium permanganate solution until the pink color persists for two minutes. When the end-point is approached, the permanganate solution should be added, 0.5 cc. at a time, and the fading timed with a watch. Each cubic centimeter of potassium permanganate solution used is equivalent to 0.0001 g. of magnesium.

Various amounts of the standard magnesium solution from 1 cc. (0.0001 g. of magnesium) to 50 cc. (0.0050 g. of magnesium) were run, and up to 0.0025 g. of magnesium the results were very accurate. Larger amounts of magnesium than 0.0025 g. caused the end-point to be obscured by colored oxidation products imparting a brown color to the solution. Magnesium in amounts up to 0.0025 g. is determined to very good advantage by this method. In amounts larger than this, the gravimetric method is preferable. Of course, the sample can be diluted and an aliquot taken in order to bring the amount of magnesium into the effective range if it is too high to work to good advantage volumetrically. The table shows how results obtained compared with the theoretical.

TABLE II

COMPARISON OF RESULTS

Each milligram of magnesium taken represents 10 cc. of sample; each milligram found represents 10 cc. of potassium permanganate solution

Mg taken, mg.	0.10	0.20	0.30	0.40	0 50	0.80	1.00	1.20	1.40
Mg found, mg.	.14	.20	.33	.41	.48	.80	0.98	1.17	1.36
Mg taken, mg.	1.60	1.80	2.00	2.50	3.00	3.50	4.00	4.50	5.00
Mg found, mg.	1.60	1.84	2.03	2.55	3.16	3.75	4 45	5.05	5 75

III. Colorimetric Method.—The sample should not be of greater volume than 50 cc. Make alkaline with 20 cc. of ammonia reagent and add exactly 60 cc. of a solution of 8-hydroxyquinoline. (This latter solution should be prepared quantitatively.) Filter and wash with a small amount of weak ammonia. Make the volume of the filtrate up to 150 cc. with distilled water. The depth of color in the filtrate, due to the uncombined 8-hydroxyquinoline, is inversely proportinoal to the amount of magnesium in the sample. This can be compared in a 100-cc. colorimeter, using the 8-hydroxyquinoline solution as a standard. Since 1 cc. of 8-hydroxyquinoline solution is equivalent to 0.0000416 g. of magnesium, the following calculation can be made

$$\left(60 - \frac{3 \times \text{Reading}}{2}\right) \times 0.0000416 \times \frac{1{,}000{,}000}{\text{vol. of sample (cc.)}} = \frac{\text{parts of magnesium}}{\text{per million}}$$

Or if a 50 cc. sample is taken, which does not contain more than 50 parts of magnesium per million, this may be written in the form

$$1.248 \times (40 - \text{Reading}) = \text{parts of magnesium, per million}$$
$$49.92 - (1.248 \text{ X Reading}) = \text{parts of magnesium, per million}$$

If the amount of magnesium is greater than 50 parts per million, a correspondingly smaller sample should be taken and calculation made on the basis of the reduced sample. (The use of a sample containing a greater amount of magnesium than this makes necessary the use of a larger amount of 8-hydroxyquinoline solution, and is not advisable for reasons of economy.)

A range of amounts from 0.0005 to 0.0050 g. of magnesium were run as described above, and the results are shown herewith, as compared to the theoretical.

TABLE III

COMPARISON OF RESULTS

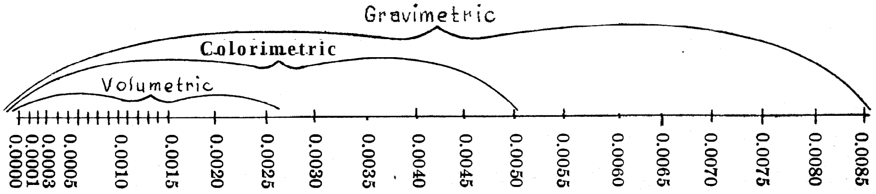
	8-Hydroxyquinoline							
	60 cc *used*					120 *cc. used*		
Mg taken, mg.	0.5	1.0	1.5	2.0	2.5	3 0	4 0	5 0
Reading.	28	24	18	10	5	18	9	4
Mg found, mg.	0.7	0.9	1.4	1.8	2.3	3.1	4.3	5.3

Summary

1. Quick determinations of magnesium can be made by precipitating it as the salt of 8-hydroxyquinoline and estimating the magnesium content of the salt either gravimetrically, volumetrically or colorimetrically. In many cases where the saving of time is an important factor and extreme accuracy is secondary, one of these methods may prove useful.

2. The most advantageous method to use depends on the amount of magnesium in the sample. (a) For amounts ranging from 0.0010 g. up to the highest concentrations, the gravimetric method is most accurate. (b) For amounts ranging from a minute trace up to 0.0025 g. the volumetric method is most accurate, and is very quick in comparison with many methods commonly used. (c) For amounts ranging from 0.0005 g. up to high concentrations (if proper aliquots are taken), the colorimetric method is very accurate and is the quickest of the three methods.

3. The following scale will illustrate at a glance the advantageous range of the three methods.



4. None of the other metals commonly found in natural waters will react with 8-hydroxyquinoline, except calcium.

THE EMISSION SPECTRA OF SOME SIMPLE BENZENE DERIVATIVES

BY J. B. AUSTIN[1] AND IAN ARMSTRONG BLACK[2]

RECEIVED AUGUST 19, 1930 PUBLISHED DECEMBER 18, 1930

The main features of the spectra obtained from the vapor of benzene and its simple derivatives under the excitation of the Tesla discharge have been described by McVicker, Marsh and Stewart,[3] who designated them as Tesla luminescence spectra to distinguish them from the fluorescence and absorption spectra. The present investigation was undertaken as an extension of this work; it was hoped on the purely chemical side to develop the suggestion made by them that a means of ascer-

taining the purity of an organic solvent, and the nature of any impurities present, could be elaborated. In this respect it has been shown that such a method is unwieldy in practice, except perhaps for routine work in which a large number of samples are to be tested. Its application to a qualitive analysis would be relatively simple since a mere comparison of the unknown spectrum with a series of spectra of suspected impurities would suffice, but unfortunately the number of substances which yield satisfactory spectra under this means of excitation is rather limited. For a quantitative estimation of the amounts of impurities present it is necessary to compare the intensities of the bands, a procedure which is rendered difficult by the presence of a continuous background in many of the spectra.

On the other hand, it was thought that more comprehensive data on such spectra could be obtained which, with an increased accuracy, might enable the regularities observed in the bands to be given some theoretical interpretation. In this object some success has been achieved. A great many new band heads have been recorded with an accuracy believed to be ±0.5 Å. or better, except in the case of the faintest and most diffuse bands.

The spectrum of benzene appears to be unique among the substances thus far investigated in that it possesses an unusual completeness, its bands are very sharp and there is little if any continuous background. Because of these features it has been given special attention and has been discussed in a previous paper.[4] The present paper describes the spectra of toluene, ethylbenzene and the xylenes.

It was our original intention to extend this work to some of the aliphatic compounds but all the substances investigated, including pentane, 2,2,4-trimethylpentane and acetylene gave unsatisfactory results. The molecules broke down into fragments yielding spectra similar to those obtained with the electrodeless discharge. These have been described elsewhere.[5]

Experimental

Each hydrocarbon was shaken with concd. sulfuric acid until no color was imparted to fresh acid; it was then washed successively with concd. sodium hydroxide, dilute sodium hydroxide and distilled water until the final wash water was neutral to litmus. The resulting product was dried over sodium and distilled. The several boiling points were as follows:

Toluene	110–111° at 758 mm.
o-Xylene	142–142 5° at 750 mm.
m-Xylene	137–138° at 750 mm.
p-Xylene	136–137° at 750 mm.
Ethylbenzene	136–137° at 770 mm.

[5] Austin, THIS JOURNAL, 52, 3026 (1930).

The materials as finally used appeared to be quite pure and were at least free from each other, since in no case did the spectrum of any one contain the spectrum of any other.

The apparatus used in obtaining and measuring these spectra is described in detail in our paper on benzene. In each instance the pressure of the vapor was of the same order of magnitude as that used in the benzene study, being about 0.05 mm. Various vacuum waxes and cements were used in sealing the window on the discharge tube but no difference in the spectrum was observed A Hilger size C quartz spectrograph, giving a photograph 200 mm. in length for the range 2100 to 7000 Å. was used throughout, with exposures ranging from three to twelve hours. Since the resolution of this instrument was not very great the lines in the bands were not resolved, therefore most of the bands appeared as band heads shading off toward the red. The measurements given in Tables I to V were made on the heads of these bands.

Results

The first column in Tables I to V gives the wave lengths of the band heads in Ångström units as measured by us, the second column those of McVicker, Marsh and Stewart and the third column our values expressed as wave numbers in cm.$^{-1}$ ($\nu = 1/\lambda$). Our values are in general in agreement with those of McVicker, Marsh and Stewart, in most cases the differences being within their limit of error.

Table I gives the data for the bands in the toluene spectrum, which contains, beside the bands, a continuous background starting sharply at A2667 and gradually shading out at about λ3100. The bands seem to be related in much the same way as are those of benzene but do not show the division into groups which is so evident in the latter.

The data for o-xylene are found in Table II. In this case the heavy background is the most prominent feature of the spectrum. It neither starts nor ends sharply but extends from about 12700 to 13300. No band groupings are apparent as with the other substances.

m-Xylene (Table III) also has a strong continuous spectrum superimposed on the band system. It begins sharply at A2700 and disappears at 13300.

The *p*-xylene bands (Table IV) are quite strong and are easily visible against the continuous background which starts sharply at A2750 and extends to 13300.

Discussion

It became evident early in the work that an analytical method based on the equipment described would be quite unwieldy. The apparatus is costly and rather troublesome to assemble and the time required to make a good exposure, at least three hours, is rather long; moreover, the decomposition of the vapors makes it necessary to use a new discharge tube for each exposure. However, to gain some idea of the possible utility of the method one trial analytical run was made on the contents of a bottle marked "xylene" which had been standing around the laboratory for some time. On comparing the spectrogram of this unknown with those of the three pure xylenes it was found that the unknown contained all three isomers. The continuous background rendered the task of estimating the amount of each hopeless.

Thus far our attempts to apply the formulas of modern band spectroscopy to these data have not met with success. The problem is very difficult, much more so than in the case of benzene, because comprehensive data of the required accuracy are not available. Even were these at hand the complexity of the emitting molecule would make their interpretation far from simple However, it is interesting to consider our results in the light of some of the older and less precise generalizations. The first of these was set forth by Staudinger.[6] All chemical substitution which displaces the bands toward the red diminishes the state of saturation of the molecule. The second was made by Henri.[7] Organic bodies which react most easily, that is, are most labile, possess the strongest ultraviolet bands.

---

[6] Staudinger, "Les Cetenes," Stuttgart, 1912, p 98

[7] Henri, *Compt.* rend., 156,1979 (1913).

Let us now apply the first law to our measurements. We may be sure that the extreme ultraviolet ends of the spectra are lacking because of the absorption by the unexcited vapor and therefore the terminations of the various spectra are not to be taken alone as criteria for displacement. We may, however, arrive at a more reliable standard for obtaining the shifts due to changes in composition by comparing certain sharp band heads which seem to correspond in each spectrum. On making such a comparison on our plates it appeared that the toluene bands are displaced to the red as compared to those of benzene. o-xylene showed an increased shift toward the red, while the *p*- and m-isomers were still further displaced. Ethylbenzene, however, gave a spectrum in the same general region as toluene

These shifts are confirmed by the spectra of these compounds in the solid at liquid-air temperatures[8] Under these conditions these band systems actually show terminal bands whose positions are easily compared. The shifts observed in these spectra are in agreement with the above results. The most significant difference is that the *p*-xylene is slightly, though definitely, shifted toward the red as compared to the m-compound.

Interpreted on the basis of Staudinger's law these shifts mean that benzene is the most saturated of the substances studied; toluene is less saturated; o-xylene is still less so, while the *p*- and m-isomers are the least saturated of all, which conclusions are borne out by the well-known chemical behavior of these compounds; this would indicate that the band spectra data are in complete accord with Staudinger's law.

When attention is directed to the law of Henri, an apparent difficulty arises at once, for the bands of benzene are easily the strongest and most complete, yet there can be no doubt as to the pronounced stability of benzene. This leads us to the conclusion that considerable care must be exercised in applying this "law" to organic compounds. One explanation of this apparent exception is that the intensity of the ultraviolet bands is dependent on the number of excited electrons, which, in general, is related to the relative ease of excitation. The chemical activity on the other hand depends on the ease with which electrons may be removed or shared, which is quite a different thing. Thus it may be possible to have an electronic structure capable of being easily excited by the proper radiation and yet resistant to actual change of configuration, *i. e.*, chemical reaction.

Another explanation of the unique character of the benzene bands may be sought in a study of the source of the emitted radiation. If it is assumed that each C and H atom can vibrate independently, there is at once an explanation of the greater intensity of the benzene bands.

---

[8] Data shortly to appear in the *Bureau of Standards Journal of Research.*

Since each C and H atom is equal to all the others, it follows that the frequency of the light emitted will be independent of the portion of the ring from which it emanates and therefore the light in the frequencies which are emitted will be intense. This leads to a strong spectrum with sharp bands and little if any continuous background, which is just what benzene does give.

In the case of toluene a different state of affairs exists. One of the atoms is definitely marked by having a methyl group attached and the neighboring C atoms are probably slightly affected by the presence of this group; consequently, the various parts of the molecule when excited by the discharge do not all emit the same frequency but instead there appears a series of frequencies which are but slightly different. This leads to a group of strong bands arising from certain favored modes of vibration which are blurred by bands of slightly different frequency arising from other vibrations. An extension of this argument shows that it applies equally well to ethylbenzene and the xylenes. One would expect the bands of these substances to be less sharp than those of toluene, as indeed they are.

It should perhaps be emphasized here that these views are to be regarded as but tentative suggestions. The extreme complexity of the problem and the comparative lack of detail in the spectra of these simple derivatives render it difficult to be more specific in their interpretation.

A study of these spectra also leads one to believe that we should be more careful in keeping the meaning of our chemical symbols constantly in mind. All the existing theories of saturation and stability can be readily reconciled with the ordinary equilateral hexagonal formula for the simple benzene ring; indeed the observations force us to accept such a symbol. Whether the ring is coplanar or not is of small importance in this connection. On the other hand, it should be clearly recognized that the introduction of a group of any kind immediately sets up electrical and magnetic disturbances which are transmitted around the ring, and cannot fail to give a twist to the molecule so that to be accurate in our symbolism we should now write a warped or non-equiangular hexagon. The exact nature of this twist is not at present known but the accumulation of more data will undoubtedly elucidate this point. Meanwhile, we can keep in mind that the substituted benzene ring is not at all the same as the original symmetrical structure.

It is a pleasure to acknowledge our indebtedness to Professor H. S. Uhler for his advice in matters of spectroscopic technique, to Professor John Johnston for his general interest and help and to Mr. L. E. Faulhaber for help in preparing the manuscript. We wish also to thank the Commonwealth Fund for the fellowship held by one of us during the course of this research.

Summary

The emission spectra of toluene, ethylbenzene, *o*-, m- and *p*-xylene have been photographed using the Tesla discharge as a means of excitation; they are found to contain a number of bands generally accompanied by a continuous background. The numerical data are in agreement with previous measurements. A comparison of these spectra indicates that substitution produces a profound disturbance in the electrical and magnetic symmetry of the benzene ring. Further, these spectra have a limited application in qualitative analysis but are rendered less suitable for quantitative work because of the continuous background.

THE CONDUCTIVITY AND VISCOSITY OF SOLUTIONS OF LITHIUM NITRATE IN CERTAIN BINARY ALCOHOLIC SYSTEMS[1]

BY J. L. WHITMAN AND D. M. HURT

RECEIVED AUGUST 19, 1930 PUBLISHED DECEMBER 18, 1930

Investigations of conductivity in mixed solvents were first made by Lenz,[2] and have since been extended from time to time by many other workers. Perhaps the most systematic and extensive results have been obtained by Jones[3] and his co-workers using various solvents such as water, methyl alcohol, ethyl alcohol, propyl alcohol, acetone and glycerin, and a considerable number of solutes.

Data for the conductivity and viscosity of solutions of lithium nitrate in certain aqueous–alcoholic solvents have been reported in a previous paper.[4] As a continuation of these studies data are now given for systems containing various proportions of water, ethyl alcohol, n-propyl alcohol and isopropyl alcohol. In some cases density data have also been included.

Materials.—The lithium nitrate, water and ethyl alcohol were prepared and purified by the methods used by Whitman and Spencer. High grade n- and isopropyl alcohols from the Eastman Kodak Company were purified by the same method that was used in purifying ethyl alcohol. The specific conductivities of the purified solvents were as follows: water,

1.1×10^{-6}; ethyl alcohol, 0.85×10^{-6}; n-propyl alcohol, 4.96×10^{-6}; isopropyl alcohol, 0.51×10^{-6}.

Apparatus and Measurements.—A Leeds and Northrup slide wire bridge with extension coils, tunable head phones, Curtis coil resistance boxes, adjustable air condensers and the usual shieldings and sheathings were used. A Vreeland oscillator was used as the source of alternating current. Conductivity cells similar to those described by Schlesinger and Martin[5] were calibrated by the method of Kraus and Parker.[6] The cell constants were checked at frequent intervals during the course of the measurements.

Temperature measurements were made with a thermometer which had been compared with one certified by the Bureau of Standards. All measurements were made at 25 ± 0.01°. A well insulated, double-walled constant temperature bath of about 100 liters' capacity, filled with a light mineral oil, was used. Through a glass window in one side, readings were made on an Ostwald type quartz viscometer, which had a period for water of about eighteen minutes. Density determinations were made with a pycnometer of about 25 ml. capacity.

Conductivity data have been corrected for the conductivity of the pure solvent.

Experimental

Water-Ethyl Alcohol Mixtures (2).—The equivalent conductivities of solutions of lithium nitrate of various concentrations and in solvents ranging in composition from pure water to pure ethyl alcohol are recorded in Table I. This system has been previously studied by Jones and Lindsay,' but it was thought best to repeat the work since they obtained but three points on the curve. The conductivity data for the 0.1 molar and the 0.00625 molar solutions are shown graphically in Fig. 1. Absolute viscosities of water-ethyl alcohol mixtures according to Noack are also shown

Discussion

The various systems studied have been numbered and will subsequently be referred to by number. Nos. 1 and 5 are the water–methyl alcohol and methyl alcohol–ethyl alcohol systems, respectively, previously reported by Whitman and Spencer.

In systems 1, 2, 3 and 4, *i. e.*, those which contain water as one of the components of the solvent, a maximum viscosity is found for some composition. In only one of these, No. 1, does the conductivity-composition curve exhibit a minimum. In systems 5, 6, 7 and 8, *i. e.*, those systems which contain two alcohols as the components of the solvent, no maxima or minima are observed in either the viscosity or the conductivity curves.

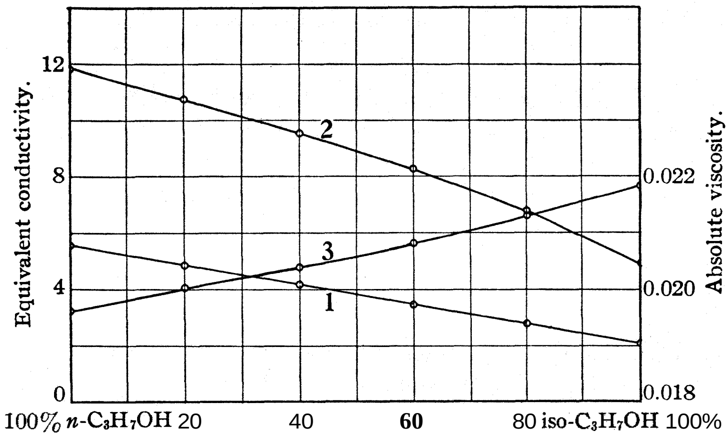

Fig. 6.—Lithium nitrate in n-propyl–isopropyl alcohol mixtures. Curve 1, composition–conductivity, 0.1 M; Curve 2, 0.00625 M; Curve 3, composition–viscosity.

In several of the latter cases the curves are very nearly straight lines, as might be expected since the components of the solvent are very similar chemically.

Jones concluded that a minimum in the conductivity curve was the direct result of the increase in viscosity. However, in attempting to explain this minimum other factors must also be considered, such as change in degree of dissociation with change in composition of solvent. But Jones[10] found that the degree of dissociation in a solvent containing 50% water and 50% methyl alcohol was greater than that in either pure solvent. This factor should therefore cause an increase in conductivity. It is thus evident that the viscosity explanation alone is far from satisfactory as a means of explaining the observed conductivity changes.

The viscosity data here recorded are believed to be accurate to ap-

---

[10] Jones and Carroll, *Am. Chem. J.*, 32, 521 (1904)

proximately 0.05%. For the viscometer used the time of outflow for water was approximately 1000 sec., while the stop-watch used was accurate to 0.2 sec. An error of 0.4 sec. in time would thus introduce an error of 0.04%. If the weighings involved were accurate to only 1 mg., then the errors of weighing for the pycnometer used (about 25 g. capacity) would amount to only 0.004%. According to the "International Critical Tables," Vol. V, p. 10, the change in viscosity of water per 0.01' at 25° is approximately 0.02%. Thus the appreciable errors will total not more than 0.06% and it is believed that an error of 0.05% represents the reasonable degree of precision of results obtained.

It should be noted that the values recorded for the water–*n*-propyl alcohol system are probably the least accurate of the conductance data, since the solvent corrections for this system are unusually large.

Summary

1. Measurements have been made of the conductivities of lithium nitrate in the mixed solvents containing various proportions of the following components: water, ethyl alcohol, *n*-propyl alcohol and isopropyl alcohol.

2. Viscosity and density determinations have also been made on the same pure solvent systems.

THE EFFECT OF LIGHT ON THE FERROCYANIDE–FERRICYANIDE IODINE–IODIDE EQUILIBRIUM

BY ROSCOE G. DICKINSON AND S. FREDERICK RAVITZ

RECEIVED AUGUST 20, 1930 PUBLISHED DECEMBER 18, 1930

It is well known that ferric salts oxidize iodides in aqueous solution at a moderate rate and that ultimately an equilibrium, $2Fe^{+++} + 2I^{-} \rightleftharpoons 2Fe^{++} + I_2$, is reached. Sasaki[1] investigated the effect of light on systems containing the substances involved in this equilibrium. Using sunlight and light from an incandescent lamp, he found that the illuminated systems always contained less titratable iodine than similar unilluminated systems. He further adduced evidence that the effect of the light was a displacement of the equilibrium rather than some other mode of disappearance of iodine. Further photochemical experiments were made by Rideal and Williams[2] who concluded, among other things, that the region of visible photoactive radiation was within the range 5500-6500 Å., and that one quantum of absorbed radiant energy caused one molecule of iodine to react. However,

---

[1] N. Sasaki, *Z. anorg. Chem.*, **122**, 61 (1922).

[2] E. K. Rideal and E. G. Williams, *J. Chem. Soc.*, **127**, 258 (1925).

Kistiakowsky[3] extended these experiments and concluded that radiations of the wave lengths 5460, 4360 and 3660 Å. were all effective; determinations of the quantum yield showed a disappearance of approximately one molecule of iodine per quantum absorbed at each of these three wave lengths.

In systems containing the ions $Fe(CN)_6^{\equiv}$ and $Fe(CN)_6^{==}$ instead of the ions Fe^{+++} and Fe^{++}, the thermal rates of reaction are again moderate, and directly measurable equilibria are again attained. The reaction may be expressed by the equation $2Fe(CN)_6^{\equiv} + 2I^- \quad 2Fe(CN)_6^{==} + I_2$. Both the kinetics and the equilibria in these systems have been the subject of considerable study.[4] We have found that such systems are sensitive to light not absorbed by the complex cyanides. However, preliminary experiments showed that when light was directed into an equilibrium mixture containing the complex cyanides, free iodine was produced rather than consumed. The present paper describes experiments in which the light sensitivity of solutions containing the complex ions is compared with that of solutions containing the simple ions.

Apparatus

The source of illumination was a 500-watt lamp whose filament covered an area about 1.3 cm. square. The lamp was controlled with the aid of a variable resistance and an ammeter in series with it; the lamp current was maintained constant at 4.3 amperes. Light from this lamp passed through a 6% copper sulfate solution in a flat cell, 1 cm. thick; this filter absorbed the infra-red. This cell was fastened to the front of the thermostat, which was a large flat-sided glass jar, so as to leave a pocket 3 cm. in thickness between the cell and the jar. In this pocket was placed a second filter mounted on a sheet of brass with a rectangular opening; this filter served to isolate the desired spectral region. The pocket was filled with water to minimize reflection losses. The reaction cell which contained the solution to be illuminated was a flat-sided bottle, the face of which was 4.5 × 10 cm., and the thickness 2.86 cm. This reaction cell was silvered externally except on the face toward the lamp. The thermostat with its attached filters was contained in a box provided with a shutter and thermal insulation. Arrangement was made so that the lamp and cell could, from one experiment to another, be brought into the same positions. The experiments were carried out at 0°; to permit this, the thermostat was kept well packed with clean ice except in front of the reaction cell, which was close to the thermostat wall. Water was circulated from bottom to top of the thermostat by an air lift. Ice was also kept in the upper part of the filter pocket.

Analytical Method

The solutions to be analyzed, whether ferrous–ferric iodine–iodide mixtures or ferrocyanide–ferricyanide iodine–iodide mixtures, were ordinarily not greatly removed

from equilibrium. They were analyzed for free iodine by the following method: from a 0.1 *N* thiosulfate solution, a solution of convenient strength, usually 0.004 *N*, was freshly prepared by dilution. Five cc. of this solution was pipetted into 50 cc. of water and starch was added. A sample of the solution to be analyzed was withdrawn from the reaction cell into a 10-cc. graduated pipet. The solution was then immediately run from this pipet into the thiosulfate solution to the appearance of a blue color, permanent on stirring. The elapsed time between the withdrawal of the sample and the attainment of the end-point was less than two minutes, and most of the solution analyzed was discharged into the thiosulfate in considerably less time. The suitability of this method for the titration of solutions containing ferrocyanide and ferricyanide has been discussed by La Mer and Friedman and by La Mer and Sandved.[5]

The Nature of the Photochemical Reaction

As mentioned above, when light is directed into a ferrocyanide–ferricyanide iodide–iodide equilibrium mixture, the concentration of titratable iodine increases. We have supposed that this increase in iodine concentration arises from a displacement of the equilibrium, *i. e.*, from the oxidation of iodide by ferricyanide. If this be the case then a solution which has been removed from equilibrium by shining in light should, when placed in the dark, return to equilibrium at the same rate as a solution of the same composition which has been equally removed from equilibrium by some other method, for example, by the dilution of a more concentrated equilibrium solution. We have tested this by the following experiment, which was carried out in an atmosphere of nitrogen in order to eliminate possible oxidation by dissolved air.

Tank nitrogen which had been bubbled through two bottles of strong alkaline pyrogallol solution and one bottle of water was used. All flasks used were first filled with nitrogen by filling them with water and displacing the water with nitrogen. Solutions were made up of distilled water which had been boiled for several minutes and allowed to cool with a fairly strong stream of nitrogen passing through it; the solutions were transferred from one flask to another by the use of nitrogen pressure.

Sixteen grams of c. p. potassium ferricyanide was dissolved in about 100 cc. of water, filtered into a 500-cc. volumetric flask, and a vigorous stream of nitrogen was passed through the solution for several minutes; 20.00 g. of c. p. potassium iodide was likewise dissolved in about 100 cc. of water and nitrogen was passed through this solution for several minutes. It was then transferred to the volumetric flask and water was added to the 500-cc. mark. The resulting mixture was transferred to an Erlenmeyer flask and nitrogen was passed through it for about ten minutes, during which time very little iodine was formed. The mixture was then carefully packed with ice and allowed to stand for several days at 0° until equilibrium was practically attained.

To 250 cc. of the resulting equilibrium solution at 0° an equal volume of oxygen-free water (previously cooled to 0°) was added. The flask containing the resulting solution was packed in ice water and allowed to stand in the dark. Samples of this diluted solution were withdrawn at intervals by forcing the solution into the 10-cc. graduated pipet with nitrogen pressure, and were titrated by the method described above. The results of these titrations are plotted as circles in Fig. 1.

---

[5] V. K. La Mer and H. B. Friedman, This Journal, 52, 877 (1930); V. K. La Mer and K. Sandved, *ibid.*, 50, 2659 (1928).

After about twenty-four hours, this diluted solution had nearly reached equilibrium; 160 cc. of it was then transferred to the reaction vessel in the ice thermostat and illuminated for three hours through the copper sulfate filter and a 1-cm. layer of 16% potassium chromate solution. Immediately upon ceasing the illumination the solution was placed in the dark and samples were withdrawn at intervals and titrated as before.

The results of this series of titrations are shown as crosses in Fig. 1; the time origin for the plot relating to the illuminated solution was so chosen that the first point (highest iodine concentration) fell on the curve relating to the unilluminated solution. If the effect of light was simply the displacement of equilibrium, then the concentrations of all materials should be the same in the two solutions at this point. It may be seen from Fig. 1 that these two solutions returned toward equilibrium at the same rate at all times. Moreover, the final iodine concentration arrived at was the same in each case; twenty-nine hours after the beginning of each experiment that for the illuminated solution had become 0.00396 and that for the unilluminated solution, 0.00398 N.

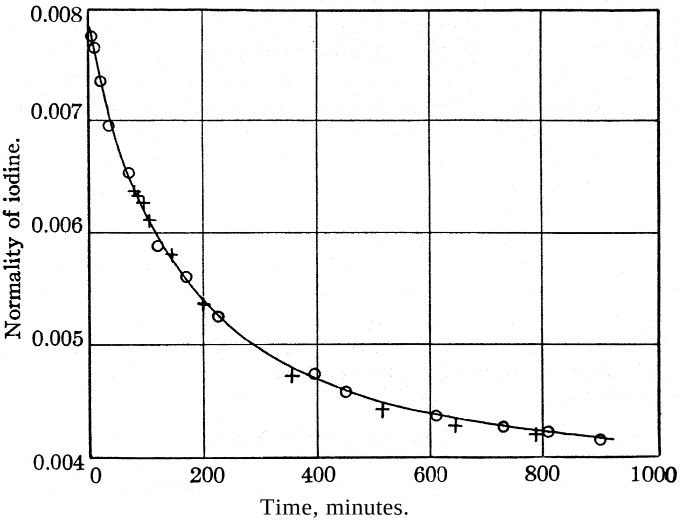

Fig. 1.—Comparison of change of iodine concentration with the time for two solutions of the same composition, one (circles) having been removed from equilibrium by dilution, the other (crosses) having been illuminated. The curve is drawn through the circles.

When similar experiments were carried out without the precaution of excluding air, the coincidence of the two curves was not so complete and was especially incomplete if the illumination was a prolonged one; a solution which had been given twenty hours' illumination finally came in the dark to an equilibrium concentration of iodine about 12% lower than that of a corresponding unilluminated solution.

In the experiments of Fig. 1, the concentration of the iodine before illumination was 0.00398 N; the equivalent concentration of the ferrocyanide (since the solution was made up from ferricyanide and iodide) was the same. During illumination, the iodine concentration rose to 0.00636 N, an increase of 60%. If this increase were not due to a shift in the equilibrium, the illuminated solution would then not be expected to contain the same amount of ferrocyanide as the unilluminated solution of equal iodine concentration prepared by dilution, and an equality in the rate of return to equilibrium would not be expected, nor should the same equilibrium concentration of iodine be reached in the two cases. We take the observed equality as evidence that the photochemical reaction with the radiation used is a reduction of ferricyanide to ferrocyanide by iodide.

Further evidence that this is the case is furnished by the following experiment in which the formation of ferrocyanide on illumination is shown directly. Two solutions, the first 0.008 N in iodine and 0.016 formal in potassium iodide, and the other 0.010 M in potassium ferricyanide, were made up with no effort to exclude air, and brought to 0°. Equal volumes of the two solutions were then mixed, and half the resulting solution was immediately transferred to a reaction vessel placed in the ice thermostat. Illumination with the 500-watt lamp (through the copper sulfate and potassium chromate filters as above) was started at once. At intervals 10-cc. samples of the illuminated and of the unilluminated solutions were withdrawn simultaneously and pipetted into large test-tubes, each containing 50 cc. of water at 0° to which had been added 2 cc. of a 2% solution of ferric ammonium sulfate in 0.012 N sulfuric acid. After five minutes' illumination the test with the illuminated solution gave a decided blue color of ferric ferrocyanide, whereas the test with the unilluminated solution showed no visible trace of blue. After ten minutes the results were similar, the color obtained with the illuminated solution being somewhat stronger than before. After twenty minutes the illuminated solution gave a still stronger color, while the unilluminated solution now gave a faint blue color resulting from the formation of ferrocyanide in the comparatively slow thermal reaction.

The Quantum Yield

A series of experiments was made in which the photochemical rate of production of iodine in ferrocyanide–ferricyanide mixtures was compared with the rate of disappearance of iodine in ferrous–ferric mixtures. In carrying this out, a pair of solutions, one of each kind, was made up and the solutions allowed to come substantially to equilibrium at 0°; the concentrations were so chosen that the titratable iodine content was about the same in each. The ferrocyanide–ferricyanide solutions were all made up as described in the previous section, by starting with 16.00 g. of potassium ferricyanide and 20.00 g. of potassium iodide; in different experiments, the extent of dilution was varied. The ferrous–ferric solutions were made up by dissolving 4.82 g. of ferrous ammonium sulfate and 0.66 g. of ammonium sulfate in water containing 4.2 cc. of 6 N sulfuric acid; to this was added a solution of 3.74 g. of potassium iodide and the resulting solution diluted so as to give the desired free iodine concentration. The solutions were successively exposed in the same reaction cell under the same conditions. During each exposure samples with withdrawn from time to time and titrated.

The results of two typical pairs of such experiments are shown plotted in Fig. 2. The abscissas are the time of exposure in minutes and the ordinates are the concentration of titratable iodine in millimoles per liter. Only at the beginning of each exposure can the rate of change of iodine concentration be considered to be due to light alone; when sufficient departure from thermal equilibrium has been attained, the thermal reverse reaction should lower the rate of change of iodine concentration. We have sought to decrease this difficulty by working at 0°. With exposures of one hour, in our apparatus, no appreciable change in rate was observable; consequently, as in Fig. 2, a straight line has been taken as the best representation of the data.

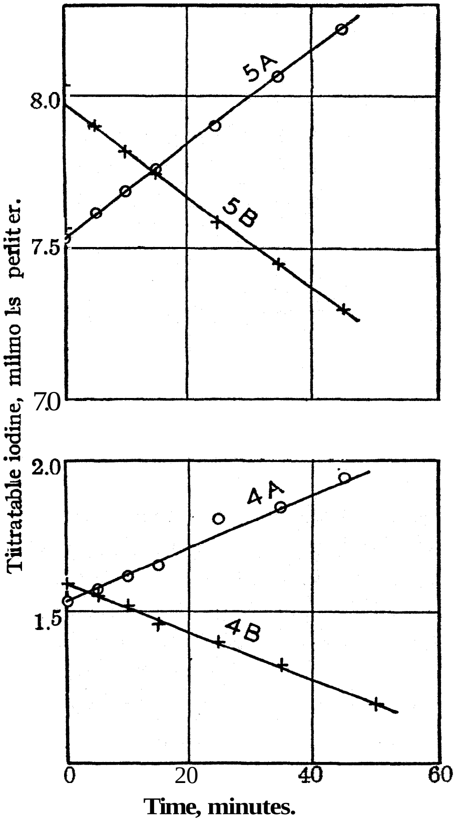

Fig. 2.—Change of iodine concentration with the time in ferrocyanide–ferricyanide solutions (circles) and in ferrous-ferric solutions (crosses) under the same illumination.

The results of all pairs of experiments are summarized in Table I. The concentrations, given throughout in millimoles per liter, apply to the beginning of exposure. In Col. 2 is given the concentration of titratable iodine; this is equal (since the solutions were made up from iodide and ferricyanide or ferric iron) to one-half the millimolal concentration of ferrocyanide or ferrous iron as the case may be. The total iodide, given in Col. 3, is the iodide taken minus the milliequivalents of titratable iodine. The concentrations of ferricyanide or ferric iron in Cols. 4 and 5 are similarly obtained from the titratable iodine and the amounts of ferricyanide or ferric iron taken. In Col. 6 is given the fraction of the titratable iodine existing as I_3^-. This was obtained using the equilibrium constant $(I^-) \times (I_2)/(I_3^-) = 0.000686$, which is the value obtained by Jones and Hartmann[6] in 0.1 *N* potassium iodide. Although the solutions involved here are by no means perfect, the calculations suffice to show that most of the titratable iodine was in the form of I_3^-.

The potassium chromate filter used in addition to the copper sulfate

[a] Air was not excluded. Filters: K_2CrO_4 and $CuSO_4$ in Expts. 1-6 inclusive; methyl violet, $Cu(NO_3)_2$ and $CuSO_4$ in Expt. 7.

filter in Expts. 1–6 inclusive was a 1-cm. layer of 16% solution. Examination with a spectroscope showed that this filter removed substantially all radiation below 5000 Å. None of the materials involved in the experiments except I_3^- and I_2 gives appreciable absorption of visual radiation of wave lengths longer than 5000 Å. when present in the amounts used. Consequently all of the light absorption is attributed to I_3^- and I_2. The total light absorption in any ferrocyanide–ferricyanide solution must have been nearly the same as in the companion ferrous–ferric solution, for the proportion of titratable iodine in the form I_2 was not large even in these latter cases. Moreover, unpublished measurements made by Mr. C. F. Carlson in this Laboratory have shown that the absorption coefficient of I_2 is the same as that of I_3^- at about 5500 Å., and that the absorption coefficients do not change rapidly in this neighborhood.

In Col. 8 of Table I are given the ratios of the rates of appearance of iodine in the ferricyanide solutions to the rates of disappearance in the companion ferric solutions. For Expts. 1–6 inclusive, where the light absorption was due simply to I_3^- (and I_2), the ratios are within a few per cent. of unity in all cases, *i. e.*, the quantum yield of the two reactions is substantially the same. If we may assume that the quantum yield in the ferrous–ferric solutions is the same at 0° as in Kistiakowsky's quantum yield determinations, we are led to conclude that in the ferricyanide reaction, one molecule of iodine is formed per quantum absorbed by I_3^-.

Experiment 7 was made using filters of methyl violet and copper nitrate solutions; the combination absorbed strongly above 5000 Å. and transmitted freely below 4700 Å. It accordingly transmitted radiation which was absorbable by ferricyanide as well as by I_3^-. In this case the rate in the ferricyanide solution fell considerably below that in the ferric solution. Apparently, then, absorption by ferricyanide leads to little, if any, production of iodine.

Discussion

In the present photochemical experiments resulting in the reduction of ferricyanide, the absorbing species was almost exclusively I_3^-. The formation of a theory of this reaction is hampered by lack of knowledge of the elementary act accompanying the light absorption. In reviewing the photochemical ferrous-ion oxidation, Kistiakowsky[7] considered two reaction mechanisms to be possible

$$\begin{array}{ll} \text{(I)} & I_3^- + h\nu \longrightarrow I^- + 2I \\ & I + Fe^{++} \longrightarrow I^- + Fe^{+++} \\ \text{(II)} & I_3^- + h\nu \longrightarrow I_3^- \text{ (activated)} \\ & I_3^- \text{ (activated)} + Fe^{++} \longrightarrow 2I^- + Fe^{+++} + I \\ & I + Fe^{++} \longrightarrow Fe^{+++} + I^- \end{array}$$

Neither elementary act here provides very naturally for the reduction of $2Fe(CN)_6^{\equiv}$, but either can be made to do so by supplementing with the reaction $I + I^- \longrightarrow I_2^-$ and supposing that I_2^- (as well as I_3^- (activated) in II) can act as a reducing agent. The hypothetical ion I_2^- has been employed by Wagner[8] to account for the inhibiting effect of the products in the thermal reactions

$$2Fe^{+++} + 2I^- \longrightarrow 2Fe^{++} + I_2 \quad \text{and}$$
$$2Fe(CN)_6^{\equiv} + 2I^- \longrightarrow 2Fe(CN)_6^{\equiv -} + I_2$$

and for this purpose has been attributed both oxidizing and reducing properties. If it be introduced here, the following mechanisms of ferricyanide reduction result

$$\begin{array}{ll} \text{(I)} & I_3^- + h\nu \longrightarrow I^- + 2I \\ & I + I^- \longrightarrow I_2^- \\ & I_2^- + Fe(CN)_6^{\equiv} \longrightarrow I_2 + Fe(CN)_6^{\equiv -} \\ \text{(II)} & I_3^- + h\nu \longrightarrow I_3^- \text{ (activated)} \\ & I_3^- \text{ (activated)} + Fe(CN)_6^{\equiv} \longrightarrow I_2 + I + Fe(CN)_6^{\equiv -} \\ & I + I^- \longrightarrow I_2^- \\ & I_2^- + Fe(CN)_6^{\equiv} \longrightarrow I_2 + Fe(CN)_6^{\equiv -} \end{array}$$

To these may be added a mechanism based on a third elementary act

$$\begin{array}{ll} \text{(III)} & I_3^- + h\nu \longrightarrow I_2^- + I \\ & I + I^- \longrightarrow I_2^- \\ & I_2^- + Fe(CN)_6^{\equiv} \longrightarrow I_2 + Fe(CN)_6^{\equiv -} \end{array}$$

---

[7] G. B. Kistiakowsky, "Photochemical Processes," Chemical Catalog Co., Inc., New York, 1928, p. 65.

[8] C. Wagner, *Z. physik.* Chem., 113, 261 (1924).

Any of these mechanisms is readily reconciled with our present knowledge of the photochemical ferrous-ion oxidation.

In an investigation of the photochemical reaction between potassium oxalate and iodine in iodide solution, Berthoud and Bellenot[9] developed a mechanism of that reaction which led to their empirical kinetic expression; this mechanism supposed that light absorbed by I_2 (producing iodine atoms) was effective while light absorbed by I_3^- was ineffective. This mechanism would then rule out any elementary act in which iodine atoms are produced from I_3^-; this would eliminate I and III above. However, we are at present disinclined to accept this conclusion; for it is possible to set up a mechanism leading to the kinetic expression of Berthoud and Bellenot without assuming light absorbed by I_3^- to be ineffective.[10]

In conclusion we may say that whatever the elementary act accompanying light absorption by I_3^- may be, it is clear that in it or in the subsequent reactions both oxidizing and reducing configurations are produced which are not to a great extent present in the unilluminated solution. The tentative assumption of the ion I_2^- is a simple hypothesis which satisfies these requirements.

Summary

It is found that when a ferrocyanide–ferricyanide iodine–iodide solution is illuminated with light absorbable by I_3^- but not by the complex cyanides, reduction of ferricyanide and oxidation of iodide occurs. The quantum yield is found to be substantially the same as that in the oxidation of ferrous ion in iodine–iodide solutions. Some possible mechanisms of the reaction are discussed.

PASADENA, CALIFORNIA

---

[9] A. Berthoud and H. Bellenot, J. *chim. phys.*, *21*, *308* (1924); *Helv. Chim. Acta*, 7, 307 (1924).

[10] This is accomplished, for example, by the following mechanism which is similar to that of Berthoud and Bellenot but differs from it in two important respects: (1) light absorbed by I_3^- is effective; (2) the inhibiting effect of I^- is attained through the formation of I_2^- from I^- and I. The reactions are:

$$\begin{array}{llll} & h\nu + I_3^- & \longrightarrow I_2^- + I \text{ (or } I^- + 21) & (1) \\ & I + C_2O_4^{=} & \longrightarrow C_2O_4^- + I^- & (2) \\ & I_3^- + C_2O_4^- & \longrightarrow 2CO_2 + I_2^- + I^- & (3) \\ \text{or} & I_2 + C_2O_4^- & -\!\!+\ 2CO_2 + I_2^- & \\ & I_2^- + I_2^- & \longrightarrow I_3^- + I- & (4) \\ & I + I^- & \rightleftharpoons I_2^- & (5) \end{array}$$

If the equilibrium (5) is assumed to be rapidly established, the usual treatment leads to the expression

$$-\frac{d(C_2O_4^{=})}{dt} = k_2K_5\sqrt{\frac{k_1}{k_4}I_0\,(I_3^-)}\ (\text{Cod-})$$

for the case of low absorption, which agrees with that of Berthoud and Bellenot.

KINETICS OF THE REACTION BETWEEN PERSULFATE AND THIOSULFATE IONS IN DILUTE AQUEOUS SOLUTION

BY CECIL V. KING AND OTTO F. STEINBACH

RECEIVED AUGUST 20, 1930 PUBLISHED DECEMBER 18, 1930

In the year 1897 Marshall[1] found that if a very slight stoichiometric excess of potassium persulfate were allowed to react with potassium thiosulfate, he could prepare pure tetrathionate. He also found that if excess thiosulfate were used, he could prepare trithionates.[2] These experiments are reviewed by Price,[3] who, however, did not investigate the reactions himself.

Marshall used rather concentrated solutions and did not study the speed of the reaction. No such study has been made until the present time, although the reaction was investigated from a quantitative standpoint by Schwicker.[4]

Schwicker found that in dilute solution in the cold the reaction was very slow, but that if a small amount of persulfate were boiled with excess $N/10$ thiosulfate, titration with iodine showed quantitative oxidation to tetrathionate. With potassium iodide present the oxidation to tetrathionate was also quantitative and much faster.

Experiments in this Laboratory[5] confirmed the fact that in dilute solution, at room temperature, the formation of tetrathionate is quantitative, within a few tenths of one per cent. with either persulfate or thiosulfate in considerable excess, with or without potassium iodide present.

A series of preliminary experiments on the velocity of the reaction in dilute solution[6] showed some interesting results. First, the reaction is catalyzed enormously by copper salts, much less by iron salts, very little by silver salts; other catalysts are quinone, quinhydrone and hydroquinone. Second, impurities in the water or the salts used have a large and uncontrollable catalytic effect. Consequently, most of the experiments reported here were carried out with water redistilled from dilute permanganate. Third, although the uncatalyzed reaction is stoichiometrically trimolecular

$$S_2O_8^{=} + 2S_2O_3^{=} \longrightarrow 2SO_4^{=} + S_4O_6^{=}$$

kinetically it follows the unimolecular law with some tendency in certain solutions to deviate in the direction of a zero or second order reaction.

[5] By Miss Elinor Cook.

[6] Most of the experiments by Mr. Abraham Berkowitz.

Over a considerable range of concentrations, in ordinary distilled water or specially purified water, the velocity is unimolecular with respect to the persulfate ion and almost, though not quite, independent of the thiosulfate concentration.

Materials and Methods

Potassium persulfate was recrystallized from ordinary distilled or redistilled water between 50 and 0° until free from sulfate and dried over sulfuric acid. Standard solutions were made by direct weighing. Sodium thiosulfate was recrystallized two or three times, dried in air and the solutions made up in freshly boiled water; 0.08 M solutions in ordinary distilled or redistilled water were standardized by the persulfate–iodide or the permanganate method, and did not change their titer over periods as long as four months.

Potassium iodide, chloride and sulfate were recrystallized similarly, dried in air at suitable temperatures and standard solutions made by direct weighing of the salts. A stock solution of copper sulfate was made from recrystallized $CuSO_4 \cdot 5H_2O$ and standardized by adding potassium iodide and titrating the liberated iodine, as recommended by Fales.[7] The solutions used were made from this by quantitative dilution.

In the preliminary experiments mentioned before, the persulfate and thiosulfate concentrations were varied considerably to establish the character of the reaction. In the experiments reported in detail here the persulfate concentration was always made 0.01 M and the thiosulfate 0.02 *M*, these being the correct stoichiometric proportions; the main interest here lies in the catalytic effects, and with these concentrations the unimolecular law is followed closely over two-thirds of the reaction, except in certain solutions, as will be shown later. Suitable standard solutions of the salts used were pipetted from flasks in a large thermostat at 25° (±0.01°), thoroughly mixed and replaced in the thermostat. After suitable time intervals 50-cc. portions were withdrawn and titrated with a 30–40% alcoholic solution of iodine (about 0.01 M I_2) containing about 0.02 M potassium iodide. An aqueous solution containing more potassium iodide could not be used, since the persulfate oxidizes the iodide too rapidly during the titration; and from an aqueous solution 0.02 M in potassium iodide the iodine escapes too rapidly for accurate titration unless special precautions are taken.

The experiments using ordinary distilled water and redistilled water are listed in separate tables for comparison. It will be noted that the velocity in individual experiments is far different, but in spite of this the conclusions with regard to the catalytic effects are changed very little.

The velocity constants were obtained by plotting the logarithm (to the base 10) of the number of cc. of iodine used for the individual titrations, against the time in minutes; the slope of the straight line drawn through these points, multiplied by **2.303,** gives the velocity constant. In other words, $\log_{10} (a - x)$ is plotted against t in the equation

$$kt = 2.3 \log \frac{a}{a - x}$$

where a is the initial concentration of persulfate and $a - x$ the concentration at the time t, both expressed in cc. of iodine solution required. The value of k obtained is, of course, the same as if moles per liter of persulfate

---

[7] Fales, "Inorganic Quantitative Analysis," The Century Co., New York, 1925.

were substituted; and the method does not even require standardization of the iodine solution. The logarithm of the initial titration is given, if desired, by the extrapolation of the straight line to zero time.

The reproducibility of these experiments is not high, but is, on the whole satisfactory when we consider the ease with which thiosulfate is oxidized and the anomalous character of the persulfate oxidations. It will be recalled that the velocity of the persulfate–oxalate oxidation catalyzed by silver ion is quite uncontrollable.[8] Here we have a very easily oxidized substance (thiosulfate) and a very active oxidizing agent (persulfate, capable even of oxidizing manganese salts to permanganate (with a catalyst)); the system is unstable and extremely sensitive to traces of catalysts. Consequently the highest degree of reproducibility cannot be expected.

1\. **The Uncatalyzed Reaction.**—An example of the actual titrations obtained is given in Table I.

TABLE I

DETAILS OF THE MEASUREMENTS IN ONE EXPERIMENT

Discussion

Tables II and III show that the purity of the water has an enormous effect. The experiments in Table II are far from reproducible; this finally led to the use of redistilled water, and the experiments in Table III are much more concordant. Water redistilled in different stills, with glass or tin condensers, from ordinary distilled water from different sources, gave

---

[8] King, THIS JOURNAL, 50, 2089 (1928).

fairly concordant results, and it is doubtful whether a very elaborate purification of the water would give much lower velocities. It is just possible that in absolutely pure water no reaction would occur, and that the reaction shown here is catalytic in character. Further experiments are in progress to establish this point.

Another observation from Tables II and III would agree with this. The salt effect is positive, abnormally high and with the ordinary distilled water at least, of an abnormal type—the salt effect increasing as the salt concentration increases. Now according to the well-substantiated theory of Bronsted, no unimolecular reaction could have a positive salt effect, since the salt effect is indicated in the equation

$$k = k_0F$$

where k is the observed velocity constant, k_0 the constant at zero ionic strength and F the "kinetic activity factor," in this case the activity coefficient of the reacting ion. F must decrease as the salt concentration is increased, at least in any usual case at low ionic strengths.

The same is true for a pseudo-unimolecular reaction between an ion and one or more neutral molecules present in constant concentration. The only kind of reaction which will satisfy the observations here is one between the persulfate ion and another negative ion present in constant concentration. A positive ion would mean a negative salt effect. The thiosulfate ion cannot be the negative ion, for its concentration is continually changing and the velocity is independent, or nearly independent of its concentration: The alternate conclusion is that the velocity-determining reaction is between the persulfate ion and an unknown, negative ion present in small amount as an impurity in the water. This mechanism seems untenable too, for the catalyst in ordinary distilled water is apparently some nearly nonvolatile substance and it seems improbable that such impurity would always be present in practically the same concentration in the redistilled water.

2. The Catalysis by Iodide Ion.—Since the persulfate–iodide oxidation

$$S_2O_8^{=} + 2I^- \longrightarrow 2SO_4^{=} + I_2$$

is much faster than the reaction

$$S_2O_8^{=} + 2S_2O_3^{=} \longrightarrow 2SO_4^{=} + S_4O_6^{=}$$

and the reaction between thiosulfate and iodine

$$2S_2O_3^{=} + I_2 \longrightarrow S_4O_6^{=} + 2I^-$$

is practically instantaneous, it is reasonable to expect that iodides will catalyze the oxidation of thiosulfate. If the mechanism of the catalysis is entirely as outlined above, it should be possible to measure the velocity of the persulfate–iodide reaction from the catalytic effect on the persulfate–thiosulfate reaction; the two should be additive. Since the iodide is regenerated as fast as it is used up, its concentration is constant, and the total reaction will be unimolecular in character. By subtracting the unimolecular constant for the uncatalyzed from that for the catalyzed reaction (at the same ionic strength), and dividing by the iodide concentration, we will obtain the himolecular constant for the persulfate–iodide reaction. This can then be compared with the persulfate–iodide constants determined directly with no thiosulfate present.

Similar examples of "induced catalysis" of this type are known, as the catalysis of the persulfate oxidation of phosphorous acid by iodide, measured by Federlin.[9] Here the reactions are

$$S_2O_8^{=} + H_3PO_3 + H_2O \longrightarrow 2SO_4^{=} + H_3PO_4 + 2H^+ \qquad (1)$$

$$S_2O_8^{=} + 2I^- \longrightarrow 2SO_4^{=} + I_2 \qquad (2)$$

$$H_3PO_3 + I_2 + H_2O \longrightarrow H_3PO_4 + 2I^- + 2H^+ \qquad (3)$$

and the net effect is similar, except that (3) is slower than the iodine–thiosulfate reaction; consequently, free iodine makes its appearance in the solution. Federlin concluded that the total rate of oxidation of phosphorous acid could be predicted exactly from the rates of the three reactions; as a mattter of fact, our examination of his data shows that the agreement is by no means good.[10]

In our experimental work we have two series of experiments in each of which the iodide-ion concentration is varied while the ionic strength is kept constant by suitable addition of potassium chloride to take the place of potassium iodide. The first series was run with both ordinary distilled and redistilled water, and it will be noticed that the persulfate–iodide constant is not much different, although the observed velocity is considerably different in the two cases.

Tables IV, V and VI give the results of these experiments. The total observed unimolecular constant is k; with no potassium iodide present, but potassium chloride to keep the ionic strength the same, $k_1 = k$. $k_2 = k - k_1$, i. e., k_2 is the increase in velocity constant caused by the potassium iodide; and k_3 is k_2 divided by the concentration of potassium iodide, i. e., the bimolecular persulfate–iodide constant in the presence of thiosulfate.

Discussion

From Tables V and VI it is seen that the salt effect on the persulfate–iodide reaction is positive, as is to be expected for **a** reaction between two ions of the same sign, and it is also normal in magnitude. We now come to the question of whether the velocities of the two slow reactions concerned are additive; *i.* e., whether the mechanism of the catalysis is as outlined above and the two independently measurable reactions with the one instantaneous reaction account for the observed velocity. A comparison of the persulfateiodide constant recorded here with constants recalculated from the data of Price on this reaction,[11] and measurements in this Labora-

---

[11] **Price.** *Z. physik. Chem.*. 27, 474 (1898).

tory[12] led us to suspect that these constants were somewhat lower than the persulfate–iodide constants determined directly in solutions of the same ionic strength; however, the authors mentioned did not use solutions of exactly comparable composition. It is not always possible to compare velocities in solutions of the same ionic strength, even if the salts involved are of the same valence type, because of a considerable difference in specific salt effect, unless the concentrations are extremely low.

For this reason, a few experiments were made on this reaction in comparable solutions, replacing sodium thiosulfate with potassium sulfate, a salt of the same valence type. The constants were calculated from measurements made on the first one-fourth of the reaction, to avoid the complicating influence of the iodine formed (see previous work on this reaction). The results are recorded in Table VII.

TABLE VII

BIMOLECULAR CONSTANTS FOR THE PERSULFATE–IODIDE REACTION (NO THIOSULFATE PRESENT)

0.01 M $K_2S_2O_8$; 0.02 M K_2SO_4; redistilled water; 25°

c_{KCl}	c_{KI}	k_a
0.012	0.008	0.213
.008	.012	.216
.052	.008	.262
.048	.012	.268

As expected, these results show that the persulfate–iodide reaction, measured in the presence of thiosulfate, is several per cent. slower than when measured independently. This might be explained in one of three ways: (1) the specific salt effect of sodium thiosulfate is far different from that of potassium sulfate, which seems hardly probable; (2) the iodine–thiosulfate reaction is not as fast as supposed (which would keep the iodide concentration lower than that specified, and would necessitate the appearance of free iodine in the solution; this was never observed even with the aid of the starch test); or (3) one of the reactions, persulfate–iodide or iodine–thiosulfate, takes place in steps, resulting in the accumulation in solution of some colorless intermediate compound. This last seems possible, as both reactions are stoichiometrically trimolecular. We have, however, no way of testing this possibility. Two comments can be made: the agreement observed here is as good as that observed by Federlin in the case of the reaction mentioned before, and work in progress in this Laboratory shows that the velocity of the persulfate–iodide reaction is normal in the presence of extremely small concentrations of thiosulfate (10^{-5}–10^{-6} M).

3. The Catalysis by Copper Ion.—Price,'' in his early work on the persulfate–iodide reaction, found that the velocity was increased enormously by iron and copper salts. The work reported here shows that cop-

---

[12] Jette and King, THIS JOURNAL, 51, 1048 (1929).

per salts have also an enormous effect on the persulfate–thiosulfate reaction. Price found a different catalytic effect of iron and copper salts in neutral and acid solution; both were fairly reproducible. Because of the decomposition of thiosulfate in acid solution most of our experiments were in neutral solution; a few, however, were carried out with a low concentration of acid present and are reported in the table.

It has been reported that traces of copper salts greatly accelerate the atmospheric oxidation of thiosulfates.[13] However, we believe this caused little error in the experiments reported here. A more important reaction which occurs in the system is that of cupric ion and thiosulfate.[14] Cupric ion is reduced to cuprous by thiosulfate, and negative complex ions of the type $Cu(S_2O_3)_y^{-x}$ are formed. The importance of this knowledge will be seen in the discussion.

If we assume that the cuprous copper is oxidized to cupric and instantly reduced by thiosulfate to cuprous again, we have a plausible mechanism for the catalysis. The relatively enormous catalytic effect is explained by the great speed of the persulfate–cuprous reaction. In this case again, by subtracting the constant of the uncatalyzed reaction (k_1), we obtain the part of the constant due to the copper catalysis, or, in other words, the constant of the persulfate–cuprous reaction. This reaction is pseudo-unimolecular, since the cuprous-ion concentration remains constant. On dividing this value by the copper-ion concentration, we obtain the bimolecular constant for the persulfate–cuprous reaction (k_4). The agreement of these constants as the copper-ion concentration is varied shows that this reaction is bimolecular, and gives a method of learning the velocity of this reaction, which cannot be measured directly as can the persulfate–iodide reaction.

With copper ion as the catalyst, there was a deviation from the unimolecular law, amounting to as much as 6 or 8% on the logarithmic plot when the reaction was half over. Hence a straight line was drawn as well as possible, tangent to the actual curve at zero time, and the slope of this line was taken as the best measure of the velocity in the first part of the reaction. The deviations were probably caused by the catalysis of side reactions; for instance, if the copper-ion concentration is high enough, sulfur is precipitated in the solution and the odor of hydrogen sulfide is apparent.

Since the copper-ion concentrations were so low, it was unnecessary to add varying amounts of another salt to keep the ionic strength constant. Experiments were run side by side with the catalyzed and uncatalyzed re-

actions, to eliminate any effect from different samples of water. The results are given in Tables VIII–XIV.

Discussion

The constancy of the values of k_4 in each table indicates that we are actually measuring the velocity of a definite bimolecular reaction, which probably is, as suggested before, the oxidation of cuprous ion (in a negative complex with the thiosulfate ion) by persulfate. The tables show that in this case the character of the water used has an effect on the persulfate–cuprous reaction, though not as large as on the persulfate–thiosulfate reaction. The salt effect is positive, in complete agreement with the belief that the velocity-determining reaction is between two negative ions. The effect of hydrogen ion is curious; although it increases the velocity of the persulfate–thiosulfate reaction a great deal, its effect on the persulfate–cuprous reaction is negligible. Although cupric ion would be considerably hydrolyzed in pure water solution, evidently in the thiosulfate solution the copper ion is all in the same form whether H^+ is present above its normal value in water or not. This is different from the effect of copper salts on the persulfate–iodide reaction; Price found that acids had a considerable effect on the velocity, presumably because they decrease hydrolysis of the copper ion. Price's data show considerable variation in the value of the persulfate–cuprous constant, chiefly because the straight line obtained by plotting copper-ion concentration against increased velocity constants does not extrapolate to zero effect at zero concentration for some reason.

Inspection of Price's results shows that copper ion does not have as great an effect on the persulfateiodide reaction as on the persulfate–thiosulfate reaction; 0.0025 M copper ion increases the velocity three to five times in the former case, very much more in the second. The mechanism of the catalysis in the two cases is different; in the first the copper is probably kept in the form of positive cupric ion, in the second by the extremely rapid reaction with thiosulfate, in the form of negative cuprous complex ion.

A point worthy of interest is the possibility of measuring the velocity of extremely rapid reactions by such a catalytic method as this. The iodide catalysis shows that the assumption of additive velocities is not far from true, and, if the same is true in the copper catalysis, we have a means of ascertaining, roughly at least, the velocity of a reaction up to 1000 times as fast (for equal concentrations) as those easily measured by the usual means. Direct measurement of such velocities can be accomplished only by some such scheme as that of Hartridge and Roughton,[15] used later by Saal[16] and by La Mer and Read.[17]

4. The Combined Catalysis by Iodide and Copper Ions.—The addition of both copper and iodide ions to the persulfate–thiosulfate system presents interesting possibilities. Price studied the effect of both copper and iron ions together on the persulfate–iodide reaction and found that the two together had practically twice the catalytic effect calculated from adding their separate effects. He was unable to explain this, except rather vaguely as a "promoter" effect.

There is a possibility in this system of at least six reactions, some measurable, some immeasurably fast.

(1) The persulfate–thiosulfate reaction
(2) The persulfate–iodide reaction } measured before
(3) The persulfate-cuprous reaction
(4) The thiosulfate-cupric reaction } "instantaneous"
(5) The thiosulfate–iodine reaction
(6) The cupric–iodide reaction very fast

The copper salt may catalyze the persulfate–iodide reaction, and so increase the effect of the iodide on the persulfate–thiosulfate reaction; or the iodide may catalyze the persulfate–cuprous reaction, through Reaction 6, and hence increase the effect of the copper salt on the persulfate–thiosulfate reaction; *i. e.*, if the iodide can complete its cycle of iodide–iodine–iodide through the path of Reactions 6–5 faster than through Reactions 2–5, or the copper can complete its cycle cuprous–cupric–cuprous faster through Reactions 3–6 than through Reactions 3–4, there will be an unusually large catalytic effect.

By a process similar to that used in the last section, from a suitable number of experiments we can obtain the constant for either Reaction 2 or 3 in this mixed solution, and compare it with those obtained before. To obtain the most concordant results, it was found necessary to run all experiments used in these calculations simultaneously, since, in general, the velocity constants were reproducible on the same day, with the same materials, but might vary 5–10% on different days. Consequently, experiments were run with no copper or iodide, some with copper, some with io-

dide and some with both, on the same day. Tables XV and XVI show the results of these experiments: k is again the total observed unimolecular constant; k_1 the constant with no catalyst present; k_3 the persulfate–iodide constant, obtained by subtracting k with copper but no iodide present from k with iodide and the same copper-ion concentration and dividing the difference by the iodide-ion concentration. Again, k_4 is the constant of the persulfate–cuprous reaction, obtained by subtracting k with iodide and no copper ion present from k with copper ion present and the same iodide concentration and dividing the difference by the copper-ion concentration.

Discussion

It will be noticed that in these mixed solutions the values of the persulfate–cuprous constants and of the persulfate–iodide constants are not as concordant as in the previous experiments with simpler solutions. This is to be expected since the experimental errors are greater, and the more catalytic effect, the greater the deviation from the unimolecular law for individual reactions (however, the deviation of points in the logarithmic plot never exceeded 8% when the reaction was half over). One consistent variation seems to be that the catalytic effect of the copper, per mole of copper salt, increased with decreasing copper-ion concentration. This is difficult to explain, but is exactly what Price found in the copper-ion catalysis of the persulfate–iodide reaction. When the catalytic effect is plotted against copper-ion concentration, the straight line found does not extrapolate to zero effect for zero concentration.

In these solutions it will be noticed that the persulfate–iodide constant is increased practically to the normal value (see Table VII). We cannot tell whether this is because the additional catalytic effect of this small copper-ion concentration is just sufficient in these solutions to bring the value up fortuitously, or whether the copper prevents some other reaction which has an inhibiting effect on the persulfate–iodide reaction. However, there is by no means the same catalytic effect of copper ion on the persulfate–iodide reaction that would be found if thiosulfate were absent; while there is undoubtedly some effect of the iodide on the persulfate–cuprous reaction, it is not large; there is no large unexplained "promoter" effect such as Price found with two catalysts present. In other words, only few if any copper and iodide ions go through the alternative cycles discussed at the beginning of this section.

5. The Effect of a Non-electrolyte (Cane **Sugar)** on the **Velocity.**—Several attempts have been made in recent years to correlate the effect of non-electrolytes on the velocity of ionic reactions, without a high degree of success. If the effect of the non-electrolyte were merely to change the activity coefficients of the reacting ions, then we should be able to make predictions. From the expression

$$\ln f = z^2 \frac{e^2}{2DkT}\sqrt{\frac{4\pi e^2 nz^2}{DkT}}$$

we see that any change in D, the dielectric constant, caused by a non-electrolyte should show a corresponding change in f; in fact

$$\ln f \sim \frac{1}{D^{3/2}}$$

With regard to "neutral salt effect" on ionic reaction velocities, there is no doubt that the activity coefficient is all-important, but the effect of non-electrolytes is by no means merely that of changing the activity coefficients.

By measuring the effect of a non-electrolyte on the persulfate–thiosulfate reaction alone and in the presence of iodide, we can also find the effect on the persulfate–iodide reaction. The latter has been measured before in solutions containing no thiosulfate; hence we can compare the effect in the two cases.

The experimental methods were the same as before. Ordinary distilled water was used, hence Table XVII should be compared with Table IV.

Discussion

The constants for both the persulfate–thiosulfate and the persulfate–iodide reactions are increased by the cane sugar; this agrees with the work of Kiss and Hatz[18] on the persulfate–iodide reaction above.

---

[18] **Hatz,** *Magyar Chem. Folyoirat, 34,* 141, 154, 177 (1928); C. *A.*, 23,4872 (1929); **Kiss and Hatz,** *Rec. trav. chim., 48,* 7 (1929).

For these reactions it was noticed that the presence of sugar caused deviations from the unimolecular curve; with the highest sugar concentrations the reaction was practically of zero order over two-thirds of its course. Hence many of the constants in the table were determined on this basis. When iodide is present, however, the curve again becomes unimolecular, as the persulfate–iodide reaction is pseudo-unimolecular and much faster than the uncatalyzed reaction.

It can be seen from the table that the effect of the sugar on the persulfate–iodide reaction appears to have reached a maximum between 0.7 M and 1.05 M concentrations. This is far different from the results reported by Kiss on the direct reaction, where the sugar has an increasingly greater effect up to a concentration of one molar. The presence of the thiosulfate has apparently modified the character of the reaction.

It is difficult to draw any general conclusions with respect to the effect of the non-electrolyte. For the persulfate–iodide reaction Kiss found that sugar and urea increase the velocity, while methyl and ethyl alcohols and glycerol decrease it. In all these cases the dielectric constant of the medium is decreased; hence the effect is more than that of change in dielectric constant on the activity coefficients.

6. Catalysis by Iron and Silver Salts.—It is well known that ferric salts oxidize thiosulfates, being thereby reduced to ferrous; and that ferrous salts are rapidly oxidized to ferric by persulfate. Hence it might be expected that iron salts would catalyze the persulfate–thiosulfate reaction. Unfortunately it is difficult to run suitable experiments since ferric or even ferrous salts are considerably hydrolyzed in neutral solution; if the solution is acid enough to control this hydrolysis and prevent precipitation of ferric hydroxide, the thiosulfate decomposes too rapidly. The first titrations in a few experiments showed that iron salts are not as effective catalytically as copper salts.

It may be of interest to discuss the similar iron salt catalysis of the persulfate–iodide reaction. The rate of the extremely rapid oxidation of ferrous ion by persulfate ions has been measured directly by Saal.[19] His method of expressing concentrations is obscure and apparently burdened with typographical errors, but if we have interpreted correctly, for a solution containing 0.0005 M $S_2O_8^=$, 0.0005 M Fe^{++}, 0.01 M H^+, 0.1 *M* KCl, at 12.8°, the bimolecular constant for the reaction is approximately 2000.[20] At a lower salt concentration and 25°, to compare with the work of Price on iron salt catalysis of the persulfate–iodide reaction, this value would be increased to perhaps 5000. It is difficult to calculate the velocity of the persulfate–ferrous constant from Price's data; the persulfate–iodide re-

---

[19] Saal, Rec. trav. *chim.*, 47, 385 (1928).

[20] Recalculated according to the scale used here from the equation $(-dC_{S_2O_8^=})/dt = kC_{S_2O_8^=}C_{Fe^{++}}$, with concentrations in moles per liter and t in minutes.

action is bimolecular, and if the catalysis by ferrous ion follows the mechanism

$$S_2O_8^{=} + 2Fe^{++} \longrightarrow 2SO_4^{=} + 2Fe^{+++} \qquad (1)$$
$$2Fe^{+++} + 21- \longrightarrow 2Fe^{++} + I_2 \qquad (2)$$

Reaction **1** will be pseudo-unimolecular if it is the velocity-determining reaction; if **(2)** is the slower, velocity-determining reaction, it will be pseudo-unimolecular.

Assuming that **(1)** is the velocity-determining reaction the velocity equation becomes

$$-\frac{dC_{S_2O_8^{=}}}{dt} a\ k_1C_{S_2O_8^{=}}\ C_{I^-} + k_2C_{S_2O_8^{=}}$$

where k_1 is the velocity constant of the uncatalyzed reaction; $k_2 = k_3C_{Fe^{++}}$, and k_3 is the bimolecular velocity constant of the persulfate–ferrous reaction.

From Price's data, for a solution containing **0.00625 M $S_2O_8^{=}$, 0.025 M I–, 0.005 *M* H+, 25°,** we obtain the value **0.147** for k_1. For the same solution +0.00025 M Fe^{++}, by reading $-dC_{S_2O_8^{=}}/dt$ from the plotted curve and using the above value of k_1, we calculate for k_3 values ranging from **65** to **40** during the course of the reaction. The complete lack of agreement with the work of Saal indicates that the above mechanism is incorrect; perhaps Reaction **2** is the velocity-determining reaction. If so, values not far different from these above **(40–65)** become the bimolecular constants for the reaction

$$2Fe^{+++} + 2I^- \longrightarrow 2Fe^{++} + I_2$$

In any case, the mechanism of this and similar catalytic reactions is far from clear.

Silver nitrate was also tried as a catalyst, since silver salts are so effective in other persulfate oxidations. However, it was not a good catalyst; the trivalent silver compound described by Yost and others[21] precipitated even with low silver-ion concentrations, and the catalysis was not very great.

Summary

The velocity of the reaction

$$S_2O_8^{=} + 2S_2O_3^{=} \longrightarrow 2SO_4^{=} + S_4O_6^{=}$$

has been measured, **(1)** alone, **(2)** with iodide ion as a catalyst, (3) with copper ion as a catalyst, **(4)** with both iodide and copper ions as catalysts in a mixed solution and **(5)** in the presence of cane sugar with and without iodide ion as a catalyst.

From these measurements, certain observations about the nature of the several reactions involved have been made.

1. The uncatalyzed reaction is pseudo-unimolecular or nearly so, *i.* e., independent to a great extent of the thiosulfate concentration; but the salt

---

[21] Yost, Tars JOURNAL. 48, 374 (1926).

effect indicates the velocity-determining reaction to be between two negative ions.

2. From the iodide catalysis can be calculated a constant for the bimolecular persulfate–iodide reaction; this constant is some 20–30% lower than when the velocity is measured independently, at least in solutions containing 0.02 *M* thiosulfate.

3. From the copper catalysis a constant can be calculated for the persulfate–copper ion reaction; the salt effect on this catalysis shows that the persulfate–copper ion reaction is between two negative ions, as might be expected from the fact that Cuff is reduced and changed into a negative complex cuprous ion by thiosulfate.

4. The effect of sugar is to increase the velocity of the persulfate–thiosulfate reaction, and to increase the velocity of the persulfate–iodide reaction in the presence of thiosulfate in a somewhat abnormal fashion.

Further work on this reaction is in progress.

A POTENTIOMETRIC STUDY OF ACID-BASE TITRATION SYSTEMS IN THE VERY STRONGLY ACID SOLVENT FORMIC ACID[1]

BY LOUIS P. HAMMETT AND NICHOLAS DIETZ, JR.

RECEIVED SEPTEMBER 15, 1930 PUBLISHED DECEMBER 18, 1930

If the ionization of an acid depends upon a reaction of the type

$$HCl + OH_2 \rightleftharpoons OH_3^+ + Cl^-$$

then the effect of the solvent upon the acidity of the solution obtained and upon the extent of the ionization may conveniently be separated into two factors.[2] One of these may be represented as the inherent basicity of the solvent and acts in such a way that a decreased basicity decreases the ionization of the acid but increases the acidity of the solution because the ionization takes place only as a result of the transfer of a proton from a weaker to a firmer binding. Thus hydrochloric acid is a strong electrolyte in water, but is only incompletely ionized in formic acid.[3] Nevertheless, indicator experiments show that the solution in formic acid is more acid than that in water. It is clear that the properties of a base should depend upon the acidity of the solvent in analogous fashion.

---

[1] This article is based upon a dissertation submitted by Nicholas Dietz, Jr., to the Faculty of Pure Science of Columbia University in partial fulfilment of the requirements for the degree of Doctor of Philosophy, May, 1930.

[2] Hammett, THIS JOURNAL, 50, 2666 (1928).

[3] (a) Schlesinger and Calvert, *ibid.*, 33, 1924 (1911); (b) Schlesinger and Martin, *ibid.*, 36, 1589 (1914).

The other factor is a medium effect which may be represented as the result of changes in ionic activity coefficients, that is, in the interionic electrical forces. A change in medium resulting in an increase in these forces results in a decreased ionization but probably in no great change in true acidity. Thus a solution of hydrogen chloride in ether is much less ionized than one in water. Basic indicators show decreased, acid indicators increased, acidity. It may further be expected that solvents of low dielectric constant, in which these forces seem always to be large, should exhibit large and specific salt effects. That is, relatively dilute electrolyte solutions in such a solvent should exhibit the same kind of complicated behavior as do very concentrated aqueous solutions. The potentiometric studies of Hall and Werner[4] on acetic acid solutions of bases seem to show this sort of effect in a pronounced degree.

It has seemed desirable to test further this point of view by the investigation of the properties as a solvent for acids and bases of a substance which is less basic and more acidic than water but which has the high dielectric constant and generally high solvent power for salts which may be taken to indicate interionic forces of relatively small magnitude.

We have therefore investigated potentiometrically solutions of acids and bases in formic acid. This solvent has a dielectric constant of 62.0 at 15°, it is a solvent for many salts,[5] including sodium and potassium chlorides; which have a very low solubility in most organic solvents, and solutions of salts give cryoscopic and conductivity values which correspond to extensive dissociation.[6] In these respects formic acid is much more like water than is such a solvent as acetic acid, in which salts give cryoscopic effects indicating association rather than dissociation[5] and conductivity dilution curves with maxima and minima. With respect to acidity and basicity, however, formic acid differs greatly from water, and solutions in it are even more deserving of the term superacid than are those acetic acid solutions in which Hall and Conant[7] did their pioneer work on the potentiometric investigation of strongly acid solvents. There is further interest in the potentiometric investigation of this solvent because of the existence of the precise and thorough conductivity studies of Schlesinger and his co-workers.[3,6]

In contrast the solvent offers considerable experimental difficulties. Solutions cannot be made anhydrous by the addition of an anhydride. The pure liquid decomposes slowly, and this decomposition is hastened by the presence of strong acids. We have found it impossible in spite of

very considerable investigation and the preparation of electrodes of a wide range of catalytic activity to obtain reliable hydrogen electrode potentials. Duplicate electrodes failed to agree and all electrodes adjusted themselves very slowly to changes in hydrogen-ion concentration. Nevertheless several titration curves were obtained with breaks qualitatively similar to those obtained with quinhydrone electrodes. Entirely satisfactory results were obtained with the *p*-benzoquinhydrone electrode. Even here, however, greater pains were necessary in the selection of electrodes than is the case in aqueous solutions, and it was necessary, moreover, to carry out measurements within a fairly short time interval because the potentials were found to drift in a negative direction (that is, in the direction of reduction) in acid solutions. Chloranil and 1,4-naphthoquinone were tried as substitutes for the benzoquinone, the former because it has no nuclear hydrogen and because it has been recommended by Conant and Hall for use in acetic acid solutions; the latter because it has a lower oxidation potential than benzoquinone. Chloranil seemed somewhat inferior to benzoquinone in definiteness and reproducibility. The behavior of the naphthoquinhydrone system is greatly affected by small variations in the method of preparation of the quinhydrone from the quinone. Some preparations gave results which were greatly superior to benzoquinone in reproducibility and freedom from drift in acid solutions, others were very inferior.

The method of investigation consisted in carrying out potentiometric titrations. Benzene sulfonic acid was found to be a suitable strong acid, as was expected from Hantzsch's indicator experiments. Sodium salts are in general strong electrolytes, and sodium formate if it is a strong electrolyte must have the greatest base strength possible in this solvent. As a reference half-cell we used a purely arbitrary constant system, and as a salt bridge a solution saturated with the very soluble sodium benzene sulfonate. There is of course no reason to believe that this bridge reduced the junction potential to zero, but it seems entirely probable that it should decrease to a small value the variation in contact potential with not too great changes in composition of the solution being titrated. The validity of the assumption seems justified by the results, as was the case with the similar scheme of Hall and Werner in acetic acid solutions.[4]

Materials

Formic Acid.—Kahlbaum 100% formic acid was first distilled in vacuo; the distillate was then purified by the method described by Coolidge.[5] The most highly purified acid had a melting point of 8.24°. The corresponding value obtained by Coolidge after more prolonged purification was 8.26°. The melting point was determined with the usual precautions, using a thermometer which was carefully compared with one recently calibrated by the Bureau of Standards. The purified acid was carefully pro-

---

[5] Coolidge, THIS JOURNAL. 50, 2166 (1928).

tected from moisture and kept at a temperature of 10" to decrease the rate of decomposition. The purest acid (melting point **8.23** to 8.24°) was used for the titration cell solutions. Less highly refined acid (melting point **8.21** to **8.22")** was employed in the bridge and in the reference cell. Although formic acid is hygroscopic, it is not extraordinarily so: for example, a sample with a melting point of **8.05"** was freely exposed to the atmosphere for thirteen minutes, after which the melting point had not changed measurably.

Sodium Formate.—The Kahlbaum salt was used after careful drying. Analysis by conversion to sodium sulfate gave a figure of **99.9%.**

Benzene Sulfonic Acid.—After considerable difficulty with purchased material we made this substance by the method described by Fierz[9] for toluene sulfonic acid with excellent results. The aqueous solution after removal of sulfuric acid was evaporated to a sirup and then dehydrated and distilled at a pressure of **0.01** to **0.001** mm.[10] The white crystalline product was again distilled in a special apparatus, under the full vacuum of a diffusion pump with a liquid-air trap, and at a temperature of 120°, directly into glass bulbs, **10** to 15 mm. in diameter, which were then sealed off. By titration against sodium hydroxide free from carbon dioxide and standardized with Bureau of Standards benzoic acid it was found to have a purity of **99.7** to **99.9%.** The anhydrous sulfonic acid is extremely hygroscopic. In preparation for a titration, a weighed bulb was broken in a dry mortar, and solution of the sulfonic acid in formic acid, which does not take place very rapidly, was allowed to proceed in the shelter of a desiccator kept dry with phosphorus pentoxide. After rinsing with formic acid, the glass fragments were collected and weighed.

Urea.—The sample melted at **133°.**

Triphenyl Carbinol.—The Eastman Kodak product was used. It melted at 162.5°.

Benzoquinhydrone.—The Eastman Kodak product melting at **170–171°** was used.

Apparatus and Method

The pyrex cell employed is illustrated in Fig. 1. It was found to be compact and convenient in use, and mixing of the solutions was avoided without the introduction of too great electrical resistance.

The electrodes were in most cases gold film burned on glass from a concentrated solution of pure gold chloride in glycerin containing a little oil of lavender. Electrical connection was established by a strip of platinum foil fused through the end of the glass tube which served as support. Before use they were cleaned with chromic acid, washed and heated to dull redness. Such electrodes gave very reproducible results, and readjusted themselves rapidly upon addition of acid or base. Electrodes of pure gold wire were found to give equally satisfactory results. Platinum electrodes were very unsatisfactory, showing differences of potential in a single solution of several millivolts. Gold plated platinum electrodes were no improvement upon bare platinum. This is in agreement with the observation frequently made in this Laboratory that platinum is particularly prone to contain electromotively active impurities. It is not clear, however, why these differences are so much greater in formic acid solutions than in aqueous ones. Two electrodes were always used in both titration and reference half-cells, and were frequently checked against each other during the course of the titration. The agreement obtained was approximately **0.1** millivolt.

In preparation for a titration, the salt bridge solution, consisting of formic acid saturated with sodium benzene sulfonate and carrying excess solid salt in suspension,

---

[9] "Grundlegende Operationen der Farbenchemie," Zurich, 1920, p. **190.**

[10] The smaller apparatus described in the leaflet, "Synthetic Organic Chemicals," Vol. II, No. 3, issued by the Eastman Kodak Company, February, **1929,** was used.

was introduced through a funnel into the salt bridge. The glass plugs were then firmly put into place with tongs, leaving a film of conducting solution around the sides of each plug. The excess solution squeezed out into the half-cells by this procedure was removed and the half-cells were rinsed several times with formic acid.

The solution to be titrated and the reference solution were then introduced into their respective half-cells. The reference solution consisted of formic acid saturated with sodium benzene sulfonate and containing 0.098 molar sodium formate. Quinhydrone was then added to both half-cells until an appreciable excess remained. Rough measurements indicated that the solubility of benzoquinhydrone in formic acid is about 0.1 molar. hi

Quinhydrone reacts slowly with formic acid in the presence of benzene sulfonic acid, the reaction being evidenced by a change in color with eventual formation of tarry products, and by a drift in potential toward less positive values. There was, however, no evidence of such reaction in sodium formate solutions, which are, of course, basic with respect to the solvent formic acid. For this reason titrations were started in basic solution, the reference half-cell solution was basic, and the titrations were completed within a time which experience showed would prevent a serious change in the potentials on the acid side of the end-point. The rate of potential drift was found to be 0.1 millivolt per minute in a 0.1 molar sulfonic acid solution, and not more than 0.01 millivolt per minute in a 0.025 molar sulfonic acid solution.

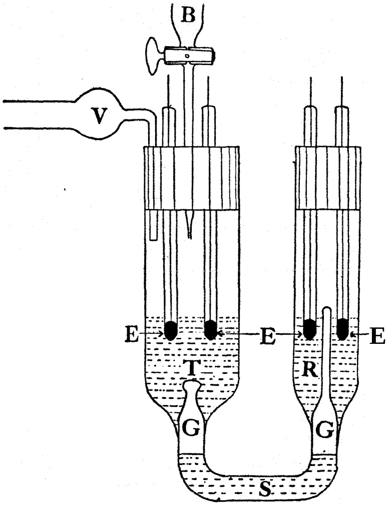

Fig. 1.—Titration cell. T, titration half-cell; R, reference half-cell; S, salt bridge; G, ground-glass plugs; E, electrodes; B, buret; V, vent.

Before use all glassware was thoroughly baked at 110° and was stored over phosphorus pentoxide or otherwise protected from moisture. In use the vent of the cell and the opening of the buret were protected by tubes containing pentoxide.

All measurements were made at a temperature of 25.00°, maintained by immersion of the cell in a Freas water thermostat. A properly calibrated potentiometer and standard cell and a galvanometer with a sensitivity of 2602 megohms gave the electrical measurements a precision of one to two-tenths of a millivolt with the highest resistance cells used.

Sodium Formate Titrations.—In Tables I, II and III are listed the data for titrations by the above described method of various concentrations of sodium formate against benzene sulfonic acid. Under C_b are calculated the concentrations of sodium formate not neutralized, under C_a the concentrations of benzene sulfonic acid in excess of that required to neutralize the sodium formate. The calculations assume a simple and complete neutralization, volume additivity, and a specific volume of dissolved quinhydrone equal to that of the solid substance. The values in the column headed pK are calculated by the equation

$$pK = \frac{E_{ab}}{0.0591} - \log C_aC_b$$

[a] **Omitted in the average.**

where E_{ab} is the observed difference in potential between a point on the acidic side and another point on the basic side of the titration end-point, all points on the basic side being referred to a single point (given in the heading of the column) on the acidic side, and all points on the acidic side being referred to a single point on the basic side. C_a is the concentration of sulfonic acid at the acid point and C_b the concentration of sodium formate at the basic point.

If the liquid junction potential remains constant during the titration, and if benzene sulfonic acid and sodium formate are completely ionized

$$E_{ab} = 0.0591 \log \frac{C_a f_a}{C_{ab} f_{ab}}$$

where C_{ab} is the concentration of hydrogen ion (probably $H_3CO_2^+$) in a solution of formate ion concentration C_b, f_{ab} is the activity coefficient of hydrogen ion in the same basic solution, and f_a is the activity coefficient of hydrogen ion in a solution of benzene sulfonic acid of concentration C_a. It follows that

$$pK = \frac{E_{ab}}{0.0591} - \log C_a C_b = -\log C_a C_b \frac{f_{ab}}{f_a}$$

With complete dissociation C_b is the concentration of formate ion in the basic solution, and C_{ab} is the hydrogen ion concentration of the same solution. The radio f_{ab}/f_a is nearly one, since it is the ratio of the activity coefficients of a given ion in two solutions of approximately the same total ion concentration. The quantity pK is therefore the negative logarithm of the product of the concentrations of the ions of the solvent, and the analog for formic acid of the quantity 14 for water.

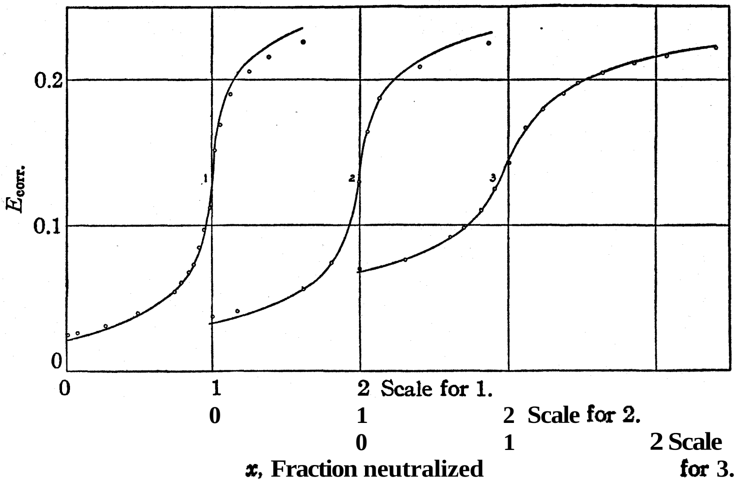

Fig. 2.

Figure 2 presents titration curves 1, 2 and 3 corresponding, respectively, to Tables I, II and III. The plotted points are the experimental values corrected to constant (initial) volume by means of the relationship

$$E_{corr.} = E_{obs.} + 0.0591 \log \frac{V_2}{V_1}$$

where V_2 is the volume corresponding to $E_{obs.}$ at any point during the titration and V_1 is the initial volume. The smooth curves are calculated by the equations

$$E = E_0 - 0.0591 \log [HCO_2']$$

$$X = 1 + \frac{K}{[HCO_2']C} - \frac{[HCO_2']}{C}$$

where X is fraction neutralized, C is the initial concentration of sodium formate, K is obtained from the average pK for the titration concerned, which is given in the tables, and E_0 is chosen by graphical methods to give the best fit. The latter of the above equations is essentially that of Eastman.[11]

Within a titration there is satisfactory agreement in the values of pK and likewise between observed and calculated curves. This would not be the

---

[11] Eastman, THIS JOURNAL, 47, 332 (1925).

case if there were any great change in liquid junction potential during the titration; it would not be the case if either benzene sulfonic acid or sodium formate were anything but strong electrolytes in this medium; it would not be the case if the activity coefficients of hydrogen ion were subject to large specific effects instead of being determined principally by the total ion concentration. The pK values obtained do therefore give a real measure of the self-ionization of the solvent formic acid.

In the titration of certain apparently strong bases in the solvent acetic acid, Hall and Werner obtained curves which agree with the assumptions here used in the calculation of pK, but their titration curves for weak bases and their dilution curves for both strong and weak bases indicate the presence of very great salt effects accompanying the large changes in total ion concentration which occur in these cases but not in the titration of a strong base. Such intense interionic forces manifested by large salt effects are, however, absent in formic acid. Thus the pK is **5.65** at a salt concentration of **0.13** molar, **5.73** at a salt concentration of **0.075** molar and **5.83 at** a salt concentration of **0.022.** Furthermore, the agreement of these potentiometric values with the figure which may be calculated from the conductivity measurements of Schlesinger and his co-workers is as close as that of the corresponding values for aqueous solutions. They found at 25° a conductivity at infinite dilution for ammonium formate in formic acid of **70.4 r.o.**, for ammonium chloride of **52 r.o.**, and for hydrogen chloride of **75 r.o.**, the latter two values being somewhat uncertain on account of incomplete ionization of the hydrochloric acid and solvolysis of ammonium chloride. The conductivity 6.3×10^{-5} which was found for pure formic acid leads to a pK of 6.3, somewhat larger than our values, as it should be, since it is calculated for zero electrolyte concentration.

The titration data on the acid side of the end-point may be considered as a determination of the effect of varying acid concentration upon the hydrogen-ion activity with a constant concentration of salt present. This excess foreign electrolyte should tend to decrease variations in activity coefficients.[12] These dilution curves for benzene sulfonic acid in the presence of the three different salt concentrations are shown in Fig. 3, which also includes a dilution curve for benzene sulfonic acid without any salt present. The data for the last curve are given in Table IV. Where salt is present the curves are straight lines with the theoretical slope. In the absence of salt the slope is still about 70% of the theoretical value for a strong electrolyte.

From these various considerations it appears that formic acid is **a** solvent in which salt effects are **not** extraordinarily great **as** compared with water: in terms of a physical chemistry of solutions which has been based largely upon the study of aqueous solutions it may be called a normal solvent.

Because the ion product constant of formic acid is 10^8 times that of water, the break at the end-point of a titration is considerably less in formic acid than in water, and the range of acids and bases which can be titrated is more limited. A tenth normal solution of a base with an ionization constant less than 3×10^{-5} will give a titration curve with no inflection point.[13]

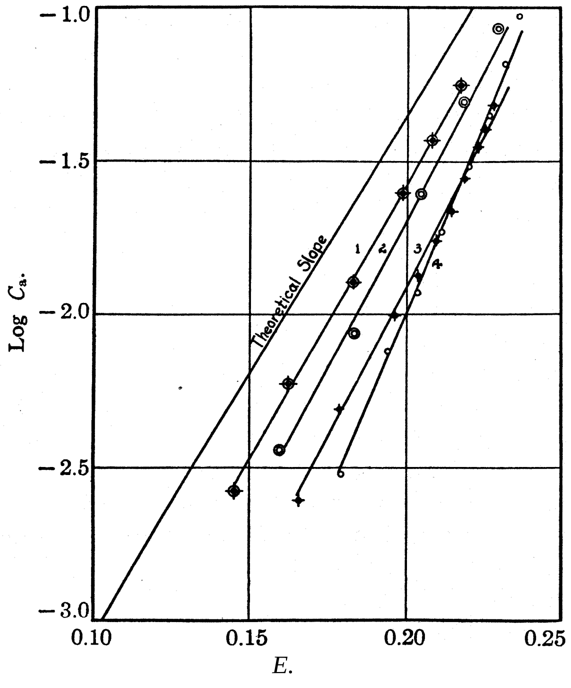

Fig. 3.—Dilution of benzene sulfonic acid Curve 1, data from Table I; Curve 2, data from Table II; Curve 3, data from Table III; Curve 4, data from Table IV.

If free hydrogen ions are incapable of existence in solution, and if ionization of a solvent depends upon its basicity as well as upon its acidity, the decrease in basicity in the transition from water to formic acid must be less than the increase in acidity.

[13] Roller, THIS JOURNAL, 50, 1 (1928).

Other Bases.—The behavior of several other basic substances in formic acid was investigated with the object of acquiring information as to the strengths of such substances in this solvent, and of learning more about the degree of acidity of the solvent itself.

To judge from color, benzene-azo-dimethylaniline and benzene-azo-diphenylamine are completely ionized, not only in formic acid but even in sodium formate–formic acid solutions. In water these indicators are so weakly ionized that their color changes occur at P_H 2.9–4.0 and P_H 1.2–2.1, respectively.[14]

Benzalacetophenone, which is so weak a base in acetic acid that it cannot be titrated,[15] imparts a yellow color to formic acid which is destroyed by the addition of a considerable quantity of sodium formate. This fading is due presumably to the reversal of the ionization

$$\underset{\text{colorless}}{B} + HCO_2H \rightleftharpoons \underset{\text{colored}}{BH^+} + HCO_2^-$$

Triphenylcarbinol is also so weakly basic in acetic acid that it cannot be titrated in that solvent.[7] It likewise gives a yellow solution in formic acid, which is decolorized by excess of sodium formate. Data for its titration with benzene sulfonic acid in formic acid solution are presented in Table V. The constancy of the pK values and their agreement with the values obtained with sodium formate show that it is a univalent strong electrolyte.

[14] W. Mansfield Clark, "The Determination of Hydrogen Ions," Williams and Wilkins Co., Baltimore, Maryland. 1928, p. 77.

[15] Conant and Hall, THIS JOURNAL, 49, 3062 (1927).

There is evidence however that the ionization of triphenylcarbinol is more complex. Hantzsch[16] found that the freezing point depression which it produces in sulfuric acid indicates the formation of four instead of two products of ionization, probably by the reaction

$$(C_6H_5)_3COH + 2H_2SO_4 \rightleftharpoons (C_6H_5)_3C^+ + OH_3^+ + 2HSO_4^-$$

and Conant and Hall have found evidence that the reaction of the carbinol with strong acids in acetic acid solution produces water.

An ionization of the sort found by Hantzsch would make triphenylcarbinol act like a diacid base. That it acts here like a monoacid base corroborates the conclusion (for which direct evidence is given later) that water has a negligible basicity in formic acid. If the reaction is

$$(C_6H_5)_3COH + HCO_2H \rightleftharpoons (C_6H_5)_3C^+ + HCO_2^- + H_2O$$

the addition of water should decrease the formate-ion concentration and therefore increase the acidity. Using the utmost precautions to exclude water other than known amounts deliberately added, it was found that addition of water up to a concentration of 1% or 0.7 molar to a solution of triphenylcarbinol in formic acid was accompanied by a total increase in potential of only 0.0025 volt. This is an eighty-fold increase over the maximum concentration of water which, it is believed, could have existed in the original solution. The surprisingly small effect found may perhaps arise from a balancing of the above acidity-increasing reaction by a small basic ionization of the water, but some such reaction as

$$(C_6H_5)_3COH + HCO_2H \rightleftharpoons (C_6H_5)_3COH_2^+ + HCO_2^-$$

is also worthy of consideration. This is analogous to the reaction of hydroxo-pentammine cobaltic ion with acids.

Preliminary experiments with urea in formic acid indicated that a slow reaction involving changes in acidity takes place, and precise titrations were impossible. Nevertheless it was clear qualitatively that urea is a strong or moderately strong base in formic acid, Hall and Conant[7] found that urea is a very weak base in acetic acid, and its ionization constant in aqueous solution is only 10^{-14}.

The complete ionization of these bases, which are very weak in water and even in acetic acid, demonstrates the extremely high degree of acidity attainable in formic acid solutions.

If water and ether are bases in the sense that ammonia and the amines are, and there is much evidence to support such a conclusion, they are extremely weak bases, decidedly weaker than are urea and the halochromic ketones and carbinols. For example, 8.0 cc. of a 1.0 molar solution of water in formic acid titrated into 13 cc. of a 0.53 molar solution of benzene sulfonic acid caused a decrease in potential of only 0.025 volt. A large part of this change may be attributed to dilution of the acid alone. Like-

---

[16] Hantzsch, *Z. physik. Chem.*, 61, 257 (1907).

wise it was found that a 1.0 molar water solution was approximately 0.015 volt less acid than pure formic acid, Ether is also a very weak base: 7.4 cc. of a 1.0 molar solution of ether in formic acid added to 15 cc. of a 0.5 molar benzene sulfonic acid solution caused a potential change of only 0.026 volt, nearly half of which may be attributed to dilution.

The amounts of water and ether added in these experiments are so large and the changes in potential so small that a change in the nature of the solvent cannot be neglected as a possible source of part or all of the effect. The ionization constants (3×10^{-6} for water and 5×10^{-6} for ether) that may be calculated from these data cannot therefore be given much quantitative validity.

Measured by the ionization of dissolved weak bases, the solvent formic acid is very much more acid than the solvent acetic acid—the ratio of the acidity constants must be more than 10^4. Most of the difference is a medium effect rather than a difference in the inherent acidities of the two acids, for the ionization constant of formic acid in water is only ten times that of acetic acid in the same solvent. This difference in the properties as a medium is exactly what must be expected from the fact that formic acid is a better salt solvent, is a solvent in which interionic forces and therefore ionic activity coefficients are smaller than they are in acetic acid.[2]

Summary

1. Acid–base titrations have been carried out potentiometrically in the solvent formic acid. Benzene sulfonic acid has been found to be a strong acid, and sodium formate, triphenylcarbinol and urea have been found to be strong bases.

2. The ion product constant of the solvent has been calculated with a result in good agreement with that obtained from the conductivity data of Schlesinger. Its large value indicates that formic acid does not differ from water as much in basicity as it does in acidity.

3. Extremely pronounced salt effects were not found to occur in formic acid. In this respect it resembles water more than it does acetic acid.

4. Water and ether were found to have little or no basic properties in this solvent, and their basicities are therefore decidedly smaller than are those of urea and of the halochromic ketones and carbinols.

5. The ratio of the acidity of the solvent formic acid to that of the solvent acetic acid is much greater than the ratio of the acidities of the solutes formic and acetic acids in water. This is interpreted as the result of a medium effect predicted from other known properties of the two solvents.

THE CALCULATION OF FREE ENERGY FROM SPECTROSCOPIC DATA

BY W. F. GIAUQUE

RECEIVED SEPTEMBER 22.1930 PUBLISHED DECEMBER 18,1930

For many years it has been evident that the utilization of the observed energy levels of atoms and molecules was destined to occupy a prominent place in the application of thermodynamics and statistics to chemistry. However, it is doubtful whether the very real simplicity of this application has been appreciated as it should be. Perhaps this is not surprising when one considers the unnecessarily complicated methods often used in treating such problems. It is the purpose of this paper to give the few simple statements necessary in connection with the exact determination of certain thermodynamic properties from the energy levels of matter as supplied by spectroscopy.

At the present time it is possible to make accurate calculations only for the perfect gaseous state. Interpreted spectroscopic data are available only for relatively simple molecules.

For the usual purposes of chemistry it is convenient to consider a large group of molecules as a single state without investigating the intimate details of their individual existences. However, in order to make a precise statistical calculation of a thermodynamic property, one must have an itemized account of all the states among which the molecules are distributed in appreciable concentrations. It may be well to add that the state of a molecule has a perfectly definite meaning only to the extent to which it is not appreciably influenced by neighboring molecules.

Let us be clear as to the meaning of a state. Every state corresponds to certain definite quantum specifications which are not possessed in every particular by any other state. Fortunately spectroscopy supplies the necessary information about atomic and molecular states and often more accurately than is necessary for ordinary purposes.

Every state is assumed to have equal statistical weight. This means that given equal opportunity to possess the energies necessary for their separate existences, all states are equally probable. The convenient use of *a priori* probability to include a group of states has caused some ambiguity in the use of the term state. A statement to the effect that a certain "state" has an *a priori* weight of three, means that the "state" is really three states which have been grouped together for simplicity of calculation. This is customary when the states have so nearly the same energies that they are affected in nearly the same way by temperature. However, it should be remembered that they are individual states in a statistical sense.

The problem of finding the distribution of atoms and molecules among the various possible states existing in a gas may, for convenience, be divided into two parts, namely, the problem of translation, and that dealing with all other possible energy absorption. The quantum-statistical treatment of the properties of an ideal gas was first given by Sackur[1] and by Tetrode.[2] Later Stern[3] and Ehrenfest and Trkal[4] contributed much clearer treatments. The logic of these earlier treatments left much to be desired, but this difficulty has recently been removed by the introduction of Bose–Einstein statistics. A very satisfactory treatment of this subject, with references to the previous work, has been given by Lewis and Mayer.[5] The final results for the properties of an *ideal* gas possessing translation alone are always the same for the various treatments which have been given. We have nothing to add to this subject but recall attention to the fact that the translational properties of all molecules, however complicated, are represented by the same equations when they are in the ideal gas state. This will be used as a starting point. The equations for the entropy of translation will be quoted later.

The thermodynamic properties of gases are usually referred to the standard state, which is the ideal gas state, and this may be treated simply and accurately when the necessary energy levels are available. The corrections to the actual gas at moderate pressures may usually be neglected at ordinary temperatures or above, but in any case are readily obtained from the data of state. The determination of the distribution of atoms and molecules among the various possible states may be approached by means of thermodynamics or by statistics. The usual thermodynamic method considers the equilibrium between any two states

$$\mathrm{B} = \mathrm{B}' \qquad \Delta F^\circ = -RT \ln \frac{n'}{n}$$

There is no entropy change in such a transition since each of the states has unit a *priori* statistical weight. Thus for this simple process the free energy change $\Delta F = \Delta E$, the energy change, when the particles are taken to be a perfect gas. Then the ratio of the numbers in the two states

$$\frac{n'}{n} = e^{-\Delta E/RT} = e^{-(\epsilon' - \epsilon)/kT} \quad \text{the Boltzmann factor}$$

$\epsilon' - \epsilon$ and k refer to the energy difference and the gas constant per molecule, respectively.

Derivations of the Boltzmann factor from statistics may be found in numerous books dealing with statistical mechanics. A simple derivation has been given by Lewis and Mayer.[5] In agreement with Einstein they show that the Boltzmann factor is not quite correct, due to quantum

[5] Lewis and Mayer, *Proc. Nat. Acad. Sci.*, 15,208 (1929).

degeneracy, but since our discussion will deal only with the standard state which is non-degenerate by definition, we may accept the Boltzmann factor as exactly true.

With the assistance of the Boltzmann factor one may readily obtain the desired thermodynamic properties. Let N be Avogadro's number and A the number of molecules in the lowest energy, or zero state (excluding translation). Then as usual the number in the first state is equal to $Ae^{-\epsilon_1/kT}$, where ϵ_1 is the observed energy per molecule with reference to the zero state. The number in the r^{th} state will be $Ae^{-\epsilon_r/kT}$. From this it follows that

$$N = p_0A + p_1Ae^{-\epsilon_1/kT} + p_2Ae^{-\epsilon_2/kT} + \dots \tag{1}$$

where the p's are the *a priori* probabilities referred to above and it may be well to repeat for emphasis that each term in the above expression is actually p separate terms with so nearly the same Boltzmann factors that the difference may be neglected. The total energy above the zero point of the system (excluding translation) is given by the expression

$$E^\circ - E^\circ_0 = 0p_0A + \epsilon_1p_1Ae^{-\epsilon_1/kT} + \epsilon_2p_2Ae^{-\epsilon_2/kT} + \dots \tag{2}$$

where E°_0 is the energy of the substance in the perfect gas state at the absolute zero of temperature. The superscript ° is used to designate a property of the substance in its standard reference state, in this case the hypothetical ideal gas state with a pressure of one atmosphere. This follows the conventions of Lewis and Randall,[6] which will be used where possible. Eliminating A from Equations 1 and 2, and making use of the abbreviation afforded by the summation sign

$$E^\circ - E^\circ_0 = N\frac{\Sigma\epsilon pe^{-\epsilon/kT}}{Zpe^{-\epsilon/kT}} \tag{3}$$

$$= RT^2\frac{\mathrm{d}\ln Q}{\mathrm{d}T},\ \text{where} \tag{4}$$

$$Q = p_0 + p_1e^{-\epsilon_1/kT} + p_2e^{-\epsilon_2/kT} + \dots \tag{5}$$

These series contain terms for every state that the molecule can assume.

Differentiation of $E^\circ - E^\circ_0$ with respect to T gives the heat capacity due to the degrees of freedom considered, thus

$$\frac{\mathrm{d}E^\circ}{\mathrm{d}T} = \frac{N}{kT^2}\left[\frac{\Sigma\epsilon^2pe^{-\epsilon/kT}}{\Sigma pe^{-\epsilon/kT}} - \left(\frac{\Sigma\epsilon pe^{-\epsilon/kT}}{\Sigma pe^{-\epsilon/kT}}\right)^2\right] \tag{6}$$

$$= -R\frac{\mathrm{d}}{\mathrm{d}T}\frac{\mathrm{d}\ln Q}{\mathrm{d}\,1/T}\,^{7} \tag{7}$$

a well-known equation which was first applied to the actual energy levels of a molecule by Hicks and Mitchell,[8] who, at the suggestion of Tolman, calculated the rotational–vibrational heat capacity of hydrogen

---

chloride. Their results are unfortunately marred by an error in connection with the *a priori* probabilities."

Later the heat capacity of hydrogen chloride was correctly calculated by Hutchisson.[10]

The entropy can be calculated very simply from the observed energy levels of molecules by a method to be given below, the principle of which is due to Tolman and Badger,[11] who, assuming rigid molecules, obtained expressions for the rotational entropy. Their paper unfortunately contains a number of errors in connection with the neglect of integration constants due to the multiple *a priori* probabilities of the zero state in several of their assumed cases.

It was shown by Giauque and Wiebe[9] that the equation given by Tolman and Badger holds exactly for molecular entropy due to rotation–vibration or electron excitation, regardless of how irregular these levels might be.

The method is as follows

$$\mathrm{d}S^\circ = \frac{\mathrm{d}E^\circ}{\mathrm{d}T}\cdot \mathrm{d}\ln T \tag{8}$$

$$S^\circ - S^\circ_0 = \int_0^T \frac{\mathrm{d}E^\circ}{\mathrm{d}T}\cdot \mathrm{d}\ln T \tag{9}$$

$$= -R\int_0^T \frac{\mathrm{d}}{\mathrm{d}T}\,\frac{\mathrm{d}\ln Q}{\mathrm{d}\,1/T}\cdot \mathrm{d}\ln T \tag{10}$$

$$= R\left[\ln Q + T\frac{\mathrm{d}\ln Q}{\mathrm{d}T}\right]_0^T \tag{11}$$

$$= R\left[\ln Q_T - \ln Q_0 + T\frac{\mathrm{d}\ln Q_T}{\mathrm{d}T}\right] \tag{12}$$

$$= R\left[\ln \Sigma p e^{-\epsilon/kT} - \ln p_0 + \frac{1}{kT}\,\frac{\Sigma p\epsilon e^{-\epsilon/kT}}{\Sigma p e^{-\epsilon/kT}}\right] \tag{13}$$

Particular attention is called to the term $-R\ln p_0$ in Equation 13 since this has been the cause of considerable misunderstanding. p_0 represents the number of states which have nearly the energy of the zero state and have thus been grouped together for convenience. However, this method leads to an assumed situation where even at the absolute zero of temperature the molecules are distributed equally between p_0 states, thus leading to a zero point entropy of $R\ln p_0$. The question as to whether this could actually happen at the unattainable absolute zero, infinite volume and zero magnetic and electric field strengths which would be necessary under equilibrium conditions need not seriously concern us in this case. $S^\circ_0 = R\ln p_0$ and S°, the absolute entropy, is given by

---

[9] Giauque and Wiebe, THIS JOURNAL, 50, 101 (1928).

[10] Hutchisson, *ibid.*, 50, 1895 (1928).

[11] Tolman and Badger, *ibid.*, 45, 2277 (1923). Urey, *ibid.*, 45, 1445 (1923), essentially used this method by graphically integrating one of Reiche's heat capacity equations.

$$S^\circ = R\left[\ln Q_T + T\frac{\mathrm{d}\ln Q}{\mathrm{d}T}\right] \qquad (14)$$

This equation, which holds for all types of states which have been observed, is so general that it should hold for any that are likely to be discovered. This includes the multiplicities due to nuclear effects such as spin.

We believe it is desirable to give another, even simpler, derivation of the important Equation 14, which is the foundation of all the important equilibrium data which may be obtained from spectroscopic observations on molecules.

Let us consider a box with two compartments and a total volume such that it will hold one mole of an ideal gas at pressure P. Let one compartment be filled with gas 1 and the other filled with gas 2, each at pressure P. If the two gases are allowed to intermix uniformly, the entropy increase is given by"-

$$AS^o = -R\,(N_1 \ln N_1 + N_2 \ln N_2) \qquad (15)$$

where N_1 and N_2 refer to the respective mole fractions of the two gases. In general when there are a large number of gases and corresponding compartments in the molal box, the expression for the increase in entropy on mixing becomes

$$AS^o = -R(N_1 \ln N_1 + N_2 \ln N_2 + \ldots N_r \ln N,) \qquad (16)$$

It is extremely useful to regard the various states among which molecules are distributed as supplying the basis for referring to different kinds of molecules in much the same manner as it is convenient to distinguish between optical isomers for some purposes. The number of the molecules in each of the states (excluding translation) is so large that it is convenient to think of a gas having such degrees of freedom as rotation, vibration and electron excitation as consisting of a mixture of a large number of kinds of gases, each kind being distinguished by its quantum numbers.

Let us imagine the molal box to be divided into a sufficient number of compartments of such volumes as are necessary to contain the equilibrium numbers of molecules of each kind or state (excluding translational states), at pressure P. Each of the compartments will contain what may be considered as a perfect monatomic gas. Each molecule within a given compartment is like every other within the same compartment except for the translational distribution. In such a case as that described, the total entropy is simply that of a monatomic gas. The entropy due to all other degrees of freedom in the equilibrium mixture is just the entropy associated with the uniform mixing of the various segregated portions. It may be well to emphasize in connection with the above statements that zero entropy with regard to a certain degree of freedom in no way implies that the molecules are necessarily all in the lowest energy state but only

---

[12] Lewis and *Randall*, Ref. *6*, p. *440*.

that all the molecules are in the same state, the "lack of randomness" of Lewis and Gibson.[13]

The entropy of mixing, referred to above, may be calculated as follows

$$N_0 = \frac{1}{Q},\ N_1 = \frac{e^{-\epsilon_1/kT}}{Q},\ \text{etc.} \tag{17}$$

From Equation 16

$$\Delta S^\circ = -R\left[p_0 \times \frac{1}{Q}\ln\frac{1}{Q} + p_1 \times \frac{e^{-\epsilon_1/kT}}{Q}\ln\frac{e^{-\epsilon_1/kT}}{Q} + \ldots\right] \tag{18}$$

$$= R\left[\ln Q + \frac{1}{kT}\frac{\Sigma p\epsilon e^{-\epsilon/kT}}{Q}\right] \tag{19}$$

$$= R\left[\ln Q + T\frac{\mathrm{d}\ln Q}{\mathrm{d}T}\right]$$

which is the previous equation (14). The significance of the p's before the terms in Equation *18* is that there are p terms of equal mole fraction.

The Absolute Entropy.—The well-known equations for the translational entropy of a gas, for which references were given earlier, are

$$S^\circ = \frac{3}{2}R\ln M + \frac{3}{2}R\ln T + R\ln V + \frac{5}{2}R + C \tag{20}$$

where M is the molecular weight, V the molal volume in cc. and $C = R \ln [(2\pi k)^{3/2}/h^3N^{5/2}] = -16.024$ calories per mole per degree,[14] where h is Planck's constant, and from the gas law

$$S^\circ = \frac{3}{2}R\ln M + \frac{5}{2}R\ln T - R\ln P + \frac{5}{2}R + C + R\ln R \tag{21}$$

when P is the pressure in atmospheres. $C + R \ln R = -7.267$.

To obtain the absolute entropy the amount $R \ln Q + RT(\mathrm{d}\ln Q/\mathrm{d}T)$ must be added to either Equation *20* or *21*.

The Calculation of Free Energy.—The free energy F is given by the equation[6]

$$F = H - TS \tag{22}$$

where the heat content

$$H = E + PV \tag{23}$$

For the ideal gas

$$H^\circ = E^\circ + RT \tag{24}$$

Then

$$F^\circ = E^\circ + RT - \frac{3}{2}RT\ln M - \frac{5}{2}RT\ln T + RT\ln P - \frac{5}{2}RT - CT - RT\ln R - RT\ln Q - RT^2\frac{\mathrm{d}\ln Q}{\mathrm{d}T} \tag{25}$$

The total energy E° is equal to the sum of the energy at the absolute zero E_0°, the energy of translation *3/2* RT, and the energy due to all other degrees of freedom $RT^2(\mathrm{d}\ln Q/\mathrm{d}T)$.

$$E^\circ = E_0^\circ + \frac{3}{2}RT + RT^2\frac{\mathrm{d}\ln Q}{\mathrm{d}T} \tag{26}$$

---

[13] Lewis and Gibson, **Ref.** 6, Chap. XXXI.

[14] **The** values used for all natural constants are those given by "International Critical Tables." Vol. I, p. 16.

Combining Equations 25 and 26

$$F^\circ - E_0^\circ = -\frac{3}{2}RT\ln M - \frac{5}{2}RT\ln T + RT\ln P - CT - RT\ln R - RT\ln Q \quad (27)$$

When the necessary atomic or molecular energy levels are known, Q may be calculated for any desired temperatures and tables of $F^\circ - E_0^\circ$, or preferably $(F^\circ - E_0^\circ)/T$ may be prepared. By combination of these values for the various substances involved in a given reaction, the value of $\Delta(F^\circ - E_0^\circ)$ may be obtained. F° is the nomenclature of Lewis and Randall for the standard state, in this case, the hypothetical ideal gas state with $P = 1$ atmos.

$$\Delta F^\circ = -RT\ln K^6 = \Delta(F^\circ - E_0^\circ) + \Delta E_0^\circ \quad (28)$$

From Equation 28 the equilibrium constant may be calculated for any desired temperature provided that ΔE_0° may be determined.

The Determination of ΔE_0°.—There are three general methods of evaluating ΔE_0°. (I) When the various excited states of a molecule are known up to dissociation into atoms, ΔE_0° is known for that reaction from spectroscopic data alone. By proper combinations ΔE_0° can then be obtained for other reactions. This method which gives great promise has already been applied to the dissociation of a number of diatomic molecules,[15] while most existing calculations of this type are uncertain, due principally to considerable extrapolation, it seems certain that this difficulty will be minimized by future work on this relatively new method. In several cases where the extrapolation is small, the method already provides our best source of this information.

(II) ΔE_0° may be calculated by means of Equation 28, when one reliable value of the equilibrium constant is known, or if K is known over a range of temperatures, a more reliable value of ΔE_0° may be obtained by making use of the several data.

(III) when ΔH° is known from a calorimetric determination at temperature T, ΔE_0° may be obtained with the assistance of Equations 24 and 26.

$$\text{Thus } \Delta E_0^\circ = \Delta H^\circ - \Delta\left[\frac{5}{2}RT + RT^2\frac{d\ln Q}{dT}\right] \quad (29)$$

Equilibrium between Solids, Liquids and Gases.—There are many cases where it will be necessary to consider equilibrium between some condensed state or states and gases, for example

$$C + \tfrac{1}{2}O_2 = CO$$

Here the third law of thermodynamics may be used for carbon in combination with spectroscopic observations on the gases. Thus

$$F^\circ - E_0^\circ = \int_0^T C_p\,dT - T\int_0^T C_p\,d\ln T \quad (30)$$

Recent values of this function are given by Rodebush and Rodebush.[16]

---

[15] Birge, "International Critical Tables," 1929, Vol. V, p. 418.

[16] Rodebush and Rodebush, "International Critical Tables," Vol. V, p. 87.

The F used in these tables is our $F^\circ - E_0^\circ$. These may be combined with the values of $F^\circ - E_0^\circ$ obtained for gases.

It is evident that the $F^\circ - E_0^\circ$ values for gases are of great utility even when no low temperature heat capacity measurements are available. However, as usual, this will necessitate the evaluation of at least one undetermined constant from equilibrium data.

In concluding these derivations, it is interesting to note that the exact determination of $F^\circ - E_0^\circ$ from spectroscopic data is a relatively easy calculation, involving only the summation of the Q series. The calculation of entropy or energy involves, in addition, the temperature derivative of the Q series, in which case the terms do not become negligible so rapidly.

The calculation of heat capacity involves the second derivative of the Q series, which is somewhat more laborious to sum. Fortunately the heat capacity need not be calculated in the process of determining an equilibrium and in many cases the entropy and energy may also be left undetermined.

The calculation of values of the free energy function to high temperatures is now in progress for the atoms and molecules for which the energy levels are known and it is expected that it will be possible to begin publication of this material in the near future.

Summary

Methods and equations for the *exact* calculation of free energy and other properties of the thermodynamic standard state of gases have been discussed.

A simple method of deriving a general expression for the absolute entropy of ideal gases has been given. This covers molecular rotation, vibration, electronic excitation and nuclear spin. In addition the method supplies a valuable insight into the simple relationship of complicated molecular states to the entropy.

The equations given will serve as the basis for an extended series of tabulations of free energy of gases based on available spectroscopic data.

THE ENTROPY OF HYDROGEN AND THE THIRD LAW OF THERMODYNAMICS
THE FREE ENERGY AND DISSOCIATION OF HYDROGEN

BY W. F. GIAUQUE

RECEIVED SEPTEMBER 22, 1930 PUBLISHED DECEMBER 18, 1930

The band spectrum data of the hydrogen molecule have recently been considered by Birge, Hyman and Jeppesen.[1] They have shown that the observed rotational energies associated with the vibrational levels may be represented with a very high degree of accuracy by means of simple equations for which they give the constants. Accepting their representation of the observed behavior of the molecule, we will illustrate the application of such data in the exact calculation of several thermodynamic properties. The equations required for this purpose have been given in the preceding paper.[2] These eliminate the necessity of such assumptions as molecular rigidity and other approximations.

These calculations will serve not only in making available important and very accurate thermodynamic properties of the hydrogen molecule, but will furnish an introduction to an extended series of papers in which similar data will be given for the elements and simpler molecules. At the present time calculations have been made on about one-third of the elements and a number of other substances.

A second purpose of this paper is to clear up the numerous misunderstandings which have arisen concerning the effect of nuclear spin on the entropy of hydrogen and the use of this entropy in conjunction with the entropies obtained from the third law of thermodynamics.

The situation existing in hydrogen has been correctly stated in the paper of Giauque and Johnston[3] and the use of the entropy of hydrogen in connection with the third law has been discussed by Kelley[4] as a personal communication from this author. Following this, a paper by Rodebush[5]

[5] Rodebush, *Proc. Nat. Acad. Sci.,* 15, 678 (1929). A paper [*Phys.* Rev., 36, 1398 (1930)] has recently appeared in which D. MacGillavry, who did not know of the paper by Rodebush, has raised the same objection, although he agrees with our result. This objection, which concerns the reliability of an *a priori* calculation of the entropy of a system when molecules such as ortho and para hydrogen are not in complete equilibrium, has been answered more specifically by Giauque and Johnston [*Phys. Rw.,* 36, Nov. *15.* (1930)].

We add here for the sake of completeness that most, if not all, of the systems has criticized not only our method of considering the problem, but also the numerical result, although his value is identical with ours. However, confusion has arisen since the paper by Rodebush, while giving the correct value for the absolute entropy of hydrogen, leaves the impression that this value should be used in conjunction with values obtained far other substances from the $\int_0^T C_p \, d \ln T$ with the assistance of the usual extrapolation methods at very low temperatures. The papers of Giauque and Johnston and of Kelley make a very specific point of the fact that this cannot be done. We have learned from a number of personal communications and also from criticism of Kelley for using our correct values, which we have recently noticed, that it is desirable to restate this problem which has implications relating not alone to hydrogen, but to all the elements excepting a few which are without nuclear spin. We will return to this problem later in this paper.

The results of Birge, Hyman and Jeppesen for the normal electronic state of the hydrogen molecule may be represented by the equation

$$E = E_v + B_v m^2 + D_v m^4 + F_v m^6$$

where m has the values $\frac{1}{2}, \frac{3}{2}, \frac{5}{2}, \ldots\ldots\ldots;\ m = j + \frac{1}{2}$ where j represents the number of units of rotational momentum; v refers to the number of units of vibration in addition to the half unit of zero point vibration. The values of the constants of the above equation are given in Table I.

---

considered by means of thermodynamics or statistics are not in complete equilibrium. Not only "stable" molecules but even the elements are potentially unstable with respect to others.

If we knew the absolute entropies of two organic isomers we believe that no criticism would be made if the total entropy of a system consisting of an isomeric mixture was calculated by adding the entropy of mixing to that of the pure constituents. However, when this generally accepted method is applied to the identical case of the recently discovered hydrogen isomers, the method is considered not plausible.

The calculation of absolute entropy is not appreciably complicated by the co-existence of some non-equilibrium states. The substitution of a lengthy calculation along a reversible path through limiting high temperatures for the simple and direct isothermal reversible path, usually used in such cases, does not increase the certainty of the result. In most cases the former method would require information not yet available.

The conclusion of Heisenberg,[6] on the basis of wave mechanics, that two general classes of hydrogen molecules exist has been amply substantiated by experiment. In the normal electronic state the para form, which has the nuclear spins opposed in the molecule can have only the even molecular rotational levels, $j = 0, 2, 4, 6, \ldots\ldots\ldots$, or $m = \frac{1}{2}, \frac{5}{2}, \frac{9}{2}, \frac{13}{2} \ldots\ldots\ldots$, while the ortho form can have only the odd rotational levels. The ortho hydrogen has three times the statistical weight which it would have in the absence of nuclear spin since the additive coupling of the two half-unit nuclear spins leads to $j_s = 1$ and an *a priori* probability $p_s = 2j_s + 1 = 3$. The para hydrogen with the canceling coupling has $j_s = 0$, $p_s = 2j_s + 1 = 1$. Thus at high temperatures a ratio of 1:3 between para and ortho states is found. The first definite experimental evidence for this ratio was given by Hori[7] from his measurements on the relative intensities of the lines in the band spectrum of hydrogen. Dennison[8] then showed that the long unexplained shape of the rotational heat capacity curve, first obtained experimentally by Eucken,[9] was in complete agreement with the above conditions. It was assumed that the rate of conversion of ortho and para hydrogen into each other is so slow as to be negligible under the conditions of experiment. At the suggestion of E. U. Condon, Giauque and Johnston[3] kept hydrogen at the temperature of liquid air to study the rate of conversion. A bomb containing about 10 moles of hydrogen at a pressure of 75 atmospheres was kept at about 85°K. for 197 days. On liquefying some of this hydrogen the vapor pressure when solid and liquid phases were present was found to have been lowered. Smits[10] has called attention to the fact that ordinary hydrogen has no triple "point" since the solid is in reality a solid solution.

The observed lowering of the vapor pressure, while small, was beyond the limit of experimental error and thus indicated the predicted readjustment of the relative proportions of ortho and para hydrogen. The further experiments promised by these authors were discontinued following the publication of the excellent work of Bonhoeffer and Harteck,[11] who carried out further investigations of the vapor pressure and made quantitative measurements of the rate of conversion with the assistance of a charcoal catalyst and an analytical method depending on the different thermal conductivities of the ortho and para forms. [12] McLennan and MacLeod, *Nature*, 113, 152 (1929).

have shown from measurements of Raman spectra on liquid hydrogen that the two forms exist under this condition. Further substantiation from heat capacity and heat content measurements will be considered later.

The Equilibrium Composition of Hydrogen.—From Equation 1 of the previous paper

$$N = p_0A + p_1Ae^{-\epsilon_1/kT} + p_2Ae^{-\epsilon_2/kT} + \dots\dots = AQ$$

where N is Avogadro's number and A the number of molecules in the lowest energy state, we have calculated the ratio of ortho and para molecules existing at various temperatures under equilibrium conditions. In place of the usual rotational *a priori* weights 1, 3, 5, 7, 9, ..., the weights 1, 9, 5, 21, 9, ..., must be used.

The fraction of the molecules in the para states is given by

$$\frac{p_0 + p_2e^{-\epsilon_2/kT} + p_4e^{-\epsilon_4/kT} + \dots\dots}{p_0 + p_1e^{-\epsilon_1/kT} + p_2e^{-\epsilon_2/kT} + p_3e^{-\epsilon_3/kT} \dots\dots} = \frac{Q_{\text{para}}}{Q}$$

The energies used in calculating the exponents are the actual energy levels of the molecule and, of course, include such effects as work done in the stretching of the molecule with increasing rotation and the change in the moment of inertia due to the same cause. The results are given in Table II.

TABLE II

EQUILIBRIUM DISTRIBUTION OF HYDROGEN MOLECULES IN ORTHO AND PARA ROTATION STATES

T, degrees absolute	Percentage para	T, degrees absolute	Percentage para	T, degrees absolute	Percentage para
0	100	75	51.776	250	25.257
15	99.989	100	38.461	273.1	25.141
20	99.814	125	31.871	298.1	25.074
25	98.996	150	28.544		
30	96.951	175	26.836		
40	88.547	200	25.953		
50	76.798	225	25.495		

It will be seen that the 1:3 ratio is closely approximated at room temperature

The Energy Content of Hydrogen.—From Equations 1 and 2 of the previous paper the total energy of the system (excluding translation) with reference to the zero state may be calculated.

$$E^\circ - E^\circ_0 = \frac{N\Sigma p\epsilon e^{-\epsilon/kT}}{\Sigma pe^{-\epsilon/kT}}$$

The calculations have been made for four conditions, pure para hydrogen, pure ortho hydrogen, for the equilibrium mixture of the two, and for the 1:3 mixture. The first, third and fourth cases are easily realizable experimentally, while the data on ortho hydrogen are useful for the calculation of the wide range of realizable systems intermediate between pure para hydrogen and the equilibrium mixture. The values are given in Table

III. The amount $3/2RT = 2.9804$ T cal./deg. per mole should be added for translational energy if the total energy is required.

TABLE III

ENERGY OF HYDROGEN GAS WITH REFERENCE TO THE ZERO STATE

(Translational Energy is not Included)

125	80.09	341.83	258.41	276.39
150	146.61	351.40	292.94	300.20
175	219.09	368.54	328.44	331.17
200	290.22	393.59	366.76	367.75
225	357.04	425.69	408 19	408.53
250	419.27	463.46	452.30	452.41
273.1	473 34	502.16	494.84	494.91
298.1	529.12	546.92	542.46	542.47

Elbe and Simon[13] have calorimetrically determined the difference in energy content of the 1:3 mixture and the equilibrium state by means of adsorption of each on charcoal. At 77.5°K. the difference found was 74 calories per mole. By interpolation we find the value of 83 calories per mole at this temperature. At 20 4°K. the difference was 241 calories against 252 calories from Table III. Considering the difficulty of experiment, this is good agreement and is well within the limits of error indicated by Elbe and Simon, who made a similar comparison.

The Heat Capacity of Hydrogen.—The heat capacity for several conditions of hydrogen was calculated from Equation 6 of the previous paper.

$$\frac{dE^\circ}{dT} = \frac{N}{kT^2}\left[\frac{\Sigma\epsilon^2pe^{-\epsilon/kT}}{\Sigma pe^{-\epsilon/kT}} - \left(\frac{\Sigma\epsilon pe^{-\epsilon/kT}}{\Sigma pe^{-\epsilon/kT}}\right)^2\right]$$

For example, in making this calculation for pure para hydrogen, only the even terms are considered in the summations. The method of using the actual energy levels of the molecules gives the heat capacity with an accuracy exceeding that of any direct experimental measurement. The values are given in Table IV. The value of 3/2 R = 2.9804 cal./deg. per mole should be added to these values on account of translation if the total heat capacity at constant volume is required.

---

298.1	2.1862	1.8377	1.9254	1.9248

Similar calculations were given by Dennison[8] and by Beutler[14] both of whom assumed the molecule to be rigid. Their results are expressed in terms of the variable B/kT, where B is the same as in the first term of the equation used above to represent the energy levels of the molecule. This can be done only when the condition of rigidity is imposed. By interpolation of Dennison's values it is found that the neglect of molecular stretching leads to results about 1% too low at 200°K. and about 1.3% too low at 298.1°K. The necessity of considering molecular stretching in this connection was pointed out by Kemble and Van Vleck.[15]

The various experimental measurements on the rotational heat capacity of hydrogen have been summarized by Eucken and Hiller,[16] who have carried out a very interesting series of experiments on hydrogen with 95, 43.1, 36.4 and 31.1%, respectively, of the para variety in addition to ordinary hydrogen with 25%. It is interesting to note that when we consider the effect of molecular stretching, the good agreement of the results of Cornish and Eastman[17] with the theoretical curve is further improved.

The Entropy of Hydrogen.—The important and much misunderstood value of the entropy of hydrogen may be calculated from Equation 14 of the previous paper.

$$S^\circ = R\left[\ln \Sigma p e^{-\epsilon/kT} + \frac{1}{kT}\,\frac{\Sigma p\epsilon e^{-\epsilon/kT}}{\Sigma p e^{-\epsilon/kT}}\right]$$

---

[16] Eucken and Hiller, *Z. physik. Chem.*, 4B, 142 (1929).

[17] Cornish and Eastman, THIS JOURNAL, 50,627 (1928).

$$= 4.5750 \left[\log 7.7533 + \frac{3.0839}{7.7533}\right] = 5.889 \text{ E.U.}$$

when $T = 298.1°K$. To this must be added the entropy due to translation, namely 28.090 E.U. This is obtained from the Sackur equation given as Equations 20 and 21 in the previous paper.

$$S° \text{ Translation} = 3/2\ R \ln M + 5/2\ R \ln T - 7.267$$

where M is the molecular weight and the pressure of the gas is one atmosphere.

The absolute entropy of hydrogen is thus found to be **33.98** calories per degree per mole, in agreement with our previous value mentioned above. However, we hasten to add that this is not the value which should be used as the entropy of hydrogen in combination with $\int C_p \text{ d In T}$ for other substances.

This can perhaps best be made clear by discussing the application of the third law of thermodynamics to hydrogen. It was shown by Giauque and Johnston[3] that ordinary solid hydrogen had an entropy of **4.39** E.U. above the vibrational entropy. This is due to the existence of ten kinds of molecules within the solid state. These kinds of molecules are distinguished only in that each has a different rotational or nuclear spin quantum specification. Of these one-fourth are para hydrogen with $j = 0$ and three-fourths are equally divided between nine kinds of ortho hydrogen, with $j_{\text{rot.}} = 1$ and $j_s = 1$, each of the latter therefore making up one-twelfth of the total amount. This can be considered by the usual expression for the entropy of mixing

$$\text{AS} = -1/4 \text{ R} \ln 1/4 - 9/12 \text{ R} \ln 1/12 = 4.39 \text{ E.U.}$$

The best determinations of the heat capacity of condensed hydrogen are due to Simon and Lange,[18] who also directly determined the heat of vaporization. They found that their results on solid hydrogen could be represented by a Debye function with an $h\nu/k = 91$. The most accurate determinations of the heat capacity of hydrogen gas are those of Cornish and Eastman,[17] who used the velocity of sound method at low temperatures. The greatest uncertainty in calculating entropy from the experimental measurements lies in the estimation of the correction of the actual hydrogen gas to the ideal gas at low temperatures, since the heat capacity of the actual hydrogen gas has not been measured at the temperatures of condensed hydrogen. For this reason we have used the heat of vaporization at the melting "point(?)" of hydrogen but even here where the pressure is but **5.38** cm., the correction obtained by combining the thermodynamic equation $(\partial S/\partial P)_T = -(\partial V/\partial T)_P$ with the equation of Berthelot is **0.13** E.U., while that obtained from the equation of van der Waals is **0.03** E.U. A summary of the calculation is given in Table V.

---

[18] Simon and Lange, *Z. Physik*, **15**, 312 (1923).

TABLE V

CALCULATION OF THE ENTROPY OF HYDROGEN

Solid	Cal./deg. per mole
0–13.95°K., $h\nu/k = 91$	0.52
Fusion, 28.0/13.95	2.01
Vaporization at 5.38 cm. pressure, 217.8/13.95	15.61
Correction to ideal gas	0.13 Berthdot, or .03 van der Waals
Compression from 5.38 cm. to 76.0 cm.	–5.26
$\int_{13.95}^{298.1} C_p \, d \ln T$	16.73
	29.74 Berthelot gas, or 29.64 van der Waals gas

Subtracting the entropy of mixing referred to above from the absolute entropy, the value **33.98 – 4.39 = 29.59 E.U.** is found to be in excellent agreement with the observed value. This is a very interesting confirmation, not only of the truth of the third law, but also of the correctness of the situation assumed to exist in solid hydrogen.

Recently Simon, Mendelssohn and Ruhemann[19] have published a preliminary report of an investigation of the heat capacity of solid hydrogen at the temperatures of liquid helium. They have found that the heat capacity fails to follow the Debye curve and at about 2°K. is increasing with decreasing temperature. For the ordinary mixture this additional loss of entropy amounts roughly to 0.7 E.U. to 2°K. and shows that hydrogen is beginning to dispose of the **4.39 E.U.** referred to above.

In a recent paper Pauling[20] gives convincing reasons for believing that not only hydrogen but many other molecules containing hydrogen are rotating in the solid state. Pauling supports the conclusions of Giauque and Johnston and predicts that the process of losing the **4.39** E.U. will not approximate completion until temperatures below 0.001°K. are reached.

From the above results it will be evident that it is not practical to obtain the absolute entropy of hydrogen from heat capacity measurements alone. It is equally certain that in the case of other substances with nuclear spin, and this includes nearly all substances, heat capacity measurements over the attainable temperature range will not suffice to give the absolute entropy. This situation which would at first sight seem fatal to the exact practical application of the third law of thermodynamics is by no means so serious since there is reason for believing that hydrogen may be the only substance which does not cause a very simple type of deviation for which a correction may be applied.

To make this clear we will consider an important observation of Gibson

---

[19] Simon, Mendelssohn and Ruhemann, *Naturwiss.*, 18, 34 (1930).

[20] (a) Pauling, *Phys. Rev.*, 36,430 (1930); (b) Personal communication.

and Heitler,[21a] who carried out, from spectroscopic data, the calculation of the dissociation of gaseous iodine into its atoms. They show with the assistance of wave mechanics that in reactions involving diatomic and monatomic substances that nuclear spin contributes equally to the absolute entropy of the reactants and to the products. Using this fact Gibson and Heitler were able to make a very accurate calculation of the dissociation constant even though the nuclear spin of the iodine atom is unknown. Gibson[21b] has expressed the opinion that cancellation will occur in reactions involving polyatomic molecules.

However, it must be pointed out that the nuclear spin cancellation is only a limiting approximation which is valid when the temperature is high enough. For gas reactions there is little reason for doubting that room temperature is always sufficient. As an example the equilibrium reaction $H_2 = 2H$ would approximate an error of $2 R \ln 2 = 2.75$ E.U. at 20°K. where, at equilibrium, nearly all of the diatomic hydrogen would be in the zero state of the para form which has unit weight, whereas the monatomic hydrogen still retains equal distribution among its spin multiplets. At 100°K. the discrepancy has been reduced to 0.88 E.U., while at room temperature it is negligible. It may also be added that hydrogen shows this effect to a much greater degree than is possible in any other diatomic molecule at the same temperatures and almost certainly to a greater degree than will be found possible in polyatomic molecules. If solid substances always retain the high temperature multiplicity due to nuclear spin over the experimental range used in connection with the third law of thermodynamics, it is obvious that it will be unnecessary to consider it. Very probably this is nearly always true, the one known exception being hydrogen, with some compounds containing hydrogen being somewhat uncertain.

On the experimental side the results of Giauque and Wiebe[22] on hydrogen chloride, hydrogen bromide and hydrogen iodide all prove that the limiting entropy due to spin persists to temperatures below 15°K. They showed that the entropy given by the third law agreed with that obtained from spectroscopic data when nuclear spin was ignored in the calculation. This author will soon publish a paper showing that the available data on iodine lead to the same result. This is particularly important since, in distinction from the polar hydrogen halides, the symmetry of the iodine molecule must lead, as in all such cases, to ortho and para molecular species. Pauling, in the paper referred to above, indicates that this is due to the fact that a molecule like iodine cannot rotate in the solid state, whereas

[21] (a) Gibson and Heitler, Z. *Physik*, 49, 465 (1928); (b) Gibson, personal communication.

[22] (a) Giauque and Wiebe, THIS JOURNAL, 50, 101 (1928); (b) 50, 2193 (1928); (c) 51, 1441 (1929).

hydrogen can. Experimental work on nitrogen and methane is in progress in this Laboratory in order to decide this question.

From the above it is concluded that all polar molecules which do not have the possibility of ortho and para rotational series of the type illustrated by hydrogen, will retain their high temperature nuclear spin entropy to temperatures far below 1°K. In the case of molecules having two or more similar atoms symmetrically placed within the molecule, all those containing such symmetrically placed atoms other than hydrogen will probably retain their limiting spin entropy to temperatures below 1°K. In the case of hydrogen it must be considered that the size of the proton places it in a class far removed from the other atoms whose "size" depends on the electron configuration about them. Many organic compounds undoubtedly have symmetrically placed hydrogen atoms. This does not necessarily mean that nuclear spin cancellation does not occur, since these molecules differ from hydrogen in that they condense at temperatures where the high temperature nuclear spin entropy is established, whereas the hydrogen molecules are frozen out at temperatures greatly below this point.

In many recent references to the use of the third law in connection with reactions involving hydrogen, the authors seem to feel that the entropy of hydrogen is in doubt. We hope it has been made clear that the entropy of hydrogen is definitely established and that the remaining doubt concerns other molecules which contain hydrogen. Since the effects discussed are of primary importance in connection with the use of the third law of thermodynamics in organic chemistry, it is interesting to note that the predominant isotopes carbon **12** and oxygen **16** are without nuclear spin.

The value of the entropy of hydrogen which should be used in conjunction with data obtained from the third law of thermodynamics is **31.23** E.U. This is the value which has been used by Kelley[4] at our suggestion. It is obtained by subtracting the high temperature nuclear spin entropy $R \ln 4 = 2.75$ **E. U.** from the absolute entropy of hydrogen $33.98 - 2.75 = 31.23$ **E. U.** This places hydrogen on the same basis as other molecules in most of which, and perhaps in all of which, the subtraction is taken care of by the fact that heat capacities are not usually measured below temperatures of a few degrees absolute.

The Dissociation **of** Hydrogen.—Langmuir and Mackay[23] have determined the heat of dissociation of hydrogen and the equilibrium constant over a range of temperatures. They utilized measurements of the energy conducted away from a heated filament operating in hydrogen gas at various pressures. As is well known, the evaluation of the heat of reaction

---

[23] (a) **Langmuir,** THIS JOURNAL, 34, 860, 1310 (1912); (b) 37, 417 (1915); (c) **Langmuir and Mackay,** *ibid.*, 36, 1708 (1814).

and dissociation constant from data where both occur as unknowns is very difficult and for this reason no very high accuracy has been claimed for the values obtained. However, with the assistance of the data and methods discussed above it is possible to show that the values of the dissociation of hydrogen given by Langmuir over the temperature range where his method was considered to be reliable are very satisfactory even though their temperature coefficient is somewhat in error.

From Equation 27 of the previous paper we have

$$\frac{F^\circ - E_0^\circ}{T} = -3/2\,R \ln M - 5/2\,R \ln T + R \ln P - R \ln Q + 7.267$$

R = 1.9869 calories per degree per mole.

From the energy equations of Birge, Hyman and Jeppesen[1] the values of the absolute $Q = \Sigma p e^{-\epsilon/kT}$ for the hydrogen molecule have been calculated. The values of $(F^\circ - E_0^\circ)/T$ are given in Table VI.

TABLE VI

ABSOLUTE $(F^\circ - E_0^\circ)/F$ FOR THE HYDROGEN MOLECULE

1200	36.782	3100	43.770		

The values given in heavy type have been directly calculated, the others have been carefully interpolated.

In calculating the values in Table VI the effect of nuclear spin has been included. However, if these values are to be combined with similar data for substances where the nuclear spin is unknown, and thus is conveniently ignored, the amount of $R \ln 4 = 2.755$ should be added to $(F^\circ - E_0^\circ)/T$. For example, the value of $-(F^\circ - E_0^\circ)/T$ for 298.1°K. becomes 24.436 calories per degree per mole.

For monatomic hydrogen the absolute $Q = 1$ per atom, a multiplicity of 2 arising from nuclear spin with an additional factor of 2 due to the electron spin in this atom. Thus the absolute

$$\frac{F^o - E_0^\circ}{T} = -3/2\,R \ln 1.0076 - 5/2\,R \ln T - R \ln 4 + 7.267$$

In Table VII the values of $+5/2\,R \ln T - 7.267$ are given instead of the whole function because these values are necessary in connection with all other gaseous substances. The constant amount $3/2\,R \ln 1.0076 + R \ln Q = 2.784$ must be added to the values in Table VII to give $-(F^o - E_0^\circ)/T$ for atomic hydrogen. For example, the value for 298.1°K. is **23.818** calories per degree per mole.

To eliminate the contribution of nuclear spin the amount $R \ln 2 = 1.378$ should be subtracted, thus giving **22.440** at 298.1°K.

TABLE VII

VALUES OF $\frac{5}{2} R \ln T + R \ln \frac{(2\pi k)^{3/2}}{h^3 N^{5/2}} + R \ln R$

1150	27.740	3000	32.503	5000	35.040
1200	27.951	3100	32.665		

For the reaction $H_2 = 2H$, values of $\Delta(F^o - E_0^\circ)/T$ may be obtained from the above tables.

$$\frac{\Delta F^\circ}{T} = -R \ln K = \Delta\left(\frac{F^\circ - E_0^\circ}{T}\right) + \Delta E_0^\circ$$

where $K = [H]^2/[H_2]$.

ΔE_0° has been evaluated by a number of authors from vibration bands which have been observed to dissociate in the case of one of the higher electronic levels. A knowledge of the molecular and atomic excitation energy completes the necessary information. The basis of such calculations has been discussed by Birge and Sponer[24] and a summary of recent work has been given by Birge.[25]

The most reliable value is that given by Richardson and Davidson,[26] namely, 4.46 ± 0.04 volt electrons or since 1 volt electron = 23,059 calories per mole, $\Delta E_0^\circ = 102{,}800 \pm 1000$ calories per mole.

Bichowsky and Copeland[27] have calorimetrically determined the ΔH of the above reaction to be 105,000 ± 3500 calories per mole at room temperature. With the assistance of Table III it is found that this should be decreased by 940 calories in order to obtain ΔE_0°. Thus $\Delta E_0^\circ = 104{,}000 \pm 3500$ calories in satisfactory agreement with the spectroscopic value.

Using the value $\Delta E_0^\circ = 102{,}800 \pm 1000$ calories per mole with Tables VI and VII, the values given in Table VIII have been computed.

TABLE VIII

FREE ENERGY OF DISSOCIATION OF HYDROGEN

T, degrees absolute	$-\Delta\left(\frac{F^\circ - E_0^\circ}{T}\right)$ Calories per degree	$\frac{\Delta F}{T}$	$K = e^{-\Delta F/RT} = [H]^2/[H_2]$
298.1	20.445	324.406	$(1.2 \pm 4.7) \times 10^{-71}$
500	22.054	183.546	$(7.6 \pm 12) \times 10^{-41}$
1000	24.153	78.647	$(6.4 \pm 3.8) \times 10^{-18}$
1500	25.328	3.205	$(3.6 \pm 1.3) \times 10^{-10}$
2000	26.106	25.294	$(2.96 \pm 0.77) \times 10^{-6}$
2500	26.662	14.458	$(6.92 \pm 1.4) \times 10^{-4}$
3000	27.060	7.207	$(2.66 \pm 0.45) \times 10^{-2}$
3500	27.384	1.987	$(3.68 \pm 0.52) \times 10^{-1}$
4000	27.656	−1.956	2.68 ± 0.32
5000	28.064	−7.504	43.7 ± 4.4

Additional values may be calculated similarly from the data given in Tables VI and VII. The estimate of the accuracy is based on the assumption that the ΔE_0° is reliable to 0.04 volt electrons. When a more accurate value of ΔE_0° becomes available, a very simple correction may be applied.

In Table IX the values of the percentage dissociation at one atmosphere pressure are given: percentage dissociation = $100\sqrt{K/(K + 4P)}$, where P = total pressure. The values given by previous authors have been included for comparison.

We have previously mentioned the good agreement between the calculated values and those obtained by Langmuir. This would not be so if the spin effects were not properly considered. For example, neglect of the electron spin multiplicity in the hydrogen atom would decrease all the

calculated dissociation constants by a factor of four. This same effect has been even more definitely demonstrated by Gibson and Heitler[21] in the case of the dissociation of iodine.

The agreement also supports the statement of Gibson and Heitler that nuclear spin effects cancel in chemical reactions and can thus be ignored. Although this factor was not ignored in the above calculation, the results above ordinary temperatures would be identical if it had been, since the limiting contribution to the free energy of both reactant and product is $-RT \ln 4$.

It is evident that the results of spectroscopy will permit the determination of chemical equilibria involving simple molecules with an accuracy not attainable by previous experimental methods.

Summary

The band spectrum data of the hydrogen molecule have been used to illustrate the exact calculation of several thermodynamic properties.

The relative amounts of ortho and para hydrogen molecules under equilibrium conditions have been given over the significant temperature range with high accuracy.

The energy contents and heat capacities of pure para hydrogen, pure ortho hydrogen, the equilibrium mixture and the mixture consisting of one part para to three parts of ortho hydrogen have been calculated over the range from 0° to 298.1°K.

The free energy of the reaction $H_2 = 2H$ has been calculated at various temperatures up to 5000°K. The equilibrium constants and percentage

dissociation have been given and comparison has been made with the results published by others. The fractions dissociated as obtained from band spectrum data alone are shown to be in good agreement with those given by Langmuir on the basis of the amount of heat conducted from a hot filament in an atmosphere of hydrogen.

Tables of the free energy function for hydrogen have been given for temperatures up to 5000°K. These will be useful in connection with chemical reactions in which hydrogen takes part, and will be followed by the publication of similar tables for other substances.

The absolute entropy of hydrogen was found to be 33.98 calories per degree per mole. The entropy which should be given by the ordinary application of the third law of thermodynamics, including the usual Debye extrapolation below the temperatures of liquid hydrogen, is shown to be 29.59 E.U. This is in close agreement with the experimental value 29.7 or 29.6 depending on whether the equation of Berthelot or that of van der Waals, is used in correcting for gas imperfection. The theoretical value of 29.59 E.U. is obtained from the assumption that the lowest levels of ortho and para hydrogen, with their combined total of ten quantum species, are present in the solid state as a perfect solution. The relative amounts are those determined by the room temperature equilibrium of ortho and para hydrogen. This is one of the best proofs of the third law of thermodynamics.

The effect of nuclear spin on the entropies obtained from the third law has been discussed. This question is of first importance in the practical application of the third law since nearly all elements have a nuclear spin and it contributes a considerable amount of entropy. It is concluded that the portion of the absolute entropy resulting from nuclear spin will usually persist to temperatures below those at which measurements are ordinarily made. There is reason to believe that hydrogen will prove to be the one exception to the above statement but further experiments are necessary to lend weight to this.

Gibson and Heitler have shown that the effect of nuclear spin, like the isotope effect, cancels in reactions. While this is a high temperature approximation, the sense of our above statements is that a few degrees absolute is usually a sufficiently high temperature to effect cancellation. This being so the ordinary method of applying the third law automatically corrects for the neglect of nuclear spin entropy through cancellation in the chemical reaction concerned. This explains the previous successful tests of the third law.

In the case of hydrogen a few degrees or even a hundred degrees absolute is not sufficient to approach the limiting case. Thus in order to obtain an entropy value for hydrogen which may be used in combination with those obtained by the ordinary application of the third law to other substances, we may adopt the artifice of subtracting the limiting spin entropy from the known absolute entropy, giving the value **33.98** $-$ R ln 4 $=$ **31.23 E.U.**

This is in agreement with the fact that the ordinary, and incorrect, application of the third law to hydrogen has, in general led to discrepancies which would be reduced by the use of this value.

We wish to emphasize that while some uncertainty may remain as to the effect of nuclear spin on other substances, no reasonable doubt exists as to the value of the entropy of hydrogen.

Lipscomb and Hulett[4] found for Cell 2 the value $E_{25} = 0.67080$ v. For Cell **3** Gerke[5] found the value $E_{25} = 0.5299$ v. Calculating the electromotive force of Cell **1** from these values gives a result which agrees well with the value found by Obata. Cell **3** and the similar cell with a solid lead electrode have been studied by numerous other investigators.[6] Values calculated for Cell 1 from the results for Cell 3 obtained by some of these investigators are in better agreement with Vosburgh's value. Cells **1** and **3** have therefore been studied further.

The electromotive force–temperature curve of Vosburgh's cell shows a transition point at 26° which does not correspond to the transition point of cadmium chloride. An explanation of this was sought also.

Preparation of Materials

Mercury was purified by washing with mercurous nitrate solution and distilling under reduced pressure in a current of air.

Water for the preparation of materials was redistilled from alkaline permanganate. Water for the electrolyte solutions was redistilled a second time in an all-silica still.

Three preparations of mercurous chloride were used. Preparation 1 was made by adding dilute hydrochloric acid slowly to mercurous nitrate solution. Preparation 2 was made by adding mercurous nitrate solution to dilute hydrochloric acid. Preparation 3 was made by a modification of the electrolytic method of Hulett.[4] All three preparations were digested under dilute hydrochloric acid at a temperature near the boiling point for at least eight hours.

Lead chloride was precipitated by adding a solution of recrystallized lead nitrate drop by drop to a solution of redistilled hydrochloric acid.

Baker's c. P. cadmium chloride and potassium chloride were recrystallized from redistilled water.

Lead amalgam was made electrolytically from purified mercury and lead chloride and contained approximately 6% of lead.

To make cadmium amalgam, cadmium was electrolyzed from c. P. metal sticks into commercial redistilled mercury through cadmium sulfate solution. From the amalgam thus formed the cadmium was again electrolyzed into purified mercury, forming a 12% amalgam. This was diluted with mercury to make a 10% amalgam.[7]

Experimental

Preparation of Cells.—The cells were set up in glass H-vessels 16 cm. high and 5.5 cm. wide. The tubes had an inside diameter of 10 mm. In the preparation of Cells 2A and 2B, the mercurous chloride was filtered in a Gooch crucible and mixed in an agate mortar with crystals of cadmium chloride. This paste was transferred to a separatory funnel and washed several times in an atmosphere of nitrogen with the electrolyte solution. It was then put into the cell vessel on top of the mercury, the end of the separatory funnel being kept under the surface of some electrolyte solution above the mercury. Cadmium chloride crystals were then placed above the paste. The melted amalgam was put into the vessel by means of a heated glass tube, and the surface washed with some slightly acidified electrolyte solution to remove cadmium oxide. Then the surface was washed several times with electrolyte solution and finally crystals of cadmium chloride and electrolyte were put on top of it. The vessels were filled to the cross arm with electrolyte and closed with paraffin-coated corks. All the other cells (except Cells 3C and 3D, which were prepared without precautions to protect from air) were prepared in a similar manner. In the preparation of Cells 1C, 1D, 1E, 2C, 2D, 3E and 3F the paste was not washed in a separatory funnel. Instead, the cells were alternately evacuated and filled with nitrogen several times. Cells 2E, 2F, 3G and 3H were prepared using both these precautions.

In Cells 3A and 3B saturated lead chloride solution was used as the

---

[7] The cadmium amalgam was prepared by Kelly L. Elmore.

electrolyte. In Cells 3G and 3H, 1.0 *N* potassium chloride solution was used. All the other cells contained saturated cadmium chloride solution as the electrolyte. In cells with saturated cadmium chloride solution as the electrolyte, cadmium chloride crystals were mixed with the paste and were present in excess in both arms of the cell.

The cells were kept at 25°, except as otherwise indicated, in an electrically controlled oil thermostat, the temperature of which fluctuated not more than ±0.01° and under favorable conditions not more than ±0.005°. The temperatures are probably correct to within ±0.02°.

Electromotive Force Measurements.—The electromotive forces were measured by means of a calibrated Leeds and Northrup Type K potentiometer. Standard Weston cells Nos. 353–356 and 496 previously described[8] were used as reference standards. They were found to agree within one or two parts in 100,000 with two portable saturated cells certified by the Bureau of Standards.

A number of the cells started with abnormally high electromotive forces. The electromotive forces of such cells decreased continuously over a period of several weeks until finally constant values were obtained. Changes in temperature appeared to hasten the attainment of a constant value. Other cells were practically constant from the beginning. Table I shows the initial and final constant values of cells of each of the three types. In most cases the constant values of duplicate cells agreed to within 0.1 mv., but in two cases duplicates differed by 0.6 mv. The latter were given less weight in selecting the final values.

Of the three types of cells, the calomel standard cell of Lipscomb and Hulett, Cell 2, was the easiest to reproduce. The quality of Cell 3 depended somewhat on the electrolyte used, potassium chloride giving the best results. When no electrolyte other than the lead chloride was used, the electromotive force was about 1 mv. too high, and the cells did not agree well.

[a] Cells 1 and 2 were metastable at these temperatures. [b] These values were obtained after stable equilibrium had been reattained. [c] This value was for Cell 1A. Cell 1B did not come back to a definite equilibrium. [d] This is a second determination of the temperature coefficient of Cell 1A. [e] One leg of each of these cells became stable while the other remained metastable.

librium. Beginning at 25° the temperature was changed as indicated in the first column of Table II. Usually three days or more were allowed for the cells to come to equilibrium at each temperature. In a few cases, when measurements at intervals showed no change taking place, less time was allowed. Electromotive force measurements were made every day. The results are given in Table II.

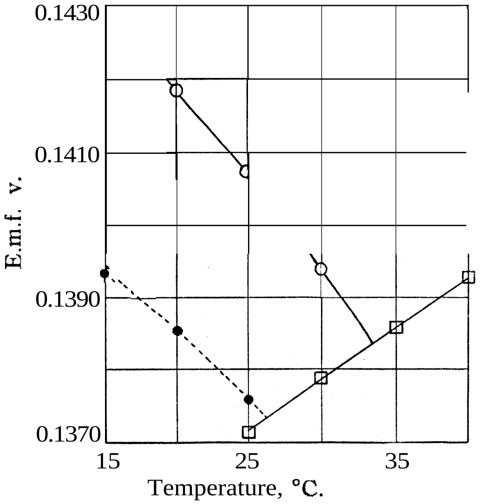

Fig. 1.—Variation of the electromotive force of Cell 1 with temperature. The circles are values of Cell 1 obtained in this investigation. The dotted curve gives the values previously found by Vosburgh. The squares are points at which Vosburgh's cell and Cell 1 were in close agreement and represent the values of the electromotive force when monohydrated cadmium chloride is the solid phase.

Since cadmium chloride changes from the hemipentahydrate to the monohydrate at about 34° there is a sharp change of slope at that point in the electromotive force–temperature curve of the cells with cadmium as illustrated by Fig. 1. On decreasing the temperature, the monohydrate did not change back to the hemipentahydrate immediately, sometimes not even at 25°. To hasten this change, after the first temperature coefficient determination, the cells were put into an ice–salt mixture for a day. After the second determination, instead of this treatment the cells were opened and seeded with crystals of the hemipentahydrate. The latter method is much more effective. The electromotive forces then returned to the values for the stable cells at 25°, except in the case of Cell 113 which, after being cooled, became variable.

Discussion

The value found for Cell 2, $E_{25} = 0.6706$ v., was about 0.2 mv. lower than the value given by Lipscomb and Hulett.[4] This, while not a serious disagreement, may perhaps have been caused by the digestion of the mercurous chloride. It has been shown[9] that digestion of mercurous sulfate gives a more stable preparation, leading to lower and more reproducible results when used in Weston cells. The same was found to be true in the case of lead dioxide.[10]

Cell 2 became metastable when the temperature was raised above 34° and then cooled again. The metastable cells readily assumed their normal value at 25° on being seeded with hemipentahydrate crystals or subjected to cooling treatment. The electromotive force of Cell 2 between 20 and 30° is given by the formula

$$E = 0.6706 - 0.000102\,(t - 25) - 0.0000025\,(t - 25)^2$$

the temperature coefficients being those found by Lipscomb and Hulett. From 34 to 40° and for the metastable cell between 25 and 34° the electromotive force is given within 0.1 mv. by the formula

$$E = 0.6699 + 0.000284\,(t - 35)$$

Five cells of the type of Cell 1 were made which gave good results. Three of them did not come to equilibrium until the middle of the temperature coefficient determination, but their values in the metastable state as well as their values in the final stable state at 25° were in good agreement with the other two cells.

The values at different temperatures of Cell 1A, which was subjected to both temperature coefficient determinations, are given in Table III, together with those calculated from the formula given by Obata.[2]

[a] Cells 1A and 1B. [b] Cells 1A, 1B, 1D and 1E. [c] It is to be noted that Vosburgh used an amalgam containing lead. His values have been corrected as indicated in his paper (Ref. 3) and the values given here apply to a cell with pure cadmium amalgam, and so are comparable with the values of Cell 1.

The data in Tables III and IV are plotted in Fig. 1. The tables and figure show that the values of Cell 1 agree with Obata's value rather than with Vosburgh's from 17 to 30°. When the monohydrated cadmium chloride is the solid phase they agree well with the values given by Vosburgh for his cell when in a similar condition. The cadmium chloride in Vosburgh's cell must have been in some unknown metastable state before his temperature coefficient determination. This would account for the transition point being at 26° instead of at 34°. An attempt to duplicate Vosburgh's cells as they were before carrying above the transition point was not successful.

Of the cells of the type of Cell 3, Cells 3C, 3D, 3F, 3G and 3H gave the best results. Table V gives the electromotive forces of these cells at different temperatures, together with the values calculated from Gerke's value[5] with his temperature coefficient. The line marked "Calcd. I" gives the values calculated by subtracting the value of Cell 1 from the corresponding value of Cell 2. The line marked "Calcd. II" gives the values calculated in the same way from the same cells with monohydrated cadmium chloride as the solid phase.

TABLE V

ELECTROMOTIVE FORCE OF CELL 3 AT DIFFERENT TEMPERATURES

Summary

The following cells have been set up and their electromotive forces and temperature coefficients measured.

$$\mathrm{Cd(Hg)} \mid \mathrm{CdCl_2{\cdot}2.5H_2O\ (sat.)} \mid \mathrm{CdCl_2{\cdot}2.5H_2O\ (sat.),\ PbCl_2} \mid \mathrm{Pb(Hg)} \quad (1)$$
$$\mathrm{Cd(Hg)} \mid \mathrm{CdCl_2{\cdot}2.5H_2O\ (sat.)} \mid \mathrm{CdCl_2{\cdot}2.5H_2O\ (sat.),\ Hg_2Cl_2} \mid \mathrm{Hg} \quad (2)$$
$$\mathrm{Pb(Hg)} \mid \mathrm{PbCl_2\ (sat.)} \mid \mathrm{PbCl_2\ (sat.),\ Hg_2Cl_2} \mid \mathrm{Hg} \quad (3)$$

When hemipentahydrated cadmium chloride was the solid salt in equilibrium with the electrolyte in Cell 1, the values were in good agreement with the values found by Obata. When monohydrated cadmium chloride was the solid salt in equilibrium (or metastable equilibrium) with the electrolyte, the values were in good agreement with those found by Vosburgh when his cells had the monohydrate as the solid phase.

A value only slightly lower than that of Lipscomb and Hulett was found for Cell 2.

From the values for Cells 1 and 2 a value for Cell 3 was calculated which agreed with the observed values for Cell 3 and with Gerke's values for this cell. Of the three this cell was the most difficult to reproduce.

KINETICS OF THE ACETYLENE–OXYGEN REACTION

BY ROBERT SPENCE AND GEORGE B. KISTIAKOWSKY

RECEIVED SEPTEMBER 29, 1930 PUBLISHED DECEMBER 18, 1930

Although of extraordinary technical and general interest, the problem of the mechanism of hydrocarbon combustion has yielded very little exact, reproducible information despite numerous investigations, principally owing to the complexity of the process and the consequent possibility of considerable variation in the course of reaction with changing conditions. However, the results of more recent experimental work on the slow oxidations of gaseous hydrocarbons have led several workers to postulate a chain mechanism.[1] Thus, it was found that in vessels packed with pieces of the same material as that of the containing walls, the reaction velocity is slower and the products are, in general, somewhat different. An even more direct evidence in favor of this hypothesis has been obtained by Spence and Taylor,[2] who showed that small amounts of ozone introduced into a stream of slowly reacting oxygen and ethylene accelerate the rate of reaction between the latter. In the few cases that have been studied, the reaction kinetics appear to be somewhat unusual and favor the assumption of a chain mechanism. Thompson and Hinshelwood[1] observed that the velocity of the ethylene–oxygen reaction is proportional to a high power of ethylene concentration and is almost independent of oxygen. Very similar

observations have been made with acetylene,[3] hydrogen,[4] higher aliphatic hydrocarbons,[5] and benzene.[6] Hence, it appears that many gaseous hydrocarbon oxidation reactions have common properties and therefore anything which is found true for one of them may very probably apply to other hydrocarbons with little modification.

Since the complexity of the oxidation reaction undoubtedly increases with the size of the hydrocarbon molecule, the authors decided to study the oxidation of that one having the smallest number of atoms, namely, acetylene, which reacts with oxygen at moderate temperatures and thus makes the isolation of unstable intermediary products more probable. Those who have studied this reaction previously employed two methods of attack. Bone and Andrew[3] enclosed various mixtures of oxygen and acetylene at known total pressures in glass bulbs, raised the bulbs to given temperatures for a certain time, then noted the pressure change after cooling to room temperature and finally analyzed samples of the gases. The principal gaseous product was carbon monoxide. In a second series of experiments they employed a flow system, but in this case their reaction vessel was packed with broken porcelain and the gaseous product contained a much larger percentage of carbon dioxide. The work of Kistiakowsky and Lenher[1] on flowing mixtures of acetylene and oxygen showed that Bone and Andrew's bulb reactions were of the homogeneous kind, while the packed tube reactions giving a larger proportion of carbon dioxide were principally of the wall variety. The authors decided to use a circulating system for their experiments because it combines the advantages of the previous static and flow methods. In the apparatus finally adopted, gases could be admitted in any given amounts up to atmospheric pressure, could be circulated through the furnace at a given rate and the total pressure in the apparatus noted at intervals. A U-tube cooled in carbon dioxide and ether removed all condensible products immediately on leaving the furnace and these could be analyzed after the experiment, together with a sample of the gaseous products.

Circulating Pump.—Mixtures of acetylene and oxygen are extremely sensitive and will explode with great violence on the slightest provocation. A circulating pump necessitates considerable friction, particularly in valves, with the consequent possibility of electrical discharges. In the first apparatus the circulating pump was equipped with mercury non-return valves but these would detonate the gas mixture without warning after working satisfactorily for as many as six experiments. Then an all-glass valve was evolved, similar in design to that shown in Fig. 1. A

flexible glass plate, no more than 0.002 in. thick was held against the flat, ground end of a capillary tube by a fine glass rod sealed into a side tube. A non-return valve of this type is efficient, sturdy and simple to make. However, despite the fact that practically all mechanical friction had been eliminated, explosions still resulted. Here the source of the trouble seemed to be the "Armstrong effect" of dry gases streaming from a narrow jet, giving an electrical charge to the jet which eventually discharged to the glass plate, the latter having meanwhile taken the opposite charge from the gases. In the design eventually adopted, and which proved to be quite successful (Fig. 1), the tip of the capillary jet was coated with a mirror of platinum and the glass plate replaced by a thin plate of beaten platinum foil welded to a tungsten wire sealed into the side tube. The end of the tungsten wire was connected to earth and all possibility of an accumulation of electrical charge removed. While not so efficient as the glass or mercury valves the new type allowed of a reasonable rate of pumping, which was all that was required. Attempts were made to localize explosions in order to prevent complete destruction of the apparatus which inevitably ensued when all the gas mixture was detonated. Tubes containing fairly tight wads of cotton wool placed at either end of the circulating pump proved to be very efficient and while they were in use no explosion spread beyond the valves of the circulating pump. Fig. 1 illustrates the arrangement of the circulating pump. Four valves were connected to the steel pump barrel by two glass tubes longer than a barometric column. These columns were filled with mercury which could be given an oscillating motion by movement of the piston in the steel cylinder. A packing composed of a mixture of stopcock grease, asbestos pulp and graphite, enclosed in the piston gland, effectively prevented any leakage of mercury, while cheesecloth filters placed at the foot of the mercury columns helped to keep the mercury free from grease contamination.

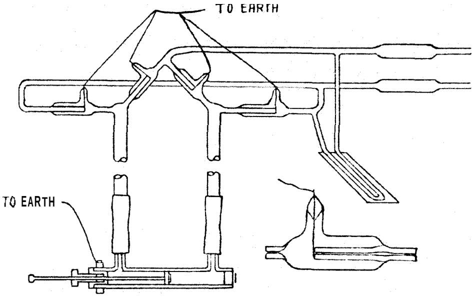

Fig. **1.—Circulating pump and** valve.

Main Apparatus.—By far the larger part of the total gas enclosed in the apparatus was contained in two glass bulbs, each of 200 cc. capacity, placed next to the pump. A large very stout wooden cover surrounded the bulbs, which were connected to the cotton wool safety tubes on either end of the pump. The gases could be circulated around the pump and bulbs to ensure thorough mixing, then admitted to the furnace circuit which had previously been evacuated. The furnace consisted of a pyrex glass tube of 98 cc. capacity into which was sealed a tube containing a thermocouple. Immediately on leaving the furnace, the gases passed into a U-tube cooled in a carbon dioxide–ether mixture and which was connected to the apparatus by two ground-glass joints sealed with piceine wax. To ensure uniformity of conditions before and after the reaction, another U-tube cooled in carbon dioxide–ether mixture was placed immediately before the furnace, while the pressure of the gases entering this U-tube was measured on a mercury manometer having a barometer attached to the same scale.

Purification of the Gases.—Oxygen from a tank was dried in a sulfuric acid wash bottle, then passed into a storage bulb via a U-tube immersed in a solid carbon dioxide-ether mixture. Acetylene, obtained from a small Prestolite tank, was bubbled through water, a mixture of cupric and ferric chloride solutions, caustic potash and finally passed over calcium chloride into a vessel cooled in liquid air, where it condensed to a white solid. Inert gases were removed by evacuation, the solid was distilled from a carbon dioxide-ether bath and the middle fraction collected in a storage bulb. After further solidification and evacuation, the acetylene was again allowed to evaporate into the bulb, where it was ready for use.

Calibration of the Apparatus.—The volume of the apparatus and its parts was determined by admitting gas at known pressure and volume into the evacuated apparatus and reading the pressure.

Volume of circulating pump and capacity bulbs	550 cc.
Volume of furnace (cold)	98 cc.
Volume of U-tubes, etc.	26 cc.
Total volume	674 cc.

In order to know the time of contact of the gases with the furnace at the various pressures studied, the U-tube was replaced by two 500-cc. bulbs connected by a stout, wide bore, rubber tubing, containing a strong solution of calcium chloride. The time necessary to transfer 500 cc. of liquid (the levels of the solution in the two bulbs being kept the same) was noted over a large range of pressures and pumping rates and the results were plotted so that the contact period for any given conditions could easily be read off.

Experimental Method.—Before beginning an experiment, the furnace was adjusted to the required temperature, the U-tubes surrounded with carbon dioxide–ether mixtures, and the whole apparatus evacuated. After having shut off the furnace section from the rest of the apparatus, definite amounts of acetylene and oxygen, measured on the manometer, were admitted and circulated for about five minutes to ensure good mixing of the two gases. At this point the necesary stopcocks were turned, bringing the furnace into the circulating system and closing the by-pass. Readings of manometer, barometer, temperature and pumping rate were taken immediately and at given intervals thereafter until the experiment was finished. Upon completion of an experiment, the furnace was again shut off, evacuated, and a sample collected from the remaining gas by a mercury pipet in which it was retained for analysis.

Analysis of the Products.—At the end of an experiment, the U-tube contained a mixture of polymerized glyoxal, formaldehyde, formic acid and water. These were washed out with hot water, in which the polyglyoxal dissolves, a hot solution of the hydrochloride of p-nitrophenylhydrazine added and the mixture filtered through a tared Gooch crucible. After drying and weighing, the crucible was placed in a Soxhlet apparatus and extracted with chloroform. This treatment removed the *p*-nitrophenylhydrazone of formaldehyde and left the *p*-nitrophenylosazone of glyoxal behind. A final drying and weighing gave the weight of formaldehyde and glyoxal. The p-nitrophenylosazone of glyoxal crystallizes from pyridine in long red needles, m. p. 318°. *Anal.* Calcd. for $C_{14}H_{12}O_4N_6$: C, 51.2, H, 3.7. Found: C, 51.35, H. 3.9. In an identical experiment, the condensate was made up to 10 cc. and two 5-cc. portions were titrated with $N/100$ baryta solution, using brom cresol purple as indicator. This gave the amount of formic acid present. The gas collected over mercury was analyzed for acetylene (by fuming sulfuric acid), carbon dioxide, oxygen, carbon monoxide and hydrogen (over heated copper oxide). From these figures, a balance of carbon, before and after the reaction, could be made.

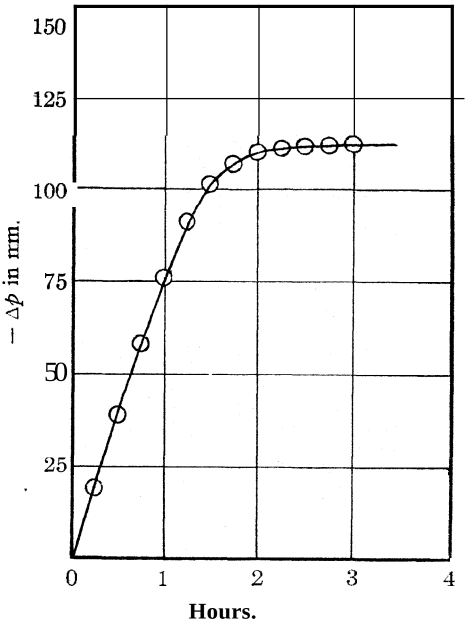

Fig. 2.—$-\Delta p$ curve for a mixture of approx 400 mm C_2H_2 and 100 mm O_2 at 320°, reaction carried to completion

Experimental Part

Figure 2 represents a typical experiment which has been carried to completion and shows the general form of the pressure–time curve. The example shown, however, was not obtained with an apparatus identical with that used in the principal experiments. The results of all the experiments quoted below were plotted in a similar manner and dx/dt, the initial rate of reaction in mm. per minute, obtained by direct measurement.

The Induction Period.—To ascertain the effect of varying rates of pumping on the reaction velocity, series of mixtures of constant composition were circulated at different rates and the reaction velocity determined.

35	173.4	191.4	37	.56

We see that for contact periods greater than about twenty-five seconds, the rate is independent of the pumping Speed. The rapid falling off in reaction rate with higher pumping speeds must be due to the existence of an induction period.

Temperature Coefficient.—Measurements of rates of reaction of given mixtures at different temperatures are given in Table II. In all succeeding experiments the rate of pumping was arranged so as to give a constant contact period of about forty seconds.

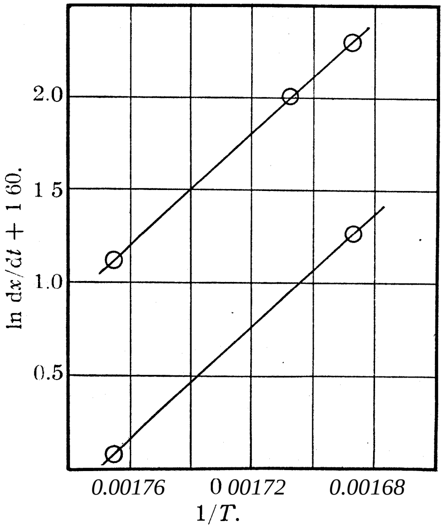

Fig. 3.—Logarithm of rate of reaction plotted against $^1/_{T_{\text{abs}}}$. for two different mixtures.

In Fig. 3 are plotted the logarithms of the reaction velocity against the reciprocal of absolute temperature. Within the narrow temperature interval investigated, the experimental points lie on straight lines and the slope is independent of the composition of the gas mixture, but it is realized that more extended experiments may show a deviation from these results. From the observed temperature coefficient, the activation energy of the reaction is calculated to be 34,700 cal. at 320°.

Influence of Acetylene and Oxygen Concentrations.—Table III gives the initial concentrations of acetylene and oxygen, the pressure decrease at five-minute intervals and the initial rate as measured from each curve. The meaning of K_0 is explained below. All experiments were carried out at 320° with a contact period of forty seconds.

Plotting rate against oxygen concentration, we obtain the four curves

shown in Fig. 4. In each case, increase in the oxygen concentration from zero causes an increase in the rate of reaction, until a region is reached where the rate is practically independent of oxygen. Further increase in oxygen concentration somewhat retards the rate of reaction, as illustrated by the negative slope of the latter half of the curves. The experiments indicate that the maximum rate is obtained with mixtures of approximately constant composition irrespective of total pressure. In these optimum mixtures the rate is very nearly proportional to the square of acetylene concentration, as is shown by Table IV, while at relatively low oxygen concentrations the rate is proportional to the first or even lower power of acetylene.

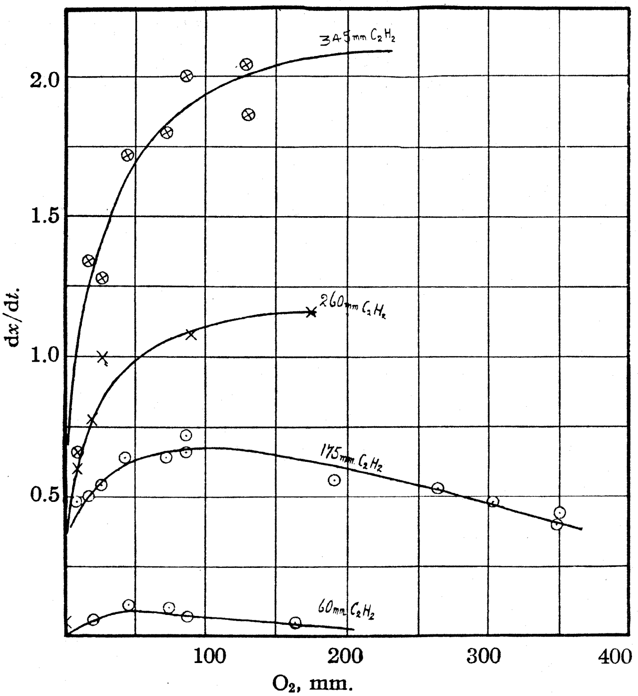

Fig. 4.—Oxygen concentration (for fixed acetylene concentration) plotted against rate of reaction (d*x*/d*t*); temp., 320°.

TABLE IV

DEPENDENCE ON ACETYLENE

The iodine test gave no indication of the presence of a per-acid in the condensate.

Discussion of Results

The experiments here presented show that oxidation of acetylene can proceed at a perfectly reproducible rate and has well-defined kinetics. The reaction would, therefore, seem to lend itself readily to kinetic treatment. However, any theory of the reaction mechanism would have to account not only for the dependence of the rate—as measured by the manometer—on the concentrations of the reactants, but also for such things as the presence of an induction period and the fate of the intermediate products. It is in the attempt to bring all these phenomena together in one theory that the chief difficulty is encountered.

It seems fairly certain that the induction period is an inherent part of the reaction and is not due to impurities. Thus, Kistiakowsky and Lenher, working with a different method and using considerably less purified gases than in the present work, observed that the lower the temperature at which the reaction proceeded, the longer was the induction period. Using contact times of fifty to two hundred seconds, they failed to notice an induction period at 313°—the highest temperature then studied. This present research, however, shows that an induction period is present even at 320° but is of much shorter duration. The two sets of experiments agree well together and indicate that the length of the induction period is roughly, at least, inversely proportional to the rate of reaction. These facts, together with the character of the present experimental method—a continuous circulation of the gases with removal of condensible products—make it most probable that the induction period is caused by a gradual accumulation of some condensible substance which is necessary for the oxidation of acetylene to acquire its full rate. Since the induction period is of considerable duration, this catalytic substance must possess some degree of stability at the temperatures employed and it thus becomes very probable that it can be identified as one or all of the three condensible intermediate products described above: glyoxal, formaldehyde or formic acid. Although a definite proof of this conclusion is still lacking, some evidence can be brought forward to show that formaldehyde at least must take an active part in the acetylene reaction. According to the theory of Bone[3] formaldehyde is not a by-product but one of the main stages in the oxidation of acetylene, which seems most plausible to the present writers. Furthermore, the experiments of Askey[7] show that mixtures of pure formaldehyde and oxygen are quite stable at 320°, the time of half reaction being of the order of one hour. Thus with a contact time of less than a minute, one should expect to find all the reacted acetylene in the form of formaldehyde. Instead, it is found that the major part of the formaldehyde is oxidized further into formic acid, carbon monoxide and water, its stationary concentration in the reacting mixture being attained in less than a minute at 310° according to experiments of Kistiakowsky and Lenher.[1] This means that in presence of acetylene, formaldehyde is oxidized some hundred times faster than when alone. Owing to lack of experimental data, no similar comparison can be made in the case of glyoxal and formic acid.

The induction period and the behavior of formaldehyde lend additional evidence in favor of a chain mechanism of acetylene oxidation. There is a large series of possible mechanisms for this reaction. The simplest, which does not involve any unidentified intermediate products

$$\begin{aligned} C_2H_2 + O_2 &\longrightarrow C_2H_2O_2 \\ C_2H_2O_2 &\longrightarrow CO + HCHO \\ HCHO + O_2 &\longrightarrow CO_2 + H_2O \end{aligned}$$

must, however, be neglected, since it accounts neither for the observed dependence of the rate on the reactant concentration, nor for the induction period, the oxidation of formaldehdye, nor the presence of chains. Several other schemes involving the least possible number of intermediate reactants were tried and it was found that mechanisms involving, in addition to the substances actually isolated, a compound of the per-acid or per-

---

[7] Askey, THIS JOURNAL, **52**, 974 (1930).

oxide type such as have been identified in many other oxidations, led to kinetic equations which could be made to reproduce the general trend of the experimental results. Schemes involving oxygen atoms were, in general, unsatisfactory. The equations derived from the per-acid theory, however, necessitated the assumption of chains sufficiently long that the primary reaction between acetylene and oxygen became insignificant in the total balance of reaction—in agreement with the observed retarding effect of the walls. On the other hand, assuming that each molecule of formaldehyde or glyoxal causes the oxidation of only one or two acetylene molecules, it can be calculated—from the amounts of the intermediary products recovered in the trap—that the chain length, *i. e.*, the number of acetylene molecules oxidized as the result of one primary reaction, does not exceed three to six. To reconcile these conclusions is difficult and it seemed to the writers that, until more experimental data are accumulated, an attempt to set up a detailed theory of the reaction mechanism would be premature. The constant K_0 of Table III was calculated therefore with the aid of an empirical equation

$$\frac{dx}{dt} = K_0 \frac{[C_2H_2]^2[O_2] + 3.5\,[C_2H_2]^2}{0.9\,[O_2] + 0.25\,\frac{[O_2]^2}{[C_2H_2]} + 0.0029\,\frac{[C_2H_2]^2}{[O_2]}}$$

which represents the observations reasonably well.

One of the authors (R. S.) wishes to express his indebtedness to the Commonwealth Fund for a Fellowship which enabled him to take part in this research.

Summary

1. The slow oxidation of acetylene has been studied by a circulation method allowing the isolation of more stable intermediate compounds.

2. It is found that these latter consist of glyoxal, formaldehyde and formic acid.

3. The rate of reaction is accelerated by oxygen when acetylene is in excess but is slightly retarded by it when present in excess.

4. At the optimum oxygen concentration the rate is proportional to the square of the acetylene concentration, while when less oxygen is present it is proportional to a lower power of acetylene.

5. Nitrogen has a very slight retarding influence on the rate.

6. The reaction exhibits an induction period which is due to gradual accumulation of an intermediary product taking part in the chain.

7. It is pointed out that in the presence of reacting acetylene, formaldehyde reacts with oxygen many times faster than when alone.

8. The bearing of these observations on the reaction mechanism is discussed.

THE ATOMIC WEIGHT OF URANIUM LEAD FROM SWEDISH KOLM

BY GREGORY PAUL BAXTER AND ALLEN DOUGLASS BLISS

RECEIVED OCTOBER 9, 1930 PUBLISHED DECEMBER 18, 1930

In connection with the work of the Committee of the National Research Council on the Measurement of Geologic Time by Atomic Disintegration, the determination of the uranium–lead ratio in the ash of Swedish kolm[1] has recently been completed. Thorium could not be detected. Since the accuracy of the age estimation is vitally dependent on the freedom of the material from lead of non-radioactive origin, the atomic weight of this lead has been compared with that of ordinary lead.

The ash of the kolm constitutes from 20 to 40% of the original, and contains a few hundredths of a per cent. of lead. In the extraction process outlined below the lead recovered amounted to 0.03% of the ash and 0.01% of the original kolm.

After various exploratory experiments the procedure finally adopted for treating the 50 odd kilograms of kolm was as follows. The material was burned in portions in electrically heated muffles of fused quartz. Practically all of the combustible portion was removed in this way. The almost insoluble ash, which yielded little lead to aqueous reagents except hvdrofluoric acid, was then heated to redness in a current of dry hydrogen chloride. Almost no lead chloride distilled during this treatment but the solution obtained by digesting the residue with hot water was found to contain the greater part of the lead, for the insoluble residue, when tested spectroscopically in an arc of pure graphite, was found to be nearly lead free. The lead was separated from the solution by double precipitation as the sulfide in ammonium acetate solution, and then was precipitated once as chromate. The total yield of lead chromate from the fifty kilograms of kolm was 7.2 g., equivalent to 4.6 g. of metal.

The outline of the further purification of this material was as follows: (1) conversion of the chromate to chloride by evaporation with hydrochloric acid; (2) conversion of chloride to nitrate by evaporation with nitric acid; (3) three crystallizations of the nitrate, once from concentrated nitric acid, twice from water; (4) conversion of the nitrate to chloride by repeated evaporation with an excess of hydrochloric acid; (5) recrystallization of the chloride, once in glass and twice in platinum;

---

[1] A shale-like material reported to be an upper Cambrian sedimentary with trilobites. For further details and references as to the lead–uranium ratio, age, etc., see the reports of the Committee on the Measurement of Geological Time by Atomic Disintegration to the Division of Geology and Geography of the National Research Council.

(6) distillation of the chloride in a current of dry hydrogen chloride in a quartz tube. The product was used in Analysis K2

A second sample was obtained from the combined mother liquors of the nitrate and chloride crystallizations by evaporation with hydrochloric acid, and was crystallized twice in glass and three times in platinum. After distillation in hydrogen chloride the product was used in Analysis K1.

As soon as the first two analyses had been completed, the resulting lead nitrate solution was evaporated, freed from silver with a small amount of hydrochloric acid, and subjected to a new purification consisting of three crystallizations of the nitrate from nitric acid and four of the chloride from water, once in quartz and three times in platinum (Analysis **K3).** From the chloride mother liquors of **K3** a fourth, less pure, sample was prepared by one crystallization of the chloride in glass and one in quartz (Analysis K4).

All of the material was again combined and purified, this time by five crystallizations of the nitrate from nitric acid and five of the chloride from water, once in quartz and four times in platinum (Analysis K5).

Analysis K6 was carried out with the same material after six crystallizations of the nitrate, and six of the chloride, one of the latter being conducted in quartz and five in platinum.

Common lead chloride[2] for comparison was prepared by three crystallizations as lead nitrate, and three as lead chloride. The latter was then distilled once in a current of hydrogen chloride as described above.

To prepare the lead chloride for weighing it was fused, while contained in a weighed quartz boat in a quartz bottling apparatus, in a current of dry hydrogen chloride, and allowed to solidify in an atmosphere of pure dry nitrogen. After displacement of the nitrogen by dry air, the boat was transferred to the weighing bottle and reweighed. Solution in hot water was followed by precipitation with a weighed, very nearly equivalent amount of the purest silver,[3] and the end-point of the precipitation was determined nephelometrically in the usual way. Final observations of the end-point were taken only after a period of from three to five weeks.

Purification of reagents followed conventional lines. Especial pains were taken during the extraction of the lead from the kolm that all reagents should be lead-free.

Weighings were made by substitution, a counterpoise being employed with the weighing bottle containing the boat. Vacuum corrections of +0.000058 and −0.000031 gram were applied to each gram of lead chloride and silver, respectively.

---

[2] From Coeur d'Alêne lead–silver ores.

[3] The silver used in all analyses except K3 and K4 was purified by Professor S. Ishimaru [THIS JOURNAL, 51, 1729 (1929)]. In Analyses K3 and K4 material was used prepared in the same way for this work with the assistance of Mr. J. P. Marble.

TABLE I

THE ATOMIC WEIGHT OF LEAD

K2	1.60407	1.24958	+ .00025	1.24983	1.28343	205.999
K3	2.56499	1.99848	− .00006	1.99842	1.28351	206.016
K4	1.83748	1.43153	+ .00014	1.43167	1.28345	206.003
K5	3.32075	2.58750	− .00021	2.58729	1.28349	206.011
K6	3.07451	2.39535	− .00005	2.39530	1.28356	206.027
				Average	1.28347	206.008
				Average omitting K1 and K4	1.28350	206.013

The determinations with common lead are consistent and in accord with the modern value for the atomic weight of this substance. The analytical procedure seems therefore to be satisfactory.

The atomic weight of the kolm lead seems to be close to 206.01 whether or not the two analyses with possibly less pure material, K1 and K4, are omitted. This value is surprisingly low, for the lowest value previously obtained, by Honigschmid and Horowitz, is 206.046, for lead from Morogoro pitchblende. Since Aston has found the lead isotopes to be integral with the mercury isotopes, and since these, making allowances for the presence of O^{18}, possess integral values on the basis of ordinary oxygen, the kolm lead seems to be composed almost exclusively of the isotope Pb^{206}. Compensation between isotopes of mass above and below 206 is unlikely, for there is no certain evidence of the existence of lead isotopes below 206.

The low value for the kolm lead excludes the possibility of serious contamination with common lead, which consists largely of the isotopes Pb^{207} and Pb^{208}, and is in accord with the fact that thorium has not been detected in the kolm ash. If the small excess in the atomic weight of the kolm lead over 206 is due to the isotope Pb^{207}, the proportion of this component is not far from 1%. Aston has found this isotope to be more than one-tenth as abundant as Pb^{206} in uranium lead from broggerite. If Pb^{207} is the end product of the actinium series, on the basis of Aston's result an atomic weight not less than 206.1 is to be expected for uranium lead unless the broggerite lead was badly contaminated with ordinary lead.

If actinium is not a direct product of the disintegration of U^{238}, but of an isotope, it may be that the organic process which produced the kolm exerted a selective action upon uranium isotopes, which resulted in the concentration of the isotope of mass 238. Examination of the uranium contained in the kolm might throw some light upon this question. This we propose to do.

THE ATOMIC WEIGHT OF URANINITE LEAD FROM WILBERFORCE, ONTARIO, CANADA

BY GREGORY PAUL BAXTER AND ALLEN DOUGLASS BLISS

RECEIVED OCTOBER 9, 1930 PUBLISHED DECEMBER 18, 1930

As a check on the age determination of a specimen of uraninite occurring in Cardiff township near Wilberforce, Ontario, Canada, by means of the uranium–thorium–lead ratio the atomic weight of the lead has been determined.[1]

A selected crystal of 700 g. was broken up with a clean hammer and anvil and the fragments crushed in a carefully cleaned jaw crusher. The product was then coarsely ground in a Quaker grinding mill. This mill had been previously cleaned by passing through it a considerable quantity of marble. The marble powder was found to be free from detectable quantity of lead.

About 300 g. of the powdered uraninite was boiled with concentrated nitric acid, and the residue, which later was found to consist largely of fluorspar, was separated and washed by decantation. From the solution the lead was precipitated by adding an excess of sulfuric acid and the precipitate was washed by decantation. The lead sulfate was metathesized to the carbonate by repeated treatment with hot sodium carbonate solution, and after the lead carbonate had been washed by decantation it was dissolved in nitric acid and freed from a small amount of insoluble material.

The original insoluble residue was further boiled first with nitric acid, and again after the addition of sulfuric acid, and the whole was evaporated to the fuming point of sulfuric acid. After being washed with water the residue was extracted with hot ammonium acetate solution, and the lead was precipitated as chromate. This in turn was washed and converted to sulfate by treatment with nitric and sulfuric acids. Conversion to nitrate was accomplished as in the case of the main portion and the two portions were then combined.

---

[1] For a description of geologic occurrence and analyses, by Ellsworth, Todd. Spence and Carnochan, see Exhibit A, appended to the mimeographed report of the Committee on the Measurement of Geological Time by Atomic Disintegration to the division of Geology and Geography of the National Research Council, May 3, 1900. Also *Trans. Can. Inst. Min. and Met.*, *2* (1930); *Amer. Mineralogist*, (Oct., 1930).

Since the glass dishes employed were obviously etched, owing to liberation of hydrofluoric acid from the fluorspar, in order to discover whether lead had been introduced from the dishes, they were separately heated with hydrofluoric acid solution, and the extract after evaporation was tested for lead. Since the total quantity of lead chromate recovered by treatment of three watch glasses, a beaker, flask and two porcelain evaporating dishes was only 0.0022 g., no serious contamination with common lead could have occurred during the treatment of the uraninite with acid.

The combined lead nitrate solution was evaporated to dryness to expel the excess of acid and then was recrystallized four times by solution in water and precipitation with a large quantity of concentrated nitric acid. The earlier experience of Baxter and Grover[2] showed that this treatment is adequate for removal of foreign metals. Solution of the nitrate in water was then followed by filtration through a platinum sponge crucible into a quartz dish. A considerable excess of hydrochloric acid was next added and the precipitated lead chloride was washed by decantation. Finally the chloride was recrystallized from water, once in quartz and three times in platinum.

To remove traces of silica the chloride was dried and sublimed in a current of dry hydrogen chloride in a quartz tube. It was prepared for weighing by fusion in a weighed quartz boat in a Richards bottling apparatus. Weighing of the chloride was followed by solution and precipitation with a weighed equivalent amount of the purest silver,[3] and the end-point of the precipitation was found with the assistance of the nephelometer by the addition of small amounts of dilute silver and chloride solutions.

Only two determinations were made since the original estimate of the probable atomic weight of this lead proved to be correct and the concordance of the two experiments was all that could be desired. Weighings were made by substitution and the weights of lead chloride and silver were corrected to vacuum by applying for each gram the corrections +0.000058 and −0.000031 g., respectively.

TABLE I

THE ATOMIC WEIGHT OF LEAD

	Ag = 107.880			Cl = 35.457	
Wt. of $PbCl_2$ in vacuum, g.	Wt. of Ag in vacuum, g.	Ag added, g.	Corrected wt. of Ag in vacuum, g.	Ratio $PbCl_2/2Ag$	Atomic wt. of lead
3.74779	2.91798	+0.00010	2.91808	1.28433	206.194
5.63102	4.38431	+ .00005	4.38436	1.28434	206.196
			Average	1.28434	206.195

Wells has analyzed the identical specimen of uraninite from which the lead which we have investigated was extracted and finds 53.52% of ura-

---

[2] Baxter and Grover, THIS JOURNAL, 37, 1031 (1915).

[3] Purified by Professor Ishimaru for an investigation on the atomic weight of meteoric nickel, *ibid.* 51, 1729 (1929).

nium, 10.37% of thorium and 9.26% of lead. If one assumes (1) that our material is essentially free from ordinary lead, (2) that the relation of Pb^{206} to Pb^{207} found by Aston in broggerite material, 86.8 to 9.6, is the relation in which these isotopes are produced from uranium and (3) that the uranium equivalent of thorium in lead-producing power is 0.38, the average atomic weight of the lead in this specimen of uraninite may be calculated to be 206.23. The difference between this value and our experimental value is far larger than the experimental uncertainty.

With Wells' percentages and the thorium–uranium constant, 0.38, together with the experimental value of the atomic weight of the lead in this uraninite, the average atomic weight of uranium lead is found to be 206.06, while Aston's ratio of Pb^{206} to Pb^{207} gives 206.10. On this basis the ratio of Pb^{207} to Pb^{206} would be a little over half as large as that found by Aston.

The assumption of Aston's ratio of Pb^{207} to Pb^{206} in uranium lead together with Wells' percentages of uranium and thorium and the atomic weight of our specimen of uraninite lead makes it possible to calculate the Th/U constant to be 0.27, a value believed by some to be within the bounds of possibility.

The uncertainty of the assumptions makes the last three calculations of doubtful value.

THE ACTIVITY COEFFICIENT OF COPPER IODATE IN AQUEOUS SALT SOLUTIONS

BY BEN H. PETERSON AND EARL L. MEYERS

RECEIVED OCTOBER 15, 1930 PUBLISHED DECEMBER 18, 1930

Bronsted and La Mer[1] have reduced the Debye and Hückel equation[2] to $-\log f = 0.505\, z_1\, z_2 \sqrt{\mu}$ as a limiting law which is valid when the ions are separated to such distances that the actual volume occupied by the ions is of no effect. Considerable research has been done testing the validity of this equation by measuring the activity coefficients of slightly soluble compounds in aqueous salt solutions. La Mer and Goldman[3] have determined the activity coefficients of thallous and lanthanum iodates, and Lewis and Randall[4] have calculated them for barium iodate using the data of Harkins and Winninghoff.[5] The slight solubility of

these salts in pure water ($Ba(IO_3)_2$, 0.000790; $La(IO_3)_3$, 0.00089006; and $TlIO_3$, 0.001844 mole per liter), and the accuracy with which the concentration can be measured render them especially suitable for testing the limiting law. In such dilute solutions the activity coefficient of the solute may be defined by the relation[6]

$$-\log f = \log S/S_0 - \log f_0$$

in which S is the solubility of the saturating salt in the salt solution of varying concentrations, S_0 the solubility in pure water, and f_0 the activity coefficient in pure water. In such dilute solutions the value of f_0 as calculated from the limiting law may be assumed for the purpose of testing the equation. In case of most of the solvent salts used by La Mer and Goldman[3] the curve of the observed values of $-\log S/S_0$ fused into the ideal curve but a characteristic "hump" was observed in the case of potassium sulfate as the solvent salt. The theoretical significance of this positive deviation has been discussed by Gronwall, La Mer and Sandved,[7] and by La Mer and Mason.[8] In as much as the data of La Mer and Goldman[3] are for a mono- and trivalent iodate it seemed advisable to compare these deviations with those of a bivalent iodate in order to determine whether the "hump" observed by them would be in evidence and the relative magnitude of such a positive deviation.

Experimental

The salt chosen for this purpose was copper iodate. This was prepared by metathesis using purified copper sulfate and potassium iodate. Equivalent amounts of these salts were placed in solution and added dropwise to six liters of doubly distilled water kept at 60° and constantly stirred. The addition required about four hours. The precipitate was then washed several times by decantation and placed in six liters of doubly distilled water. This was kept at 60° and stirred by an electrical stirring device for several days. The salt so prepared was "sedimented" in a tall cylinder and all particles that did not settle readily were siphoned off. By several repetitions of this process it was possible to obtain a crop of crystals which appeared to be uncontaminated with small particles and should consequently be of uniform solubility. This technique is appreciably the same as used by La Mer and Goldman with lanthanum iodate. The salt when filtered and dried over calcium chloride analyzed for $Cu(IO_3)_2 \cdot H_2O$. The solvent salts were recrystallized from a high grade analyzed product, dried and analyzed for moisture and water of crystallization.

The experiments were carried out in a large especially constructed thermostat maintained at 25 * 0.02'. Ten pyrex Erlenmeyer flasks fitted with especially constructed stoppers through which a stirring rod extended were placed in the thermostat and 5 g. of the iodate added with 250 cc. of the solvent solution. The contents of the flasks were gently agitated for five days, then allowed to stand for twelve hours. These solutions were analyzed for dissolved copper iodate by dissolving 2 g. of potassium iodide in 250 cc. of water in a 500-cc. iodine flask, 5 cc. of 6 M sulfuric acid was added, then 25 cc. of

the iodate solution. The contents of the flask were immediately titrated with $N/20$ sodium thiosulfate. The thiosulfate was restandardized before and after each run by exactly the same technique using 25 cc. of $N/20$ potassium iodate as the standard. Some trouble was experienced with a slow reaction between the iodide and cupric ions but the technique finally adopted allowed sufficient time to elapse between the completion of the iodate and the beginning of the cupric reaction. This was repeatedly checked using solutions of potassium iodate to which small quantities of copper sulfate had been added. In Table I is given a set of representative data illustrating the reliability of the method.

TABLE I

REPRESENTATIVE DATA

VI	200	2	5	100	25	28.38

Experimental Results

The solubility of copper iodate in solutions of potassium chloride, potassium sulfate, magnesium chloride and magnesium sulfate is given in Table II. The column headings are self-explanatory. The limiting law takes the form

$$-\log f = 1.01\sqrt{\mu}$$

from which the values in Column 6 are calculated. $-\log f_0$ equals 0.1063, obtained from the above equation when μ represents the ionic strength of the copper iodate in the pure water solution.

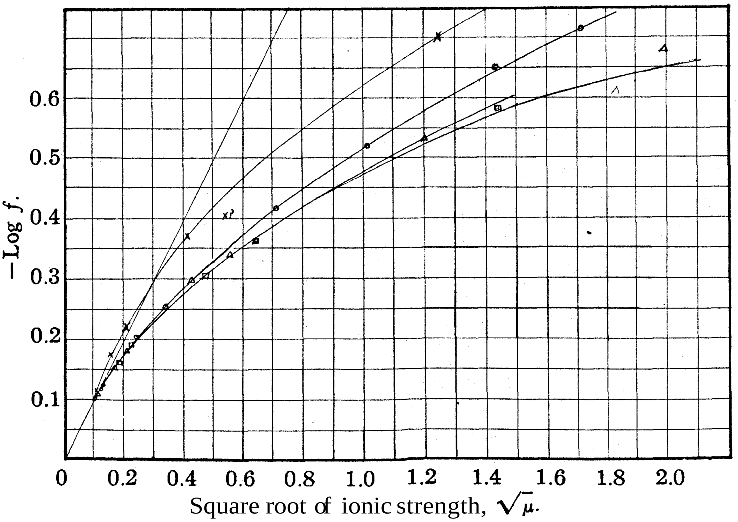

Fig. 1.—The relation of the activity coefficient, f, and the ionic strength, M, for copper iodate. The straight line is the theoretical equation, $-\log f = 1.01\sqrt{\mu}$; X, K_2SO_4; O, KCl; A, $MgCl_2$; □, $MgSO_4$.

A plot of the data is shown in Fig. 1. The line marked "limiting tangent" is the Debye and Huckel limiting law. The potassium chloride,. magnesium chloride and magnesium sulfate curves fuse fairly well into the limiting tangent but the potassium sulfate curve shows the characteristic "hump" obtained by La Mer and Goldman for lanthanum and thallous iodates. This salt also increases the solubility of the iodate more than the others. The general deviation from the theoretical lies somewhere between the deviations of the uni- and trivalent iodates mentioned.

Summary

The activity coefficients of copper iodate have been measured by the solubility method in aqueous solutions of the chlorides and sulfates of potassium and magnesium. The solubility of copper iodate is **0.003693** mole per liter at 25°.

CEDAR RAPIDS, IOWA

NOTES

The Detection of Cobalt as Cesium Cobaltinitrites.—The oxidation of cobaltous ion in acid solution by a concentrated solution of potassium nitrite and its precipitation as the yellow cobaltinitrite are well known in the conventional scheme of analysis. The potassium salt, however, has an appreciable solubility and for low concentrations of cobaltous ion has the undesirable property of precipitating slowly. The corresponding cesium salt, on the other hand, is more insoluble and precipitates and settles much more rapidly. At 17° one cubic centimeter of saturated solution contains approximately 0.05 mg. of the cesium salt.[1] In terms of cobaltous ion the concentration is considerably less and hence serves as a very delicate test for this ion.

Procedure.—The mixture of cobalt and nickel sulfides, from the usual procedure, is dissolved in aqua regia and evaporated just to dryness. The residue is dissolved in one or two cc. of 6 M acetic acid. To this solution 2 cc. of 6 *M* sodium nitrite and 0.5 cc. of 0.5 *M* cesium nitrate (or 0.25 *M* cesium sulfate suggested as a reagent for aluminum)[2] are added and the yellow $Cs_2NaCo(NO_2)_6$ precipitates.

The following table illustrates the delicacy and rapidity of the test

Concn. of cobaltous ion, mg. per cc..	0.5 and greater	0.2–0.5	0.05
Time for precipitation, min..	Instantaneous	0.5	2

The sensitivity of the test may be increased by substituting potassium nitrite for the corresponding sodium salt in the previously described pro-

[2] Yagoda and Partridge, THIS JOURNAL, 52,3579 (1930).

cedure. If this is done, a solution of cobaltous ion containing 0.01 mg. per cc. will yield a yellow precipitate (probably $Cs_2KCo(NO_2)_6$) in about three minutes.[3]

Considerable quantities of iron, manganese or nickel do not interfere with the cobaltinitrite precipitation.

The authors acknowledge with thanks the kind cooperation of the Maywood Chemical Works.

Inorganic Lubricants. IV. Lubricants for Temperatures Above and Below Normal. A. For Temperatures Above Normal.—Aqueous metaphosphate and metaphosphoric acid solutions yield clear, viscous lubricants capable of operating up to 120° and by selection to 160°, the operating range of temperature (Op. r.) over which any particular solution has satisfactory lubricating properties depending upon the temperature at which boiling of that solution is stopped (T. b.) Typical examples are listed in Table I.

TABLE I

BOILING TEMPERATURES AND APPROXIMATE OPERATING TEMPERATURE RANGES FOR VARIOUS METAPHOSPHATE SOLUTIONS

A. Aqueous solutions of metaphosphoric acid containing approximately 20% of added orthophosphoric acid

T. b., °C.	140	150	165	185	205
Op. r., °C.	25–30	40–60	45–70	55–75	65–80
T. b., °C.	230	260	300	350	
Op. r., °C.	70–85	80–95	105–120	Fumes	

B. Solutions of sodium metaphosphate

T. b., °C.	107 [a]	110 [a]	115	120
Op. r., °C.	25+	50–65	60–85	65–90

C. Solutions of sodium metaphosphate containing approximately 20% of borax and 10% of added orthophosphoric acid

T. b, °C.	110	115	122 [a]	118	125
Op. r., °C.	25+	60–80	70–90	50–80	90–160

[a] The solution was then diluted and again boiled down to avoid crystallization at the operating temperature range.

These lubricants in their respective operating ranges have properties quite similar to those of the phosphoric acid and metaphosphate lubricants

---

[3] Cf. Noyes and Bray, "A System of Qualitative Analysis for the Rare Elements." The Macmillan Company, New York, 1927, p. 202.

previously described.[1a] In general, the operating range rises during their protracted use at elevated temperatures because of further slow dehydration.

A variety of salts melted in their water of crystallization and, at higher temperatures, certain anhydrous salts yield liquids which, when mixed with sufficient quantities of finely powdered, non-reacting, stable solids to form stiff, creamy pastes, afford lubricants similar to those obtained by mixing such solids with aqueous solutions of deliquescent substances,[1b] but having operating ranges up to their reaction or decomposition temperatures.

TABLE II

OPERATING RANGES OF MIXTURES OF FUSED SALTS WITH FINELY DIVIDED SOLIDS

Subs.	M. p., °C.	Mixed with powdered	Op. r.. °C.	Remarks
$Ca(NO_3)_2 \cdot 4H_2O$	42	Graphite	45–120	Supercools
$Na_2B_2O_4 \cdot 2H_2O$	57	Graphite	55–110	Supercools
$Na_2S_2O_3 \cdot 5H_2O$	48	Graphite	70–110	SO_2 evolved
$Mg(NO_3)_2 \cdot 6H_2O$	90	Kaolin	110–200	
KSCN	172	Kaolin	175–320	
KNO_3	337	Kaolin	340–360	Decomposes above 360"

A mixture of equal parts by weight of crystallized calcium nitrate and potassium nitrate when heated to 120° and stirred until a clear solution of calcium nitrate in the potassium salt was thus obtained yielded a liquid that when mixed with kaolin gave a series of lubricants of increasing temperature ranges depending on the temperatures at which boiling the liquid was stopped.

TABLE III

BOILING TEMPERATURES OF MIXED CALCIUM AND POTASSIUM NITRATES AND OPERATING RANGES OF LUBRICANTS CONTAINING KAOLIN

T. b., °C.	150	185	200	225
Op. r., °C.	140–160	150–180	155–190	160–220
T. b., °C.	260	300	340	
Op. r., °C.	170–260	170–300	170–340	

It appears to be possible, therefore, to select a mixture of fused salt and non-reacting solid to melt under almost any required condition of high temperature inorganic lubrication. Mixtures of this kind are also useful as reversibly thermoplastic lutes.

B. Lubricants Operating at Temperatures Below Normal.—The same classes of materials in different concentrations also yield lubricants capable of operating at subnormal temperatures. Thus aqueous solutions of metaphosphoric acid boiling at the stated temperatures give approximately the following ranges of temperature for satisfactory lubrication.

---

[1] Boughton, THIS JOURNAL, 52, (a) 2813; (b) 4335 (1930).

TABLE IV

BOILING TEMPERATURES AND OPERATING RANGES FOR A SOLUTION OF METAPHOSPHORIC ACID

T. b., °C.	105	110	115	120
Op. r., °C.	−75 to −65	−60 to −50	−40 to −30	−15 to 0

Sodium metaphosphate solutions have more limited usefulness as low temperature lubricants. Those boiling at 104–106° have an operating range of −25 to 0°. More dilute solutions freeze when cooled to a temperature of a few degrees below zero.

Lubricating cream mixtures of salt solutions and finely divided solids may be prepared in the usual way and can then be used at temperatures down to approximately the freezing points of the respective solutions. Thus, a 35% solution of calcium chloride mixed with kaolin may be used as a lubricating paste to temperatures as low as −20°.

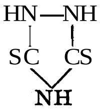
CONSTITUTION OF THE SO-CALLED DITHIOURAZOLE OF MARTIN FREUND. IV. ISOMERISM OF HYDRAZODITHIODICARBONAMIDES, IMINO-THIOL-THIOBIAZOLES AND IMINO-THIOBIAZOLONES

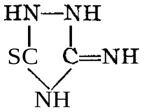
BY SHAHA L. JANNIAH AND P. C. GUHA

RECEIVED MAY 24, 1930 PUBLISHED DECEMBER 18, 1930

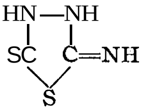
The ring-closing action of various reagents upon hydrazodithiodicarbonamides and their alkyl and aryl substituted derivatives has been studied by a number of workers, *viz.*, by Freund, Busch, Arndt, Fromm, Guha and their collaborators beginning from the year 1893, and all the possible four types of triazoles and thio-biazole compounds, I, II, III and IV, obtainable from the hydrazides, have been isolated.



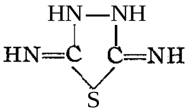
I



II



III



IV

A careful survey of the literature reveals the fact that various authors attribute different melting points to one and the same substance. As an example, to imino-thio-tetrahydro-4,1,2-thiodiazole, Freund[1] gives the

---

[1] Freund, Ber.. 28, 946 (1895).

melting point 243°; Guha[2] attributes three different melting points, *viz.*, 244, 233 and 224°, and Fromm[3] gives 228–235°. So it appears that the various investigators did not take sufficient care to define exactly the conditions under which they worked, so that the attempted repetitions were hindered by a lack of exact knowledge of the experimental conditions employed by earlier investigators. The present work was, therefore, undertaken with a view to defining more clearly the various factors which are concerned in the formation of each of the types of compounds.

In this paper, which forms the beginning of a series of investigations, it is proposed to deal with hydrazodithiodicarbonamides and the imino-thiolthiobiazoles.

Hydrochloric acid being rather an important ring-closing agent, its behavior on the hydrazides has now been very systematically studied and the utmost care has been taken to learn the influence of two important factors, *viz.*, the concentration of the acid and duration of treatment. After several trials 2 *N* acid, 5 N acid, strong (d 1.16) acid and concentrated (*d* 1.19) hydrochloric acid have been found to be suitable.

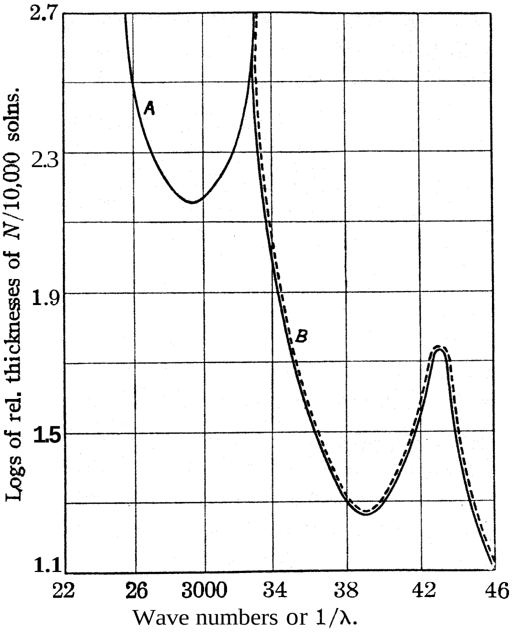


Fig. 1.—A, $NH{=}C(SH)NHNHC(SH){=}NH$, m. p 203°; B, $NH_2CSNHNHC(SH){=}NH$, m. p. 223°.

Hydrazo-dithio-dicarbonamide (m. p. 223°) on being boiled with dilute hydrochloric acid for a short time gave instead of a ring compound another hydrazide having the same chemical composition, $C_2H_6N_4S_2$, yielding derivatives (acetyl, methyl ether) identical with those of the parent hydrazide but differing in the melting point (m. p. 203°), suggesting thereby that the new compound is an isomer. While the hydrazide (m. p. 223°) has given only one absorption band (B) in Fig. 1, the isomer has given two bands (Curve A); and when the lower-melting variety was reconverted to the higher one, only one band, identical with that of the parent hydrazide, was obtained.

In these substances, we are dealing with a simple case of tautomerism,

---

[2] Guha, This Journal, **44,** 1502–1517 **(1922).**

[3] Fromm. Ann.. 426,313 **(1922).**

for they do not contain anything benzenoid in structure, which is always accompanied by absorption bands. From a consideration of the investigation on the ultraviolet absorption spectra of some enol–keto tautomerides by Baly and Desch,[4] the conclusion to be drawn from these results can only be that the 223° variety exists in the monothiol form, whilst the new variety exists in the dithiol form, thus

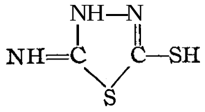
$NH_2CSNHNHC(SH){=}NH$ (m. p. 223°)
$NH{=}(HS)CNHNHC(SH){=}NH$ (m. p. 203°)

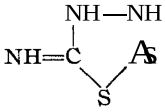
In the former, the hydrogen atom of only one of the (—$CSNH_2$) groups can oscillate to give rise to the tautomeric thiolimino form —C(SH)=NH, accounting for one absorption band; and in the latter, the hydrogen atoms of both such groups can oscillate, as the result of which it gives two bands.

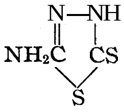
Both the hydrazides on being boiled with dilute hydrochloric acid for a long time, or with concentrated acid for a short time, yielded a ring compound of composition $C_2H_3N_3S_2$ melting at 234°.[3] In all chemical behavior it was identical with Freund's compound melting at 244–245°.

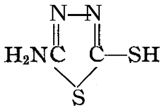
The acetyl derivative (m. p. 303°) of the above compound (m. p. 234°) when hydrolyzed with hydrochloric acid, gave back a substance possessing the same chemical composition, *viz.*, $C_2H_3N_3S_2$, but melting at 245°. This compound was obtained also by boiling the hydrazodithiodicarbonamide with concentrated hydrochloric acid (sp. gr. 1.19) for about half an hour. It does not respond to the tests of the amino group and behaves chemically identical with the parent substance (m. p. 234°).

It has also been observed that the higher-melting variety, obtained by either of the methods as stated above, on standing for several weeks is converted into the lower-melting variety 234°. The question naturally arises whether it is possible to explain this difference by any other tautomeric formula.









Of these the third and the fourth can easily be discarded owing to the fact that the substances do not respond to any test for the amino group. As regards the first and the second, it is very doubtful whether any such tautomeric compounds can exist at all as separate individuals.

Chemical methods proving of no avail in finding out the real cause of the difference, it was thought advisable to examine and compare the absorption spectra of these two compounds. It will be noticed that the difference existing among all the four suggested formulas is only due to a labile hydrogen atom. If this is really the case, then there ought to have been only

---

[4] **Baly and Desch,** *J. Chem. Soc.*, **85, 1033–1036 (1904).**

a slight difference either in the persistence of the band or in the number of bands obtained from the two varieties. It has been actually found that the lower-melting variety gives a band between the wave numbers 3400 and 4200 in Fig. 2, while the higher-melting variety gives the band in the region between 2500 and 3600. This means that there has been a shift in the curve while passing from one variety to the other isomeric form. This eliminates the possibility of the difference being due only to a labile hydrogen atom.

It is necessary here to describe another case of isomerism observed by us. Martin Freund, by treating hydrazomonothio-dicarbonamide with strong hydrochloric acid, obtained a compound (m. p. 177°) which he called monothiourazole.[5] The same hydrazide on being treated with acetic anhydride[6] was found to give a basic compound possessing the same chemical composition as that of Freund, but melting at 235°. The latter compound differs from the former in that it forms derivatives with aldehydes, isocyanates and mustard oils, proving conclusively the presence of an amino group.

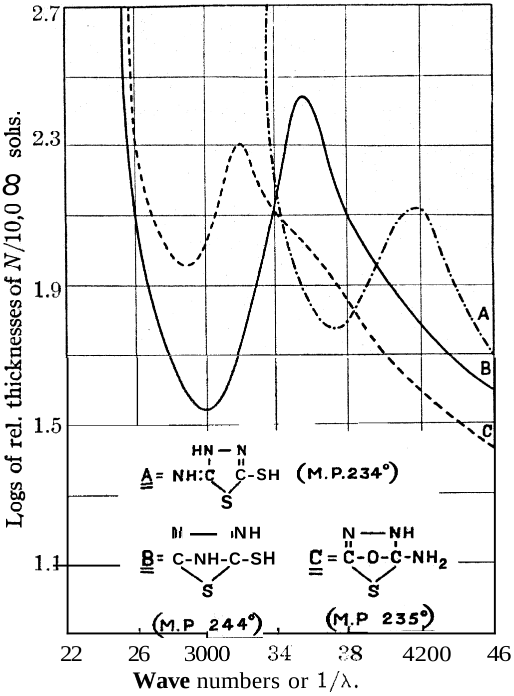


Fig. 2.

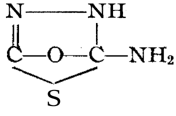
In view of these observations the new isomeric compound can only be represented by an endo formula, *viz.*, 3-amino-3,5-endoxy-2,3-dihydro-4, 1,2-thiodiazole (X). Freund's compound possesses none of these properties, and is feebly acidic in character, due evidently to the presence of an (—NH—CO—) group. So, to account for the pronounced basic nature of the new compound and to explain the mechanism of conversion of Freund's monothiourazole to that obtained by Guha, it is proposed to attribute an endo structure to the latter, and the changes involved in the transformation can be represented thus

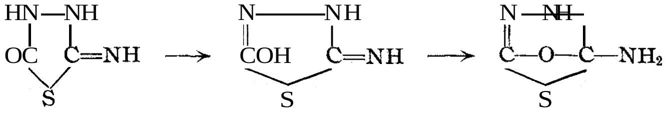


X

---

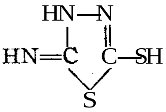
[5] Proved by Arndt to be imino-thiobiazolone, Ber., 55,341 (1922).

[6] Guha, This Journal, 45,1038 (1923).

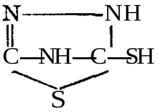


For purposes of analogy the curve of the endoxy-aminothiodiazole is also given, and it will be noticed that the curve of the 245° variety occupies almost the same region.

From all that has been said so far, and also to explain the difference between the two forms, melting at 234 and 245°, on a structural basis, as distinct from a basis of tautomerism, as established by absorption spectra curves, it is proposed that an imino-thio-tetrahydro-thio-diazole **(A)** structure be attributed to the lower-melting variety and an endo structure (*viz.*, 3-thiol-3,5-endo-imino-2,3-dihydro-4,1,2-thiodiazole) to the higher-melting variety.



(A, m. p. 234°)



(B, m. p. 245")

Similar experiments have also been made with the substituted hydrazides. The results have corroborated the observations made in this paper and will be communicated shortly.

Experimental

Isomeric **Hydrazodithiodicarbonamide.**—Five grams of hydrazo-dithio-dicarbonamide, m. p. 223° (prepared according to the method of Freund[1]), was heated with 100 cc. of 2 *N* hydrochloric acid over a small flame until dissolved and the solution kept boiling for just ten minutes. The solution was then allowed to cool slowly, when colorless tiny needles separated. These were filtered, washed with a little water and recrystallized from hot water. The colorless crystalline needles thus obtained melted sharply at 203°. The melting point remained unchanged on repeated crystallizations; yield almost quantitative. This substance was found to be soluble in alkali more readily than the parent hydrazide; but both the hydrazides gave identical compounds when treated with dimethyl sulfate (m. p. 174°), and even the analytical values were the same. (The absorption spectra of the two have been studied in aqueous solutions.)

Anal. Calcd. for $C_2H_6N_4S_2$: N, 37.33; S, 42.66. Found: N, 37.2; S, 43.0.

Interconversion of the Two **Hydrazides.**—Two grams of hydrazodithiodicarbonamide (m. p. 223°), was dissolved in a little excess of 2 N sodium hydroxide and the clear solution kept aside in a closed flask for about twenty-four hours. The solution was then acidified with dilute hydrochloric acid, when a thick colorless solid was thrown down. This solid was filtered, washed and crystallized from hot water, when colorless tiny needles were obtained, melting sharply at 203°. This was proved by mixed melting point to be identical with the isomeric hydrazide obtained previously. The yield was almost quantitative except for a little loss during crystallization.

Two grams of the hydrazide (m. p. 203°) was placed in a glass dish, covered with a watch glass, in an air-oven at 120° for about four hours, when the hydrazide was found to melt at 223°. The higher-melting variety thus obtained showed no change in the melting point on repeated crystallization and was proved to be identical with the parent hydrazide (m. p. 223") by taking the mixed melting point. The absorption spectra of the 223° variety as obtained by conversion were found to be identical with that of the parent hydrazide.

Imino-thiol-dihydro-thiobiazole.—Two grams of hydrazodithiodicarbonamide (m. p. 223°) or its isomer (m. p. 203°) was boiled with 25 cc. of concd. hydrochloric acid (d 1.19) for about ten minutes. The crystalline solid obtained from the clear solution on cooling was carefully washed and recrystallized from hot water (m. p. 234°).

When the experiment was repeated with 2 N hydrochloric acid, about 60 cc. of the dilute acid was required to dissolve 3 g of the hydrazide on heating, and the solution had to be kept boiling for half an hour. The imino-thiol-dihydrothiobiazole thus obtained crystallized as very pale yellow needles, melting sharply at 234°, the yield being about 1.4 g. from 3 g. of hydrazide. It dissolves in cold dilute sodium hydroxide solution, and with iodine it gives the disulfide (m. p. 240°); with methyl sulfate it gives the thiomethyl ether (m. p. 178°); with acetic anhydride, the acetyl derivative (m. p. 303°).

Anal. Calcd. for $C_2H_3N_3S_2$: N, 31.6; S, 48.1. Found: N, 31.8; S, 47.8.

Endo-imino-thiol-thiobiazole.—Three grams of imino-thiol-dihydro-thiobiazole (m. p. 234") was heated with 20 cc. of concentrated hydrochloric acid (d 1.19) to boiling for about ten minutes and the solution was allowed to cool. Dull yellow prismatic crystals were found to separate out from the solution gradually, and were filtered, washed and recrystallized from hot water; m. p. 244°; yield, 1.2 g.

Two normal acids failed to give the endo compound (m. p. 244°) even when the solution was boiled for more than an hour, but 5 N hydrochloric acid was found to be better than concentrated acid, as it gave greater yield. The actual yield of the endo compound from 3 g. of the parent thiobiazole was 1.8 g. as compared with 1.2 g. with concentrated acid

Starting with hydrazodithiodicarbonamide (m. p. 233°) or its isomer (m. p. 203°), 5 g. of the hydrazide was heated with 40 cc. of 5 *N* hydrochloric acid until dissolved. The solution was kept boiling over a small flame for a quarter of an hour and then cooled. The solid obtained was filtered, washed and crystallized from hot water, m. p. 244°; it was found to be identical with that obtained from imino-thiobiazole (and behaving chemically identically with the "so-called 'dithio-urazole' " of Martin Freund).[1] 5 N hydrochloric acid was employed in preference to concentrated acid for good yields; yield, 3.2 g.

The substance gave with methyl sulfate the methyl ether, m. p. 178°, and the acetyl derivative, m. p. 303°, both identical with those of imino-thiol-dihydro-thiobiazole.

Acetyl Derivative of Imino-thiol-dihydro-thiobiazole.—Two and one-half grams of the thiobiazole was heated gently with 15 cc. of acetic anhydride until dissolved. The brownish-yellow solution obtained was heated to boiling and kept at that temperature for about twenty minutes. The clear solution was poured into about 100 cc. of water and when thoroughly stirred by a glass rod, a yellow solid separated, which was filtered, washed with water and crystallized from very dilute acetic acid. The pale yellow needles thus obtained melted at 303° to a dark brown liquid; yield, 1.4 g.

Hydrolysis.—The acetyl compound was boiled gently with 2 N hydrochloric acid until very little acetic acid was present in the vapors. The insoluble solid which separated on slight cooling was filtered off from the mother liquor, washed and crystallized from boiling water. The crystalline needles so obtained melted sharply at 243–244°, identical with the endo-imino-thiol-thiobiazole.[7]

---

[7] The endo-imino-thiol-thiobiazole when treated similarly with acetic anhydride gave the same acetyl derivative, m. p. 303°, which on hydrolysis gave back the endo compound.

Summary

1. Hydrazodithiodicarbonamide has been found to tautomerize into the thiol-imino form under experimental conditions which have been determined, and the interconvertibility of the two forms established.

2. Imino-thiol-thiobiazole has been isolated as an intermediate compound during the formation of Freund's "Dithio-urazole"—now shown to be endo-imino-thiol-thiobiazole; the latter has been found to be formed either by the prolonged action of hydrochloric acid on the hydrazide or the imino-thiol-thiobiazole, or by acetic anhydride treatment on the thiobiazole with subsequent deacetylation.

3. Similar cases of isomerism have been observed with the alkyl and aryl substituted mono- and dithio-hydrazides.

SOME HALOGEN DERIVATIVES OF ACYL AND ALKYL RESORCINOLS

BY C. M. BREWSTER AND J. C. HARRIS[1]

RECEIVED JUNE 19, 1930 PUBLISHED DECEMBER 18, 1930

Since the acyl and alkyl resorcinols have been given much attention by investigators recently, due to their germicidal and other interesting properties, we have undertaken to prepare and study certain halogen derivatives of these compounds, and also to improve the methods of preparation of the intermediate compounds already reported by others.

The acyl groups were introduced into the resorcinol nucleus by condensing the latter with the desired fatty acid in the presence of fused zinc chloride, a method proved to be very satisfactory for this purpose by Nencki[2] and others. The ketones were prepared without difficulty, and increased yields obtained by varying the conditions of temperature, concentration and time, as shown in the tables in the dissertation.[3] These acyl compounds were then reduced according to Clemmensen's method,[4] which employs amalgamated zinc with hydrochloric acid as reducing agent. The alkyl compounds obtained by reduction were halogenated in various solvents and in the presence of carriers.

The same halogenated alkyl resorcinol was obtained whether the halogenated ketone was reduced or the ketone reduced before halogenation. For example, dibromo-ethylresorcinol was prepared as follows.

---

[1] This paper is an abstract of part of a thesis presented by J. C. Harris in partial fulfilment of the requirements for the degree of Master of Science.

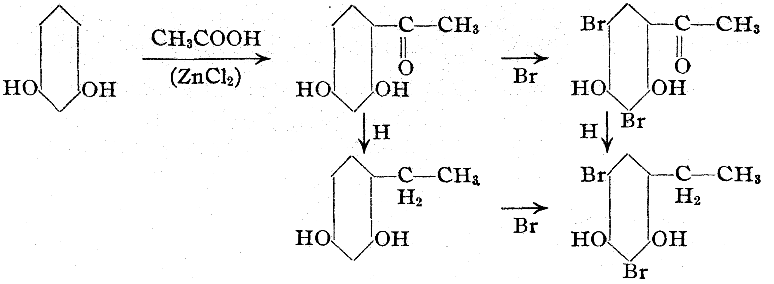
[3] Dissertation, by J. C. Harris, 1930.

[4] Clemmensen, Ber., 46, 1837 (1913).



Von Pechmann and Duisberg[5] established the position of the acetyl group when they fused β-methylembelliferone with potassium hydroxide and obtained resacetophenone. Dahse[6] determined the position of the bromine atoms in the ketone by oxidation with chromic acid and obtained a dibromo-dihydroxybenzoic acid which was identical with that formed by bromination of β-resorcylic acid. The reduction of the dibromo ketone would definitely place this compound as 2,4-dihydroxy-3,5-dibromo-ethylresorcinol.

The corresponding dichloro-ethylresorcinol was prepared by reduction of the chlorinated ketone, but we were unable to isolate the same compound when ethylresorcinol was chlorinated, although it was evident that a similar reaction had taken place. The solubility of dichloro-ethylresorcinol in water is appreciably greater than that of the dibromo-ethylresorcinol, and we could not find an extraction agent which would bring about a clear separation and yet remain immiscible with the original solvent.

On bromination of resacetophenone in acetic acid with iodine as carrier, a tetrabromo derivative was obtained. On reduction by Clemmensen's reagent, the tetrabromo derivative gave 2,4-dihydroxy-3 5-dibromo-ethylresorcinol, indicating that two of the bromine atoms are in the nucleus and two in the methyl group of the side chain.

The halogenated acyl resorcinols gave a wine-red color to an aqueous solution of ferric chloride, while the corresponding alkyl compounds gave merely a slight yellowish-green coloration. The melting points for the halogen derivatives are considerably higher than for the non-halogenated ketones, but show the usual decrease with lengthening of the side chain. Since there are two bromine atoms in the side chain pf the tetrabromoresacetophenone, their introduction reduces the melting point. Inasmuch as the melting point of tribromopropionylresorcinol is higher than that of the dibromo compound it is possible that the third bromine atom of the former may be in the benzene nucleus.

We were unable to prepare tribromoresacetophenone, reported by Segalle[7] as produced by passing an excess of bromine into an acetic acid

solution of the ketone. Numerous trials with different proportions and in different solvents, varying also the temperature and time, resulted in forming the dibromo compound, or in the presence of iodine as carrier, the tetrabromo derivative. However, when propionylresorcinol was brominated in glacial acetic acid, tribromopropionylresorcinol was obtained, also when iodine was used as carrier.

Halogenation products of propylresorcinol and butylresorcinol were prepared by the reduction method of Clemmensen, and the color change when tested with ferric chloride indicated complete reduction, but samples were oils of which we did not have a sufficient quantity for purification.

In the preparation of butyrylresorcinol, when the condensation was permitted to continue at boiling temperature for several minutes, the final purification gave two products: one the normal product melting at 69–70°, and the second a compound melting sharply at 111–112°, composed of clear colorless prism-shaped crystals. Several analyses were made of different trial samples but no conclusions can be reached as to its constitution until more work is done on the compound.

We are investigating further the halogen derivatives of other members of the resorcinol series, with acyl, alkyl and aryl side chains. We have also made a number of similar derivatives of hydroquinone and of the naphthols, and are continuing their study in this Laboratory.

Experimental Part

ω-Dibromo-3,5-dibromo-2,4-dihydroxyacetophenone.—Bromination took place in a hot glacial acetic acid solution of resacetophenone, using several crystals of iodine as carrier. On dilution with water, yellow crystals separated and were purified by crystallization from acetic acid and from alcohol. The characteristic sheaves of yellow platelets melt sharply at 110–110.5°.

Anal. Calcd. for $C_8H_4O_3Br_4$: Br, 68.35. Found: Br, 68.08, 68.42.

The compound is readily soluble in alcohol, benzene, ether, chloroform and acetic acid, difficultly soluble in petroleum ether and in boiling water. With ferric chloride a wine-red color is produced, as with other brominated ketones. On reduction tetrabromoresacetophenone gave 3,5-dibromo-2,4-dihydroxy-1-ethylbenzene, indicating that two of the bromine atoms of the tetrabromo derivative were in the methyl group of the side chain.

Dichloro-2,4-dihydroxyacetophenone was prepared by direct chlorination of resacetophenone in a variety of solvents and at different temperatures; the best yield (78%) was obtained when using 80% acetic acid as solvent, and the solution was heated to 80° at the beginning of the chlorine addition. Segalle[7] also used acetic acid in preparing the compound. The glistening white needles melt at 195–196°. They are insoluble in water, slightly soluble in chloroform, carbon disulfide, and petroleum ether, readily soluble in alcohol, benzene and acetic acid.

2,4-Dihydroxypropiophenone.—Propionic acid distilling between 135–145° was used in numerous trials, and most satisfactory results were obtained by dissolving 80 g. of fused zinc chloride in 80 g. of propionic acid, and adding 50 g. of resorcinol to the hot solution. The mixture was heated under reflux to an intense bubbling of the solution, which occurred between 160–165°. The solution was then allowed to cool slowly, and on the following day was warmed sufficiently to permit it to be poured into a water and ice mixture acidified with hydrochloric acid. The dark brown oil solidified on standing, and the product was purified by dissolving in alcohol and refluxing the solution with animal charcoal. Bright yellow needles separated, m. p. 96°, which were readily soluble in alcohol, benzene, ether and acetic acid, but difficultly soluble in carbon tetrachloride, chloroform, petroleum ether and water. A yield of 73% was obtained, which is lower than that reported by others[8] who used a larger proportion of acid, but the above method is more economical as technical propionic acid can be used. The oxime was prepared as bright yellow needles, m. p. 186–187°.

3,5-Dibromo-2,4-dihydroxypropiophenone.—Gnagy[9] prepared this compound by slow addition of an acetic acid solution of bromine to the ketone dissolved in acetic acid. We tried carbon disulfide as well as acetic acid as solvent, but obtained the best yield (51%) by use of 80% acetic acid, adding bromine slowly through a dropping funnel. The mixture was allowed to stand for a day, filtered, the filtrate diluted with water and allowed to stand two to four hours for crystal formation. The crystals were dissolved in alcohol, refluxed with animal charcoal and recrystallized by addition of water; m. p. 151–152°; white needles, difficultly soluble in petroleum ether, insoluble in water, but readily soluble in other solvents.

Tribromo-2,4-dihydroxypropiophenone.—The ketone, dissolved in glacial acetic acid, was treated with two and one-half times the amount of bromine theoretically required for the dibromo compound. The solution was heated to 80° before adding the bromine. On cooling, an equal volume of water was added and the crystals were filtered, washed and dried. Repeated crystallization from alcohol gave yellow flaky crystals, m. p. 157–158°, which may be dissolved with difficultly in hot water or petroleum ether, but are readily soluble in other solvents.

Anal. Calcd. for $C_9H_7O_3Br_3$: Br, 59.37. Found: Br, 59.15, 59.49.

Dichloro-2,4-dihydroxypropiophenone.—The ketone was dissolved in 80% acetic acid and chlorine was passed through until no further change was observed. A mass of white needle-like crystals separated, and dilution with water gave more of the same compound, which was recrystallized from acetic acid and water. The product was washed, dried and finally crystallized repeatedly from benzene giving white needles, m. p. 146–147°, very slightly soluble in petroleum ether, insoluble in water, but readily soluble in alcohol, benzene and other solvents.

Anal. Calcd. for $C_9H_8O_3Cl_2$: Cl, 30.18. Found: Cl, 29.97, 29.96.

2,4-Dihydroxybutyrophenone.—Sixty grams of technical butyric acid (b. p. 153–163") and 50 g. of fused zinc chloride were refluxed and when dissolved 30 g. of resorcinol was added. The mixture was heated to an intense bubbling, which occurred at about 165°. The dark brown viscous product was allowed to cool slowly until the next day, then warmed and poured into an acidified mixture of ice and water. The ketone was washed free of zinc chloride, dried and distilled repeatedly under diminished pressure, giving a light yellow oil. The product was crystallized from a mixture of equal parts of chloroform and benzene, m. p. 68–70". Johnson and Lane[8] purified the ketone by distillation under diminished pressure and crystallization from a mixture of three parts of carbon tetrachloride and one part of benzene

Gnagy[9] dissolved the oil in aqueous sodium hydroxide, refluxed repeatedly with animal charcoal and precipitated with hydrochloric acid.

Second Product.—In repeating the above process, but maintaining the mixture at the boiling temperature of 165" for two to five minutes before cooling, a different

---

[8] Johnson and Lane, THIS JOURNAL, 43, 357 (1921).

[9] Gnagy, *ibid.*, 45, 807 (1923).

substance was obtained. The condensation product was purified as above, but the crystallization from chloroform and benzene gave about 20% of clear colorless crystals, m. p. 111–112°, the rest being the normal compound with melting point of 68–70'. The new compound crystallized in large clear prisms and appeared to be pure, but analyses showed less carbon and hydrogen than found in the normal compound. Unfortunately not enough of the compound was available to make derivatives for further study. We prepared the oxime of the normal compound (m. p. 68–70"), obtaining pale yellow needles, m. p. 188–189°.

3,5-Dibromo-2,4-dihydroxybutyrophenone.—Direct bromination of the ketone in 80% acetic acid solution, as employed by Gnagy, gave satisfactory results, though the yield was low. A yield of 10% was obtained when 15 g. of the ketone was brominated with 30 g. of bromine, 100 g. of 80% acetic acid being used as solvent. The compound was much more difficult to purify than the halogenated propionyl or acetyl resorcinol. It was necessary to reflux the solution repeatedly with animal charcoal, and finally to crystallize by fractional crystallization from alcohol and water. The crystals melt at 108–109°. The compound can be reduced to the alkyl form.

Dichloro-2,4-dihydroxybutyrophenone.—Twenty grams of butyrylresorcinol was dissolved in 100 g. of 80% acetic acid and chlorine passed through in excess. On dilution white crystals separated, which were refluxed in alcoholic solution with animal charcoal, and finally crystallized from benzene. The white needles (yield, 21%) were very slightly soluble in petroleum ether and in water, but readily soluble in alcohol, benzene or carbon tetrachloride. The melting point was 110.5–111°.

Anal. Calcd. for $C_{10}H_{10}O_3Cl_2$: Cl, 28.48. Found: Cl, 28.80, 28.76, 28.96.

2,4-Dihydroxy-1-ethylbenzene.—Resacetophenone was reduced by the Clemmensen method.[10] A yield of 82% was obtained as follows. Mossy zinc was amalgamated by covering with a 5% solution of mercuric chloride for one hour, then the liquid was drained off and the zinc used immediately without washing. Two hundred grams of the amalgamated zinc was placed in a flask, 50 g. of the ketone added, and 300 cc. of 20% hydrochloric acid gradually poured in to maintain steady evolution of hydrogen while the mixture was gently boiled. When a drop of the liquid gave no red color test with aqueous ferric chloride, which in this trial required about three hours, the solution was decanted, saturated with sodium chloride, cooled and extracted with ether. This general procedure was followed in all reductions and gave much better yields than the use of sodium amalgam or other reducing agents tried. When crystallized from benzene, the pale yellow crystals melt sharply at 97–98°, as reported by Clemrnensen, and also by Johnson and Hodge.[11]

3,5-Dibromo-2,4-dihydroxy-1-ethylbenzene. Reduction Method.—Dibromoresacetophenone was reduced by Clemmensen's method until the ferric chloride test showed complete reduction. The warm suspension was saturated with salt, cooled and extracted with ether. On evaporation of the ether the oily residue was dissolved in alcohol and refluxed repeatedly with animal charcoal. On cooling the diluted alcoholic solution silky crystals slowly separated. The long silky needles when first filtered were transparent, but became opaque when dried. They melted sharply at 74°.

Anal. Calcd. for $C_8H_8O_2Br_2$: Br, 54.01. Found: Br, 53.93, 54.21.

Bromination Method.—Ethylresorcinol was dissolved in a variety of solvents and the calculated amount of bromine for the dibromo product was added. The solvents tried were glacial acetic acid, 80% acetic acid, ether, carbon disulfide, chloroform and carbon tetrachloride; ether gave the best results with a 60% yield in several trials.

---

[10] Clemmensen, *Ber.*, **47**, 51 (1914).

[11] Johnson and Hodge, THIS JOURNAL. **35**, 1020 (1913).

The bromine was added slowly through a dropping funnel, and the mixture allowed to stand for several hours The ether was then permitted to evaporate slowly, leaving clumps of characteristic wavy buttons. These were dissolved in alcohol, and crystallized by the procedure outlined above, giving crystals melting at 73.5–74.5°. A mixed melting point, taken using equal parts of the compound prepared by the two methods, did not vary by more than a half degree from the melting points of the two separate 'samples.

Anal. Calcd. for $C_8H_8O_2Br_2$: Br, 54.01. Found: Br, 54.25, 53.88.

The compound is very slightly soluble in water, but readily soluble in most other solvents.

Dichloro-2,4-dihydroxyethylbenzene.—Dichlororesacetophenone (m. p. 190–193") was reduced and purified by the same method used with the dibromo derivative. The crystals are small snow-white prisms, which become opaque on standing. Crystallized from alcohol, the crystals melt at 78–79".

Anal. Calcd. for $C_8H_8O_2Cl_2$: Cl, 34.26. Found: Cl, 33.95, 34.04.

The compound is soluble in the same solvents as the dibromo derivative, but it is somewhat more readily soluble in water than any of the other compounds prepared in this study.

Attempts were made to prepare the conipound by chlorination of ethylresorcinol in acetic acid and other solvents. The same compound apparently was formed, but owing to its solubility in water and other solvents, it proved more difficult to purify than when prepared by the reduction method.

3,5-Dibromo-2,4-dihydroxy-1-propylbenzene.—When propylresorcinol was brominated in acetic acid solution, on dilution an oil separated, which was washed and its alcoholic solution refluxed with animal charcoal, then filtered and the filtrate diluted. No crystals were formed, so the solution was evaporated to dryness on a steam-bath, and the residue cooled with ice. This gave buttons of waxy crystalline material similar to those of the dibromo-ethylresorcinol. Working at zero temperature, a few white crystals were obtained, but these soon melted to a pale brown oil. Attempts were made to obtain a crystallizable product by reduction of the dibromopropionylresorcinol, using the Clemmensen method. This also gave a pale brown oil, which was dissolved in alcohol and water, and cooled to 0° for several hours, when fine white needles formed. The needles melted at the same temperature as those obtained by the bromination method. Owing to the limited quantity and difficulty of separating from the solvent, the compound was not analyzed.

Tribromo-2,4-dihydroxy-1-propylbenzene.—Tribromopropionylresorcinol (m. p. 157") was reduced by the Clemmensen method. The reduction was complete, as indicated by the ferric chloride test. On extraction with ether and distilling off the solvent the residue was dissolved in alcohol and refluxed with animal charcoal. On dilution a yellow oil was obtained which did not crystallize when kept at zero temperature for several days. The compound is being investigated further.

Reduction of Tetrabromoresacetophenone.—Ten grams of tetrabromoresacetophenone was refluxed in 300 cc. of hydrochloric acid (20%) with the Clemmensen reagent. At the end of thirty minutes the solution gave a yellowish-green color when tested with ferric chloride solution, indicating complete reduction of the carbonyl group. The solution was saturated with salt, cooled and extracted with ether. On evaporation of the ether an oil remained which was recrystallized from alcohol and water, giving long silky crystals melting at 74–75'. As the appearance and melting point corresponded closely to those of dibromo-ethylresorcinol,a mixed melting point was made and gave 74–75°, indicating that the two compounds were identical. Two of the bromine atoms of tetrabromoresacetophenoue must therefore be in the methyl group of the side chain of the ketone, since the 3,5-dibromo-2,4-dihydroxy-1-ethylbenzene was prepared by reduction of 3,5-dibromo-2,4-dihydroxyacetophenone.

Summary

1. Improvements in methods of preparation and purification of acyl and alkyl resorcinols are reported.
2. Six new halogen derivatives of acyl and alkyl resorcinols were prepared and their properties described.
3. Evidence was presented to establish the position of the bromine atoms in dibromo-ethylresorcinol and tetrabromoresacetophenone.

NAPHTHOL STUDIES. I. THE BROMINATION OF 1,5-DIHYDROXYNAPHTHALENE

BY ALVIN S. WHEELER AND DAVID R. ERGLE[1]

RECEIVED JUNE 23, 1930 PUBLISHED DECEMBER 18, 1930

The halogenation of juglone was first investigated by Wheeler and Scott.[2] Two atoms of chlorine entered the quinone nucleus when chlorination took place in warm glacial acetic acid. However, under like conditions three atoms of bromine were substituted in the molecule. Only a dichloro and a tribromo derivative could be obtained by direct action of the halogens. Attention has now been turned to the halogenation of the dihydric naphthol, 1,5-dihydroxynaphthalene, from which by oxidation with chromic acid, juglone is obtained. By varying the conditions we have introduced into the nuclei two, three and four atoms of bromine, whereas in another study now in progress in this Laboratory only two and three atoms of chlorine have been introduced into the rings. These halogenated naphthols have been oxidized to halogenated naphthoquinones, but none of them corresponds to the halogenated juglones.

The commercial raw material, the dihydroxynaphthalene, was purified by recrystallization from hot water. For bromination glacial acetic acid solutions were used for preparing the dibromo and tribromo derivatives. Iodine was used as a catalyst and a temperature of 80° was necessary in order to obtain the best yields. In order to introduce four atoms of bromine, a chloroform solution of the diacetate was necessary, a catalyst such as iodine and six moles of bromine.

We believe that the structures indicated in the charts are the correct ones

[1] This paper is a portion of a thesis presented by David R. Ergle to the Faculty of the University of North Carolina in partial fulfilment of the requirements for the degree of Doctor of Philosophy in 1930.

[2] Wheeler and Scott, THIS JOURNAL, 41, 833 (1919).

for these new compounds. The bromine atoms in the dibromo compound B are placed in the beta positions since we are dealing with naphthols. The naphthoquinone C is undoubtedly a para quinone since this isomer forms so readily in general. The tribromo naphthoquinone has been proved to be such (see below). In the dibromo compound it is clear that one bromine atom is in the quinone ring since one is readily replaced by the aniline radical. As for the tribromo compound K, the third bromine atom enters para to the hydroxyl group. In this compound positions 4 and 8 are identical. The bromine atoms in the tetrabromo compound S are placed in positiohs 2,4,6,8, making this a symmetrical molecule. Its oxidation by chromic acid yields a naphthoquinone which is a para quinone, the bromine atom in position 4 being lost in the process. For final proof of its structure the naphthoquinone was found to yield a pyroboracetate ester, a reaction which ties an hydroxyl group to *a* carbonyl group only when these are ortho to each other, as shown by Dimroth and Faust[3] and later by Dimroth.[4]

When five moles of bromine were used and the reaction mixture was kept at room temperature, the dibromo compound was first formed and much later the tetrabromo derivative. However, one of the two acetyl groups in R was hydrolyzed, as proved by the formation of a monobenzoate, V.

The dibromohydroxynaphthoquinone C is not identical with but is isomeric with the 2,3-dibromojuglone (m. p. 167°) of Wheeler and Naiman.[5] The tribromohydroxynaphthoquinone L likewise is an isomer of the tribromojuglone (m. p. 170°) of Wheeler and Scott.[6]

Experimental

Dibromodihydroxynaphthalene

Purification of **1,5-Dihydroxynaphthalene.**—Thirty grams of the commercial product was made into a thick paste with water, suspended in 3 liters of water containing 200 cc. of methyl alcohol and boiled under a reflux for three hours. After cooling to 80° it was saturated with sulfur dioxide and then digested below the boiling point for an hour. It was filtered on a large fast filtering paper in a hot water funnel, the filtrate falling on crushed ice; nearly colorless needles, m. p. 258°; yield, 15–20 g.

2,6-Dibromo-1,5-dihydroxynaphthalene, $C_{10}H_4(OH)_2Br_2$(B).—This compound was first made at room temperature but the yield was greatly increased when the temperature was elevated; 10 g. of dihydroxynaphthalene was dissolved in 350 cc. of glacial acetic acid, a few small crystals of iodine were added and, while the solution was stirred and kept at 80°, 6.5 cc. of bromine (2 moles) dissolved in 25 cc. of glacial acetic acid was added dropwise during the course of thirty minutes. On cooling the solution, the product crystallized out in pale olive green needles. It was washed on the filter with petroleum ether; weight, 14.5 g. or 76% of the theoretical yield; colorless needles on

recrystallizing from glacial acetic acid. The substance darkens at 200° and does not melt at **300°**. It is soluble in ether and dilute sodium hydroxide, difficultly soluble in chloroform and insoluble in carbon tetrachloride.

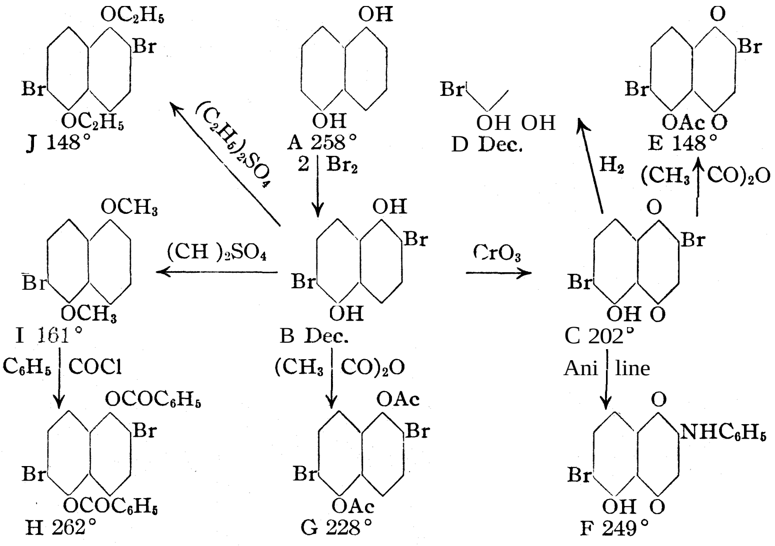
Anal. Calcd. for $C_{10}H_6O_2Br_2$: Br, **50.31.** Found: Br, **50.52**

Diacetate, $C_{10}H_4(OCOCH_3)_2Br_2$(G).—Compound B was heated with an excess of acetic anhydride for an hour at 100°, giving straw yellow needles, colorless on recrystallizing from alcohol; product m. p. **228"**; soluble in ether, benzene and acetic acid; insoluble in petroleum ether.

Anal. Calcd. for $C_{14}H_{10}O_4Br_2$: **Br, 39.80.** Found: Br, **39.68.**

Dimethyl Ester, $C_{10}H_4(OCH_3)_2Br_2$(I).—Compound B was dissolved in 2 moles of dilute sodium hydroxide. To this solution at 60° an excess of **dimethyl** sulfate was added in small amounts until an acid reaction was obtained. More alkali was added and more sulfate but not enough to give an acid reaction. Reddish-purple crystals formed. These were washed on the filter with water. An alcoholic solution with charcoal was boiled until colorless. The filtered solution was concentrated and gave a small amout of colorless microscopic plates which melted at 161°. The **dimethyl** ether is soluble in ether, benzene and chloroform; slightly soluble in cold alcohol and in petroleum ether.

Anal. Calcd. for $C_{12}H_{10}O_2Br_2$: Br, **46.24.** Found: Br. **45.90.**



Diethyl Ether, $C_{10}H_4(OC_2H_5)_2Br_2$(J).—The crude product was a dull red solid. This was dissolved in benzene and boiled. After filtration the solvent was distilled off and the pink residue was recrystallized from hot alcohol as nearly colorless needles, m. p. 148°; soluble in benzene, slightly soluble in cold acetic acid and insoluble in petroleum ether.

Anal. Calcd. for $C_{14}H_{14}O_2Br_2$: Br, **42.89.** Found: Br, **42.77.**

Dibenzoate, $C_{10}H_4(OCOC_6H_5)_2Br_2$(H).—The dibenzoate was prepared by treating a pyridine solution of B with an excess of benzoyl chloride. Much heat was evolved and the whole quickly became a solid mass of yellow crystals. Addition of water gave a heavy yellow oil which was washed with sodium hydroxide and finally with **water.** **Ad-**

dition of alcohol changed the oil to a solid. This was recrystallized from warm pyridine as colorless needles, m. p. 262°; slightly soluble in hot acetic acid; insoluble in ether and in alcohol.

And. Calcd. for $C_{24}H_{14}O_4Br_2$: Br, 30.41. Found: Br, 29.94.

2,6-Dibromo-5-hydroxy-1,4-naphthoquinone, $C_{10}H_3O_2OHBr_2$(C).—To a suspension of 10 g. of B in 200 cc. of glacial acetic acid was added at one time 20 g. of chromic acid dissolved in the smallest amount of water. The mixture turned red, effervesced and the temperature rose to 85°. During the vigorous effervescence, which continued for about fifteen minutes, the material went into solution with a brownish-yellow color. Sometimes it was necessary to start the evolution of gas by warming the mixture. The oxidation was complete when a drop of the solution showed red needles under the microscope, about fifteen minutes in time. After cooling the solution the crystals were filtered off and washed with water; weight, 2.8 g. On recrystallizing from hot acetic acid, the product was obtained in rich red needles, sharply pointed and in clusters; m. p. 202°; soluble in benzene and in chloroform; difficultly soluble in ether and alcohol. It dissolves in alcoholic sodium hydroxide with a purple color which quickly changes to red.

Anal. Calcd. for $C_{10}H_4O_3Br_2$: Br, 48.19. Found: Br, 48.11.

Acetate, $C_{10}H_3O_2(OCOCH_3)Br_2$(E).—The quinone was boiled in acetic anhydride for fifteen hours and the product recrystallized from hot alcohol as golden-yellow needles. m. p. 148°; soluble in acetic acid and insoluble in petroleum ether.

Anal. Calcd. for $C_{12}H_6O_4Br_2$: Br, 42.78. Found: Br, 42.95.

2,6-Dibromo-1,4,5-trihydroxynaphthalene, $C_{10}H_3(OH)_3Br_2$(D).—One gram of C was dissolved in 35 cc. of warm acetic acid. The solution was shaken with additions of zinc dust until the red solution became pale yellow. The filtered solution was dropped upon crushed ice. The crystals so obtained were recrystallized from alcohol by adding water until separation began; colorless needles, darkening at 110° and decomposing at 157°; very soluble in acetic acid, less soluble in carbon tetrachloride and insoluble in petroleum ether; dissolves in dilute sodium hydroxide with a violet coloration, quickly turning to a reddish-brown; readily oxidized back to the quinone with ferric chloride.

Anal. Calcd. for $C_{10}H_6O_3Br_2$: Br, 47.90. Found: Br, 47.74.

6-Bromo-5-hydroxy-2-anilino-1,4-naphthoquinone, $C_{10}H_3O_2OHBrNHC_6H_5$(F).—One-half gram of C was dissolved in 70 cc. of hot alcohol, 1.5 g. of aniline was added and the solution boiled for five minutes. Needles of gun metal luster and red by transmitted light resulted. When heated a red vapor was evolved at 190°. After recrystallization from hot benzene the melting point was 249°.

Anal. Calcd. for $C_{16}H_{10}O_3NBr$: Br. 23.25. Found: Br, 23.27.

Further Notes on Compound **C.**—An attempt was made to prepare the pyroboroacetate ester. A reddish-purple color was obtained and a product which was too unstable to be isolated.

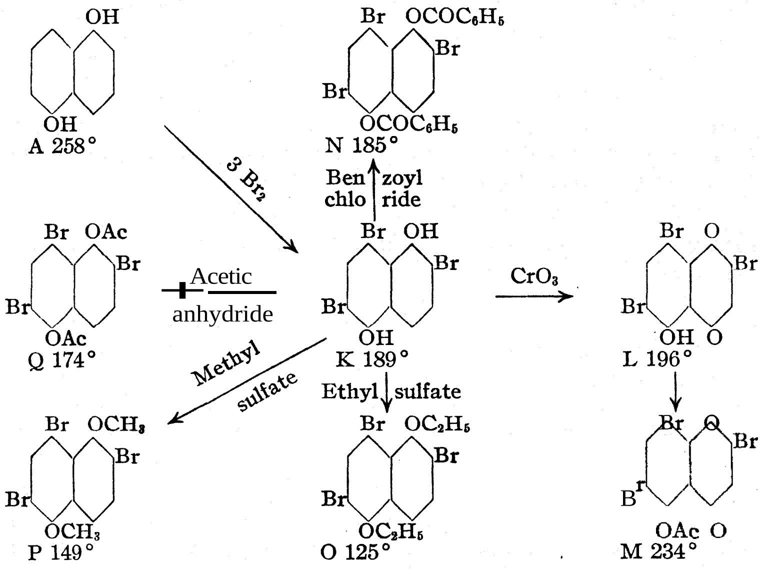
If a glacial acetic acid solution of C is treated with a little concd. nitric acid, short yellow needles crystallize out. This product explodes at 243". It dissolves in dilute sodium hydroxide, giving a red solution which stains the skin. It contains nitrogen but no bromine.

Tribromodihydroxynaphthalene

2,6,8-Tribromo-1,5-dihydroxynaphthalene, $C_{10}H_3(OH)_2Br_3$(K).—Twenty grams of dihydroxynaphthalene was dissolved in 700 cc. of hot glacial acetic acid and a few crystals of iodine added. While the temperature was maintained at 80° a solution of 19.5 cc. of bromine dissolved in 50 cc. of glacial acetic acid was added as follows: 46 cc. was allowed to drop in slowly. Much hydrogen bromide was evolved. One-half of the remainder was added in one portion and after ten minutes the last portion was added slowly. The solution was removed from the water-bath, allowed to stand for fifteen minutes and then cooled. The pale greenish-yellow crystals which formed were **filtered** and washed with petroleum ether; weight, **35** g. or **70.5%** of the theoretical. Purification was effected by dissolving the product in glacial acetic acid at **100°** (decomposes at higher temperatures), shaking with charcoal and filtering. An abundant mass of colorless cotton-like crystals appeared on cooling. The substance melts with decomposition at 189°, is soluble in acetone and in ether, slightly in cold acetic acid and insoluble in petroleum ether.

Anal. Calcd. for $C_{10}H_5O_2Br_3$: Br, 60.45. Found: Br, **60.08.**

It is converted by **concd.** nitric acid into a compound containing nitrogen but no bromine. It consists of yellow needles which explode at **249**" and dissolve in dilute sodium hydroxide with a blood red color.



Diacetate, $C_{10}H_3(OCOCH_3)_2Br_3$(Q).—**Compound** K was boiled for four hours with acetic anhydride, giving yellow needles which became colorless on boiling an alcoholic solution with charcoal; m. p. **174°**; soluble in benzene; insoluble in ether.

Anal. Calcd. for $C_{14}H_9O_4Br_3$: Br, **49.89.** Found: Br, **49.78.**

Dibenzoate, $C_{10}H_3(OCOC_6H_5)_2Br_3$(N).—*Compound* K was treated in pyridine solution with benzoyl chloride. The yellow crystals which formed were changed to an oil with water. The ether solution of the oil was decolorized with charcoal. On mixing the filtered solution with petroleum ether, colorless microscopic plates slowly formed. The substance liquefies with turbidity at 185° but becomes transparent at 189°. **It** is soluble in ether and in chloroform, insoluble in acetic acid, acetone and carbon tetrachloride.

Anal. Calcd. for $C_{24}H_{13}O_4Br_3$: Br, **39.67.** Found: Br, **39.47.**

Dimethyl Ether, $C_{10}H_3(OCH_3)_2Br_3$(P).—The crude product was a reddish-purple solid but in alcoholic solution charcoal removed the color; colorless needles, m. p. **149°**; easily soluble in benzene and in ether. insoluble in petroleum ether.

Anal. Calcd. for $C_{12}H_9O_2Br_3$: Br, 56.47. Found: Br, 56.26.

Diethyl Ether, $C_{10}H_3(OC_2H_5)_2Br_3$(O).—The crude product crystallized from hot alcohol in colorless needles, m. p. 125"; solubilities as above.

Anal. Calcd. for $C_{14}H_{13}O_2Br_3$: Br, 52.98. Found: Br, 52.68.

2,6,8-Tribromo-5-hydroxy-1,4-naphthoquinone, $C_{10}H_3O_2OHBr_3$(L).—To a suspension of compound K dissolved in 250 cc. of glacial acetic acid was added 20 g. of chromic acid dissolved in very little water. The temperature rose to 55°. It was heated to 80° for about fifteen minutes while vigorous effervescence occurred. It was then heated for ten minutes longer. The solution was filtered and poured into much cold water. The orange-colored precipitate was filtered and washed with water. It was dried and extracted with boiling petroleum ether. The solvent was distilled off and the residue recrystallized from hot glacial acetic acid; rich red needles; m. p. 196°; yield, small. The quinone is very soluble in chloroform and in benzene; slightly soluble in alcohol and in ether.

Anal. Calcd. for $C_{10}H_4O_3Br_3$: Br, 58.49. Found: Br, 68.60.

Monoacetate, $C_{10}H_2O_2OCOCH_3Br_3$(M).—The quinone on boiling for seven hours with acetic anhydride gave an acetate consisting of golden-brown scales, m. p. 234". when recrystallized from acetic acid; soluble in chloroform, insoluble in alcohol and in petroleum ether.

Anal. Calcd. for $C_{12}H_5O_4Br_3$: Br, 52.98. Found: Br. 52.84.

Tetrabromodihydroxynaphthalene

2,4,6,8-Tetrabromo-1,5-dihydroxynaphthalene, $C_{10}H_2(OH)_2Br_4$(S).—To 10 g. of diacetoxynaphthalene dissolved in 200 cc. of chloroform containing a few crystals of iodine was added 14 cc. of bromine. The solution was well shaken and allowed to stand. Much hydrogen bromide was evolved. After ten minutes the product began to crystallize out; most of the product had formed in ten hours. This was filtered off and a second crop was obtained at the end of two days; total yield, 19.5 g.; colorless glistening feathery needles which did not melt below 300°. It can be recrystallized from hot benzene, 90 cc. of which dissolves 0.5 g. only. The product decomposes if solvents of higher boiling point are used. It is insoluble in most of the organic solvents. Crystals exposed to direct sunlight turn rose-pink in color within two hours.

Anal. Calcd. for $C_{10}H_4O_2Br_4$: Br, 67.23. Found: Br, 67.45.

Dimethyl Ether, $C_{10}H_2(OCH_3)_2Br_4$(T).—The methyl ether was prepared in the usual way and the crude product boiled in benzene with charcoal. It was then filtered and the solvent evaporated off. The residue was dissolved in the least amount of hot benzene, cooled and an equal amount of alcohol added, giving colorless microscopic needles, m. p. 226°; soluble in benzene and in acetic acid, insoluble in ether and in petroleum ether.

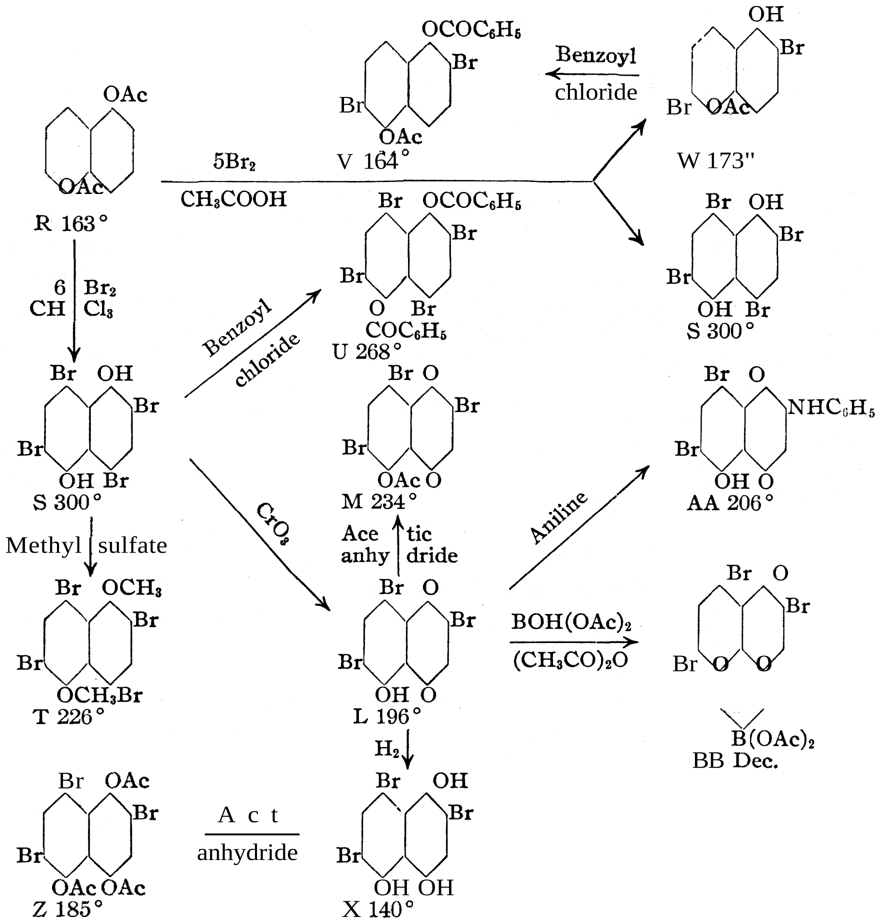
Anal. Calcd. for $C_{12}H_8O_2Br_4$: Br, 63.41. Found: Br, 63.21.

Dibenzoate, $C_{10}H_2(OCOC_6H_5)_2Br_4$(U).—Compound S was benzoylated by the Schotten–Baumann method. The product was purified as was the dimethyl ether. and gave irregularly shaped plates, m. p. 268°; soluble in benzene; insoluble in alcohol and in ether.

Anal. Calcd. for $C_{24}H_{12}O_4Br_4$: Br, 46.92. Found: Br, 46.85.

Further Notes on the Tetrabromonaphthalene.—Compound S was oxidized with chromic acid in acetic acid solution. One atom of bromine was eliminated and a quinone identical with L was obtained, as was shown by its melting point. 196°, by the identity of the acetyl derivatives and by the following analysis.

Anal. Calcd. for $C_{10}H_3O_3Br_3$: Br, 58.39. Found: Br. 58.41.



Compound S gave a product with concd. nitric acid in acetic acid: chrome-yellow needles, m. p. 232" with decomposition. It contains nitrogen but no bromine. It dissolves in dilute sodium hydroxide, the solution coloring the skin red.

Certain dibromo and tribromo derivatives follow since a part of the bromine is eliminated in some reactions.

6,8-Dibromo-2-anilino-5-hydroxy-1,4-naphthoquinone, $C_{10}H_2O_2OHNHC_6H_5Br_2$ (AA).—Two cc. of aniline in 5 cc. of glacial acetic acid was added to a hot solution of 1 g. of L in 40 cc. of acetic acid, giving an abundant yield of dark red glistening needles of hair-like structure, showing a green fluorescence when recrystallized from acetic acid. It melts at 206" is soluble in chloroform and slightly soluble in alcohol and in ether.

Anal. Calcd. for $C_{16}H_9O_3NBr_2$: Br, 37.82. Found: Br, 37.66.

2,6,8-Tribromo-1,4,5-trihydroxynaphthalene, $C_{10}H_2(OH)_3Br_3$ (X).—A suspension of 1 g. of the naphthoquinone L in 50 cc. of ether was underlaid with 50 cc. of dilute sulfuric acid. This was shaken with additions of zinc dust until reduction was complete. The ether layer was separated and mixed with an equal volume of petroleum ether. The crystalline precipitate was purified from a like mixture of solvents as long silky flesh-colored needles which decompose at about 140°, soluble in alcohol and in acetic acid;

difficultly soluble in chloroform and in benzene; soluble in dilute sodium hydroxide with a purple color which changes to a reddish-brown. Ferric chloride oxidizes the naphthol back to the quinone.

Anal. Calcd. for $C_{10}H_5O_3Br_3$: Br, 58.11. Found: Br, 57.75.

Triacetate, $C_{10}H_2(OCOCH_3)_3Br_3$(Z).—Compound X was boiled with acetic anhydride for seven hours: white fluffy needles from alcohol, m. p. 185°; soluble in benzene, less soluble in ether.

Anal. Calcd. for $C_{16}H_{11}O_6Br_3$: Br, 44.53. Found: Br, 44.31.

Pyroboro-acetate Ester of Tribromohydroxy-naphthoquinone (BB).—To 1 g. of compound L dissolved in 50 cc. of warm acetic anhydride was added 0.5 g. of pyroboro-acetate dissolved in the smallest amount of acetic anhydride. The flask was stoppered and shaken. A reddish-purple color developed and a fluorescent solid crystallized on cooling. The product was filtered, washed with absolute ether and dried to constant weight over phosphorus pentoxide; weight, 1.2 g.; hexagonal plates, possessing a green metallic luster but red by transmitted light. The ester was easily and completely decomposed to the original quinone by water. It was affected by even a very short exposure to the atmosphere. When heated a red vapor was evolved at 200° but no melting occurred below 300°.

Anal. Calcd. for $C_{14}H_8O_7Br_3$: Br, 44.54. Found: Br, 44.47.

Determinations were also made for boric acid, acetic acid and for the quinone residue, using the method proposed by Dimroth.[7]

Anal. Calcd. for the quinone residue: 0.4592. Found: 0.4576. Calcd. for acetic acid: 14.9 cc. of 0.1457 N $Ba(OH)_2$. Found: 14.8 cc. Calcd. for boric acid: 7.4 cc. of 0.1457 N $Ba(OH)_2$. Found: 7.4 cc.

Bromination of Diacetoxynaphthalene in Acetic Acid.—When diacetoxynaphthalene is dissolved in glacial acetic acid, treated with 5 moles of bromine and allowed to stand at room temperature, a mixture of products S and W is obtained. The first crop, obtained after a few hours, was found to consist of the naphthol W. The second crop, after twelve hours' standing, was a mixture of W and the tetrabromo compound S. The naphthol was dissolved out from the mixture with acetone. After a week a final crop consisting of S only was recovered. Ten grams of the acetate gave 5 g. of W and 13 *g*. of S.

2,6-Dibromo-5-acetoxy-1-naphthol, $C_{10}H_4OCOCH_3OHBr_2$(W).—Colorless needles, m. p. 173°, from acetic acid solution.

Anal. Calcd. for $C_{12}H_8O_3Br_2$: Br, 44.44. Found: Br, 44.14.

The fact that one acetyl group was hydrolyzed was shown by the preparation of a monobenzoate in pyridine solution.

2,6-Dibromo-5-acetoxy-1-benzoxynaphthalene, $C_{10}H_3(OCOCH_3)(OCOC_6H_5)Br_2$ (V).—This product, made in the usual way, was recrystallized from a mixture of equal parts of alcohol and petroleum ether as transparent colorless rectangular plates, m. p. 164°; soluble in alcohol, slightly soluble in cold acetic acid and in petroleum ether.

Anal. Calcd. for $C_{19}H_{11}O_4Br_2$: Br. 35.57. Found: Br. 35.48.

Summary

1. 1,5-Dihydroxynaphthalene in acetic acid yields with bromine in the presence of iodine a dibromo and a tribromo substitution product.

2. The diacetate in chloroform solution similarly treated gives a tetrabromo derivative.

---

[7] Dimroth, *Ann.*, 446, 108 (1926).

3. The diacetate in acetic acid solution at room temperature gives a mixture of the tetrabromo derivative and a dibromo-acetoxynaphthol.
4. The dibromo compound is oxidized by chromic acid to a naphthoquinone; so also is the tribromo derivative, but the tetrabromo compound oxidizes with the loss of one bromine atom to the same quinone.
5. The naphthoquinones are easily reduced to dihydric and trihydric naphthols.
6. The hydroxynaphthoquinones have the 1,4-quinoid structure, as proved by the pyroboro-acetate reagent.
7. A variety of derivatives is described.
8. The naphthoquinones are isomeric with certain halogenated juglones but are not identical with any.

LEVULINIC ACID AND ITS ESTERS

BY PETER P. T. SAH AND SHAO-YUAN MA

RECEIVED JUNE 27, 1930 PUBLISHED DECEMBER 18, 1930

While levulinic acid[1] is formed quite easily from glucose and other carbohydrates by the action of boiling dilute mineral acids, the mechanism of the reaction is still obscure and there is practically no good convenient method for the preparation of a large amount of the acid in the laboratory. The common procedure described by Rischbieth[2] offers experimental difficulties and gives only low yields due to incomplete disintegration of the carbohydrate (starch). McKenzie[3] has recently described a procedure in which cane sugar is hydrolyzed with dilute hydrochloric acid, the solution is evaporated to dryness and the residue extracted with ether. We have not found that the new method has any advantage over those previously described.

By repeated trials we have found commercial glucose to be a better starting material than sucrose. The yields were higher and the amount of humus substance precipitated was comparatively less. Another experimental observation we have made is that the action proceeds rapidly if the temperature of the solution is raised to 110°. At temperatures below this,

[3] McKenzie, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1929, Vol. IX, p. 50.

the transformation of hexose to levulinic acid is very slow and incomplete and a large amount of intermediate decomposition product, oxymethylfurfural, accumulates and is lost owing to volatilization on subsequent distillation or evaporation.

Although there are quite a few functional derivatives of levulinic acid described in the literature, the number is still rather small. Of the esters,* only three, methyl, ethyl and n-propyl, have been synthesized. The ethyl ester has been quite thoroughly studied; the other two are only briefly described. We have synthesized seven esters of levulinic acid, namely, methyl, ethyl; n-propyl, isopropyl, n-butyl, isobutyl and isoamyl levulinates, thus adding four new esters to the list already described. These esters were highly purified and a few of their important physical constants determined. To characterize them, we have also prepared the corresponding semicarbazones and phenylhydrazones. Their melting points and nitrogen contents were accurately determined.

Experimental

Preparation of **Levulinic** Acid.—Five hundred cc. of commercial concentrated hydrochloric acid was mixed in a 2-liter beaker with an equal volume of water. The acid solution was heated to boiling and 500 g. of commercial glucose (solid, technical lumps from E. Merck, Darmstadt) was added in small portions with constant stirring. The solution was boiled gently for ten minutes. After cooling, the large amount of humus material was filtered off by suction. The filtrate was transferred to a 3-liter round-bottomed flask and refluxed vigorously for at least twenty-four hours, in order to convert the intermediate product, oxymethylfurfural, to levulinic acid. The humus material further precipitated out was filtered off from time to time. The filtrate was distilled at atmospheric pressure until the thermometer registered at 125". The hydrochloric acid solution thus recovered could be used over again. The residue, after filtration, was distilled under reduced pressure. The fraction boiling from 146 to 184° at 7 mm. pressure was collected and redistilled. Upon chilling, the practically colorless liquid solidified to large, glassy, shining crystals, m. p. 33–35°; b. p. 245–246°; b. p. 145° at 4 mm.; yield, about 150 g. from 1 kilo of glucose used. The acid was freely soluble in water, ethyl alcohol or ether.

Esterification.—The acid was esterified directly with excess of absolute alcohol (methyl, ethyl, n-propyl, isopropyl, n-butyl, isobutyl, or isoamyl) in the presence of a small amount of hydrochloric acid. The procedure described by Adkins and McElvain[5] for the preparation of ethyl benzoate was adopted. The yield was about 65% of the theoretical. The tables show the simple physical constants and the chemical analysis of the various esters prepared. These liquids, colorless and with faint pleasant odor, are insoluble in water (except methyl levulinate), soluble in alcohol, benzene or carbon bisulfide, and very soluble in ether, chloroform, carbon tetrachloride or ethyl acetate.

Preparation of **Semicarbazones.**—The procedure recommended by Baeyer[6] was followed. To a solution of semicarbazide hydrochloride of known strength, the calculated amount of potassium acetate in alcohol and the ester of levulinic acid were added.

The methyl and ethyl esters reacted very quickly. Their semicarbazones precipitated almost instantaneously upon shaking. The higher homologs were allowed to stand overnight, whereby beautiful crystals came out smoothly. They were white solids with definite crystalline structure, insoluble in water, only difficultly soluble in ether, carbon bisulfide or carbon tetrachloride, soluble in ethyl alcohol, ethyl acetate or benzene and very soluble in chloroform.

For analysis and melting point determinations, the pure crystals were filtered off by suction, washed with a small amount of distilled water and dried in a vacuum over sulfuric acid. The nitrogen content was found by the Dumas method.

TABLE III

Preparation of Phenylhydrazones.—The procedure described by Michael[4c] was followed. A saturated solution of phenylhydrazine hydrochloride was prepared by dissolving the hydrochloride in about twelve parts of water. A molecular equivalent of alkyl levulinate was then added to the solution. Upon shaking and then standing for a few hours, crystals of the hydrazones separated out. They were filtered off by suction, pressed between filter paper and then dried in a vacuum over sulfuric acid to constant weight. The crystals were colorless when freshly prepared. On exposure to air, they turned yellowish-brown, showing that they were unstable toward oxygen. For melting point determination and analysis, the compound must be freshly prepared and recrystallized from benzene. The hydrazones of alkyl levulinates were insoluble in water, soluble in ether, alcohol or carbon tetrachloride, and very soluble in benzene, carbon bisulfide, chloroform or ethyl acetate. Their nitrogen content was analyzed for by the Dumas method.

Acknowledgment.—The authors wish to thank Dr. Albert Carruthers of the Department of Biochemistry, Peking Union Medical College, and Professor Tsun Chang, Head of the Chemistry Department, for their kind and valuable criticisms.

Summary

1. A simple procedure for the preparation of levulinic acid from commercial glucose is described.

2. Seven alkyl levulinates (three previously described and four new compounds) have been synthesized by direct esterification of levulinic acid with various alcohols. The esters were obtained highly pure and their simple constants studied.

3. These esters were characterized by their corresponding semicarbazones and phenylhydrazones. Among these, only the ethyl derivatives were previously described.

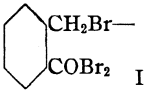
STUDIES IN THE ANTHRONE SERIES.
I. THE CONDENSATION OF PHTHALIDE WITH AROMATIC COMPOUNDS[1]

BY AL STEYERMARK WITH JOHN H. GARDNER

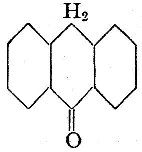
RECEIVED JUNE 30, 1930 PUBLISHED DECEMBER 18, 1930

In view of the importance in medicine of certain anthrones and dianthrones such as those found in chrysarobin, it has seemed of interest to study methods for the determination of the structures of members of this class of compounds. Most of the work which has been done heretofore has been purely analytical in nature and consequently cannot be regarded as furnishing a final solution of the problem. The present work represents the beginning of a series of studies on the methods of synthesizing anthrones and the rules of orientation involved.

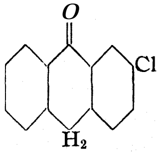
It was shown by Mayer and Fischbach[2] that w-bromo-o-toluyl bromide (I) can be condensed with benzene by means of aluminum chloride to form anthrone (II). Using chlorobenzene, they obtained a product which they identified as 2-chloro-9-anthrone (III).



I

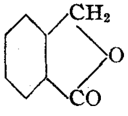


II

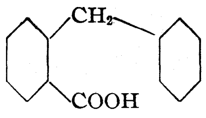


III

Since phthalide (IV) is related to w-bromo-o-toluyl bromide as an acid anhydride to its bromide, it would be expected to undergo the same type of condensation reactions. As a matter of fact, King[3] obtained *o*-benzylbenzoic acid (V) by the condensation of phthalide with benzene. In the present investigation, it has been found that anthrone is formed in this reaction in somewhat greater quantities than the benzylbenzoic acid.



IV



V

In view of the work of Mayer and Fischbach and of King, and by analogy with the product obtained in the condensation of phthalic anhydride with toluene,[4] it would be expected that phthalide could be condensed with

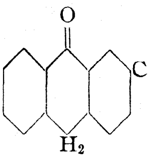
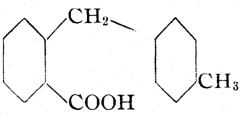
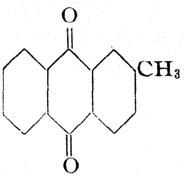
toluene with the formation of 2-methyl-9-anthrone (VI) and possibly o-(4-methylbenzyl)-benzoic acid (VII) as the principal products. However, on carrying out the reaction, the product was an oily mass, obviously a mixture, since all of the compounds which might have been expected to be formed are solids. On attempting to work up the product, a small amount of unchanged phthalide was the only pure substance which could be isolated. The crude product on oxidation gave a good yield of 2-methylanthraquinone (VIII), indicating the presence of either 2-methyl-9-anthrone (VI) or 2-methyl-10-anthrone (IX) or both.



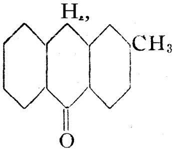
VI



VII

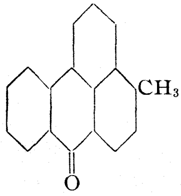


VIII

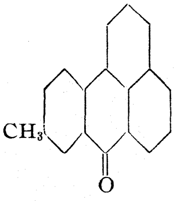


IX

As both isomers melt at practically the same temperature, it would be expected that they would exhibit practically the same solubilities in all solvents and consequently it would be impossible to separate them by fractional crystallization. This we have found to be the case. However, the benzanthrones which can be obtained from them[5] melt 30° apart and would be expected to differ markedly in their solubility relationships. This was found to be the case. 2-Methylbenzanthrone (X), m. p. 199°, is easily crystallized from a mixture of benzene and petroleum ether, while the isomeric 6-methylbenzanthrone (XI), m. p. 170°, is too soluble in benzene to be crystallized readily from it or from a mixture of benzene and petroleum ether.



X



XI

The oily mixture obtained from the condensation of phthalide with toluene was treated with glycerol and sulfuric acid and the product subjected to fractional crystallization from a mixture of benzene and petroleum ether. In this way, 2-methylbenzanthrone (X) was isolated, showing that

---

[5] Steyermark with Gardner, This Journal, 52,4887 (1930).

2-methyl-10-anthrone was present in the original condensation product. From the character of that material and by analogy with the work of Mayer and Fischbach and of King, it is certain that the isomeric 2-methyl-9-anthrone was also formed, but it was found impossible to isolate it or the benzanthrone formed from it in the reaction with glycerol and sulfuric acid.

On condensing phthalide with chlorobenzene, there was obtained a red, oily mass which, on oxidation, yielded 2-chloro-anthraquinone, indicating the presence of either 2-chloro-9-anthrone or 2-chloro-10-anthrone or both. In this case neither the anthrones nor the corresponding benzanthrones could be isolated in a sufficiently pure state for identification. All indications point to the presence of both possible isomers.

From the results of Mayer and Fischbach and of King, it would be concluded that the condensation of phthalide with aromatic hydrocarbons and their derivatives takes place exclusively through the methylene group of phthalide with the formation of o-benzylbenzoic acids which may be dehydrated to anthrones. The present work demonstrates that the carboxyl residue also reacts, leading to the formation of benzoylbenzyl alcohols, which are dehydrated to anthrones.

Experimental

Anthrone.—Ten grams of phthalide was dissolved in 50 cc. of benzene in a 500-cc. flask provided with a reflux condenser and protected by a calcium chloride tube; 20 g. of anhydrous aluminum chloride was added and the mixture heated on the water-bath for ten hours. After cooling, 100 cc. of 1:1 hydrochloric acid was added and the excess benzene driven off with steam. The residue was cooled and the solid material filtered off; yield of light yellow needles from alcohol followed by recrystallization from 3:1 benzene–petroleum ether, 4 g. (28%), m. p. 152–154°. A mixed melting point with anthrone showed no depression.

For further identification, a portion was oxidized with chromic acid in glacial acetic acid, yielding anthraquinone, m. p. 282–284°. Another portion was methylated by the method of Meyer and Schlosser[6] to 9-anthranol methyl ether, m. p. 94–95°.

Condensation of Phthalide with Toluene.—A mixture of 15 g. of phthalide in 90 cc. of toluene with 30 g. of anhydrous aluminum chloride was heated for fifteen hours on the steam-bath. On working up the product as was done with anthrone, there was obtained an oily mass from which no pure compound could be isolated.

Oxidation of the Phthalide–Toluene Condensation Product.—Two grams of the crude product was dissolved in 15 cc. of glacial acetic acid and a solution of 0.6 g. of chromic acid in 6 cc. of 50% acetic acid was added. After heating on the water-bath for five minutes, the product was precipitated by the addition of water, giving nearly colorless needles from alcohol, m. p. 168–170°. A mixed melting point with 2-methylanthraquinone showed no depression.

Preparation of 2-Methylbenzanthrone from the Phthalide–Toluene Condensation Product.—The oily mass obtained in the condensation described above was dissolved in 150 cc. of 82% sulfuric acid and 20 g. of glycerol was added. The mixture was heated in an oil-bath at 125–130° for four hours. The red solution was then poured onto

---

[6] Meyer and Schlosser, *Ann.*, 420, 126 (1920).

cracked ice. The olive-green precipitate was extracted with 500 cc. of hot 1% sodium hydroxide solution. After washing with water and drying, the residue was extracted with hot benzene. After cooling and adding petroleum ether, the benzene extract deposited 3.5 g. of yellow needles of 2-methylbenzanthrone, m. p. 198.5–199°, from benzene and petroleum ether. A mixed melting point with 2-methylbenzanthrone prepared from 2-methyl-9-anthroxle showed no depression.[5]

Anal. Subs., 0.1033: CO_2, 0.3403; H_2O, 0.0444. Calcd. for $C_{18}H_{12}O$; C, 88.49; H, 4.91. Found: C, 88.35; H, 4.81.

Condensation of Phthalide with **Chlorobenzene.**—A mixture of 10 g. of phthalide in 55 cc. of chlorobenzene with 20 g of anhydrous aluminum chloride was heated in an oil-bath at 125–130° for fifteen hours. The resulting product was worked up as before. No pure compound could be isolated.

A portion of the crude condensation product on oxidation with chromic acid gave 2-chloro-anthraquinone, m. p. 206–207°. On attempting to prepare a chlorobenzanthrone, a mixture which could not be separated into its components was obtained.

Summary

1. Phthalide can be condensed with aromatic hydrocarbons and their derivatives with the formation of anthrones.

2. Condensation takes place both through the methylene and the carboxyl residues of phthalide resulting in the formation of a mixture of isomers and rendering the method unsuitable for the synthesis of anthrones of definite structure.

STUDIES IN THE ANTHRONE SERIES.
II. THE SYNTHESIS OF SOME HYDROXYMETHYLANTHRONES[1]

BY AL STEYERMARK WITH JOHN H. GARDNER

RECEIVED JUNE 30, 1930 PUBLISHED DECEMBER 18, 1930

Since the most important of the naturally occurring anthrones are derived from 1,8-dihydroxy-3-methylanthraquinone and some related compounds, it has seemed of interest to study methods for the synthesis of hydroxy- and hydroxymethylanthrones which will afford definite proof of the structures of the products obtained. Most of the work which has been done on the determination of the structure of this class of compounds has been analytical in nature and has not always led to concordant results.[2] The only synthetic method which has been extensively investigated is the phthalaldehyde acid condensation method originated by Bistrzycki, which has been extended and improved by Adams and his students. The

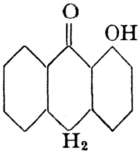
[1] Based upon a portion of a thesis submitted by Al Steyermark, Fellow in Chemistry and Physics, in partial fulfilment of the requirements for the Degree of Doctor of Philosophy in Washington University, June, 1930.

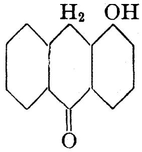
[2] Cross and Perkin, J. *Chem. Soc.*, 292 (1930), and previous papers by Perkin and his co-workers; Green. ibid.. 2341 (1927).

number of compounds obtainable in this way is distinctly limited owing to the[3] difficulty of preparing suitable substituted phthalaldehyde acids.

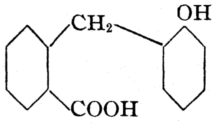
The most commonly used method for the preparation of anthrones has been the reduction of the corresponding anthraquinone with tin and hydrochloric acid in glacial acetic acid solution. This method was applied to 1-hydroxyanthraquinone by Liebermann and Mamlock and by Meyer and Sander,[4] but no satisfactory evidence as to the structure of the product obtained was presented until Cross and Perkin[6] showed that the benzanthrone which was obtained from it could not be methylated with methyl iodide and alkali, indicating that the carbonyl and hydroxyl groups are adjacent to each other. From this it must be concluded that the product is 1-hydroxy-9-anthrone (I). In the same paper they describe the preparation of an isomer, presumably 1-hydroxy-10-anthrone (11), obtained by the reduction of the acetate of 1-hydroxyanthraquinone.[6]



I



II



III

In this work the first step was the confirmation of the conclusions of Cross and Perkin by direct synthesis. o-(2-Hydroxybenzoyl)-benzoic acid was reduced to o-(2-hydroxybenzyl)-benzoic acid (III), which was in turn dehydrated to 1-hydroxy-10-anthrone. This compound, which formed colorless needles melting at 241–2°, agreed in all of its properties with the compound obtained by Cross and Perkin by the reduction of the acetate of 1-hydroxyanthraquinone. The compound obtained on the reduction of 1-hydroxyanthraquinone itself, however, formed canary yellow needles melting at 137.5–138° and consequently can be only 1-hydroxy-9-anthrone. From this it is concluded that the hydroxyl group in the a-position of the anthraquinone molecule directs the reduction to the carbonyl group farthest removed.

By a similar method, Barnett and Goodway[7] showed that the reduction of 2-methylanthraquinone yields a mixture of both possible isomeric methylanthrones. A repetition and extension of their work indicates that by far the major part of the product is 2-methyl-10-anthrone (IV) since only 2-methylbenzanthrone (V) can be obtained from the crude mix-

---

[3] Brubaker and Adams, This Journal, 49, 2279 (1927), give a bibliography of the work in this field.

[4] Liebermann and Marnlock, *Ber.*, 38, 1784 (1905); Meyer and Sander, Ann., 420, 113 (1920).

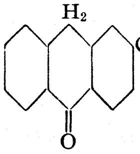
[6] Ref. 5, p. 306.

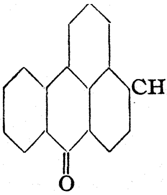
[7] Barnett and Goodway, ibid., 1754 (1929).

ture. Using pure 2-methyl-10-anthrone there was no increase in the yield of 2-methylbenzanthrone.[4] Consequently, we may conclude that the methyl group in the β-position in the anthraquinone molecule directs the reduction to the carbonyl group in the meta position of its ring.

Since the reduction of 1-hydroxyanthraquinone yields a single product and that of 2-methylanthraquinone a mixture, it would be expected that when the orienting influences of the two groups conflict, the hydroxyl group would dominate. This could be tested in the reduction of 1-hydroxy-2-methylanthraquinone.

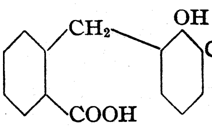


IV

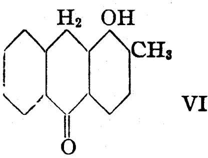


V

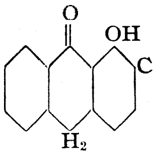
By the reduction of o-(2-hydroxy-3-methylbenzoyl)-benzoic acid, there was obtained o-(2-hydroxy-3-methylbenzyl)-benzoic acid (VI). This compound, by treatment with sulfuric acid, yielded 1-hydroxy-2-methyl-10-anthrone (VII) as colorless needles melting at 207.2–208°. On reducing 1-hydroxy-2-methylanthraquinone there was obtained an anthrone which crystallized in the form of yellow needles melting at 136.2–137° and which must be 1-hydroxy-2-methyl-9-anthrone (VIII), showing that the hydroxyl group has a stronger directive influence in the reduction of the carbonyl group of an anthraquinone derivative than does the methyl group, as was expected.



VI



VII

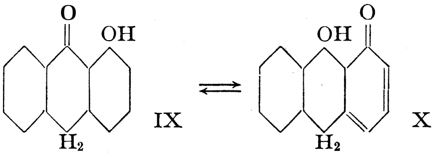


VIII

In the same way, the reduction of 1-hydroxy-3- and 4-methylanthraquinone was investigated. In each case the corresponding methyl-1-hydroxy-9-anthrone was obtained. Both of these anthrones crystallized as canary yellow needles.

By dehydration of o-(2-hydroxy-4-methylbenzyl)-and o-(2-hydroxy-5-methylbenzyl)-benzoic acid, there were obtained 1-hydroxy-3- and 1-hydroxy-4-methyl-10-anthrone, both forming light colored or colorless needles melting at much higher temperatures than the isomeric 1-hydroxy-9-anthrones.

It is of interest to note that the 1-hydroxy-9-anthrones are in every case colored while the isomeric 1-hydroxy-10-anthrones are, with one exception, colorless. 1-Hydroxy-3-methyl-10-anthrone could never be obtained entirely colorless, but the best samples which were obtained appeared to be slightly impure and it is believed that the color would be removed on complete purification. It seems reasonable to believe that the color of the 1-hydroxy-9-anthrones may be due to a benzenoid–quinoid tautomerism such as has been suggested for the hydroxyanthraquinones and demonstrated in one case,[8] the two forms represented by Formulas IX and X being in equilibrium.



Experimental

2-Methyl-10-anthrone.—2-Methylanthraquinone was reduced to the mixture of anthrones by the method of Barnett and Goodway.[9] After five recrystallizations from alcohol there was obtained an 8.8% yield of 2-methyl-10-anthrone, m. p. 101–102°.

2-Methyl-9-anthrone.—The isomeric 2-methyl-9-anthrone was obtained from p-toluyl-o-benzoic acid by the method of Limpricht.[10] The product melted at 102–103° and showed the same solubilities in alcohol, benzene, petroleum ether and various other solvents as 2-methyl-10-anthrone, explaining the extreme difficulty found in the separation of the two isomers.

2-Methylbenzanthrone.—Three grams of the crude mixture of methylanthrones obtained in the reduction of 2-methylanthraquinone was converted into the benzanthrone by the method of Scholl and Seer.[11] After recrystallization from a mixture of benzene and petroleum ether there was obtained 1 g. of 2-methylbenzanthrone, m. p. 198–199°. None of the isomeric 6-methylbenzanthrone could be isolated. Using pure 2-methyl-10-anthrone did not increase the yield.

o-(2-Hydroxybenzoyl)-benzoic Acid and its Homologs.—Phthalic anhydride was condensed with phenol and with the three cresols according to the procedure of Ullmann and Schmidt.[12] In this way there were obtained o-(2-hydroxybenzoyl)-benzoic acid and the three isomeric o-(2-hydroxymethylbenzoyl)-benzoic acids. It was noted, however, that, contrary to the results of Ullmann and Schmidt, on condensing phthalic anhydride with phenol and with o-cresol, there was formed a larger proportion of the benzoylbenzoic acid in which the condensation had taken place in the position para to the hydroxyl group than that in which the condensation had taken place in the ortho position.

Conversion of the Benzoylbenzoic Acids into Anthraquinone Derivatives.—One part of each of the benzoylbenzoic acids was mixed with two parts of boric acid and dissolved in 15–20 parts of fuming sulfuric acid of a suitable concentration. The solutions were heated for varying times and at various temperatures and were then poured onto cracked ice. The resulting yellow precipitates were coagulated by warming and filtered off. The anthraquinone derivatives were purified by solution in 10% sodium carbonate, precipitation with carbon dioxide and crystallization from alcohol. All

o-Benzylbenzoic Acids.—To a solution of one part of the benzoylbenzoic acid in three parts of water and 18–20 parts of concentrated ammonium hydroxide there was added three parts of zinc dust. The mixture was then heated gently for ten to twelve hours with mechanical stirring, ammonium hydroxide being added from time to time to maintain the concentration. The solution was filtered from the zinc and the *o*-benzylbenzoic acid precipitated by acidification with hydrochloric acid. The products were purified by solution in ammonium hydroxide, precipitation with hydrochloric acid and recrystallization from 50% methyl or ethyl alcohol, using decolorizing carbon, and from a mixture of benzene and petroleum ether. All of the acids were obtained as colorless needles. The yields and properties are given in Table II.

TABLE II

YIELDS AND PROPERTIES

a-( )-benzoic acid	M. p., °C.	Yield, %	Calcd., % C	Calcd., % H	Found, % C	Found, % H

(2-Hydroxy-3-methylbenzyl)-	158.2–159	85	74.36	5.83	74.11	5.60
(2-Hydroxy-4-methylbenzyl)-	1234	77.6	74.36	5.83	73.97	5.61
(2-Hydroxy-5-methylbenzyl)-	129–130	84.5	74.36	5.83	74.01	5.58

1-Hydroxy-9-anthrones.—To a solution of one part of the anthraquinone derivative in 40–50 parts of glacial acetic acid in a flask fitted with a reflux condenser there was added two to three parts of granulated tin. The solution was heated to boiling and three to four parts of concentrated hydrochloric acid was added in small portions during forty-five minutes. After the last addition of hydrochloric acid, the contents were boiled for an hour and then filtered while hot. Upon cooling, the filtrate deposited yellow needles of the anthrone. A further quantity was obtained by the addition of very dilute hydrochloric acid. The anthrones were purified by recrystallization from alcohol. The yields and properties are given in Table III.

1-Hydroxy-10-anthrone.—One part of the o-benzylbenzoic acid was dissolved in 20 parts of cold concentrated sulfuric acid and allowed to stand at room temperature for two hours, except that the preparation of 1-hydroxy-3-methyl-10-anthrone required fifteen hours. The resulting anthrones were precipitated by pouring the sulfuric acid solutions over cracked ice. They were purified by crystallization from alcohol and then

[a] Cross and Perkin, J. Chem. *Soc.*, 306 (1930), give 240–242°.

Summary

1. The reduction of 1-hydroxyanthraquinone and its homologs yields only the corresponding 1-hydroxy-9-anthrone.

2. 1-Hydroxy-10-anthrone and its homologs can be obtained from suitable o-benzoylbenzoic acids by reduction to the corresponding *o*-benzylbenzoic acids and dehydration.

3. 1-Hydroxy-9-anthrone and its homologs are bright yellow, while 1-hydroxy-10-anthrone and its homologs are colorless, suggesting the possibility of benzenoid–quinoid tautomerism in the former case.

ALPHA,BETA-DIPHENYLETHYL ETHER AND ALPHA-(PARA-METHOXYPHENYL-BETA-PHENYL)-ETHYL ETHER

BY CORLISS R. KINNEY AND W. GLEN BYWATER

RECEIVED JULY 7, 1930 PUBLISHED DECEMBER 18, 1930

In an attempt to oxidize the secondary alcohol, *p*-methoxyphenylbenzylcarbinol, with nitrogen trioxide, an unknown substance containing neither carbonyl groups nor nitrogen was obtained. Analyses and molecular weight determinations, as well as chemical properties, showed that the carbinol had been dehydrated to the corresponding ether, α-(*p*-methoxyphenyl)-β-phenylethyl ether. A similar reaction has been observed by a number of investigators,[1] who have shown that various acid reagents dehydrate diphenylcarbinol to its ether.

The new substance was also obtained in the preparation of *p*-methoxyphenylbenzylcarbinol, using the reaction of benzylmagnesium chloride with anisaldehyde.[2] The largest yields of the compound were obtained when the magnesium derivative was decomposed with a mixture of ice and concentrated hydrochloric acid. Following this procedure, no carbinol was isolated at all, and the major product was the dimolecular ether. Suspecting that dehydration of the carbinol was effected by the hydrochloric acid, several experiments were conducted using the pure carbinol, and varying ether–hydrochloric acid solutions. When the solution contained considerable acid, the carbinol was dehydrated to form *p*-methoxystilbene exclusively. Smaller concentrations of acid, however, in contact with anhydrous calcium chloride did give small amounts of the ether. The remainder of the carbinol was unchanged. The effect of the nitrogen trioxide gas, then, appeared to be that of an acid dehydrating agent similar to, but more effective than, hydrochloric acid. The larger yield of the ether from the Grignard reaction indicated that the dehydration occurred during the reaction or the process of decomposition of the magnesium derivative with the acid rather than a subsequent dehydration of the carbinol in an acidic ether extract.

Phenylbenzylcarbinol was transformed into its ether with somewhat greater difficulty than the methoxyl derivative. The method using nitrogen trioxide was not nearly as effective, nor was any ether isolated from the product of the reaction of benzylmagnesium chloride with benzalde-

Polski*, 15, *23* (1917). *Chem. Abst.*, **13**, 2865 (1919).

[2] The ether of diphenylcarbinol was also obtained, among other products, by Oddo, *Gazz. chim. ital., 111]* **37**, 356–66 (1907), from bromobenzene, magnesium, pyridine and benzaldehyde.

hyde. Small quantities of the ether were obtained, however, by the action of hydrochloric acid in an ether solution of the carbinol in contact with anhydrous calcium chloride.

Experimental Part

Preparation of **α-(*p*-Methoxyphenyl)-β-phenylethyl** Ether. (a) By the Action of Nitrogen **Trioxide** on ***p*-Methoxyphenylbenzylcarbinol.**—Thirty grams of pure *p*-methoxyphenylbenzylcarbinol was dissolved in 100 cc. of absolute ether and a slow stream of nitrogen trioxide from arsenic trioxide and nitric acid (sp. gr. 1.3) passed through the solution for twenty hours. The solid that crystallized out weighed nearly 8 g. and melted at 140–145°.

(b) Preparation of the Ether in the Reaction of **Benzylmagnesium** Chloride with Anisaldehyde.—The reaction of benzylmagnesium chloride with anisaldehyde normally gave yields of 64% of p-methoxyphenylbenzylcarbinol melting at 53–56" when the reaction mixture was carefully poured on ice and the precipitated basic magnesium salts dissolved with dilute sulfuric acid. None of the ether was isolated in such experiments. However, when the reaction mixture was poured into cracked ice and concentrated hydrochloric acid, the dimolecular ether separated from the solution, in which it was only slightly soluble, in large amounts. The oily residue failed to yield any of the carbinol, which is low melting.

(c) Preparation by the Action of Hydrochloric Acid.—Dry hydrogen chloride was passed into an absolute ether solution of 4 g. of p-methoxyphenylbenzylcarbinol for one hour. The carbinol was largely dehydrated to p-methoxystilbene, as proved by a mixed melting point determination. The yield was 2.54 g. or 69%.

Two grams of the carbinol and 2 cc. of concentrated hydrochloric acid were dissolved in about 40 cc. of ether and allowed to stand over calcium chloride (anhydrous) for several hours. As before, the carbinol was changed into p-methoxystilbene. The yield was 1.1 g. or 60%.

Finally 0.77 g. and 0.73 g. were allowed to stand over calcium chloride (anhydrous) in ether solutions containing one and two drops of concentrated hydrochloric acid, respectively. The first yielded 0.05 g. of the ether and the second 0.03 g. The remainder of the carbinol was recovered practically quantitatively.

Properties and Analyses of **α(*p*-Methoxyphenyl)-β-phenylethyl** Ether.—The ether was best purified by solution in a small amount of chloroform followed by dilution with several volumes of hot methyl alcohol. It crystallized in needles of m. p. 148–149° (uncorr.), was readily soluble in chloroform, moderately in acetone, slightly soluble in ether or alcohol and insoluble in petroleum ether.

Anal.[3] Subs., 0.2409, 0.2886: CO_2, 0.7274, 0.8643; H_2O, 0.1531, 0.1770. Calcd. for $C_{30}H_{30}O_3$: C, 82.19; H, 6.82. Found: C, 82.35, 81.96; H, 7.11, 6.86.

Mol. wt.: Calcd. for $C_{30}H_{30}O_3$: 438. Found: in chloroform, subs., 1.3866, 1.567; wt. of chloroform, 77.61; b. p. elevation, 0.200, 0.205"; mol. wt. 326.5, 368. Mol. wt. in camphor: subs., 0.0198, 0.0277, 0.3092; m. p. depression, 6.5, 6.9"; mol. wt., 393, 425.

The ether did not react with phenylhydrazine, hydroxylamine, sodium bisulfite, Schiff's reagent, sodium metal, nor benzoyl chloride. When boiled with hydrogen iodide in a Zeisel apparatus methyl iodide was produced, showing that the methoxyl group had not entered into a reaction. Oxidation with chromic anhydride in glacial acetic acid yielded benzoic and anisic acids. Distillation yielded a new substance melting at 107–108°, which was not p-methoxystilbene, m. p. 136°. Bromination with

---

[3] Analysis made by Mr. D. P. Langlois of this Laboratory.

evolution of hydrogen bromide yielded a bromide melting at 174–175°. The bromide was not the dibromide of *p*-methoxystilbene, m. p. 177°.

Preparation of α,β-**Diphenylethyl** Ether. (a) **By** the Action of Nitrogen **Trioxide.**—Seven grams of phenylbenzylcarbinol was dissolved in dry ether and nitrogen trioxide, obtained as before, passed into the solution overnight. The ether was evaporated and the residue extracted with methyl alcohol, which dissolved the unchanged carbinol, leaving **0.5** g. of a substance melting at 129–130°.

Several other experiments, in which dry nitrogen trioxide was used, failed to produce the compound.

(b) **By** the Action of Hydrochloric Acid.—Three grams of phenylbenzylcarbinol was dissolved in ether and 4 cc of concentrated hydrochloric acid and anhydrous calcium chloride were added. The mixture was allowed to stand for one hour and then refluxed for an hour. More anhydrous calcium chloride was added and the flask set aside for three and one-half days. The ether solution was filtered and evaporated. The residue was dissolved in hot methyl alcohol, and on cooling **1.95** g. of slightly impure carbinol crystallized out. This material was extracted with a small amount of methyl alcohol, which left **0.135** g. of ether melting at 123–127°.

Properties **and** Analyses of α,β-**Diphenyl** Ethyl Ether.—The ether was purified by recrystallization from boiling methyl alcohol. It crystallized in needles, m. p. 129.5–130.5° (uncorr.), was readily soluble in chloroform, slightly soluble in ether or alcohol and insoluble in petroleum ether.

Anal.[4] Subs., **0.0512:** CO_2, **0.1675;** H_2O, **0.0322.** Calcd. for $C_{28}H_{26}O$: C, 88.88; H, 6.87. Found: C, 89.21; H, 7.04.

Mol. wt.: Calcd. for $C_{28}H_{26}O$: mol. wt., **378.** Mol. wt. in camphor: subs., **0.0031;** wt. of camphor, **0.0478;** depression of melting point, 6.4°. Mol. wt. found: **383.8.**

Summary

p-Methoxyphenylbenzylcarbinol and phenylbenzylcarbinol have been found to be dehydrated to their ethers under certain acidic conditions.

SALT LAKE CITY, UTAH

[CONTRIBUTION FROM THE ROCKEFELLER PHYSICAL LABORATORY AND THE BAKER LABORATORY OF CHEMISTRY AT CORNELL UNIVERSITY]

THE ABSORPTION SPECTRA OF THE GAMMA-PYRONES AND PYROXONIUM SALTS[1]

BY R. C. GIBBS, JOHN R. JOHNSON AND E. C. HUGHES[2]

RECEIVED JULY 15, 1930 PUBLISHED DECEMBER 18, 1930

The unusual properties of the pyrone ring have resulted in considerable speculation concerning its structure. Investigations of the physical and chemical properties of the compounds in this group have led to the formulation of several different structures for the nucleus, none of which has been firmly established or generally accepted.

[4] Analysis made by Mr. Berne Woolley of this Laboratory.

[1] The investigations upon which this article is based were supported by grants from the Heckscher Foundation for the Advancement of Research, established at Cornell University by August Heckscher.

[2] Heckscher Research Assistant in Chemistry and Physics at Cornell University, **1928–1930.**

Qualitative investigations of the ultraviolet absorption spectra of γ-pyrone, y-dimethylpyrone, some of their derivatives and their salts have been reported.[3] Xanthene and xanthone have been studied in relation to the flavones.[4] The absorption of chelidonic acid and pyrone have been examined quantitatively by Riegel and Reinhard.[5]

It has been suggested as a result of a number of investigations from different angles of attack that the products of the action of acids upon the pyrones are oxonium compounds.[6]

In order to clarify the problem we have made a quantitative study of the series: y-pyrone, y-benzopyrone (chromone) and xanthone, and some of their derivatives. The investigation of the ultraviolet absorption spectra has been made with the Hilger sectorphotometer method as employed by Orndorff, Gibbs and McNulty.[7] The cells used were 0.331 cm. and 1.00 cm. thick. Beer's law was found to hold for all of the solutions over the range of concentrations indicated in the legends on the graphs. The molecular absorption coefficient is represented by ϵ.

The spectra of the following compounds were examined in absolute alcohol and alcoholic hydrogen chloride: pyrone (Fig. 1, A and B), dimethylpyrone (Fig. 1, E and F), benzopyrone, (Fig. 2, D and E) and xanthone (Fig. 2, A and B). Since there is a partial dissociation of the hydrochloride of dimethylpyrone in ionizing solvents, the absorption was also measured in an ether solution of hydrogen chloride. Xanthone and dimethylpyrone were also examined in sulfuric acid. The compound of dimethylpyrone with dimethyl sulfate, which has been shown to be an oxonium compound[Z1] was examined in alcohol (Fig. 3, D) and, to obviate any effects due to dissociation, in pure dimethyl sulfate (Fig. 3, E). The curves for the acid solutions of each of these compounds resemble those for the neutral solutions, except that the bands are shifted slightly toward the red. It is evident, therefore, that the formation of oxonium complexes produces no profound change in the structure of the ring.

A possible objection which might be raised to the above conclusion is that Kendall[6e] has stated that the compounds of dimethylpyrone with numerous organic acids are colored. We have found that these compounds, when made from dimethylpyrone which had been sublimed and recrystal-

The last-named investigators are, however, opposed to the view that these salts are oxonium compounds.

[7] Orndorff, Gibbs and McNulty, THIS JOURNAL, 47, 2767 (1925).

lized, are *colorless.* When a sample of Kahlbaum's dimethylpyrone was used without purification, as Kendall did, colored compounds were produced.

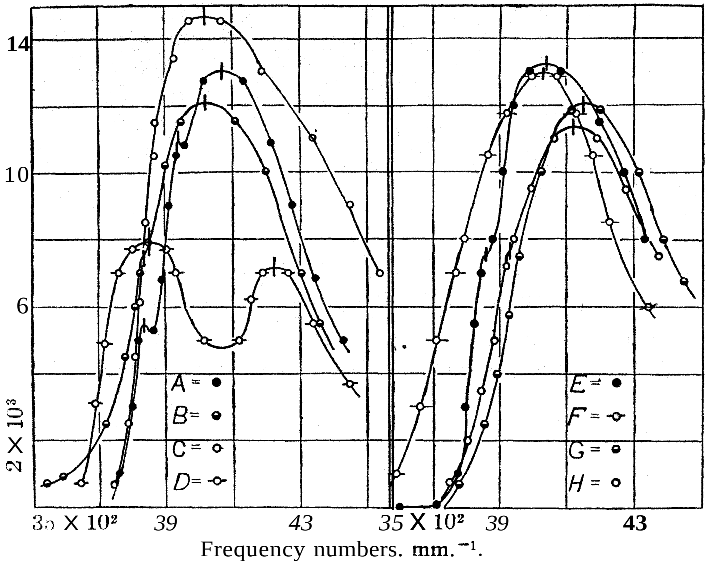

Fig. 1.—Pyrone: A, in alcohol (concn., 0.0002 to 0.00033 molar); B, same plus 5000 moles of HCl (concn., 0.0003 to 0.0005 molar). Dimethylpyrone: C, in water; D, in concd. sulfuric acid; E, in absolute alcohol, or the same plus 200 moles of sodium ethoxide; F, in absolute alcohol plus 300 moles of HCl; G, in anhydrous ether; H, same plus 2500 moles of HCl. The concentration range used in E, F, G and H was 0.0002 to 0.007 molar.

These observations lead to the conclusion that the structure of the nucleus of the pyrone ring is the same in the free pyrone as in the pyroxonium compounds. This is analogous to the similarity of the absorption spectra of the amines and the corresponding ammonium compounds.[8]

The earliest formula suggested for the pyrones is the ketone form, I, and the salts were considered to be the result of the addition of acid to either of the two oxygen atoms, II*a* and b. From a study of the absorption spectra Hantzsch[c] made the suggestion that the salts were of the coördination type as shown in III. It was then suggested by other investigator that an inner salt formula, IV*a*, would explain the anomalous properties of the pyrones. This formula is a modern conception of the formula IV*b* suggested by Baly[3a] in 1909. It is to be noted that the inner salt formula has a nucleus which is benzenoid and that the ketonic formula

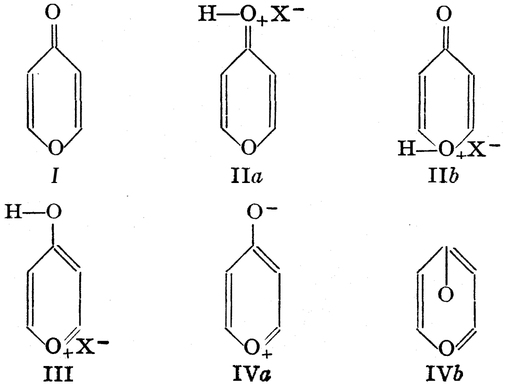
[9] Heilbron, Barnes and Morton, J. *Chem. Soc.*, 123, 2659 (1923).



FORMULAS OF PYRONE AND PYROXONIUM SALTS

has a structure which is analogous to the quinoid structure in the benzene series. Heilbron, Barnes and Morton[5] suggest the possibility of an equilibrium existing between the two forms. Since the shift from the quinoid to the benzenoid type of structure always produces a marked change in

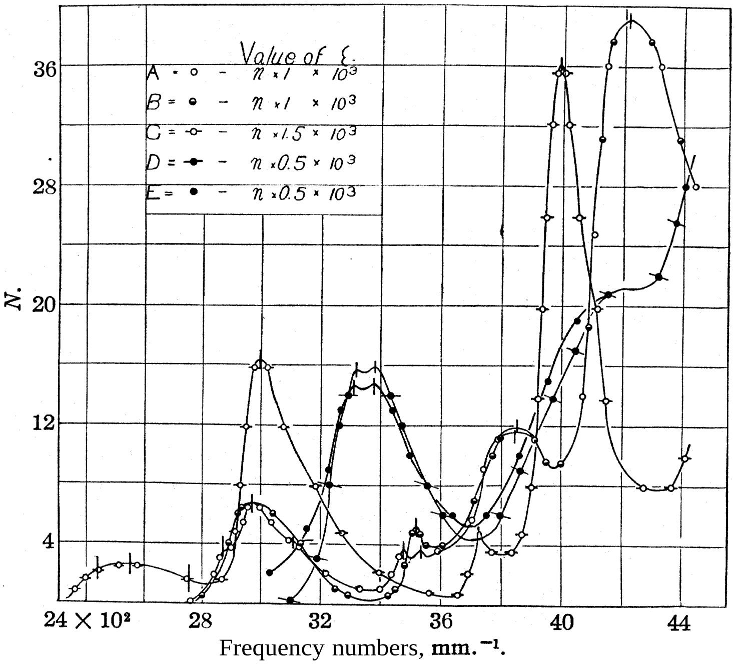


Fig. 2.—Xanthone: A, in absolute alcohol; B, same plus 5000 moles HCl; C, in concd. sulfuric acid. The concentration range used in A, B and C was 0.00003 to 0.005 molar. Benzopyrone: D, in absolute alcohol; E, the same plus 5000 moles HCl. The concentration range in D and E was 0.00005 to 0.005 molar.

the absorption spectrum, such an equilibrium could be detected by this method.

However, the absorption spectrum of dimethylpyrone in neutral alcohol is identical with that in alkaline alcohol (Fig. 1, E), and very similar to that in alcoholic hydrogen chloride (Fig. 1, F). This indicates that the pyrones do not exist in such an equilibrium in solution. Baly[3a] has reported a considerable difference between the absorption spectra in neutral and alkaline solutions. However, water was present in his solutions and it is known that the pyrone ring is unstable in the presence of aqueous alkali. In our measurements, on the other hand, absolute alcohol was used as the solvent.

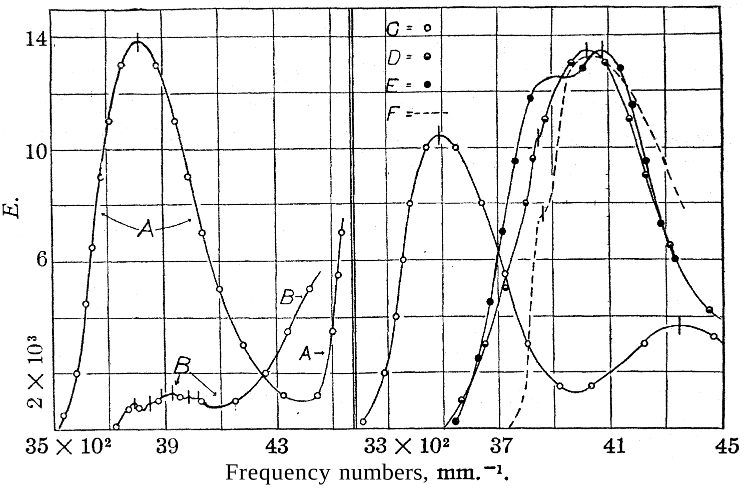

Fig. 3.—A, 1,2,6-Trimethyl-4-pyridone, in absolute alcohol (concn., 0.00035 to 0.004 molar); B, 4-methoxy-2,6-dimethylpyridine, in absolute alcohol (concn., 0.0007 to 0.004 molar); C, 2,4,6-trimethylpyroxonium perchlorate in alcohol (concn., 0.0004 to 0.0015 molar); D, dimethylpyrone + dimethyl sulfate in alcohol; E, dimethylpyrone in pure dimethyl sulfate (concn. of D and E, 0.0002 to 0.0017 molar); F, dimethylpyrone, see Fig. 1.

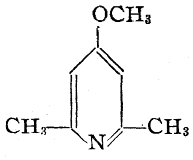
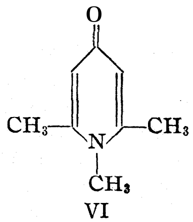
To obtain further information as an aid in deciding among the proposed structures, the product of the action of aqueous ammonia upon the oxonium complex of dimethylpyrone and dimethyl sulfate was studied. This reaction yields 4-methoxy-2,6-dimethylpyridine, V, a compound in which





VI

only the benzenoid structure is possible. The absorption spectrum of this substance is compared with that of its ketonic isomer, 1,2,6-trimethyl-4-pyridone, VI (Fig. 3, A and B). This comparison illustrates the great change in character and intensity of absorption that occurs upon transition from the benzenoid to the quinoid type of structure. The spectrum of the pyridone derivative bears a close resemblance to that of pyrone, but that of the pyridine derivative does not. This indicates that the pyrones and salts correspond to the ketonic formula. Evidently, as a result of the treatment with ammonium carbonate, the cyclic nucleus of dimethylpyrone has undergone a rearrangement. Since the product of this action is 4-methoxy-2,6-dimethylpyridine, it is assumed that the oxonium compounds are formed through the residual valences of the ketonic oxygen and not those of the ether oxygen. This assumption is supported by several investigators using different methods of study.[10] The free pyrone compounds would therefore be best represented by the ketonic structure I and the salts of the pyrones by the oxonium type of structure, II*a*.[11]

Xanthene and xanthydrol are known to have a quinoid type structure and have been examined in comparison with the absorption spectra of xanthone (Fig. 4, A and B). To illustrate the similarity between the absorption spectra of these three compounds, the frequencies of their maxima have been arranged in Table I.

TABLE I

ABSORPTION MAXIMA IN MM.$^{-1}$

Xanthone	2965	3470	3533	3850	4216
Xanthene		3425	3538		4050
Xanthydrol		3445	3533		4215

This would indicate that the pyrone group in xanthone is similar to the central portion of the molecule in xanthene and xanthydrol, that is, quinoid in structure.

In order to establish that the structure of pyrone and its derivatives is of the quinoid type, it would be desirable to show that analogous compounds, in which the structure is known to be of the benzenoid type, exhibit entirely different absorption spectra. The compounds resulting from the

---

[10] Maass and McIntosh, THIS JOURNAL, 34, 1273 (1912); Kendall and Carpenter. *ibid.*, 36, 2498 (1914); Tschelinzeff, *Bull. soc. chim.*, [4] 35, 741 (1924). The above statement should not be construed to mean that it is impossible for the ring oxygen to form an oxonium compound. The evidence is simply that the formation of oxonium compounds occurs with much greater ease through the ketonic oxygen, and that such oxonium compounds are much more stable than those derived from ethers.

[11] This would explain the failure of the attempts by Gibson and Simonsen [*J. Chem. Soc.*, 2307 (1928)] to resolve derivatives of pyrone in the form of salts. They conclude that their failure indicates that the salts have the coordination formula, III, but the attachment of the acid to the ketonic oxygen would also preclude the possibility of a resolution.

action of acids on xanthydrol have been formulated as oxonium compounds having a benzenoid structure[12] and should therefore show very different absorption spectra from those of xanthydrol, xanthene and xanthone in a neutral solvent. Trimethylpyroxonium perchlorate has also been formulated as being an oxonium compound of benzenoid structure.[13] A comparison of the absorption spectra of these oxonium salts with their pyrone analogs would possibly furnish information concerning the structure of the latter. However, the spectrum of xanthydrol in absolute alcoholic hydrogen chloride is identical with xanthene in neutral and acid solvents (Fig. 4, B). This indicates that the hydroxyl group has been directly replaced by chlorine without any profound change in the molecular structure. On the other hand, in concentrated sulfuric acid and in aqueous hydrochloric acid, xanthydrol exhibits an entirely different spectrum (Fig. 4, C).

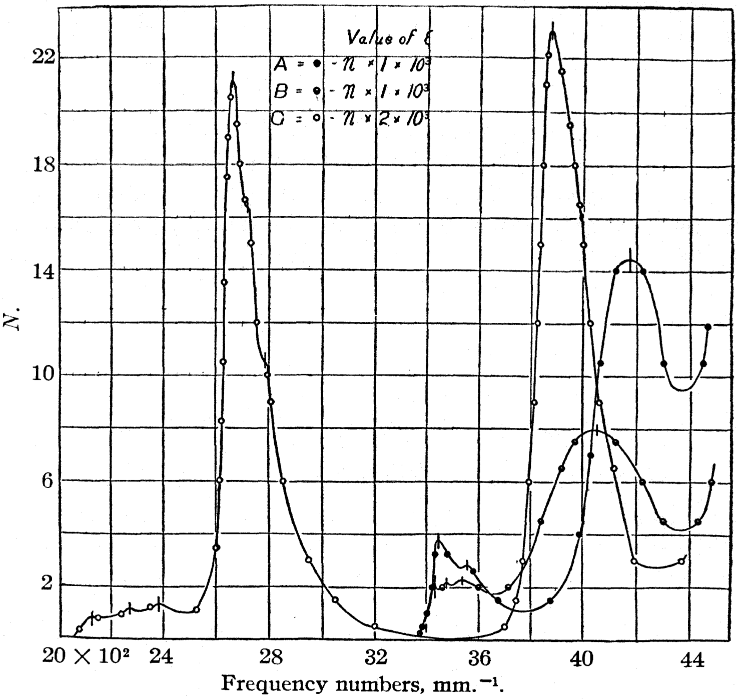


Fig. 4.—A, Xanthydrol in absolute alcohol (concn., 0.00025 to 0.001 molar); B, xanthene in alcohol, coincides with xanthene in 4 *N* alcoholic HCl and with xanthydrol in 4 *N* alcoholic HCl (concn. in all three cases, 0.00035 to 0.0017 molar); C, xanthydrol in concd. sulfuric acid (concn. 0.00008 to 0.005 molar).

---

[12] Werner, Ber., 34, 3301 (1901).

[13] Baeyer and Piccard, Ann., 384, 208 (1911); 407, 332 (1915). Hantzsch, Kef. 3c, reported the absorption spectra of this compound qualitatively.

This would indicate that the replacement or reaction of the hydroxyl group has been accompanied by a rearrangement of the cyclic nucleus.

Although the spectra of xanthydrol in the acid media differ greatly from those of xanthone, it would not be justifiable to draw conclusions as to the structure of the latter. There is considerable chemical evidence that the structure of the xanthydrol–acid complexes is not of the oxonium type.[14] The absorption spectra of fluoran[15] and of xanthene[16] in concentrated sulfuric acid are practically identical with that of xanthydrol in the same solvent. These two cannot rearrange in the way postulated for the formation of the oxonium compound of xanthydrol, without rupturing the molecule. The possibility is then indicated that the structure of these is not that of an oxonium compound. This would apply also to trimethylpyroxonium perchlorate, the spectrum of which is shown in comparison to that of dimethylpyrone (Fig. 3). If the structure is benzenoid, it should differ much more markedly from the spectrum of dimethylpyrone than it does. Hantzsch[3c] bases his deductions as to the structure of the pyrone salts upon the similarity of the spectra of these two series of salts. In the light of the above observations such a deduction is not justifiable until the structure of the perchlorate has been more firmly established.

The authors wish to acknowledge their indebtedness to Dr. C. V. Shapiro for many helpful suggestions during the course of this investigation.

Materials

The compounds used in this investigation were prepared and purified by the following methods; no particular care was given to the yield but only to the purity of the product. In the spectroscopical examination, two different samples were always used to aid in the detection of effects due to the possible presence of impurities. All melting points given are corrected.

Pyrone was prepared by the decarboxylation of chelidonic acid as described by Wiilstatter and Pummerer[17] and was purified by several fractionations under reduced pressure; b. p. 88.5° (7 mm.), m. p. 32.5°.

Dimethylpyrone was obtained from Kahlbaum, m. p. 132° before further purification. It was sublimed at 100° and twice recrystallized from redistilled ether; m. p. 132.1°.[18]

Benzopyrone (chromone) was prepared by the method of Ruhemann and that of Gomberg and Cone.[19] It was redistilled under reduced pressure and recrystallized from petroleum ether (boiling point, 70–80°). The melting point was 56° in accordance with Gomberg and Cone; Ruhemann gives 59°.

---

[14] Gomberg and Cone, Ref. 6g and *Ann.*, 370, 152 (1909).

[15] Orndorff, Gibbs and Shapiro, THIS JOURNAL, 50, 819 (1928).

[16] Unpublished data.

[17] Willstätter and Pummerer, *Be?.*, 37, 3733 (1904).

[18] Collie, J. Chem. *Soc.*, 59, 619 (1891).

[19] Ruhemann, *ibid.*, 77, 984, 1123, 1184 (1900); Heywang and Kostanecki, *Ber.*, 35, 2887 (1902); Gomberg and Cone, *Ann.*, 376, 228 (1910).

Xanthone was prepared according to the directions of Holleman[20] and was recrystallized four times from 95% alcohol. A sample obtained from Kahlbaum was also purified and examined. Both samples melted at 174°.

4-Methoxy-2,6-dimethylpyridine was prepared from purified dimethylpyrone by forming trimethylpyroxonium perchlorate (m. p. 192–193°, with dec.), and treating this with a cold solution of ammonium carbonate. It was redistilled under reduced pressure; b. p. 99–100° (21 mm.); 203.5° (748 mm.); d_{16}^{24} 1.015.[21] The refractive index of the first and last drops of the fraction used was n_D^{20} 1.5082.

1,2,6-Trimethyl-4-pyridone was prepared from the above methoxylutidine by treatment of the methiodide with freshly precipitated silver oxide. It was crystallized twice from water and once from chloroform, and dried for two days at 140° under reduced pressure; m. p. 245°.[22]

Trimethylpyroxonium perchlorate was prepared by hydrolysis with perchloric acid of the product of the reaction between dimethylpyrone and methylmagnesium bromide. It was four times recrystallized from ethyl alcohol and from water; m. p. 242–245°.[23]

Xanthene was obtained by the reduction of purified xanthone with sodium in alcohol.[24] It was steam distilled and recrystallized twice from alcohol and dried at 50°; m. p. 101°. Examination of the absorption spectrum showed that it contained no xanthone.

Xanthydrol was made by the reduction of xanthone with sodium amalgam.[25] It was twice recrystallized from alcohol without heating the solution in order to prevent the formation of dixanthyl ether. It was dried under reduced pressure over sulfuric acid for three hours and used immediately; m. p. 123–124°.[26]

Absolute alcohol was obtained from the United States Industrial Alcohol Corporation and carefully redistilled before use. In special cases when particularly anhydrous conditions were required, this product was dried over calcium oxide.

Dimethyl sulfate was obtained from Kahlbaum and was dried and distilled under diminished pressure over barium oxide in an all glass apparatus. It did not give a test for free acid and was transparent to 2200 Å.

Summary

It has been observed that the ultraviolet absorption spectra of γ-pyrone, dimethylpyrone, benzopyrone and xanthone in acid solution are very similar to the spectra in neutral solution. These data lead to the conclusion that the formation of oxonium compounds in this series does not result in any profound change in the structure of the molecule.

The identity of the absorption spectra curves of dimethylpyrone in neutral and alkaline media, and their similarity to the curve in acid solution precludes the possibility of an equilibrium existing between two different types of structure of the ring

A resemblance between the absorption spectra of dimethylpyrone (and its salts) and 1,2,6-trimethylpyridone, a compound in which only the ketone structure is possible, and between those of xanthone and of xanthene and xanthydrol has been observed. On the other hand, it has been noted that the spectrum of dimethylpyrone differs greatly from that of 4-methoxy-2,6-dimethylpyridine, an analogous compound which has the benzenoid type of structure.' From these observations the conclusion has been drawn that the structure of the pyrone and pyroxonium ring is best represented by a ketonic formula.

It has been pointed out that formulation of the salts of xanthydrol and of trimethylpyroxonium perchlorate as compounds of an oxonium type is open to question.

ELECTROLYSIS OF GRIGNARD SOLUTIONS[1]

BY H. E. FRENCH AND MARY DRANE

RECEIVED JULY 22, 1930 PUBLISHED DECEMBER 18, 1930

In a previous article[2] there is described a series of experiments on the electrolysis of certain Grignard compounds in ether solutions, using platinum electrodes. The purpose of that investigation was to determine the quantity of a Grignard compound which is decomposed by one equivalent of electricity, and to determine the products resulting from that decomposition.

The present paper describes some experiments on the electrolysis of Grignard solutions using anodes of various metals with platinum cathodes.

Apparatus and Procedure

The electrolytic cells were made of glass tubing, and were approximately 200 X 40 mm. in size. These were closed with tight fitting cork stoppers through which the two electrodes were suspended close to the stoppers by copper wires. These electrodes were held parallel to each other and about 3 cm. apart by means of bent glass rods. Short-circuiting between the electrodes through the formation of bushy deposits of magnesium on the cathode was prevented by placing on the bottom of each cell a long glass rod with which such deposits were broken off by occasionally tilting the cell.

A glass tube of 1 cm. diameter was inserted through the center of each of the stoppers which closed the cells, and extended about 1 cm. beyond the inner faces of the stoppers. Through these tubes the cells were filled and emptied.

For anode materials the following metals were used, either in the form of the foil or as long narrow flat pieces of the metal: aluminum, tin, cadmium, zinc, bismuth, gold, silver and nickel. The areas of the anodes were approximately 20 sq. cm., while those of the platinum cathodes were about 10 sq. cm. In order to eliminate the magnesium

halide etherates as factors in the electrolyses, isoamylmagnesium chloride was chosen for these experiments, the magnesium chloride etherate being but slightly soluble in the ether.

The currents through the solutions varied from 24 to 100 milliamperes, under a potential of 110 volts. Since this caused the solutions to boil vigorously, the currents were adjusted to 10 milliamperes for the first fifty hours and to 20 milliamperes for the remaining one hundred and fifty hours, by the introduction of resistances. In every case a light, bushy deposit of magnesium began to form on the cathode within a few minutes after starting the electrolysis.

When the electrolysis was complete, the solutions were drawn from the cells by suction and filtered, and both the filtrates and the residues were analyzed for the anode material. The concentration of the Grignard compound was also determined, before and after the electrolysis The results are summarized in Table I.

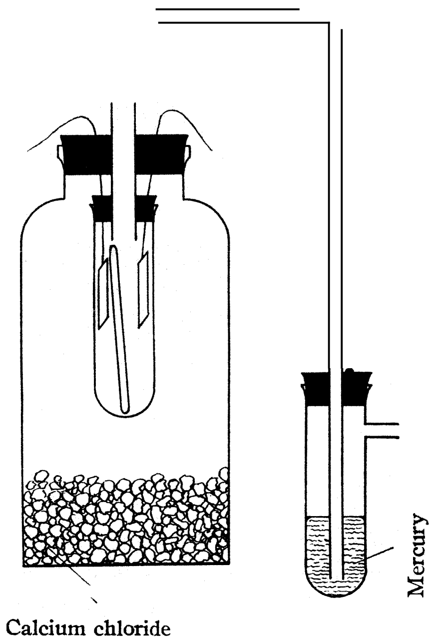

Fig. 1.

Of the various anodes, only the aluminum, zinc and cadmium were attacked during the course of the electrolysis. Of these metals, only the aluminum was found in the ether solution, presumably in the form of the aluminum alkyl. In this cell the conductance was apparently due to the magnesium compound alone, since all of the aluminum was found in the solution, and was approximately equivalent to the quantity of electricity passing through the cell. The appearance of the zinc and cadmium anodes in the earlier experiments led us to suspect that small pieces might have broken off and fallen to the bottom of the cells. Those results were therefore discarded, and the experiments were repeated using paper extraction thimbles around the anodes.

TABLE I

SUMMARY OF ELECTROLYSIS EXPERIMENTS

Cell	Anode material	Molar concn. of Grignard compound	Equiv. of Grignard compound in the cell At start	At end	Change	Equiv of anode material found In soln.	In residue	Coulometer reading in equiv.
1	Aluminum	2.231	0.383	0.104	0.279	0.074	0.000	0.082
2	Bismuth	1 692	.338	286	.052	.000	.000	.052
3	Gold	1.682	.321	260	.060	.000	.000	.063
4	Nickel	2.231	.629	490	.138	.000	.000	.104
5	Silver	2.231	.334	218	.116	.000	.000	.117
6	Tin	2.231	.334	.254	.079	.000	.000	.099
7	Zinc	1.647	288	.211	.077	000	.044	.071
8	Cadmium	1.647	288	.254	.034	.000	.022	.031

In both of these cases anode material dissolved off and was found later in the residue in the bottom of the cell, while the ether solutions contained none of that material. In neither case was the amount of anode material which was recovered equivalent to the amount of current passing through the solution. Presumably, in these two cells, the anode materials formed metallic alkyls as the result of electrolytic action and were then decomposed by the electric current simultaneously with the Grignard compound. Cadmium alkyls, however, have been reported as being decomposed by the action of light, with the deposition of metallic cadmium[3] and it is possible that the cadmium obtained in these experiments was formed, in part at least, by such action.

In Cells 2, 3 and 5 the amount of isoamylmagnesium chloride decomposed was equivalent, within experimental error, to the quantity of current passing through the solutions. In Cells 1, 4, 7 and 8 the amount of chemical change was greater than can be accounted for by the quantity of current carried. This failure of the analytical results to check is readily explained by the fact that in these cells a certain amount of hydrolysis took place with the formation of a precipitate of basic magnesium chloride. In cell No. 6, however, the amount of chemical change was less than would have been expected on the basis of the quantity of electricity carried through the cell. It is possible that this was due to a short circuit between the electrodes formed by a deposit of magnesium along the glass rod used to hold the electrodes in place. Such a deposit might have escaped observation, since the solution was dark colored.

Summary

1. Ether solutions of isoamylmagnesium chloride were subjected to electrolysis using anodes of various metals and cathodes of platinum.

2. Anodes of aluminum, zinc and cadmium were dissolved off as the result of electrolytic action. Those of bismuth, gold, nickel, silver and tin were not attacked. The amount of aluminum which went into solution was approximately equivalent to the quantity of current passing through the cell.

3. In several cases where the anode was not attacked, an amount of isoamylmagnesium chloride equivalent to the amount of current passing through the cell was decomposed.

THE PRESENCE OF URONIC ACIDS IN SOILS

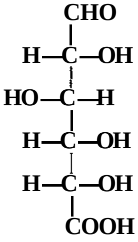
By E. C. Shorey and J. B. Martin

Received August 1, 1930 Published December 18, 1930

Uronic acids, represented by glucuronic and the isomeric galacturonic acids, while not often found free in natural products, are abundant in plant and animal tissues as part of complex bodies, frequently spoken of as polyuronides. As such they are found in some hemicelluloses, in pectin, and in the glycoproteins of animal tissues and apparently in some of the "slime" products of micro-organisms.

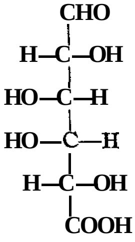
Such plant and animal tissues, of course, find their way into soils and complex compounds containing uronic acid nuclei might be expected to form some part of the organic matter of soils.

Uronic acids are represented by the formula $C_6H_{10}O_7$ and structurally



$$\begin{array}{c} \text{CHO} \\ | \\ \text{H—C—OH} \\ | \\ \text{HO—C—H} \\ | \\ \text{H—C—OH} \\ | \\ \text{H—C—OH} \\ | \\ \text{COOH} \end{array}$$

d-Glucuronic



$$\begin{array}{c} \text{CHO} \\ | \\ \text{H—C—OH} \\ | \\ \text{HO—C—H} \\ | \\ \text{HO—C—H} \\ | \\ \text{H—C—OH} \\ | \\ \text{COOH} \end{array}$$

d-Galacturonic

These acids are characterized by being rather easily decarboxylated by heating with strong acid, each molecule losing one molecule of carbon dioxide, being thereby converted into the corresponding pentose sugar

$$C_6H_{10}O_7 = C_5H_{10}O_5 + CO_2$$

d-Glucuronic acid by this process—boiling with 12% hydrochloric acid—gives d-xylose, while d-galacturonic acid gives *l*-arabinose.

Each of these sugars, when boiled with 12% hydrochloric acid for liberation of carbon dioxide, breaks down further to give furfural and water

$$C_5H_{10}O_5 = C_5H_4O_2 + 3H_2O$$

so that under this treatment there is evolution of carbon dioxide and formation of furfural at the same time.

It has been known for some time that practically all soils when boiled with 12% hydrochloric acid give furfural, the quantity of which can be determined in the usual way by precipitation as the phloroglucide. Shorey and Lathrop[1] showed that in ten soils of quite widely differing types the furfural obtained calculated to pentosan, varied from 0.055 to 2.75%—in one case representing 28.5% of the total carbon in the soil. Lathrop[2]

---

[1] Shorey and Lathrop, This Journal, 32,1680 (1910).

[2] Lathrop, unpublished data.

found in nine soils—clays and loams—the furfural calculated to pentosan varied from 0.181 to 0.598% and in sixteen peats varied from 0.50% in the peat from Lake Mattamuskete, North Carolina, to 5.25% on a brown fibrous peat from the Florida Everglades (mile post 39).

Heretofore the formation of furfural when a soil is boiled with 12% hydrochloric acid, has been ascribed to the presence of pentosans, represented in plant tissues by that somewhat indefinite group of compounds known as hemicelluloses, and assumed to be in soils as plant residues. In fact, such a pentosan was isolated from a sample of Marshall loam from North Dakota, a soil containing 6.97% organic carbon.[3]

However, it may be assumed that furfural from soils might be derived from any plant or animal constituent known to give rise to furfural and not necessarily from a pentosan.

A method for determining uronic acids based on a measurement of the carbon dioxide evolved was first proposed by Lefèvre and Tollens[4] and later modified by Dore, McKinnis, Nanji, Paton and Ling, and Dickson, Otterson and Link.[5]

This method depends on heating the material with an excess of boiling 12% hydrochloric acid until there is no further evolution of carbon dioxide, this dioxide being absorbed in a suitable apparatus for determination.

When this method is applied to soils containing carbonates the inorganic carbon dioxide must first be determined by treatment with weak acid in such a way that decarboxylation of the uronic acid is not brought about.

The method used in the work reported here is, briefly, as follows. A three-necked 500-cc. flask was used for the reaction. Into one side neck a stream of carbon dioxide-free air was passed. Into the center neck an upright reflux condenser was fitted, the other side neck being used for the introduction of acid through a dropping funnel. The outlet at the top of the condenser was connected with a carbon dioxide absorber which consisted of a Folin–Denis bell fitted into a wide-necked Erlenmeyer flask through a two-holed stopper. The outlet from this was connected to another Erlenmeyer flask similarly equipped with a Folin–Denis bell. The outlet of this was connected to a source of suction. The incoming air was freed of carbon dioxide by passing through a soda lime tower, next through a Milliken wash bottle charged with a concentrated solution of potassium hydroxide, then through a small wash bottle detector charged with barium hydroxide solution.

The absorbers were charged with a half-saturated solution of barium hydroxide.

Twenty-five grams of soil was used, except that in the case of peat 10 g. was taken. These were placed in the flask, 200 cc. of water and enough hydrochloric acid to make a 1% solution added, and the flask heated to boiling for one hour, the carbon dioxide evolved being absorbed in barium hydroxide solution and determined as described later.

The carbon dioxide given off by this treatment for one hour was, as the work was

originally planned, assumed to be derived from carbonates (inorganic carbon). The absorbers were then changed or recharged, enough hydrochloric acid added to the reaction flask to make a 12% solution, the flask placed in an oil-bath and the bath heated so that the contents were kept boiling. This usually required a bath temperature of **140–145°**.

This was continued for five hours, the carbon dioxide being absorbed in barium hydroxide.

In no case was there any precipitate formed in the second absorber, even with a very rapid current of air passing through the apparatus.

At the conclusion of the operation the absorber was disconnected and the precipitated barium carbonate filtered off rapidly by suction on a small Buchner funnel. The bell and flask were rapidly washed into the funnel and the washing continued until all barium hydroxide was removed. Barium carbonate adhering to the bell and flask was then dissolved with dilute hydrochloric acid and after changing the receiver this solution was poured on the funnel, more acid being used if necessary to dissolve all the barium carbonate and the filter thoroughly washed. To the solution of barium chloride thus obtained dilute sulfuric acid was added to precipitate the barium as sulfate. This was determined in the usual way and calculated to the equivalent of carbon dioxide.

This method has a disadvantage in the danger of carbonation of the barium hydroxide solution in the process of handling and filtering, but a little experience will enable one to overcome this. It has been found that when this operation was carried out carefully and expeditiously, the maximum error was 0.5 mg. of carbon dioxide, which, when working with *23 g.* of soil, is negligible. The method has an advantage in that errors introduced by the carrying over of hydrochloric acid or other volatile products are eliminated.

The results of the examination of eleven soils are reported in this paper. The soils were as follows.

No. 1, Houston clay No. 1. No. 2, Houston clay No. 2. No. 3, Houston clay No. 3. These three were soils from experimental fields near Austin, Texas, Nos. 2 and 3 are calcareous, that is, contain enough calcium carbonate to effervesce on the addition of acid. No. 4, Chester loam from Virginia. No. 5, Norfolk fine sandy loam from North Carolina. No. 6, Washburn loam from Aroostook County, Maine. No. 7, Caribou loam from the same location. No. 8, Greenville sandy loam from DeWitt, Georgia. No. 9, Portsmouth fine sandy loam from New Bern, North Carolina. No. 10, Muck from near North Liberty, Indiana. No. 11, Everglades peat from Belle Glade, Florida. In the tables following these soils will be referred to briefly by name.

The general organic characteristics of the soils examined, together with their reaction, are stated in Table I. All determinations were made on air-dried samples and the results calculated to the oven-dried basis.

With the exception of the Houston soils, the soils have a neutral or acid reaction but appreciable quantities of carbon dioxide were given off by the treatment for one hour with 1% hydrochloric acid.

Whether this carbon dioxide is derived from inorganic carbonate, oc-

cluded carbon dioxide or from the first stages of the decarboxylation of uronic acids, is under investigation.

In Table II are given the quantities of uronic acid carbon dioxide obtained after the preliminary treatment for one hour with 1% hydrochloric acid, together with the calculated equivalent of uronic acid, both being stated as percentage of the soil.

Since uronic acids are frequently a part of the more complex polyuronides, the total quantity of organic matter represented by the uronic acid carbon dioxide may be much larger than the calculated uronic acid shown in this table.

TABLE II

URONIC ACID CARBON DIOXIDE AND THE CALCULATED EQUIVALENT OF URONIC ACID PERCENTAGE OF SOIL

Norfolk	.08	0.352	**Peat**	1.69	7.462
Washburn	.41	1.808			

Uronic acid ($C_6H_{10}O_7$) contains **37%** carbon and some idea of the proportion of uronic acid to the total organic matter of the soil may be had by comparing the uronic acid carbon with the total organic carbon. Such a comparison is made in Table III.

The theory of the evolution of furfural to the process of decarboxylation of uronic acids has already been pointed out. Carbon dioxide is first split off, leaving a pentose sugar which further breaks down to furfural and water. In other words, the decarboxylation must be complete or the formation of furfural will not be complete.

It has been contended that complete decarboxylation of uronic acids can be brought about only by heating with 12% hydrochloric acid to 135–**140**" for four or preferably five hours,[6] and with this in mind the determinations of uronic acid carbon dioxide in soils reported here were made by heating at that temperature for five hours.

Portsmouth	.88	.113	12.8
Muck	30.9	2.86	9.25
Peat	53.3	2.75	5.15

Determinations of furfural in soils made in this Laboratory heretofore were made according to the method of the Association of Official Agricultural Chemists adopted for pentosans in feeding stuffs, and in order to have figures comparable with those previously obtained, this method was applied to the soils under discussion.

This method, which is essentially that of Kröber,[7] calls for heating to boiling with 12% hydrochloric acid at a rate such that 30 cc. distils over in ten minutes and this continued until 360 cc. has collected, which entails heating for only a little more than two hours.

It seemed that this method might give less than the theoretical quantity of furfural due to incomplete decarboxylation of the uronic acid. As a matter of fact, the quantities obtained by this method and presented in Table IV are much less than the theory calls for, and except for the peat are less than 50% of the theoretical.

TABLE IV

FURFURAL OBTAINED FROM SOILS COMPARED WITH THE CALCULATED QUANTITY

[7] Krober, J. *Landw.*, 48, 379 (1900).

To determine whether or not this was due to the shortness of time of heating, the determinations were repeated, heating for five hours, but in no case was more furfural obtained, and in most cases slightly less.

It has been generally observed that even when working with pure uronic acids the quantity of furfural obtained is less than the theoretical, whereas the theoretical quantity of carbon dioxide is obtained. This is no doubt due to the reactivity of furfural and its tendency to form reversion products or furan derivatives. It is quite likely that in a complex mixture of organic and inorganic material, such as a soil, this tendency is accentuated with the consequent greater loss of furfural.

That this is so is indicated by the following experiment.

	Phloroglucide
0.5 g. of pectin gave	0.1284 g.
10 g. of Portsmouth sandy loam	.0140 g.
Total when determined separately	.1424
When mixed and furfural determination made the mixture gave	.1402
0.25 g. of pectin gave	.0642
10 g. of Washburn loam gave	.0490
Total determined separately	.1137
When mixed and furfural determined the mixture gave	.1020

The pectin used was the commercial "lemon pectin."

The simultaneous evolution of carbon dioxide and formation of furfural on heating with strong acid being characteristic of uronic acids and the polyuronides present in plant tissues, it seems fair to assume when soils behave in the same way that they contain uronic acids or complex substances of which such acids are a part.

The identity of such compounds is part of an investigation not yet completed, but the following data are submitted in substantiation of the foregoing conclusion.

A hot water extract of one of the soils (Houston No 3) on evaporation to dryness yielded a gray powder that amounted to 0.07% of the soil and contained 61% organic matter. Another portion of the same soil heated with water in an autoclave at 30 pounds pressure yielded a similar extract, 0.11% of the soil and containing 76% organic matter.

Both these extracts were readily soluble in water again with the exception of a small portion (about 5%) that was inorganic in nature. Such a water solution gave the following reactions. It gave a strong Molisch reaction. It did not reduce Fehling's solution but did so after heating for a few minutes with hydrochloric acid. This reducing property, however, soon disappeared on continued heating with acid. Heated with hydrochloric acid and a small portion of orcin a green color was formed. Heated with hydrochloric acid and naphthoresorcinol, it gave a dark colored precipitate which was soluble in ether with a reddish-violet color, and in warm benzene with a blue color. These color reactions, with the exception of that with naphthoresorcinol, are given by pentoses or pentose yielding material.

When the water solution is subjected to dialysis there is left a somewhat opalescent viscous solution or dispersion from which several volumes (four or five) of 95% alcohol throw down a gelatinous precipitate which readily can be filtered off. This, when treated with water, forms again an opalescent dispersion which gives all the color reactions mentioned much more strongly than the original solution of the extract.

The residue from hot water extraction on heating with 12% hydrochloric acid gave 2.5% of furfural.

The residue from the water extract made under pressure when heated with 1% hydrochloric acid for one hour gave 0.5% of carbon dioxide and heating further for five hours with 12% hydrochloric acid gave 3.24% of carbon dioxide.

It is evident that water extraction under pressure as in this case extracts but a small portion of the uronic acid constituents. This soil (Houston No. 3) contained uronic acid carbon dioxide 0.13%, whereas calculating the 3.24% of the water extract back to the original soil gives but 0.0035% of uronic acid carbon dioxide.

A further separation of uronic acid material from soil was effected in the following manner. The soil was treated with 2% sodium hydroxide until the extract gave a strong Molisch reaction—this sometimes required several days. The supernatant liquor was decanted from the soil, made slightly acid with acetic acid, excess of barium carbonate added and the liquor concentrated to about one-quarter of its volume, filtered and further concentrated until it became sirupy.

This sirup, when poured into four volumes of 95% alcohol, formed a gelatinous precipitate which was readily filtered off and washed with alcohol. This precipitate dries to a horny mass which, when pulverized, forms a light gray powder. The precipitate or the dry powder when treated with water forms an opalescent solution or dispersion—more readily if a small quantity of barium acetate be added. This solution gives a precipitate of barium sulfate on addition of sulfuric acid and is evidently a barium salt or contains a barium salt of some uronic acid complex. The solution obtained in this way gave all the color reactions noted in connection with the water extract. The dry powder when heated with 12% hydrochloric acid gave off both carbon dioxide and furfural.

Separations of this kind were made from two of the soils (Houston No. 3 and Chester loam) and no differences have been noted in the character of the material so obtained. A larger quantity could be obtained from the Chester loam than from the Houston soil and larger quantities are obtainable by extraction with alkali than by water extraction.

The demonstration of the presence of uronic acid or polyuronides in soils is, in itself, the establishment of a new fact in regard to the character of the organic matter of soils, and further interest immediately connected with this fact lies in the identity of these uronic acid compounds, their origin and fate in the soil. These, naturally, are under investigation.

There are at least two points of a more or less analytical nature raised by the work here reported. One is the determination of inorganic carbon (carbonates) in soils. It is quite evident that heating soil with 1% hydrochloric acid gives rise to an evolution of carbon dioxide that, in some cases, one can scarcely conceive of as being present as inorganic carbonates. For instance, of the soils discussed in this paper five have a strong acid reaction and on heating for one hour with 1% hydrochloric acid, gave the following quantities of carbon dioxide.

These quantities of carbon dioxide were not included in stating the quantity of uronic acid carbon dioxide in Table II, but it is likely that they arise from the initial decarboxylation of uronic acids and should be added

TABLE V

CARBON DIOXIDE OBTAINED BY HEATING FOR ONE HOUR WITH 1% HYDROCHLORIC ACID

Soil	PH	Carbon dioxide, per cent. of soil
Chester	5.8	0.124
Norfolk	4.7	.044
Washburn	5.0	.204
Caribou	4.8	.220
Greenville	5.4	.075

to the figures stated there, but in view of the uncertainty as to their origin they were ignored. It seems quite probable that many of the discrepancies observed in determinations of carbon dioxide in soils have been due to variations in temperature and strength of acid used.

The other point is in connection with what may be called proximate analysis of soil organic matter. The most recent and probably at present the best known of such methods is that proposed by Waksman and Stevens.[8]

By this method the organic matter is separated into fractions: ether soluble, water soluble, alcohol soluble, hemicelluloses, cellulose, lignin, etc.

Apart from certain fundamental concepts that lead to erroneous conclusions in the application of this method, the most serious defect lies in that no place is provided for classes of organic soil constituents that from time to time may emerge from the obscurity of humus investigations. Uronic acids or polyuronides furnish an example of this. These are not soluble in ether or alcohol and are only very slightly extracted by hot water. On heating with acid, as the method calls for in the determination of hemicelluloses, they disappear as carbon dioxide and furfural, and such reducing sugar as might be formed from polyuronides completely disappears under the treatment.

Link and Niemann[9] have recently contributed to our knowledge on this point, showing that when polyuronides are hydrolyzed with weak acids the uronic acids split off and are destroyed as soon as formed.

We find, then, that a class of organic compounds that occur in soils that may represent from 5 to 25% or more of the organic carbon is, by this method, not only ignored, but so far as determination is concerned, is almost completely eliminated.

Summary

In this paper there are presented results of the examination of eleven samples of soil for the presence of uronic acid, according to methods adopted and in use for the determination of these acids in vegetable products.

The soils are from eight locations and represent types varying from sandy loams containing 0.82, 0.88 and 0.96% of organic carbon, to loams contain-

ing 3.00 and 4.90% of organic carbon, a muck containing **30%** and a peat containing 53% organic carbon. These soils varied in reaction from PH 4.7 to 8.3.

The uronic acid carbon dioxide varied from **0.07** to **1.80%** of the soil, and this, when calculated to the equivalent uronic acid, varied from 0.308 to 7.94% of the soil.

The uronic acid carbon calculated from these figures varied from **0.113** to 2.86% of the soil and this uronic acid carbon varied from 5.15 to 28.4% of the total organic carbon.

The presence of uronic acids or complex substances containing them (polyuronides) was confirmed by the separation from two of the soils of colloidal material having all the properties of such uronic acid complexes.

This separation was made both by hot water extraction and extraction with dilute sodium hydroxide.

The bearing of the presence of uronic acids in soils on certain analytical operations has been pointed out. These are the determination of carbonates in soils, and methods proposed for the proximate analysis of the organic matter of soils.

THE POTENTIALS OF SOME UNSTABLE OXIDATION–REDUCTION SYSTEMS

BY LOUIS F. FIESER

RECEIVED AUGUST 2, 1930 PUBLISHED DECEMBER 18, 1930

Although a considerable amount of data concerning the oxidation–reduction potentials of well-defined organic systems has accumulated during the past ten years, relatively few efforts have been made to study by direct potentiometric measurement those systems which are alterable and with which the potential of a solution is subject to a definite drift with time as the result of some reaction which consumes either the oxidant or the reductant, or both. Such systems, to be sure, have been studied by colorimetric and electrometric indicator methods, but these are to be classed as indirect methods inasmuch as they involve the observation of the effect of the unstable system upon the color or the potential of an oxidation–reduction system of unalterable components, and it is the potential of the latter, rather than that of the former, which actually is measured.

The potential of the alterable system has been the basis of observation in only a few investigations. Biilmann and Blom[1] have recorded the equilibrium potentials, together with the velocity constants, for the disappearance of the reductant, for two azo–hydrazo systems. They followed the

---

[1] Biilmann and Blom, J. *Chem. Soc.*, **125**, 1719 (1924).

fairly slow drift in the potentials of solutions prepared from equimolecular amounts of the oxidant and reductant and extrapolated the values to zero time. Relying not upon extrapolation but upon initial potentials obtained as soon as potentiometric balance could be reached, Clark, Cohen and Gibbs[2] obtained data for the systems from benzidine, o-tolidine and *p*-aminodimethylaniline, but their "attempts to measure the system of which p-phenylenediamine is the reductant were frustrated by the extreme instability of the system." In addition to these studies, Conant and Fieser[3] have reported approximate results obtained by rapid titration for the *o*-benzoquinone–catechol system, while Conant and Pratt[4] give some record of their attempts to measure the potential of the system formed by *p*-aminophenol and its highly alterable oxidation product, quinone-imine, and state that even under the most favorable conditions "the value of the oxidation-. reduction potential cannot-be determined accurately."

It is an unfortunate circumstance that the instability of the simple quinone-imines, quinonedi-imines and certain of the quinones has imposed such limitations upon the investigator as to prevent the accurate evaluation of the free energy of reduction of these substances, for some of the most interesting compounds fall into this group. On the more practical side, it will be recalled that the substances in question, in the form of their reduction products, have been used extensively as oxidation–reduction indicators and as photographic developers. Their suitability for these purposes is determined largely by the potentials of the systems.[5]

There is thus abundant reason for attempting to extend to some extent the limits in the field of the direct measurement of the oxidation–reduction potentials of unstable systems. We have examined several such systems with which, while the reductant is perfectly stable, the oxidant undergoes decomposition with greater or less rapidity when it is prepared in aqueous solution or in a mixture of water and alcohol. It did not appear expedient to prepare the oxidant in non-aqueous medium even where this is known to be possible, for a certain unnecessary period of time would be required for the dissolution of the material in the electrolytic solvent. It seemed much more rational to start with a solution of the reductant and to produce the oxidant in the solution at the time desired by the addition of an oxidizing agent. Ordinary electrometric titration of the reductant, however, is out of the question when a highly alterable oxidant is concerned. The decrease in potential between successive increments of the oxidizing agent is often so rapid that the results are meaningless.

The method which we have adopted as being the most satisfactory of any

yet developed may be called that of discontinuous titration. To a solution of the reductant there is added an amount of oxidizing agent estimated to produce a certain amount of the oxidant and thus to fix, at least momentarily, the ratio of oxidant to reductant. The potential of the solution is observed and followed with time. In further experiments the same quantity of reductant is treated with varying amounts of oxidizing agent so that, when all of the experiments are grouped together, a composite titration curve may be constructed and from it the normal oxidation–reduction potential and other constants may be calculated. This general scheme was employed to a certain extent by Clark, Cohen and Gibbs in the work cited, and its advantages over the continuous titration method are apparent. The most important point of difference in the present work lies in the manner of interpreting the potential readings. The choice lay between extrapolating the time–potential curve, after the manner of Biilmann, or in taking the first measurable potential, according to Clark, but the experiments themselves soon furnished reasons for giving preference to the former method. This will be shown directly, in connection with a description of some of the results obtained.

The Method of Procedure

In performing each experiment a solution of 0.0003 mole of the reductant was employed. In the case of the amines it was found convenient to prepare a 0.015 M solution of the amine hydrochloride and to add 20 cc. of this to 190 cc. of the buffer solution. Well-poised buffer solutions having a high concentration of salts (usually 0.2 *M*) were chosen in order to prevent any but very slight changes in hydrogen-ion concentration as a result of the dilution or the presence of the sample. When 0.1 M hydrochloric acid was the solvent, the PH employed was that found for the diluted solution. As the electrode vessel a tall 400-cc. beaker was employed, and the solution of the reductant was agitated vigorously in the thermostat with an efficient mechanical stirrer. The oxidizing agent used was a 0.03 M aqueous solution of potassium molybdicyanide, $K_3Mo(CN)_8$.[6] Since an unnecessary amount of time is consumed in running in the reagent from a buret, the addition was made in the following way. The reagent was carefully measured into a small dropping funnel having a wide-bore stopcock, and the stem of the funnel was inserted through the stopper of the electrode vessel. A rapid-delivering Mohr buret containing buffer solution was clamped just above the dropping funnel so that the latter could be rinsed out quickly into the vessel. When all was in readiness the stopcock was turned and the stop watch was released just as the stream of the oxidizing solution entered the stirred solution. With this arrangement it was possible to introduce 3–20 cc. of molybdicyanide solution in not more than three seconds, with about one second more for the rinsing. The potential readings were made on a student's type potentiometer and with an enclosed glass and scale galvanometer. By placing the stop watch in line of vision with the galvanometer scale and having this directly behind the potentiometer dial, the unassisted observer had little difficulty in following a very rapidly changing potential. Readings were made at intervals of fifteen seconds.

---

[6] Some observations concerning the preparation and stability of this reagent will be published in another paper.

The average volume of the solution at the time of the measurement was *220* cc. and the total concentration of the organic system *0.0014* M. When it was desirable to keep the volume the same in all experiments the amount of buffer solution used for washing out the funnel was so adjusted as to make the final volume just *230* cc.; total concentration, *0.0013 M.* The temperature was *25°* in all of the experiments.

***p*-Benzylaminophenol[7]-N-Benzyl-quinone-imine.**—The potential of a solution of these components in every case decreased rapidly with time, but the rate of change usually varied with the nature of the solvent and with the ratio of oxidant to reductant. The simplest behavior noted is illustrated by Curve II of Fig. 1. It will be observed that for one and one-fourth minutes the relationship between the decrease in potential and the time is linear.

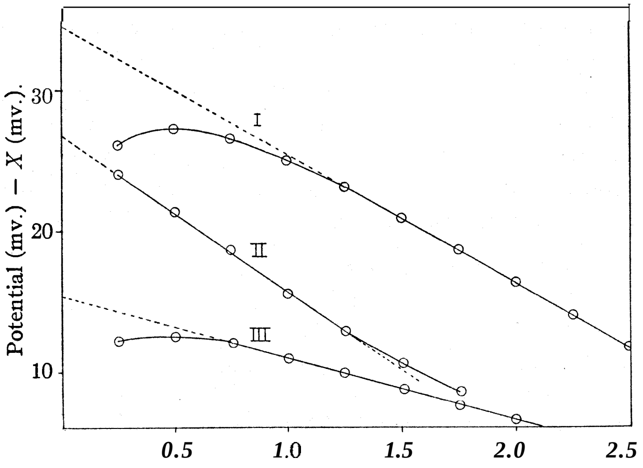

Fig. 1.—The system: *p*-benzylaminophenol–N-benzyl-quinone-imine. Curve I, P_H *7.57*, [Oxid]/[Red] = *6.25;* Curve II, P_H *1.10,* [Oxid]/[Red] = *0.387;* Curve III, P_H *7.57,* [Oxid]/[Red] = *0.403.*

The fact that the potential decreases indicates that it is the oxidant which is being destroyed, and the nature of the relationship points to a first order reaction, for both the monomolecular velocity constant and the potential of the solution are logarithmic functions of the concentration of the oxidant. The velocity constant may be defined by the following equations

$$k' = \frac{2.3026}{t} \log \frac{[\text{Oxid}]_i}{[\text{Oxid}]_i - x} \qquad (1)$$

$$E_i - E_t = \frac{RT}{nF} \log \frac{[\text{Oxid}]_i}{[\text{Oxid}]_i - x} \qquad (2)$$

$$\text{Let } k = kRT/2.3026\,nF$$

$$k = (E_i - E_t)/t \qquad (3)$$

The initial concentration of the oxidant is denoted by $[\text{Oxid}]_i$, x is the amount which has disappeared in *t* minutes, E_t is the potential at that time

---

[7] The material was crystallized as the hydrochloride.

and E_i is the initial potential of the solution. If the initial potential is taken as that found on extrapolating Curve II to zero time, the following values are obtained for the velocity constant, k (Table I). Up to one and one-fourth minutes the constancy is very good; the velocity then progressively decreases. Though the period over which the monomolecular reaction rate holds good is very brief, it may be estimated from other data on hand that the potential is a linear function of the time up to the point where 52% of the oxidant originally present has disappeared. The constancy is thus maintained for a considerable part of the life of the oxidant. It is clear that the reaction is monomolecular in the early stages, and one is consequently justified in making the extrapolation indicated by the dotted line. The only uncertainty is concerned with the timing of the experiment, but every effort was made to reduce this uncertainty to a minimum. The possible error in fixing the zero time is about two seconds, which in the case at hand would amount to an error of **0.0005** v. in the value for the initial potential.

TABLE I

VELOCITY CONSTANTS FOR REACTION PLOTTED IN CURVE II, FIG. 1

Minutes	Potential	k	Minutes	Potential	k
0	0.6880 (Extrap.)	....	1.50	0.6717	(0.0108)
0.25	,6852	0.0112	1.75	.6697	(.0104)
.50	.6825	.0110	2.00	.6677	(.0101)
.75	.6798	.0109	2.25	.6654	(.0100)
1.00	.6767	.0113	2.50	.6637	(.0097)
1.25	.6740	.0112	2.75	.6624	(.0093)

One significant conclusion to be drawn from the results just quoted is that in fifteen seconds the mixing is complete, the reaction between the reductant and the molybdicyanide has gone to completion, and electrode equilibrium has been attained. The potential at this point could hardly show the concordance with the succeeding potentials if it were otherwise. While the same observations apply equally well to many other experiments, there were other cases in which the first potential readings (15 sec.) did not fall into line with the rest in this manner, and examples of this type of behavior are given in Curves I and III of Fig. 1. Like Curve II, these results refer to the system from p-benzylaminophenol, but in neutral rather than acid solution. Instead of falling off at once, the potential shows a slight increase after fifteen seconds and only begins to drop in direct proportion to the time after one and one-fourth minutes for Curve I, and forty-five seconds for Curve III. In view of the conclusions drawn from the form of Curve II, this lag can hardly be due to incomplete mixing and it probably is not occasioned by a tardy establishment of electrode equilibrium. We are thus led to believe that the reaction between the reductant and the molybdicyanide is complete only after the time intervals noted. After the period of lag the reaction follows the monomolecular course for seven minutes, and we have extrapolated the straight portions of the curve (dotted lines) in order to obtain the initial potentials.

The initial potential obtained in this way is subject to some error if our interpretation of the lag is correct, for the amount of oxidant initially available for the decomposition reaction is not quite as great as that which the extrapolation curve implies. It seems unlikely that the phenomenon is the result of a slow attainment of potential balance, but if this is actually the case no error would be involved other than that occasioned by the extent of the extrapolation necessary. While we see no way of either obviating or evaluating this possible source of error, there is reason to believe that the error is very slight. Curves I and III both refer to the discontinuous titration of p-benzylaminophenol at P_H 7.57 and the experiments differ only in that the value of the ratio [Oxid]/[Red] was 6.25 and 0.403, respectively. Now there is much more lag, and more error if any, in the first case than in the second and yet the calculations from both experiments indicate very nearly the same value for the normal oxidation–reduction potential of the system. The case at hand, moreover, was selected for illustration because it is an extreme one; many other experiments might be cited in which a lag in the time–potential curve occurred only when the concentration of the oxidant was relatively high, and in these instances there was no detectable difference in the results for the experiments which showed this lag. There is thus justification for regarding extrapolations of the type illustrated in Curves I and III as at least close approximations.

The method which we have adopted for fixing the initial potential of the solution thus consists in extrapolating the first observed straight portion of the time–potential curve to zero time. A comparison may now be made with the procedure of Clark, Cohen and Gibbs, who took for this value the reading obtained as soon as potentiometric balance could be reached. In their experiments this required about twenty seconds; in our work the first reading was made at exactly fifteen seconds, and we are reasonably sure that a true balance had been attained. According to the interpretation which we have made of Curve II, during the time required for the attainment of electrode equilibrium and for the mechanics of measurement a considerable amount of oxidant has disappeared and the potential has fallen an appreciable extent. In other words, the error of taking the first measurable potential as the initial potential here amounts to 2.5 mv. In the case of the experiment of Curve I the error would be more serious. If one were relying entirely upon the first "significant potential" one very probably would conclude that electrode equilibrium had been reached at thirty seconds and that the potential found here was the true potential. According to the results of extrapolation the error would amount to 7.3 mv. While we thus feel that the method of Clark, Cohen and Gibbs should not be used in the study of the systems with which we are here concerned, we do not wish to imply a criticism of their own work. Each system has its own peculiarities and may require a special method of study.

Having described our method of fixing the initial potential, E_i, we shall present in Table II a summary of a typical "discontinuous titration." The potentials given are single electrode potentials at 25° referred to the hydrogen electrode potential at PH 0.

TABLE II

SYSTEM: *p*-BENZYLAMINOPHENOL-N-BENZYL-QUINONE-IMINE

PH 7.57. End-point = 17.4 cc. molybdicyanide solution

15.0	.2831	6.23	.0235	1.42	.2504	.0092
				Av. 1.39	Av. 0.2501	

The end-point of the titration was determined in the usual way except, of course, that a number of separate experiments were required, in each of which a different amount of oxidizing agent was added to the solution of the reductant. This method was found preferable to the use of standardized solutions of the molybdicyanide and of the reductant on account of some uncertainties in these standardizations. It is not difficult to ascertain the end-point with a reasonable degree of accuracy, even with these unstable systems, and often one is aided by a distinct color change.

The initial potentials obtained by extrapolation are given in the second column of the table and they are represented graphically in Fig. 2. The full line drawn through the potentials forms a smooth curve which has the logarithmic form of the usual titration curve but not the slope. For a reductant which loses two hydrogen atoms on oxidation, the slope of the curve is normally represented by the equation

$$E = E_n + 0.02957 \log \frac{[\text{Oxid}]}{[\text{Red}]} \qquad (4)$$

in which E_n is the potential when [Oxid] = [Red] in a given solution. This equation is pictured in the figure by the dotted line. The present results may be represented by the modified Equation, 3, by the introduction of an empirical constant, C, to correct for the divergent slope

$$E = E_n + C \times 0.0295 \log [\text{Oxid}]/[\text{Red}] \qquad (5)$$

At the point of half-oxidation the two equations become identical, and the potential corresponding to this point provisionally may be taken as the value for E_n. Using this value one may now calculate from Equation 5 the value of the constant, C, as has been done in the fifth column of the table. In the fourth experiment the ratio [Oxid]/[Red] is so close to unity that a calculation of C is not admissible. The constancy is sufficiently good to show that the equation accurately expresses the results.

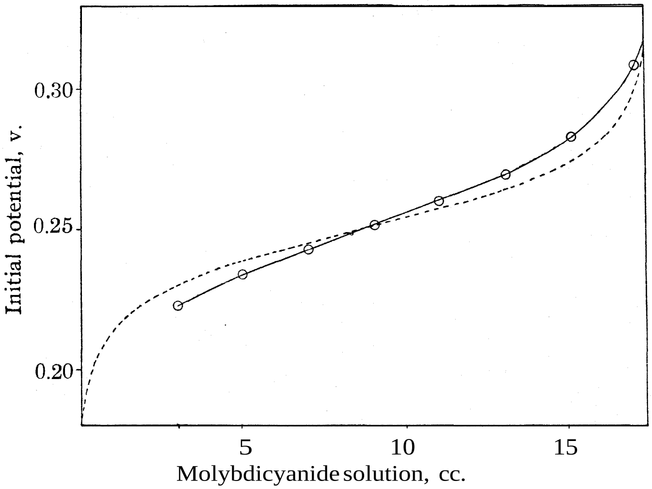

Fig. 2.—Titration curve of *p*-benzylaminophenol at PH 7.57.

An explanation of the abnormal slope is not far to seek. Several investigators have noted the influence on the potential of the quinone–hydroquinone system of the association between the components to form quinhydrone, and Clark, Cohen and Gibbs have found that such association is particularly marked among the systems of the *p*-phenylenediamine series, to which the system under study is closely related. Conant and collaborators[8] ascribed abnormal slopes of the titration curves of certain anthraquinones to quinhydrone formation. It is probable that quinhydrones or meriquinones are formed in the present case, and with most of the other substances reported on below. If the meriquinone, M, contains equal molecules of oxidant and reductant, Equation 4 must be modified as in 6

$$E = E_n + 0.02957 \log \frac{[\mathrm{Oxid}]_T - [\mathrm{M}]}{[\mathrm{Oxid}]_T - [\mathrm{M}]} \qquad (6)$$

The terms $[\mathrm{Oxid}]_T$ and $[\mathrm{Red}]_T$ refer to the total amounts of the components. It is evident that the removal of equivalent amounts of oxidant and reductant from the oxidation–reduction equilibrium would shift the potential to values progressively higher than the normal as the excess of oxidant over reductant increases, and to lower values as this ratio is reversed.

---

[8] Conant, Kahn, Fieser and Kurtz, THIS JOURNAL, 44, 1382 (1922).

The magnitude of the effect in the present instance may be estimated by relating Equations 5 and 6, and for this purpose we shall make use of an expression similar to that developed by Conant.[8,9] If the oxidant is present in excess of the reductant, and if X is the degree of association of the complex, M, then $[M] = X[\text{Red}]_T$. Expressing the concentrations of oxidant and reductant in terms of the ratio, R, of the former to the latter, the following expression is obtained.

$$E = E_n + 0.02957 \log \frac{R - X}{1 - X} \tag{7}$$

When it is the reductant which is in excess, the equation is

$$E = E_n + 0.02957 \log \frac{R - RX}{1 - RX} \tag{8}$$

To obtain the degree of association, X, Equation 7 may be combined with the empirical Equation 5, whence

$$C \log R = \log \frac{R - X}{1 - X} \tag{9}$$

Using the average value found for the constant, C, one finds the value of 0.36 for X when R = 2; 0.52 when R = 5. This indicates that the meriquinone formation takes place to a considerable extent.

Some caution should be exercised in respect to conclusions deduced in this way concerning meriquinone formation, for the subject is full of complications, as Clark, Cohen and Gibbs have pointed out. We have presented a possible interpretation of the peculiar titration curves, but in reporting our results we prefer to disregard the theoretical aspects of the question and to make use of the empirical Equation 5. A provisional value for E_n, the potential at half-oxidation, was obtained by interpolating the titration curve, and from it an average value for the constant, C, was calculated. We may now reverse the process, that is, use the average value found for C and calculate E_n from the results of each experiment. This has been done in the sixth column of Table II. The agreement between the individual values is very good, considering the rapid decomposition of the oxidant, the abnormal slope of the titration curve, and the lag in the time–potential curve (Curves III and I of Fig. 1 refer to the second and the last experiments of Table II).

Values for the velocity constant of the decomposition reaction are given in the last column. Since, by definition, $k = (E_i - E_t)/t$, the values for k represent the drop in potential per minute. In each case the rate remained constant for from six to seven minutes and the values reported represent the averages during the period of constancy. It will be observed that the velocity increases very considerably as the concentration of the oxidant is increased, though the changes are not parallel. A five-fold

---

[9] Conant's equation, p. 1391, holds when the reductant is in excess but not for the converse case.

increase in the concentration of the oxidant doubles the velocity constant. It is thus difficult to classify the order of the reaction as a whole, though in each individual experiment it appears to be strictly monomolecular in the early stages.

The oxidation of *p*-benzylaminophenol was not followed in the alkaline range, but a fairly complete study was made in acid and neutral solutions. A condensed summary of the results is given in Table III. The individual experiments at each PH are not recorded, but an indication of the agreement of the six or seven determinations of each value for E_n is given by appending the average error. Single electrode potentials on the hydrogen scale at 25° are given. Except in the first case, the solutions all contained a total of 0.2 M per liter of buffer salts. Some indication of the velocity constants observed is given by including in the last two columns the approximate constants for two values of the ratio [Oxid]/[Red], R. Experiments were not usually performed at just the ratios indicated, but the constants were obtained by interpolation.

TABLE III

VARIATION OF THE POTENTIAL OF THE SYSTEM *p*-BENZYLAMINOPHENOL–N-BENZYLQUINONE-IMINE WITH HYDROGEN-ION CONCENTRATION

PH[10]	Hydrogen electrode potential, E_n, v	Constant, C, of Eq. 5	Potential when [Oxid] = [Red], E_n, v	Av error, mv	Calcd. E, v.	Diff. E_n (Found–calcd.), mv	Velocity constant, k when [Oxid]/[Red] = 0.3	3.3

$E_0 = 0.6984$ $K_0 = 9.00 \times 10^{-12}$ $K_r = 1.48 \times 10^{-9}$

The first two series of experiments summarized in the table require a more detailed description. At PH 7 the potential of the molybdicyanide–molybdocyanide system is over 0.4 v. higher than that of the organic system, hence the reaction between potassium molybdicyanide and *p*-benzylaminophenol proceeds practically to completion at all concentrations of the reactants and a sharp inflection at the end-point of a titration is ob-

---

[10] The buffer solutions were of the following compositions: PH 1.10, HCl; PH 1.56–2.05, glycine, HCl, KCl; PH 2.69, citric acid, NaOH, NaCl; PH 3.22–3.88, KH-Phthalate, HCl; PH 4.32–4.91, sodium acetate, acetic acid, NaCl; PH 5.58, citric acid, NaOH, NaCl; PH 6.96–7.57, Na_2HPO_4, KH_2PO_4.

tained. But the potential of the organic system, in reference to a hydrogen electrode at the same P_H, increases somewhat with increasing acidity while that of the inorganic system suffers an enormous decrease, with the result that at P_H 1.10 the potentials of the two systems overlap and the reaction between the reductant and the oxidizing agent comes to a stop when an appreciable quantity of the molybdicyanide is still unconsumed. This does not necessitate giving up this oxidizing agent, but it does require that a correction be applied for the unreacted reagent.

The fraction, m, of the potassium molybdicyanide which has failed to react may be found from the potential of the solution and Equation 10

$$E = E\ (\mathrm{Mo}) + 0.05915 \log m/(1 - m) \tag{10}$$

where E (Mo) is the potential of a half-oxidized molybdicyanide solution at P_H 1.10 on the hydrogen scale and **E** is the initial potential of the mixture of organic and inorganic materials, on the same scale. **A** rough determination of E (Mo) suffices for the purpose at hand and the value used was 0.771 v., determined by titration with potassium ferrocyanide. If the end-point in the titration of *p*-benzylaminophenol, preferably as determined in another series of experiments at a higher P_H, be represented by **P** and if C cubic centimeters of molybdicyanide solution is employed in a given experiment, the correct ratio of oxidant to reductant (R) is given by Equation 11

$$R = \frac{C\ (1 - m)}{P - C\ (1 - m)} \tag{11}$$

Table IV gives the details of the results and calculations at P_H 1.10. The titration curve is not as steep as one would anticipate and there is a downward trend in the values for E_n obtained by applying the usual equation (next to last column). This cannot be caused by association between the oxidant and reductant for the trend is in the wrong direction. Indeed we have failed to discover the cause for this, but we have corrected for it by means of the empirical Equation 5, and there is reason to accept the values thus obtained for E_n (last column), for the average is identical with the mid-point potential of the titration curve.

TABLE IV

15.0	.7121	.091	3.77	.77	.6951	.6982

In the experiments at PH 1.56 there was some overlapping in the potentials of the organic and inorganic systems, except for very low values of R, and the correction was applied in the same way, using 0.782 v. as the value for E (Mo).

No general conclusions can be drawn regarding the velocity of decomposition of the oxidant, as inspection of the values for k in Table III will show. There is no definite trend with changing acidity; the rate is sometimes constant over a considerable range of concentration of the oxidant, but it often increases decidedly as the amount of the quinone-imine increases.

Some statement should be made regarding the color of the solutions at the conclusion of the experiments. From *P*H 1.10 to 3.53 the solutions were yellow; at *P*H 3.88 a faint purple developed, and at PH 4.91 and beyond a red precipitate resulted from the oxidations. In the case of the highly colored solutions or suspensions a striking and significant effect was noted. **As** the end-point of the titration was approached the solution became pale purple, and when this point had been reached or passed the solution was pure yellow in color. The more intense color is thus caused either by an association or an interaction of the quinone-imine or its decomposition products with the reductant.

We shall now turn to the interesting problem of determining whether the potentials of this system have been characterized accurately enough to reveal the dissociation constants of the oxidant and reductant. In Fig. **3** the potentials of half-oxidation of Table III are plotted against the PH of the buffer solutions. It will be observed that the points fall on a smooth curve which has certain distinct characteristics. Starting in the neutral range, there is a straight portion which is parallel to the curve for the hydrogen electrode potential and thus has the slope 0.05915 log $[H^+]$. This "0.06 slope" is characteristic, though not uniquely so, of a system in which an oxidant or reductant is either un-ionized or completely ionized, and in the present case it is altogether reasonable to assume that they are un-ionized. Close to PH 5 there is an upward inflection and the curve then approaches an "0.09 slope." This indicates that a dissociation of some basic group begins to occur at about this acidity. That the potential becomes higher than when the components of the system are un-ionized means that it is the reductant which dissociates, for the removal of some of the undissociated reductant from the oxidation–reduction equilibrium by ionization would increase the ratio

[Undissociated Oxidant]/[Undissociated Reductant]

and hence shift the potential to higher levels. The dissociation of the reductant is complete when the "0.09 slope" is reached, but a second inflection in the opposite direction is noted at PH 2.85 and the curve then swings back to a new "0.06 slope." This obviously indicates a basic ionization of the oxidant, which eventually compensates for the dissociation of the reductant and brings the curve once more parallel to that for the hydrogen electrode.

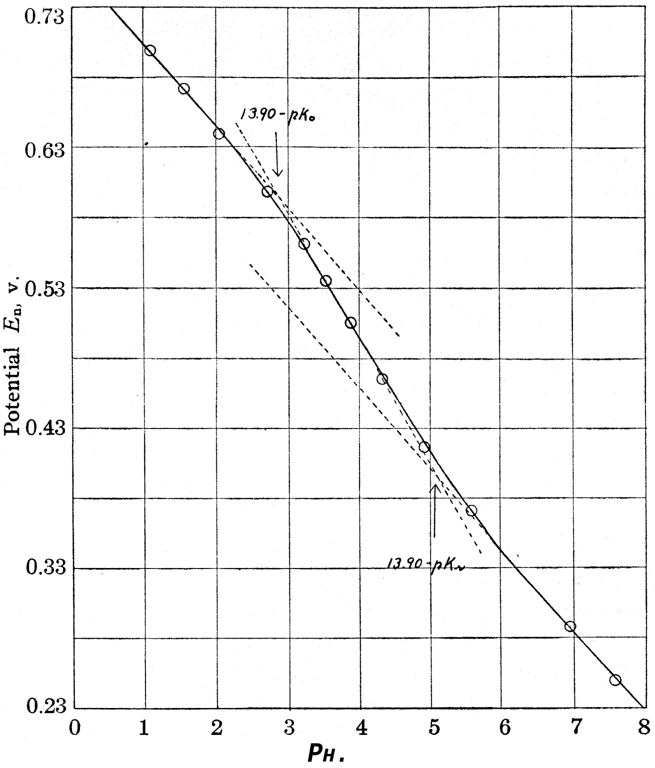

Fig. 3.—Relationship between PH and the potential of half-oxidation of *p*-benzylaminophenol. (The line is theoretical, the points experimental.)

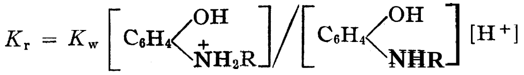
Since the study of the system has not been pursued into the alkaline range, we may omit all consideration of the acidic ionization of the reductant in developing an equation to cover the present observations. For the limited PH region investigated the equation for a system in which the oxidant and the reductant have the basic dissociation constants, K_o and K_r is as follows

$$E_n = E_0 + E_h + 0.02957 \log \frac{K_w + K_r [H^+]}{K_w + K_o [H^+]} \qquad (12)$$

The term E_n is the potential when [Oxid] = [Red], E_0 is the normal oxidation–reduction potential for the undissociated components of the system, E_h is the hydrogen electrode potential, K_w is the ionization constant of water, for which we have used the value 1.26 × 10^{-14} and K_o and K_r are defined as follows

$$K_o = K_w \left[C_6H_4 \begin{matrix} \diagup O \\ \diagdown \overset{+}{N}HR \end{matrix} \right] \Big/ \left[C_6H_4 \begin{matrix} \diagup O \\ \diagdown NR \end{matrix} \right] [H^+] \qquad (13)$$



$$K_r = K_w \left[C_6H_4 \begin{matrix} \diagup OH \\ \diagdown \overset{+}{N}H_2R \end{matrix} \right] \Big/ \left[C_6H_4 \begin{matrix} \diagup OH \\ \diagdown NHR \end{matrix} \right] [H^+] \qquad (14)$$

With the aid of this equation we have constructed a "best curve" to fit the experimental results, and the constants which we have thus found for the system are given at the bottom of Table III. In the sixth column of this table are to be found values for E_n for each PH as calculated from Equation 12 and the constants, and a comparison between the values found and those calculated is given in the following column. For further comparison the theoretical equation has been plotted in Fig. **3,** and it will be seen that the experimental values (points) lie close to the curve. Comment on these results will be reserved until other systems have been defined.

In addition to the measurements in aqueous solution, some knowledge of the nature of the system in an alcohol–water mixture was desirable. The solvent chosen contained primary and secondary phosphates in such a ratio as to give a solution of PH 7.03 in water, and we considered that very little ionization of either the oxidant or reductant would occur in the neutral solution and hence that the potential difference between the oxidation–reduction electrode at half-oxidation and the hydrogen electrode in the same solvent would give an adequate measure of the "normal" oxidation–reduction potential. The cell employed was that just indicated, and we shall term the e. m. f. of this cell the normal potential E_0 for the alcoholic solution. The results of a "discontinuous titration" are given in Table V. Comparison with the results in aqueous solution shows that the normal potential is very nearly the same (compare 0.6984), but that the velocity of the disappearance of the oxidant is noticeably less in the alcoholic buffer than in the neutral aqueous solutions.

p-Methylaminophenol–N-Methyl-quinone-i—he material used was **a** good, colorless commercial grade of the sulfate ("Photol"), crystallized six times from water. Brawn samples of the material which are offered under the name "Metol" appeared to contain a catalytically active impurity which is not easily removed. The catalyst does not affect the potentials to any noticeable extent, but it greatly accelerates the rate of decomposition of the oxidant. Three crystallizations yielded a colorless product which showed a reaction rate which was less than that for the crude material but still almost twice as great as for the purest samples which we studied.

The results for this system are summarized in Tables VI and VII. They require little comment, for the behavior was quite similar to that already

[11] The buffer solutions were similar to those described in Table III.

described. In the first two series of experiments of Table VI it was necessary to correct for incomplete interaction between the molybdicyanide and the reductant in the manner explained above. It is perhaps significant that the values for the constant, C, indicate that the slight association between oxidant and reductant noted in the neutral solutions vanishes in the more strongly acid region. No precipitate was formed as the result of the oxidations; the color produced varied from yellow at *P*H 1.10–3.56 to a purple-red at higher PH values.

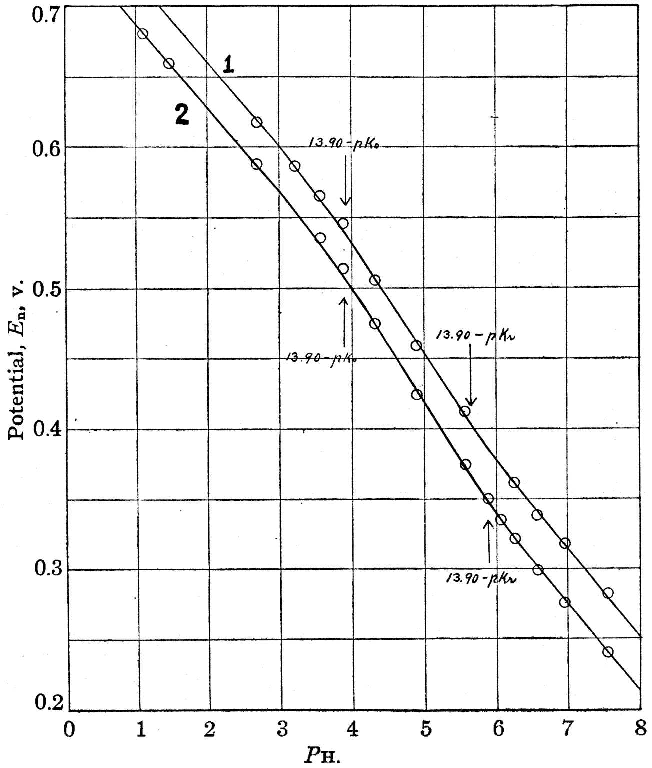

Fig. 4.—Relationship between PH and the potential of half-oxidation. 1, *p*-aminophenol; 2, methyl-*p*-aminophenol.

In spite of the low rate of decomposition of solutions containing N-methyl-quinone-imine, and the greater accuracy which this fact implies, the potentials found do not fit the "best curve" quite as well as in the above instance, as the calculations in the table and the graph of the theoretical equation given in Fig. 4 will show. In constructing this curve consideration was given to the fact that the two "0.06 slopes" are quite sharply defined, and the burden of the error was thus thrown onto the potentials in the intermediate regions.

p-Aminophenol–Quinone-imine.—A good grade of p-aminophenol was distilled at atmospheric pressure in an atmosphere of nitrogen and crystallized from alcohol. Tables VIII and IX summarize the results.

The exceedingly rapid decomposition of this system is evident from the velocity constants of Table VIII, which represent the drop in potential per minute. A preliminary study in a few buffers in the PH range 2–8 at first led us to believe that satisfactory results could only be obtained by the present method in neutral solution. At PH 7.57 the rate of change in the potential is no greater than for the system from p-benzylaminophenol, and the reaction follows the monomolecular course for about three minutes, thus permitting twelve readings for the extrapolation to each initial potential. At PH 6.96 the reaction velocity has more than doubled, but there is still a considerable straight portion of the time-potential curve, and there is little difficulty in obtaining reproducible results. In some of the more acid buffers, however, the situation becomes critical. With the potential changing more than one millivolt per second, one can still make fairly accurate settings of the potentiometer but one is seriously hampered by the fact that the time–potential curve drawn through the first few fifteen-second readings often contains no initial straight portion, the velocity decreasing progressively with time. Some of the curves resembled those calculated for a bimolecular reaction, but the reaction does not appear to be of the second order, for the velocity was not altered by a wide change in concentration.

$E_0 = 0.7280$ $K_0 = 1.05 \times 10^{-10}$ $K_r = 5.62 \times 10^{-9}$

We did note one encouraging feature of this system, namely, that there is very seldom any lag in the adjustment of the potential at the start of an experiment. This, together with the fact that the reaction appears by one rational criterion to be monomolecular, led us to a fresh attack of the problem. We suspected that the reason for the rapid decrease in the velocity so often noted is simply that a large proportion of the original quinone-imine has been destroyed by the time the first two or three readings can be made and, consequently, that more reliable results would be obtained with a high rather than a low value for the ratio [Oxid]/[Red]. One is usually faced with a greater lag in the potential under these conditions, but the present system is particularly favorable in this one respect. Our new experiments, in which particular weight was given to the experiments where the oxidant was in excess of the reductant, supported this view of the reaction. It was often observed that with a high value of R four or five of the first fifteen-second readings fell on a straight line and thus permitted an accurate extrapolation, while when R was given a low value the velocity was less at forty-five seconds than at thirty seconds. There is no way of telling whether the velocity also decreases during the first thirty seconds, but, as an experiment, we made extrapolations from the first two readings and found the results to be in agreement with the other, surer ones. The results of this type of extrapolation, however dubious in principle, usually have been included in the averages as furnishing some slight support for the none too certain characterization of the system.

Though when viewed individually some of the experiments appear questionable, it is not only true that fairly good agreement is found in the values for the potential at half-oxidation from a given series of experiments, but it will also be apparent that the complete set of results, viewed as a whole, forms a remarkably consistent picture. This can best be seen by examining Fig. 4, Curve I. There can be little question about the essential accuracy of the figure for E_n at P_H 7.57, and the value at P_H 6.96 is nearly as certain. In the next two buffers the potentials measured were shifting with extreme rapidity and the extrapolation curves were short, but the four E_n values found form a good, straight-line curve with the characteristic "0.06 slope." In fact the whole of the E_n-P_H curve conforms closely to the type which has been noted for related compounds. The occurrence of the two "0.06 slopes" connected by the "0.09 slope" could hardly be fortuitous, and we thus feel that there is justification for regarding the constants found for this highly unstable system as fairly close approximations (see Table VIII).[12] Entirely independent support of this conclusion is furnished by the comparison of Veley's value for the basic dissociation constant of *p*-aminophenol[13] with the value here deduced. By a colori-

---

[12] Equation 12 was used in making the calculations in the table. It should be noted that Conant and Pratt[4] made use of an equation for the system under discussion which can now be declared incorrect, for it takes no account of the basic dissociation of the oxidant. Our own equation is limited, for by definition it does not hold for solutions of such a P_H that acidic ionization of the reductant takes place.

[13] Veley, J. Chem. *Soc.*, 93, 2122 (1908).

metric method, Veley obtained 6.6 X 10^{-9} at 15°; the value here reported is 5.6 X 10^{-9} at 25°.

From Table **IX** it will be seen that the decomposition of quinone-imine in alcoholic solution is very much slower than in water, and that the rate of the reaction remains very nearly constant over a wide change of concentration. At the end of the experiments in the alcoholic buffer the solution was orange up to the end-point, then yellow. In aqueous solution the color varied from a very pale purple at PH 2.69 to red at PH 4.91, while from PH 5.56 to **7.57** a brown precipitate was formed until up to the point where the end of the titration had been reached.

_p_-Phenylenediamine–Quinonedi-imine.—In aqueous solution this system was less stable than that just described. We had no success with measurements attempted in solutions less acid than PH 5, and no PH region was discovered in which altogether reliable results could be obtained. There is thus little means of determining the accuracy of the few determinations which we were able to make. In view of the use of this system as an oxidation–reduction indicator, these results are reported in Table X; they probably give at least a rough idea of the true potential in the range indicated. There is a suggestion in the results that the E_n–PH curve has the "0.06 slope," for the sum ($E_n - E_h$) approximates a constant quantity;

TABLE X

VARIATION OF THE POTENTIAL OF THE SYSTEM *p*-PHENYLENEDIAMINE–QUINONEDI-IMINE WITH HYDROGEN-ION CONCENTRATION

PH	Hydrogen elect. potential, E_h, v	Potential when [Oxid] = [Red], En, v.	Constant C, of Eq. 5	$E_n - E_h$, v.	Velocity constant, *k* when [Oxid]/[Red] = 0.3	3.3

4 91	.2903	5147	2 08	8050	.074	.090

but we do not feel justified in undertaking a theoretical analysis on the basis of such scanty information.

The behavior of the system in alcoholic solution was entirely different, and we are treading on much safer ground in considering the results listed in Table XI. The decomposition was not over-rapid and the time–potential curve was accurately linear up to from one and one-quarter to one and one-half minutes. The normal potential obtained is thus regarded as wholly reliable. The most interesting feature of the results is that the velocity of the destruction of the quinonedi-imine increases steadily as the concentration of the reactant decreases. The drop in potential varies from *25.5* mv. to *6.5* mv. per minute (next to last column) and the direction of the change is particularly striking. It must mean that the reductant enters into the reaction whose rate is measured and that it is the concentration of this component of the system which causes the observed effect. But experimentation showed that the concentration of the reductant is not altered as a result of the decomposition reaction. This was ascertained by performing what amounts to a titration of the reductant remaining after the decomposition reaction had run its course.

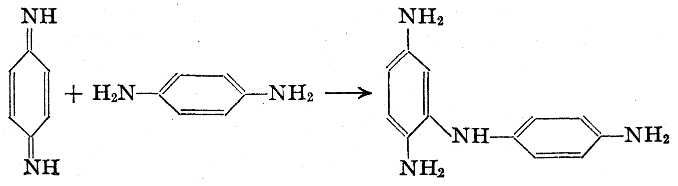
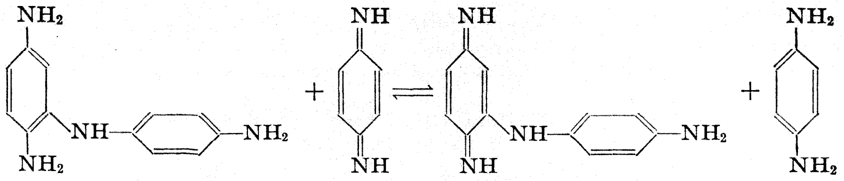
		Av. 1.20	Av. 0.7828		Av. 2.1

Among the various types of reactions by which quinonedi-imine conceivably might be destroyed, there is one which perfectly answers the requirements which the experiments seem to imply, namely, an interaction between the oxidant and the reductant without causing a change in the concentration of the latter. That reaction is the 1,4-addition of the reductant to the oxidant, as follows





From the general knowledge of substituted and unsubstituted quinones, one can say that the equilibrium point of the second reaction would be such as to favor the products almost exclusively, so that the net result of the initial addition reaction, which would be the slower of the two, would be the destruction of two molecules of quinonedi-imine and the maintenance of the reductant at its original concentration. The reaction may, and probably does, go farther, with the ultimate conversion of three molecules of quinonedi-imine into one molecule of a dianilino-quinonedi-imine, but this would not alter the nature of the reaction.

If this mechanism is correct the reaction is of the second order and the reductant functions as a catalyst. The velocity constant may be represented thus

$$k' = \frac{2.3026}{t\,[\text{Red}]_c} \log \frac{[\text{Oxid}]_i}{[\text{Oxid}]_i - x} \tag{16}$$

where $[\text{Oxid}]_i$ is the initial concentration of the quinonedi-imine and where the subscript c indicates a concentration which may be varied from one experiment to another, but which remains unaltered as a result of the reaction. The potential at any time, E_t, may be expressed as follows

$$E_t = E_i - 0.02957 \log \frac{[\text{Oxid}]_i}{[\text{Oxid}]_i - x} \tag{17}$$

Combining Equations 16 and 17 it is seen that

$$k' = 77.87\,(E_i - E_t)/t[\text{Red}]_c \tag{18}$$

This equation calls for a linear time–potential curve for each ratio of oxidant to reductant, but a decreasing velocity with an increase in that ratio. From this equation (and the value 0.0013 M for the total concentration of the organic system in all of the experiments) values for the bimolecular reaction constant have been calculated and they are included in Table XI (last column). The concordance in the values is sufficient to show that the reaction is of the type defined.

Methyl p-Phenylenediamine–N-Methyl-quinonedi-im.—The substitution of a methyl group for one of the amino hydrogen atoms of *p*-phenylenediamine produces little change in the character of the oxidation–reduction system. Measurements in aqueous solution were not very satisfactory and will not be reported. In the alcoholic buffer the decomposition reaction again appeared to be bimolecular, with the reductant functioning as a catalyst, and Equation 18 was thus used in calculating the velocity constants given in Table XII.

TABLE XII

***p,p*′-Dihydroxystilbene–Stilbenequinone.**—Owing to the lack of sufficient solubility, this system could not be studied in aqueous solution, but good results were obtained in the alcoholic buffer. The time–potential curve was linear up to about three minutes, but there usually was a lag of from one-half to one minute. The velocity of decomposition again increases with increasing concentrations of the reductant (Table XIII) and the constancy of the velocity constant calculated for the catalytic second order reaction is as good as could be expected.

TABLE XIII

THE SYSTEM *p,p*′-DIHYDROXYSTILBENE–STILBENEQUINONE IN NEUTRAL ALCOHOLIC SOLUTION

According to the interpretation given above of the nature of this type of reaction, this indicates that stilbenequinone forms an addition product with its reduction product, a behavior which appears to be common enough with the quinonedi-imines, but which is unique in the quinone series. It was noted that a bright yellow substance precipitated from the partially oxidized solutions, but failed to form when the reductant was no longer present. It seems probable that this is the quinone formed on oxidation of the primary addition product. The marked additive power of stilbenequinone has been noted by Zincke and Münch,[14] but little is known about the products formed.

p,p'-**Dihydroxydiphenyl–Diphenoquinone.**—The potentials observed for this system exhibited the linear relationship up to about three minutes, and there was usually a delay of one-half minute before the regular descent started. The rate of the reaction showed no variation with a change in the concentrations of oxidant and reductant. A brown substance precipitated from the partially oxidized solutions but not when oxidation was complete. This suggests that the reductant is in some way involved in the decomposition reaction, but the exact nature of the reaction is not clear.

Other Systems.—Oxidation experiments in the neutral alcoholic buffer solution with the following compounds were unsuccessful; the solutions were so unstable that the potentials could not be determined accurately by the present method: o-aminophenol, o-phenylenediamine, catechol, nitrohydroquinone, 2,6-dihydroxynaphthalene.

One of the purposes of this investigation was to acquire information and experience of various unstable systems which might be useful in a study of the oxidation–reduction systems which are formed when monatomic phenols and amines are oxidized. One or two such systems appear to possess a stability well above the average, and it was hoped that some such system might be discovered which would prove accessible to direct potential measurement. We have made a preliminary study by the method here described of 9-chloro-10-phenanthrol and the radical produced when it is oxidized,[15] and we have found that the system is electromotively active and that it behaves in much the same way as those which have been described above. The potentials, however, appear to be subject to a peculiar fluctuation from one experiment to another, and only a thorough investigation can determine if it is possible to characterize such systems by direct methods.

Comparison of Results

Table XV lists the rounded average values found for the normal potentials of the systems studied. This term is defined as the potential difference between a dilute solution of equimolecular quantities of the oxidant and the reductant when neither is ionized, and a hydrogen electrode in the same solvent.

TABLE XV

ROUNDED AVERAGE VALUES

System named as reductant	Normal potential, E_0 Alcohol, v.	Normal potential, E_0 Water, v.	Half-life (neutral solution) Alcohol, min.	Half-life (neutral solution) Water, min.
p-Methylaminophenol	0.693	0.688	35.6	7.4
p-Benzylaminophenol	.703	.698	3.9	1.4
p-Aminophenol	.733	.728	3.9	1.1
p,p'-Dihydroxydiphenyl	.954	..	1.6	...
p,p'-Dihydroxystilbene	.854	..	1.1	...
p-Phenylenediamine	.783	(.801)	0.5	0.1
N-Methyl-p-phenylenediamine	.751	..	.5	...

The potential of diphenoquinone (I) and its reduction product is the highest yet recorded for an organic system. Stilbenequinone (II), though it has a more extended conjugated system of linkages, falls well below this compound in potential, though it is about equal to the polyhalogenated o-benzoquinones and **0.15** v. above *p*-benzoquinone on the potential scale.

I

II

Comparison of the various quinone-imines and di-imines (in alcoholic solution) with quinone shows that the substitution of the imino group for the ketonic oxygen atom progressively increases the affinity of the quinonoid substance for hydrogen

$E_0 = 0.715$ v.

$E_0 = 0.733$ v.

$E_0 = 0.783$ v.

The N-methyl derivatives of quinone-imine and quinonedi-imine are lower in potential than the parent substances by about the same amount

$E_0 = 0.693$ v.

$E_0 = 0.751$ v.

A benzyl group has much the same effect as methyl.

A further interesting comparison is of the basic dissociation constants determined for three of the systems, and these are listed in Table XVI, along with the *pK*-values ($pK = -\log K$). We have also included in the table the data of Clark, Cohen and Gibbs for the first dissociation constants at 30° which they report for systems studied by them.

TABLE XVI

FIRST BASIC DISSOCIATION CONSTANTS

System, named as reductant	Reductant K_r	pK_r	Oxidant K_o	pK_o
p-Aminophenol	5.6×10^{-9}	8.2	1.0×10^{-10}	10.0
p-Methylaminophenol	1.0×10^{-8}	8.0	1.0×10^{-10}	10.0
p-Benzylaminophenol	1.5×10^{-9}	8.8	9.0×10^{-12}	11.1
p-Aminodimethylaniline[2]	3.9×10^{-8}	7.4	5.0×10^{-7}	6.3
o-Tolidine[2]	6.2×10^{-10}	9.2	2.7×10^{-8}	7.6

According to the present results the ionization constants for *p*-aminophenol and quinone-imine are not appreciably affected by the substitution of methyl for hydrogen, but they are both decreased by the substitution of a benzyl group. The difference between pK_0 and pK_r is fairly constant, from 1.3 to 2.2 units, and it is always in the same direction. The quinone-imine in each case has a smaller dissociation constant than its reduction product. It appears odd that in the case of the di-imines it is the oxidant which is the more highly ionized. This causes an interesting difference in the form of the E_n–P_H curves, a difference at once apparent on comparing Clark's curves with those given here.

In Table XV the systems have been listed in the order of decreasing stability. As an arbitrary basis of comparison in aqueous solution, we have taken the rates of decomposition at P_H 7.57. The half-life periods given are fairly accurate for the alcoholic solutions; for water they represent approximations. The most striking feature about these results is that the systems are all far more stable in a neutral phosphate solution when this contains 37% of alcohol than when it contains no other solvent but water. We see no way of accounting for this, but the practical implications are obvious. If a given system proves too unstable for potentiometric study in aqueous solution it is likely that the conditions will be improved on operating in a partially non-aqueous solvent. Not only is the stability greater, but it has been observed throughout this work that the velocity constants found in the various experiments of a series show much the better agreement in the case of the alcoholic solutions.

There appears to be little correlation between the velocity of decomposition and the acidity of the solution; the only marked effect noted is that quinone-imine is decidedly more stable at P_H 7–8 than in more acidic solutions. It is evident that the rate of the reaction often varies considerably according to the nature of the solution and the relative concentrations of oxidant and reductant, and that there is often a great difference in the behavior of closely related compounds.

We can say little regarding the nature of the reactions by which the oxidants suffer decomposition other than that with two quinonedi-imines and one quinone of unusual structure the reaction very probably is one of addition of the reductant to the oxidant. In the other cases there are so many possibilities that velocity measurements alone are of little assistance in establishing the complete mechanisms. It is not improbable that each of the following reactions contributes in some instances to the instability of the systems: self-condensation and self-oxidation of the oxidant, the addition of the elements of water, reaction with the reductant.

Summary

By means of a "discontinuous titration" method it has been possible to determine the oxidation–reduction potentials of systems which are so unstable that the half-life period for the decomposition of the oxidant is of the order of one-tenth to one-half minute. With the systems formed by *p*-aminophenol and two of its N-alkyl derivatives the variation of the potential with the hydrogen-ion concentration has been studied in the PH range 1–8, and the basic dissociation constants have been determined from the results. Seven systems have been studied and the more important constants found are summarized in Tables XV and XVI.

PRELIMINARY STUDY ON THE ANTIRACHITIC PROPERTIES OF SHRIMP OIL

BY F. P. BROOKS,[1] ROY F. ABERNETHY AND F. C. VILBRANDT[2]

RECEIVED AUGUST 4, 1930 PUBLISHED DECEMBER 18, 1930

Shrimp oil is the ether-soluble oil obtained when the waste of the shrimp industry is extracted. It has been obtained by the authors[3] in their study on the utilization of shrimp waste. A later chemical study of this oil showed the presence of 19% of cholesterol, the presence of which led to the study of the oil for its antirachitic properties.

This investigation consisted in the feeding study of the oil on white rats, which had become rachitic by special feeding. Standard cod liver oil and shrimp oil were fed at the same time to get a relation of the antirachitic properties of the oil. After three generations of breeding, the selected young rats were fed on Sherman's growth diet B consisting of 66.7 g. of whole wheat, 33.3 g. of whole milk and 1.3 g. of sodium chloride, until they were twenty-eight days old. Part of the series was continued on this diet to serve as normal controls, another part was fed Steenbock's diet 2965[4] for the production of rickets. When they had developed the rickets,

which condition was shown by x-ray pictures and outward appearances, the rachitic rats were divided into three divisions. The first division was fed cod liver oil, the second division was fed shrimp oil and the third division was continued on the rachitic diet. The oils were added to the rachitic diet and the feeding test was continued for a period of five days. There were four groups of rats, (1) the rachitic and (2) the normal rats to serve as extreme controls and the two classes of rats one of which was fed cod liver oil and the other shrimp oil.

In this investigation three methods of measuring the amount of cure in the rats were used: (a) McCollum's[5] line test; (b) percentage of ash in the bone[6] and (c) the amount of calcium and phosphorus in the blood. The line test and the determination of the calcium and phosphorus in the blood were made by Dr. F. P. Brooks. (These data are not available and are material for a separate and more extensive paper by Dr. Brooks.) The ash determinations on the bone and the calcium and phosphorus determinations on the ash were made according to the Standard Methods.[7] The data in Table I and II will show there was some cure by the shrimp oil, but also that there was less cure in the second series than there was in the first.

In the first series of determinations 16 rats were used. At the age of twenty-eight days twelve rats were fed the Steenbock diet 2965 for four weeks. At the end of this time x-ray pictures and the outward appearance showed the animals to be rachitic. After the animals were found to be sufficiently rachitic, four of the twelve were fed shrimp oil with the rachitic diet, four were fed the rachitic diet with cod liver oil added and the other four were fed the rachitic diet. They were fed this oil diet for five days and then the sixteen rats were killed, the blood was taken for analysis and the bones from the rear legs were removed for the line test and the ash determination. The blood from the four rats of one group was combined to get a sufficient quantity for analysis. The bones were preserved in acetone until analyzed.

The Effect of Treated Feeds on **Ash** in Bones.—The results for the rat noted K are abnormal; the amount of food consumed by this rat was small, hence the results on this rat are not taken into consideration in determining the average. Examination of the data will disclose that the rachitic rat had the smallest percentage of ash and the control the highest. The rachitic rats that were fed the oils show some cure by being between the two extremes.

Summary

In the investigation of the antirachitic properties of shrimp oil it was found from the analysis of the blood and the bones that the oil had proper-

ties akin to cod liver oil that tended to cure the rachitic rats. From an examination of the data it is found in the first series that the shrimp oil was as potent as the cod liver oil. The second series showed some cure but less than the cod liver oil, probably due to the increasing rancidity of the shrimp oil.

AMES, IOWA

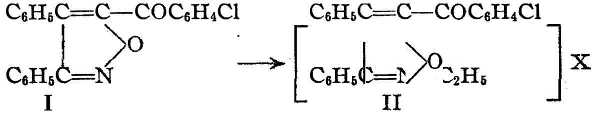
[CONTRIBUTION FROM THE CHEMICAL LABORATORY OF HARVARD UNIVERSITY]

PSEUDO BASES IN THE ISOXAZOLE SERIES. THIRD PAPER

BY E. P. KOHLER AND C. L. BICKEL

RECEIVED AUGUST 12, 1930 PUBLISHED DECEMBER 18, 1930

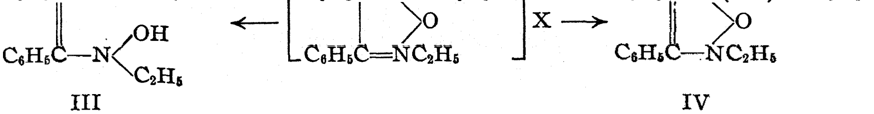
The pseudo bases that have been described in earlier papers of this series are derived from isoxazoles in which all available positions are filled with hydrocarbon residues. In all these cases the rearrangement of the true base results in a pseudo base in which the hydroxyl group occupies the 5-position. In order to determine whether this mode of rearrangement is altered by an acidic group in this position, we have alkylated a ketonic isoxazole and studied the behavior of the resulting salts toward bases



I II

The ethylation presented no difficulties and the salts could be manipulated in the same manner as those described heretofore. When they were shaken at a low temperature with aqueous sodium bicarbonate or sodium hydroxide and ether, the organic material immediately passed from the aqueous to the ethereal layer and when the ethereal solution was acidified the salts were regenerated. The alkylated ketonic isoxazole, therefore, forms a pseudo base in the usual manner.

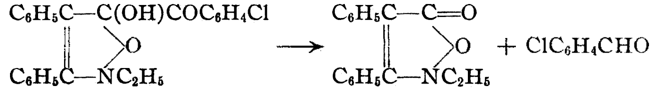
By cautious manipulation of its ethereal solution it was possible to isolate the pseudo base as a colorless crystalline compound. Ozonization of this compound yielded equivalent quantities of benzoic and *p*-chlorobenzoic acids, and a halogen-free substance which has not been identified. This result shows that the rearrangement, as usual in this series, leads to a 5-hydroxy compound, and it leaves but two possible formulas for the pseudo base



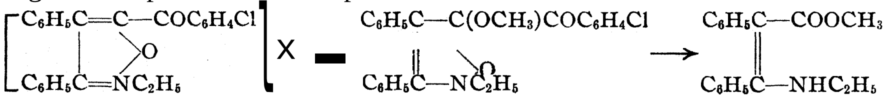
III IV

The lack of color in our pseudo base definitely excludes formula III which represents an α-diketone that would be intensely yellow. The pseudo base, therefore, is constituted precisely like all the others that we have described. It presents, however, certain peculiarities which are due to the substitution of the ketonic group for a hydrocarbon residue. It is not possible, for example, to transform the base into its ether by treatment with alcoholic potassium hydroxide. It is also impossible to secure such an ether directly from the salts. That this difference between the new pseudo base and nearly all others that are known is due to the ketonic group, is shown by the fact that it is equally impossible to methylate the ketonic hydroxy isoxazolines in which the relation between the hydroxyl and ketonic groups is the same.

Another peculiarity of the new pseudo base shows itself in the ease and in the manner in which it alters with time. Other pseudo bases of this series, in solution, and especially in the presence of alkalies, lose water more or less rapidly and pass into open-chained anhydro compounds. The ketonic compound changes spontaneously even in the solid condition and the principal product is ethyl diphenyl isoxazolone

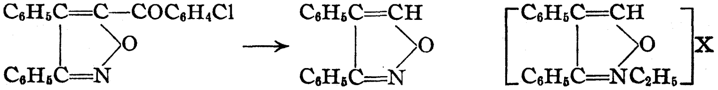


A similar cleavage accounts for some of the difficulties encountered in attempts to prepare the methyl ether directly from the salts. The ether may be formed in the operation but, if so, then it is immediately cleaved and the process goes further than in the spontaneous decomposition, ending in the open-chained compound VI



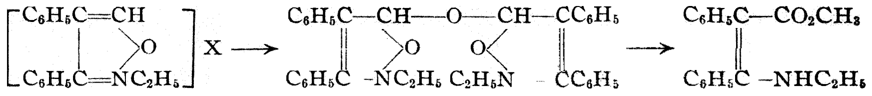
V VI

The open-chained cleavage product may, as has been stated, originate in the methyl ether V, but it is possible also that cleavage precedes methylation. In order to explore this possibility we have also examined the behavior of the salts that are obtained by ethylating 3,4-diphenyl isoxazole. These can be obtained without difficulty by means of a series of reactions which may be represented as follows



VII VIII

In this case neither the pseudo base nor its methyl ether could be isolated. When the salts VIII were treated with aqueous alkalies they immediately yielded a dimolecular anhydride, and when either this anhydride or the salts were acted on by methyl alcoholic sodium hydroxide, the product was the open-chained ester VI



VIII IX VI

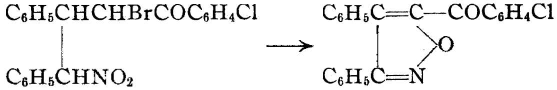
It is evident that the open-chained ester may originate either from the methyl ether V or from an antecedent cleavage product akin to VIII. Its structure is certain because it gives benzoic acid and ethyl benzamide when ozonized, therefore, has a double linkage in the α,β-position, and hydrochloric acid converts it into benzoyl phenyl acetic ester—a characteristic transformation of β-amino unsaturated esters

$$\underset{\text{VI}}{C_6H_5C(NHC_2H_5){=}C(C_6H_5)COOCH_3} \longrightarrow \underset{\text{X}}{C_6H_5COCH(C_6H_5)COOCH_3}$$

The formation of the open-chained ester represents a novel transformation of pseudo bases in the isoxazole series, a transformation which can occur only when the 5-position is unoccupied or is occupied by a group that is easily removed by bases. Since the pseudo bases derived from isoxazoles, in which both the 3- and 5-positions are unoccupied, undergo an entirely different type of rearrangement, this transformation into an open-chained ester may be regarded as a characteristic reaction of pseudo bases derived from 3,4-disubstituted isoxazoles.

Experimental Part

The isozazole that served as a starting point has been described heretofore because it turns up in small quantities whenever the corresponding bromo compound reacts with bases[1]



For preparing it in quantity we devised a method which gives a yield that is almost quantitative. The procedure was as follows.

A suspension of 100 g. of the bromo compound and an equal weight of potassium acetate in 500 cc. of methyl alcohol was boiled until bumping became serious. The mixture was then cooled and filtered. After washing the solid isoxazole with methyl alcohol until it was colorless, the filtrate and washings were boiled again and this operation of boiling and filtering was repeated as often as was necessary until no more solid separated. The filtrate was then concentrated in steps, finally evaporated almost to dryness, and set aside. It deposited a solid cake of isoxazole, bromide and acetate. The salts were removed with water, and the isoxazole washed with ether, which dissolved a green impurity along with a small quantity of the isoxazole. All fractions of the isoxazole were combined and recrystallized from glacial acetic acid. The yield was 77.5 g. or 98%; m. p. 165–166°.

Ethylation.—A suspension of 15 g. of the isoxazole in 50 g. of diethyl sulfate was heated in an oil-bath for two and one half hours at 125–130°. The isoxazole gradually

---

[1] Kohler and Addinall, THIS JOURNAL, 52, 1597 (1930).

dissolved during the heating, and the solution became quite brown. This solution was used for preparing the salts represented by II.

The Acid Sulfate.—The ethylation mixture was heated on a steam-bath with 25 cc. of concentrated hydrochloric acid and an equal volume of water until the two layers disappeared. The solution was then extracted with ether, which removed unchanged isoxazole and other impurities and evaporated. It finally deposited colorless plates. which were washed with ether, and with a little water, then recrystallized from methyl alcohol. The salt separated in colorless plates melting at 192–193°.

Anal. Calcd. for $C_{24}H_{20}O_6NClS$: C, 59.3; H, 4.2. Found: C, 59.3; H, 4.6.

The Ferric Chloride Double Salts.—The ethylation mixture was hydrolyzed as before, diluted with 20 cc. of water and thoroughly extracted with ether. The aqueous solution was then heated to expel dissolved ether, cooled and treated with a saturated solution of ferric chloride which was added drop by drop as long as a precipitate formed. The precipitate was washed with ether and a little water, dried and recrystallized from glacial acetic acid, from which it separated in yellow plates. The yield was 18.2 g.

The earlier preparations yielded a salt that melted at 130.5'. Later a new salt melting at 139.5° made its appearance, and after that only the higher-melting salt could be obtained. The composition of the two salts was the same.

Anal. Calcd. for $C_{24}H_{19}O_2NCl_6Fe$: Cl, 24.1. Found: (130") Cl, 23.1; (139°) 23.4.

The Pseudo Base IV.—Inasmuch as the pseudo base decomposes spontaneously it was made only in small quantities as needed. For this purpose 2.25 g. of either of the ferric chloride double salts was suspended in alcohol-free ether and treated with a water solution of 5 g. of sodium bicarbonate. A vigorous reaction occurred and the ether layer immediately became yellow. After removing the ferric hydroxide by filtration the ethereal layer was separated and the aqueous solution extracted with fresh ether. The ethereal solution was dried with sodium sulfate and allowed to evaporate. It deposited a slightly yellow product which became colorless when recrystallized from ether–petroleum ether; yield, 1.3 g., equal to 85%.

Anal. Calcd. for $C_{24}H_{20}O_3NCl$: C, 70.9; H, 5.0. Found: C, 70.5; H, 5.1.

The pseudo base is insoluble in water, soluble in all organic solvents except petroleum ether. It crystallizes in colorless prisms and melts with decomposition at about 128". When its solution in alcohol-free ether is shaken with 1:1 hydrochloric acid and a saturated solution of ferric chloride, it deposits in nearly the calculated quantity the ferric chloride double salt which melts at 139°.

Spontaneous Decomposition.—A 0.5-g. sample of the pseudo base which had been kept in a glass-stoppered bottle for several months and had become dark in color, was dissolved in ether. From the resulting ethereal solution sodium bicarbonate extracted an acid which was identified as 4-chlorobenzoic acid by its melting point and by comparison with a sample on hand. After removing the chloro acid, the ethereal solution was dried, concentrated and diluted with petroleum ether. It thereupon deposited a solid which crystallized in diamond-shaped prisms and melted at 145–146°.

Anal. Calcd. for $C_{17}H_{15}O_2N$: C, 77.0; H, 5.7. Found: C, 77.0; H, 5.7.

The composition, solubility, crystalline form and melting point agree with those of ethyl diphenyl isoxazolone. This substance was, therefore, synthesized by the method of Kohler and Blatt.[2] A comparison of the two products proved their identity.

Ozonization of the Pseudo Base.—A current of ozonized oxygen containing about 6% ozone was passed through a suspension of the pseudo base for one and one-half hours. At the outset the ozone was absorbed freely and the base dissolved. The ethyl bromide

was evaporated in a current of dry air, the residual oil shaken with water and the resulting emulsion extracted with ether. From the ethereal solution sodium bicarbonate extracted both benzoic and p-chlorobenzoic acids. The ethereal solution from which these acids had been removed was dried, concentrated and diluted with petroleum ether. It deposited a pale yellow solid melting at 120–130°. As no method was found for purifying the substance it could not be identified.

Attempts to Make a Methyl Ether.—Methyl alcohol containing a trace of potassium hydroxide had no action on the pseudo base and sodium methylate was found to be too destructive. The ferric chloride double salt was, therefore, treated with sodium bicarbonate in the following manner. One gram of the finely powdered double salt was suspended in 25 cc. of methyl alcohol. To this suspension were added 25 g. of ice. 40 cc. of alcohol-free ether and 0.6 g. of sodium bicarbonate dissolved in water. The mixture was shaken until the yellow salt had disappeared. The ethereal layer was then decanted and filtered, and the aqueous layer thrice extracted with ether. The ethereal solutions were dried, concentrated to small volume and diluted with petroleum ether. On cooling and rubbing they deposited 0.4 g. of a colorless solid which melted when crude at 102°. Addition of acid to the aqueous solution precipitated *p*-chlorobenzoic acid.

These same products—p-chlorobenzoic acid and a substance melting at 101–102°—were obtained when 2 g. of the ferric chloride double salt was shaken with 50 cc. of methyl alcohol, 50 g. of ice, 75 cc. of alcohol-free ether, and 2 g. of sodium hydroxide dissolved in water. The yield of the product melting at 101–102° was 0.9 g. or 90%. The product was recrystallized both from ether–petroleum ether and from acetone–methyl alcohol, but the melting point remained the same.

Anal. Calcd. for $C_{18}H_{19}O_2N$: C, 76.9; H, 6.8; OCH_3, 11.05. Found: C, 76.8; H, 6.8; OCH_3, 10.6.

The ester is readily soluble in acetone, moderately soluble in ether and methyl alcohol. It crystallizes in plates.

Methyl α,β-Diphenyl-β-ethylaminocinnamate

Ozonization of the Ester.—Through a solution of 4 g. of the ester in 35 cc. of carbon tetrachloride a rapid current of ozonized oxygen was passed for one and one-half hours—half an hour after ozone appeared in the effluent gas. The solvent was pumped off and the residual oil shaken with ice water. The resulting emulsion was heated gently, the temperature being kept below 50°, then cooled and extracted with ether. The ethereal solution contained benzoic acid, which was removed with bicarbonate and identified.

After removal of the benzoic acid, the ethereal solution was dried with sodium sulfate and evaporated. It left an oil which solidified after vigorous rubbing. By recrystalliiation from ether–petroleum ether the solid was obtained in diamond-shaped plates which melted at 68–69°.

Anal. Calcd. for $C_9H_{11}ON$: C, 72.4; H, 7.5. Found: C, 72.5; H, 7.6.

The composition of the substance corresponds to that of ethyl benzamide, and it gave benzoic acid when it was boiled with concentrated hydrochloric acid, but owing to the small quantity available ethylamine could not be identified with certainty. Ethyl benzamide was therefore prepared from benzoyl chloride and ethylamine. It melted at 68–69° and a mixture of the preparation and the ozonization product melted at the same temperature.

Hydrolysis of the Ester.—A solution of 0.55 g. of the ester in concentrated hydrochloric acid was set aside for a day. On dilution with an equal volume of water it deposited a solid which was identified as desoxybenzoin. The diluted solution on standing deposited more solid, which proved to be a mixture. It was separated by fractional crystallization from ether–petroleum ether into desoxybenzoin and a substance which melted at 72–73°.

This substance was identified as the methyl ester of benzoyl phenyl acetic acid by comparison with a sample on hand.[3] Concentrated hydrochloric acid gradually transformed it into desoxybenzoin.

Preparation of 3,4-Diphenyl Isoxazole (VII).—The preparation of this isoxazole from anisoyl diphenyl isoxazole was described in an earlier paper.[4] We obtained it in a much better yield from *p*-chloro-benzoyl diphenyl isoxazole. Since it is readily cleaved, it is necessary to operate as rapidly as possible and it is advantageous to operate with small quantities. Our procedure was as follows. A suspension of 2 g. of 3,4-diphenyl-5-(p-chloro-benzoyl)-isoxazole in 20 cc. of ethyl alcohol, and a solution of 0.5 g. of sodium hydroxide in 10 cc. of ethyl alcohol, were mixed at the boiling point. The mixture was boiled for one and one-half minutes, during which the isoxazole dissolved, then immediately cooled under the tap and filtered, to remove a small quantity of unchanged material. The filtrate was diluted with 150 cc. of water and set aside for thirty minutes, during which it deposited the diphenyl isoxazole. The yield of product was 1.15 g. or 98%, and approximately 0.1 g. of starting material was recovered.

Ethylation.—A suspension of 3.45 g. of diphenyl isoxazole in 5.0 g. of ethyl sulfate was heated in an oil-bath to 110° for four hours. The resulting light brown solution was heated on a steam-bath with 3 cc. of concentrated hydrochloric acid and 3 cc. of water until the mixture became homogeneous. The solution was then diluted with 3 cc of water, cooled and extracted with ether. The aqueous layer was heated to expel all of the ether, cooled and treated very gradually with excess of saturated ferric chloride solution.

The ferric chloride double salt is uncommonly low-melting, and when it is precipitated rapidly or in the presence of ether it tends to separate as an oil exceedingly difficult to solidify. When no crystals are available for inoculation the ferric chloride should be added a few drops at a time until vigorous scratching of the walls of the vessel starts crystallization. The salt was recrystallized from glacial acetic acid and petroleum ether. It is readily soluble in glacial acetic acid and in methyl alcohol, sparingly soluble in water, almost insoluble in ether and petroleum ether. It crystallizes in pale yellow plates and melts at 75–76°. The yield was 97%.
