o-Nitrophenylboric acid crystallizes from water in yellow needles. It is moderately soluble in water; soluble in alcohol and ether. o-Nitrophenylboric acid dissolves in aqueous solutions of sodium hydroxide, sodium carbonate and ammonia; it gives the usual qualitative tests for boron. The air-dried substance melted at 139.2–140.8° (corr.), with darkening, in a bath heated from 20°; m. p. 138.7–139.2' (corr.), in a bath preheated to 120°; m. p. 147.5' on the Maquenne block. After drying to constant weight in a vacuum desiccator, over sulfuric acid, the substance melted at 143.5–147.7' (corr.), in a preheated bath. The vacuum dried substance, evidently the anhydride $NO_2C_6H_4B{=}O$, was analyzed.

Anal. Calcd. for $NO_2C_6H_4BO$: C, 48.37; N, 9.41. Calcd. for $NO_2C_6H_4B(OH)_2$: *C*, 43.14; N, 8.39. Found: C (Parr bomb),[21] 46.14, 45.97; N (Dumas), 9.26, 9.62.

Determination of the Position of the Nitro Group.—A hot aqueous solution of 0.38 g. of the above acid was treated with a concd. solution of 0.62 g. of mercuric chloride and heated for five minutes. The resulting nitrophenylmercuric chloride was removed by filtration and crystallized three times from alcohol; m. p. 183.4–184.5" (corr.). An

---

[20] During this process a small quantity of a green oil, possibly a nitroso compound, distilled over. The quantity of the material was too small for identification.

[21] The results for carbon are undoubtedly low, since it seemed impossible to achieve a complete combustion in the Parr peroxide bomb. There were always a few specks of unoxidized carbonaceous matter in the fused mass.

authentic specimen of o-nitrophenylmercuric chloride, prepared according to the method of Dimroth,[22] melted at 181.3–183.4° (corr.); a mixture of the two substances melted at 183.4–184.5° (corr.).

***p*-Nitrophenylboric Acid.**— The less soluble fractions (III) of the acid obtained from the nitrations in acetic anhydride were combined and recrystallized from water, with the addition of decolorizing carbon. As a very small amount of this compound was obtained, no analyses were made as it seemed more essential to establish the structure of the compound by conversion to a known compound, and to reserve the remainder for a bacteriological test. The substance gives the usual qualitative tests for boron and for nitrogen.

p-Nitrophenylboric acid crystallizes from water in long, slender, yellow needles. It is slightly soluble in cold water, and is the least soluble of the three isomers; it is soluble in hot water, alcohol and ether. Like the other acids, it dissolves in aqueous solutions of sodium hydroxide, sodium carbonate and ammonia. *p*-Nitrophenylboric acid melts, with decomposition and charring, at 305° (corr.) in a capillary tube in a bath heated from 20°; on the Maquenne block the substance did not melt up to 360°.

Determination of the Position of the Nitro Group.—By the method given for *m*-nitrophenylboric acid, 0.2 g. of the nitrophenylboric acid described above was converted to a bromonitrobenzene. The latter, after crystallization from 50% alcohol melted at 122.8–124.4° (corr.). An authentic specimen of p-bromonitrobenzene (Kahlbaum) melted at 126.4–127.4° (corr.); a mixture of the two substances melted at 125.9–126.9° (corr.).

m-Aminophenylboric Acid.—Reduction of the nitro acids was effected by the use of freshly precipitated ferrous hydroxide, according to a modification of the procedure of Claisen and Thompson, and Jacobs, Heidelberger and Rolf.[23]

In a 1-liter flask (or bottle), 71 g. of ferrous sulfate crystals (95% $FeSO_4 \cdot 7H_2O$ as determined by titration) was dissolved in 250 cc. of air-free water; a suspension of 81 g. of hydrated barium hydroxide ($Ba(OH)_2 \cdot 8H_2O$) in 150 cc. of water was added in several portions, the mixture was shaken thoroughly until it reacted alkaline to litmus, and a uniform suspension of ferrous hydroxide was obtained. A uniform suspension of 12 g. of hydrated barium hydroxide and 6 g. of m-nitrophenylboric acid in 125 cc. of air-free water was added in one portion to the ferrous hydroxide, and the mixture was shaken vigorously for ten minutes, during which the green color of the ferrous hydroxide changed to the brown of ferric hydroxide. The insoluble material was filtered off with suction, suspended in water and washed thoroughly. The filtrate and washings were united and the barium ions were removed by exact precipitation with sulfuric acid, so that a test portion of the filtered solution gave no turbidity with either sulfuric acid or barium hydroxide solution. The filtered solution was concentrated at 50°, under reduced pressure, in an atmosphere of nitrogen. The resulting yellow crystals of the crude m-aminophenylboric acid were manipulated, as far as practicable, in an inert atmosphere. The filtrate from the main crop of crystals could be concentrated further to obtain a small additional quantity of the amino acid; it proved more satisfactory, however, to make use of this solution for the preparation of the benzoyl derivative. The yield of crude m-aminophenylboric acid was 2.2–2.4 g. (44–48%), and 0.3–0.5 g. of the benzoyl derivative was obtained from the mother liquors. The crude amino acid was recrystallized from a very small volume of water (in an atmosphere of nitrogen), with the addition of decolorizing carbon. The purified product formed pale yellow hexagonal plates; the slight tinge of color could not be removed by several recrystallizations.

[22] Dimroth, *Ber.*, 35, 2036 (1902).

[23] (a) Claisen and Thompson, *ibid.*, 12, 1946 (1879); (b) Jacobs, Heidelberger and Rolf, THIS JOURNAL, 40, 1580 (1918).

Undoubtedly the pure compound is colorless; the color of our product was probably due to the merest traces of impurity, since the substance had a fairly sharp melting point. In a capillary tube, either from a bath at 20° or a preheated bath, the substance melted at 92.8–93.8° (corr.), and resolidified if kept just above this temperature; upon further heating, the compound melted indefinitely, with darkening, near 200°. On the Maquenne block the material melted sharply at 176° (corr.). *m*-Aminophenylboric acid is soluble in water and alcohol, sparingly soluble in ether.

For analysis the substance was dried to constant weight in a vacuum desiccator (ten days) over sulfuric acid. After drying the melting point was 193" (corr.) on the Maquenne block; the dried substance melted indefinitely at about 168° (with darkening), in a capillary tube in a bath heated from 20°.

Anal. Calcd. for $NH_2C_6H_4B(OH)_2$: N, 10.23. Calcd. for $NH_2C_6H_4BO$: N, 11.78. Calcd. for $(NH_2C_6H_4BOH)_2O$: N, 10.95. Found: (Kjeldahl) N, 11.11, 11.12.

The nitrogen determinations indicated that the completely dried sample was an anhydride formed by the elimination of one molecule of water from two molecules of the acid.[24] The air-dried substance was undoubtedly the acid and not an anhydride, since it dissolved immediately in water and gave the typical tests for aromatic boric acids. Experience with the anhydrides of various boric acids indicates that the anhydrides do not react at once with cold water to regenerate the acids.

Since the position of the amino group was established by the relationship to *m*-nitrophenylboric acid, m-aminophenylboric acid was characterized merely by conversion to the acetyl and benzoyl derivatives, and by the identification of aniline after removal of the boric acid residue.

Elimination of the Boric Acid Residue.—To a slightly ammoniacal aqueous solution of 0.2 g. of the substance, an excess of 5% aqueous silver nitrate solution was added; the resulting precipitate of the silver salt was filtered and washed with water. This was suspended in water and boiled gently for fifteen minutes to remove completely the boric acid group, and the aniline was recovered by steam distillation. Aniline was identified by the following tests: (1) development of a transient violet color with calcium hypochlorite solution; (2) formation of a colorless precipitate with bromine water; (3) conversion to an alkali-soluble benzene sulfonamide, m. p. 107.3–110.3" (corr.), which showed no depression of the melting point when mixed with an authentic specimen of benzenesulfonanilide, m. p. 109.3–111.3° (corr.).

Acetyl-m-aminophenylboric Acid.—A solution of the amino acid obtained by the reduction of 6.8 g. of m-nitrophenylboric acid was evaporated almost to dryness and treated with 25 g. of acetic anhydride. The mixture became warm and the solid particles dissolved. The acetic acid was removed by distillation at 50°, in an atmosphere of nitrogen, by addition of small portions of water and repeated evaporations. The acetyl derivative separated from the solution as the acetic acid was removed. The first crop of crystals, amounting to 2.2 g., was colorless; an additional amount, 1.5 g., of a slightly colored product was recovered from the mother liquors. Both fractions were purified by recrystallization from a small volume of hot water, with the addition of decolorizing carbon. The total yield of the crude product was 3.7 g., which is 56% of the theoretical amount calculated from the m-nitrophenylboric acid.

---

[24] An explanation of the formation of this type of anhydride is that the amino acid may exist as a salt (as do glycine and sulfanilic acid) formed by intramolecular neutralization; thus, the elimination of a molecule of water can only occur between two molecules:

$$2\overset{+}{N}H_3—C_6H_4—B\overset{-}{O}—OH \xrightarrow{-H_2O} \overset{+}{N}H_3—C_6H_4—B\overset{-}{O}—O—B\overset{-}{O}—C_6H_4—\overset{+}{N}H_3$$

Acetyl-*m*-aminophenylboric acid crystallizes from water in colorless prismatic plates; it is moderately soluble in water, alcohol and ethyl acetate, but almost insoluble in ether. It dissolves in aqueous alkalies. In a capillary tube the substance melted, with darkening, at 274–275° (corr.) when heated from 20°. On the Maquenne block the compound melted and immediately resolidified, without decomposition, at about 160°. The transition temperature could not be determined accurately, as only the smallest particles (viewed through a magnifying glass) could be seen to melt completely and the resolidification was almost instantaneous. The air-dried product lost no appreciable weight in a vacuum desiccator over sulfuric acid.

Anal. Calcd. for $C_8H_{10}O_3NB$: N, **7.83.** Found: (Kjeldahl) N, **7.72, 7.64.**

The acid gives the usual qualitative tests for boron, and the characteristic precipitates with aqueous solutions of mercuric chloride and of silver nitrate. Elimination of the boric acid group, effected by heating the silver salt in water, gave acetanilide, m. p. **112.3–114.3** (corr.), identified by comparison with an authentic specimen.

Benzoyl-*m*-aminophenylboric Acid.—A concd. solution of the amino acid obtained by the reduction of **2.0** g. of m-nitrophenylboric acid was treated with **2** g. of sodium bicarbonate and benzoylated with **2** g. of benzoyl chloride. The crude pale yellow benzoyl derivative weighed **1.2** g. **(42%** of the theoretical yield, based on the nitro acid). A preliminary purification was effected by dissolving the crude acid in dilute alkali, filtering and reprecipitating by pouring into dilute hydrochloric acid. A final purification was made by crystallization from 30% alcohol, with the addition of decolorizing carbon.

Benzoyl-*m*-aminophenylboric acid crystallizes from dilute alcohol in colorless prisms; it is almost insoluble in cold water and in ether, soluble in hot water and in alcohol. It is completely soluble in dilute sodium hydroxide solutions but only slightly soluble in sodium bicarbonate and sodium carbonate solutions. The air-dried substance melted in *a* capillary tube, with darkening, at 290° (corr.) in a bath heated from 20°; on the Maquenne block the substance melted with immediate resolidification, at about **200"** (co.). As the behavior of this compound was very similar to that of the acetyl derivative, it was not possible to determine accurately the temperature of the transition point. An air-dried sample did not lose weight in a vacuum desiccator over sulfuric acid.

Anal. Calcd. for $C_{13}H_{12}O_3NB$: N, **5.82.** Found: (Kjeldahl) **N, 5.59, 5.80.**

This acid gives the usual qualitative tests for boron, and the characteristic precipitates with aqueous solutions of mercuric chloride and of silver nitrate. Elimination of the boric acid group, effected by heating the silver salt in water, gave benzanilide, m. p. 163.3–164.4° (corr.), which was identified by comparison with an authentic sample. Hydrolysis with hot concd. aqueous sodium hydroxide (one and one-half hours) gave benzoic acid, m. p. 121.3–122.3° (corr.). An attempt to hydrolyze the benzoyl derivative by boiling for one-half hour with strong potassium hydroxide in 90% alcohol was unsuccessful.

Benzoyl-o-aminophenylboric Acid.—Although several attempts to isolate o-aminophenylboric acid and its acetyl derivative were unsuccessful,[25] it was possible to obtain benzoyl-o-aminophenylboric acid. o-Nitrophenylboric acid was reduced by the same general procedure as the meta isomer, except that the reduction was effected at 95–

---

[25] Our experiments indicate that o-aminophenylboric acid must be present in the solution obtained by reducing o-nitrophenylboric acid. Attempts to isolate the o-amino compound yielded phenylboric acid, due evidently to a reductive deamination; phenylboric acid was isolated likewise when the crude reduction product was treated with acetic anhydride in an effort to obtain the acetyl derivative. In one experiment, after treatment with acetic anhydride, a small amount of boric acid was isolated.

100°, and the reaction mixture was boiled gently for five minutes before filtering off the precipitated ferric hydroxide and barium sulfate. The filtrate, containing the excess of barium hydroxide, was divided into three portions for benzoylation. Each portion was treated with **1** g. of solid sodium bicarbonate and 1 g. of benzoyl chloride, and shaken thoroughly until there was no odor of benzoyl chloride. Upon acidifying with hydrochloric acid, the crude benzoyl derivative separated in yellow crystals. The yield was **1.6** g. from **3** g. of the nitro acid (37% of the theoretical). The crude product was purified by crystallization from 30% alcohol, with the addition of decolorizing carbon.

Benzoyl-o-aminophenylboric acid crystallizes from dilute alcohol in colorless, transparent platelets. It is very slightly soluble in cold water and ether, soluble in hot water and alcohol. It dissolves completely in dilute sodium hydroxide solution, but not in sodium carbonate or bicarbonate solutions. It gives the usual qualitative tests for nitrogen and boron, and the characteristic tests with mercuric chloride and with silver nitrate solutions. In a capillary tube, immersed in a bath preheated to 200°, the substance melts with darkening at 283–284° (corr.); on the Maquenne block the melting point was **319.5°** (corr.), with darkening. The air-dried product did not lose weight in a vacuum desiccator over sulfuric acid.

Anal. Calcd. for $C_{13}H_{12}O_3NB$: N, **5.82.** Found: (Kjeldahl) **N, 5.92, 5.92.**

The compound was characterized by elimination of the boric acid residue in the usual way. The boron-free product, m. p. 161.5–162° (corr.), was identified as benzanilide.

TABLE I

[a] In these determinations the bath was heated to a temperature about 10° below the melting point, before immersion of the capillary tube. [b] Resolidifies.

Bacteriological Tests[26]

For the bacteriological tests the substances to be examined were prepared in a high state of purity, as evidenced by constant melting points after repeated crystallizations and homogeneous appearance under the microscope. The first experiments were made with *Staphylococcus aureus*, using the Reddish test. Five cc. of the antiseptic in the dilution noted, was added to 0.5 cc. of a twenty-four hour bouillon culture of *Staphylococcus aureus*. This *Staphylococcus aureus* when tested against phenol should be

---

[26] The authors wish to express their thanks to Dr. E. H. Volwiler, Chemical Director, and to Dr. J. F. Biehn, Director of the Department of Clinical Research, of the Abbott Laboratories, North Chicago, Illinois, for their kind cooperation in carrying out the bacteriological tests described in this communication.

killed by a 1:70 dilution in ten minutes, and may or may not be killed by a 1:60 dilution in five minutes.[27]

The following compounds were tested in aqueous solution at a dilution of 1:1000: phenylboric acid, o- and m-nitrophenylboric acids sodium *m*-aminophenylborate, sodium benzoyl-m-aminophenylborate and sodium benzoyl-o-aminophenylborate The results were entirely negative, since the organisms were not killed by any of these solutions, even after fifteen minutes. Similar experiments were made using *B. typhosus* in place of *Staphylococcus*, and the following compounds were tested, at dilutions of 1:1000: boric anilide ($C_6H_5NHB{=}O$), acetyl-m-aminophenylboric acid, and *p*-nitrophenylboric acid; phenylboric acid and boric acid itself were tested at concentrations of 1:200. In this series the tests were allowed to run for two hours. The only positive result was obtained with phenylboric acid (1:200), which killed the organisms within one hour.

Since the preliminary tests indicated a much weaker action than had been anticipated, a milder test was used to enable us to determine the effect of various substituents upon the bacteriostatic action of phenylboric acid. For this purpose the following modified technique was used. To 5 cc. of the test solution were added 5 cc. of plain bouillon and 0.1 cc. of a bouillon culture of Staphylococcus aureus. These cultures were incubated for forty-eight hours, after which they were examined to determine whether or not a bacteriostatic effect[28] had been produced. The results of these tests, shown in Table II, led us to make a more complete examination of three compounds (phenylboric acid, m-nitrophenylboric acid, and *m*-aminophenylboric acid), against *Staphylococcus* aureus. The same modified technique for bacteriostatic action was used, and the following results were obtained: (1) phenylboric acid shqwed bacteriostatic action in dilutions of 1:400 to 1:450, but not at dilutions from 1:475 to 1:1500; (2) *m*-nitrophenylboric acid showed bacteriostatic action in dilutions of 1:500 to 1:2400, but not at a dilution of 1:3200; (3) m-aminophenylboric acid showed no bacteriostatic action in dilutions ranging from 1:400 to 1:3200.

Solutions of these three compounds were also tested in concentrations of 1:200, using 5 cc. of the test solution and 0.1 cc. of a twenty-four hour bouillon culture of Bacillus *typhosus*. m-Nitrophenylboric acid killed these organisms within five minutes, phenylboric acid in ninety minutes and m-aminophenylboric acid did not kill them within two hours.

---

[27] To be labeled as an antiseptic solution, under the ruling of the Bureau of Chemistry, the antiseptic solution in the dilution recommended, must kill this *Staphylococcus* culture, under the conditions of the above test, in five minutes.

[28] A bacteriostatic effect is commonly called an antiseptic effect. According to a ruling of the U. S. Department of Agriculture, the terms antiseptic and germicide are synonymous, and the previously stated definition of antiseptic is employed. The term bacteriostatic denotes the property of hindering the growth of organisms without killing them.

TABLE II

TESTS FOR BACTERIOSTATIC ACTION

Substance	Dilution[a]	Result[b]
Phenylboric acid	1:2000	−
m-Nitrophenylboric acid	1:2000	+
o-Nitrophenylboric acid	1:2000	+
p-Nitrophenylboric acid	1:2000	+
Sodium m-aminophenylborate	1:2000	−
Sodium benzoyl-m-aminophenylborate	1:2000	
Sodium benzoyl-o-aminophenylborate	1:2000	
Acetyl-m-aminophenylboric acid	1:2000	
Boric anilide	1:2000	
Phenylboric acid	1:400	+
Boric acid	1:400	−
Boric acid	1:50	+
Control	..	−

[a] Five cc. of the test solution was mixed with 5 cc. of bouillon and 0.1 cc. of a culture of Staphylococcus aureus, and incubated for forty-eight hours.

[b] A minus sign indicates continued development of the organisms; a plus sign denotes arrested development (bacteriostatic action).

Discussion of Bacteriological Tests

It appears that the claims of Michaelis and Becker[2] for the antiseptic efficacy of phenylboric acid were exaggerated. Aside from the question of purity of the phenylboric acid used in their work, it should be pointed out that their tests were made on heterogeneous mixtures of bacteria of unknown vitality, whereas our samples were tested on pure cultures by means of a standardized procedure.

Although none of the substances examined was found to be a powerful antiseptic, several of them possessed marked bacteriostatic properties. The introduction of an amino group (in the meta position) into the molecule of phenylboric acid resulted in a practically complete loss of bacteriostatic action, while the introduction of a nitro group markedly increased the bacteriostatic action.[29]

The fact that phenylboric acid and the derivatives here reported do not act as general antiseptics, does not preclude the possibility that they may have a specific action on certain organisms. This point remains to be tested. Since some of these compounds are soluble both in ether and in water, they may be expected to possess good penetrating power. It is possible that the introduction of a more powerfully antiseptic group (such as a phenolic hydroxyl) into the aromatic boric acid may prove fruitful, since the phenylboric acid residue may serve to give the molecule a satisfactory penetrating power.

---

[29] This effect of the nitro group is to be expected, since the nitrophenols are more powerful antiseptics than phenol [Morgan and Cooper, Orig. Corn. 8th Intern. Congr. Appl. Chem., 19,243 (1912); C. A., 6,2944 (1912)].

Summary

Phenylboric acid was prepared in a pure state, and the three isomeric nitrophenylboric acids were obtained from this acid by nitration under appropriate conditions. m-Aminophenylboric acid, its acetyl and benzoyl derivatives, and the benzoyl derivative of o-aminophenylboric acid were prepared. The physical characteristics of these substances are reported.

Bacteriological tests showed that phenylboric acid and the three nitrophenylboric acids exert a bacteriostatic effect upon *Staphylococcus aureus;* m-aminophenylboric acid and its derivatives do not produce a bacteriostatic effect.

The nitrophenylboric acids are more highly bacteriostatic than phenylboric acid, which in turn is much more effective than boric acid. Although no direct comparison was made, it appears that *m*-nitrophenylboric acid (1: 200) approaches or slightly surpasses phenol (1: 70) in its bactericidal action toward B. *typhosus,* but phenylboric acid (1:200) is much weaker than phenol (1: 70).

[CONTRIBUTION FROM THE CHEMICAL LABORATORY, UNIVERSITY OF ILLINOIS]

THE EFFECT OF ETHYLENE UPON THE HYDROLYSIS OF SALICIN BY EMULSIN

BY D. T. ENGLIS AND F. A. DYKINS

RECEIVED NOVEMBER 19, 1930 PUBLISHED FEBRUARY 9, 1931

The nature of the transformations brought about by the use of ethylene in the preparation of fruits and vegetables for marketing and the mechanism of the action continue to attract attention. It is generally believed that the changes produced are due to acceleration of enzymic activity. In an earlier paper[1] a brief consideration of the subject from this point of view, along with the results of experiments as to the effect of ethylene upon diastase and invertase with pure substrate material, was presented. No significant difference between the ethylene-treated and untreated materials was observed. The enzymes investigated were selected as representative of those concerned with normal ripening changes of carbohydrates and the original plan of experimentation anticipated studies upon other enzymes more definitely associated with color changes. It has been pointed out by Harvey[2] that an overdose of ethylene causes bananas to become brown. This coloration may be similar to leaf darkening and result from an increased hydrolysis of some glucoside followed by oxidase action upon the non-sugar component. It also seems probable that other coloration phenomena might have, as an initial stage, the change of a

---

[1] Englis and Zannis, THIS JOURNAL, 52, 797 (1930).

[2] Harvey, Bulletin 247, U. of Minn., Agr. Exptl. Sta., October, 1928.

glucoside into its simpler constituents. Since emulsin, which is associated with hydrolysis of β-glucosides, has apparently not received attention in connection with ethylene treatments, a study of this enzyme was undertaken. Several factors influenced the selection of salicin as the substrate material. It can be obtained readily in a high state of purity. Its hydrolysis by the enzyme has been thoroughly studied by Hudson and Paine[3] and others[4] and the rate can be followed readily by both physical and chemical methods.

Experimental

Materials.—The emulsion was prepared from sweet almonds according to the directions of Morrow.[5] One portion of the emulsion was preserved in the dry state. Another portion was made into a 1% solution and preserved with toluene.

The salicin was obtained from the Pfanstiehl Chemical Company. Its melting point was 195–197° and the ash content 0.05%.

The ethylene was a commercial product supplied by the U. S. Industrial Alcohol Company.

Method.—The general procedure was the same as that employed in the earlier study of diastase. The substrate of salicin was buffered with an acetic acid–sodium acetate buffer at a PH of 4.66 before adding the enzyme. The progress of the hydrolysis was followed by polarimetric observations and by determination of the reducing sugar by the Munson and Walker method.

Experiment I

Procedure.—6.250 grams of salicin was dissolved in 200 cc. of buffer solution and the solution divided into two parts. One part was saturated with ethylene. Both portions were then warmed to 40° and 25 cc. of the fresh emulsin solution added to each. At various time intervals portions were withdrawn and sodium carbonate added to stop the action of the enzyme and hasten the establishment of the equilibrium value following mutarotation. The portions were then filtered and polarized in a 2-dm. tube.

TABLE I

EFFECT OF ETHYLENE UPON THE HYDROLYSIS OF SALICIN BY EMULSIN. PROGRESS OF REACTION FOLLOWED BY POLARIMETRIC METHOD

Salicin 2.5 g. per 100 cc.; temperature, 40°; PH 4.66

	per 100 cc.							

Discussion

An examination of the tables shows practically no difference in the rate of hydrolysis in the salicin in the ethylene-treated samples and the controls in any of the experiments. The slight differences observed in favor of the controls are probably not significant. The emulsin on drying lost a great deal of its activity but the results with regard to ethylene were the same as with the fresh material.

In connection with the findings of this paper and the one preceding it[1] the results of a number of other studies of similar nature may be mentioned. Hirschfelder and Ceder[6] have carried out some very interesting experiments with ethylene attempting to extend the work upon fruits and vegetables to animals. Rats were given ethylene-treated drinking water and grown in atmospheres of varying concentrations of ethylene. The growth of the rats was not favorably affected. In supplementary work with enzymes they found that pepsin, trypsin and liver lipase were not activated by ethylene. However, they report that pancreatic amylase was activated. Johnson and Wormall[7] also report that potassium thiocyanate, a material which has been used to break the dormant period of potatoes and may be considered to fall in the same group of chemicals as ethylene, accelerated the first stages of hydrolysis of starch by saliva, malt and potato diastase but did not markedly increase the rate of formation of

[6] Hirschfelder and Ceder, *Am. J. Physiol.*, 91, 624 (1930).

[7] Johnson and Wormall, *Proc. Leeds Lit. Soc. Sci.*, Sec. 1, 318–324 (1928).

reducing sugars. Denny and associates,[8] who have been perhaps the most consistent contributors in this general field, have observed that under the conditions of their experiments sodium thiocyanate, thiourea and ethylene chlorohydrin all break the dormancy of potatoes. However, the increases in enzyme activity which were found from the treatment of the potatoes with chemicals were not direct effects of the chemicals on the enzymes but were indirect and brought about by the action of the chemical upon the tubers, since the treated juice of the potato failed to show significant differences from the control. This study relative to the treatment of the juice corresponds in principle to the method followed in this paper and the results obtained here are in agreement with its findings. Perhaps the apparent contradiction in the results obtained by Hirschfeld and Ceder[6] can be attributed to a lack of buffering or some other difference in experimental detail.

The results of these experiments suggest that a very complex system of reactions is taking place. The question might be raised as to whether or not studies as to the effect of ethylene or similar substances upon purified enzymes with pure substrate material should be abandoned. Perhaps mixtures of enzymes may be studied and some "key" reaction in the chain found. If not, one must come to the tentative conclusion of Denny that the chemicals seem to induce the living matter to produce larger amounts of (or more active) enzymes and their effect is not a direct one upon the enzymes.

Summary

The fact that ethylene hastens coloration of many fruits and vegetables gave rise to the belief that its effect might be associated with the activation of the enzyme responsible for the hydrolysis of many glucosides. For this reason a study was made of its influence upon the rate of hydrolysis of salicin by emulsin.

The rate of hydrolysis was followed by polarimetric observations and determinations of reducing sugar.

No acceleration of the reaction was observed in favor of the treated samples over the controls.

The results are in accord with the idea that ethylene does not directly affect the activity of enzymes, but acts indirectly through its effect upon the living matter.

THE CATECHIN OF THE CACAO BEAN

BY W. B. ADAM, F. HARDY AND M. NIERENSTEIN

RECEIVED NOVEMBER 20, 1930 PUBLISHED FEBRUARY 9, 1931

The presence of a catechin-like substance in the cacao bean was first definitely established by Ultée and van Dorssen,[1] although it appears fairly certain that previously to them Trojanowsky,[2] Hilger[3] and Schweizer,[4] seem to have observed such a substance in the cacao bean. Cacao-ole, the name adopted by Ultée and van Dorssen for the catechin, was shown by them to have the empirical formula $C_{16}H_{16}O_6$, to melt at 220° and to yield an acetyl derivative which melted at 153–154°. The empirical formula of Ultée and van Dorssen thus showed cacao-ole, $C_{16}H_{16}O_6$, to be a methyl derivative of catechin, $C_{15}H_{14}O_6$. The existence of such a methylated catechin in nature seemed to us of great interest, as so far no derivative of catechin has been recorded in the literature to be present in the plant. We have therefore investigated the West African cacao bean. The catechin thus obtained had the empirical formula $C_{15}H_{14}O_6$, melted at 229° and gave a pentaacetyl derivative melting at 151°. The same catechin was also obtained by us from the cacao bean grown in Trinidad. Since both catechins thus derived from Forostero beans,[5] and Ultée and van Dorssen had obtained their cacao-ole from the cacao bean grown in Java, which belongs to the Criollo class, we also investigated the catechin present in the Java cacao bean. Here again a catechin having the empirical formula $C_{15}H_{14}O_6$ was obtained, and a direct comparison of the three catechins proved them to be identical in every respect. In view of this we wrote to Dr. Ultée, who kindly sent us some of his original cacao-ole. On purification, the latter proved also to have the empirical formula $C_{15}H_{14}O_6$, to melt at 229° and to yield a pentaacetyl derivative which melted at 151°. We thus find that the catechin present in the cacao bean is not a methyl derivative of catechin but catechin itself, namely, *l*-acacatechin, one of the catechins present in the cutch-producing acacias,[6] as evident from a direct comparison between the catechin from the cacao bean and I-acacatechin. Thus cacao catechin and *l*-acacatechin melt at 229" and rotate in aqueous solution $[\alpha]_D\ -69°$; they both give penta-

acetyl derivatives which melt at 151° and rotate $[\alpha]_D$ $-12°$ in tetrachloroethane. Furthermore, neither the catechins themselves nor their acetyl derivatives, respectively, show depression in their melting points on admixture.

The importance of catechin in the production of the red and brown coloring matters and the tannins of the cacao bean have been dealt with in a previous communication, which describes a quantitative method for the estimation of catechin in the cacao bean. From the results with cacao beans from West Africa, Java, Guayaquil, Trinidad, Costa Rica and Bahia it is evident that the catechin content of the cacao bean is about 0.8%.[7]

Experimental

The beans used in the investigation were freshly collected, immersed in boiling water so as to destroy enzymes and sun dried. After removal of the shells, the raw nibs were ground in a mechanical mortar and exhaustively extracted in a large Soxhlet apparatus with petroleum ether. The material was then removed from the extraction apparatus, re-ground, mixed with acid-treated white sand and again extracted for several days with petroleum ether. The product was then freed from petroleum ether by exposure to air, powdered and extracted for a week with chloroform. This treatment was found to be necessary in order to remove completely the last traces of fat and the xanthine bases. No trace of catechin was found in the petroleum ether and chloroform extracts. The dried product was then treated as before and exhaustively extracted for several weeks with ether. The solid left on evaporation was practically pure *l*-acacatechin. It was obtained in colorless, anhydrous needles by purification with lead acetate, and crystallization from water slightly acidulated with acetic acid.[8] This process of purification was also found necessary in the case of Dr. Ultke's specimen. The acetylation was carried out by heating with acetic anhydride. The acetyl derivative crystallized in beautiful thick needles from alcohol, a few drops of acetone being added. The following table summarizes the analytical data obtained for the products dried at **160°** (catechin) and **110°** (pentaacetyl derivative), respectively.

TABLE I

ANALYTICAL DATA

	Catechin, calcd. for $C_{15}H_{14}O_6$: C, 62.06; H, 4.82 Found, %		**Pentaacetyl derivative, calcd. for $C_{15}H_9O_6[CO.CH_3]_5$: C, 60.02; H, 4.82 Found, %**	
Source of cacao bean	C	H	C	H
West-Africa [Accra]	61.92, 62.13	5.07, 5.15	59.72, 60.01	4.97, 4.89
Java	61.97, 62.00	4.99, 5.12	60.03, 59.83	5.03.4.93

TEPHROSIN. I. THE COMPOSITION OF TEPMROSIN AND ITS RELATION TO DEGUELIN

BY E. P. CLARK

RECEIVED NOVEMBER 20, 1930 PUBLISHED FEBRUARY 9, 1931

Hanriot isolated from the leaves of ***Cracca*** *(Tephrosia) vogelii* a substance which he named tephrosin.[1] To this material he assigned the formula $C_{31}H_{26}O_{10}$ and reported its melting point as 187°. His results were later confirmed by work published in the Bulletin of the Imperial Institute for 1915[2] except that the melting point of tephrosin was given as 192°.

In the studies in progress in this Laboratory upon the constituents of certain tropical fish-poisoning plants, an examination of the leaves of ***Cracca*** *vogelii* from Africa and Sumatra resulted in the isolation of a physiologically active crystalline material corresponding to that obtained by Hanriot. The preparation was a mixture of at least two compounds which were carefully separated and characterized. One was deguelin, m. p. 171°,[3] and the other was a colorless crystalline substance with a melting point of 197–198°.

At the time these experiments were being carried on, the same compounds, together with several others, were also found in the rotenone mother liquors from derris and cub6 roots.[4] When working with these materials difficulty in separating the individual constituents by fractional crystallization was experienced, due to the similarity of the solubilities of the several compounds in many solvents. However, as the separation proceeded, a fraction with a melting point of 180–185° was invariably obtained. It was unusually hard to resolve, but optical methods showed it to be essentially deguelin and the compound melting at 198°. This preparation was similar to the one obtained by the writer from ***Cracca*** *vogelii* and it appears likely that it was such a mixture that Hanriot described as tephrosin. Since a mixture of these two substances melting at 187° would contain more of the compound melting at 19S° than deguelin, the name tephrosin should be assigned to the former substance. In this and subsequent communications upon the subject this name will be adopted.

To obtain tephrosin, and the substances with which it is associated, it is necessary to treat the plant extractives in which it is found with an alkali.[4] A mixture is thus obtained from which tephrosin may be separated by fractional crystallization, but since purification in this way is un-

usually difficult, it is expedient, after several fractionations, to destroy the contaminating materials (mostly deguelin) by selective oxidation. In the experimental part directions are given for conducting such a procedure.

Tephrosin, prepared by either method, crystallizes in colorless prisms whose melting point is 198° (corr.), but this value varies somewhat depending upon the rate of heating. The substance has the molecular formula $C_{23}H_{22}O_7$ and contains two methoxyl groups.

When tephrosin is dissolved in a mixture of one volume of concentrated sulfuric acid and two volumes of acetic acid and the solution maintained at about 60° for fifteen minutes, tephrosin loses a molecule of water, forming dehydrodeguelin.[4] The same result is also obtained when tephrosin is boiled with a mixture of acetic anhydride and sodium acetate. The reactions show that tephrosin is intimately related to deguelin and possibly is a hydroxydeguelin. As yet direct evidence for an hydroxyl group in tephrosin has not been obtained, but in certain derivatives of this group of compounds an hydroxyl group may be present that gives extremely poor yields or fails entirely to form acyl or alkyl derivatives. Since dehydrodeguelin is a lactone it follows that tephrosin is a lactone also.

Another reaction presented as confirmatory evidence of the C_{23} formula for tephrosin is its behavior toward potassium permanganate. When oxidized with this reagent in an acetone solution, tephrosin yields a dicarboxylic acid, $C_{23}H_{22}O_{11}$, which melts at 221°. This acid has been designated as tephrosindicarboxylic acid.

Experimental

Tephrosin from Cracca Vogelii.—Two and four-tenths kg. of the ground leaves of *Cracca vogelii* were percolated with ether and the extract was concentrated to a thick sirup. When this sirup was dissolved in 400 cc. of hot alcohol and allowed to cool, 1 g. of fine colorless waxy crystals separated. (Since this material was not of immediate interest it was not investigated.) One hundred cc. of the alcoholic filtrate from the waxy crystals, representing 600 g. of leaves, was dissolved in 750 cc of boiling alcohol; 750 cc. of hot water was added, and the resulting turbid liquid was filtered through norit. The filtrate was concentrated under reduced pressure until the extractives separated as a gummy material which adhered to the flask. The residual liquid was decanted, and the flask was dried with a current of air. The gummy material was dissolved in 100 cc. of boiling methanol and treated with 0.5 g. of dry sodium carbonate. Crystallization began at once and was completed after several hours. The yield was 2 g. or 0.33%.

The crude crystalline material was dissolved in boiling alcohol, filtered through norit and allowed to crystallize. The compound which separated was identified as deguelin by its melting point (171°), mixed melting point and optical properties. The deguelin mother liquors were concentrated to one-fourth their volume and allowed to crystallize. A small quantity of colorless prisms, m. p. 188–191°, was obtained. This substance was dissolved in a small quantity of hot chloroform and about 20 volumes of methanol added. The resulting solution was evaporated to one-half its volume and set aside to crystallize. This procedure was repeated until the product had a constant melting point of 197–198°.

The tephrosin thus obtained consists of stout six-sided colorless prisms. The extinction is inclined and the elongation is negative. In convergent polarized light with crossed nicols, partial biaxial figures are common. The optic axis of fragments is usually inclined. The refractive indices are: η_α, 1.590 (common); η_β, indeterminate, $\eta_\gamma > 1.74$. An intermediate index, η_ι, 1.680 is also common.[5]

Anal. Calcd. for $C_{23}H_{22}O_7$: C, 67.30; H, 5.41; OCH_3 (2), 15.1. Found: C, 67.31; H, 5.47; OCH_3, 15.2.

Tephrosin from Derris and Cubé Roots.—In the recent article upon deguelin[4] details were given concerning the methods for obtaining a crystalline mixture from the rotenone mother liquors of derris and cubé roots. Since tephrosin is so intimately associated with deguelin in these mixtures, details for preparing a crude tephrosin was of necessity included in the preparation of deguelin. The fraction (m. p. 180–185°) which contained the most tephrosin was subjected to fractional crystallization until a product having a melting point of 198° was obtained. This was analytically and optically identical with tephrosin from *Cracca* leaves.

A more convenient method of preparing pure tephrosin is to destroy the deguelin in the mixture melting at 180–185° with chromic acid. This may be done as follows: 25 g. of the crude mixture (m. p. 180–185°) is dissolved in 500 cc. of boiling acetic acid. To this solution is added 40 cc. of a 10% acetic acid solution of crystalline sodium dichromate, and after the mixture has been allowed to react for five minutes, 500 cc. of boiling water is added. The turbid liquid is immediately filtered through norit and allowed to crystallize. Usually 12 g. of tephrosin with a melting point of 192–193° is obtained. When this product is recrystallized two or three times from 95% alcohol, it has a melting point of 197–198° Tephrosin prepared in this manner has the same optical properties as the specimens obtained by fractional crystallization

Anal. C, 67.32; H, 5.36; OCH_3, 15.6.

The Action of Sulfuric **and** Acetic Acids upon **Tephrosin.—One** gram of tephrosin was warmed to about 60° for fifteen minutes with a solution of 3 cc. of concentrated sulfuric acid in 6 cc. of acetic acid. Fifty cc. of water was then added to the mixture and the precipitate formed was removed and washed with water until it was free from sulfuric acid. The product was dried and dissolved in a small volume of hot chloroform, filtered through norit and five volumes of methanol added to the filtrate. Crystallization began at once, yielding 0.8 g. of pure dehydrodeguelin. The product was identified by its melting point, 233°. When it was mixed with dehydrodeguelin from deguelin, no melting point depression occurred. It also possessed the optical properties characteristic of dehydrodeguelin.

Action of Acetic Anhydride upon Tephrosin.—A mixture of 0.5 g. of tephrosin, 0.25 g. of potassium acetate and 4 cc. of acetic anhydride was boiled for ten minutes. The condenser was then disconnected, and about two-thirds of the anhydride was removed by distillation. The remaining anhydride was carefully decomposed with methanol, after which ten volumes more of methanol were added Crystallization began at once, yielding a product which melted at 228–230°. Upon recrystallization from chloroform and methanol it melted at 233°, and when it was mixed with dehydrodeguelin no depression of the melting point occurred. Its optical properties were the same as those of dehydrodeguelin.

Tephrosindicarboxylic Acid.—A constantly stirred solution of 5 g. of tephrosin in 300 cc. of acetone, maintained at a temperature between 15 and 20°, was treated with

---

[5] The optical data recorded in this paper were determined by George L. Keenan of the Food and Drug Administration, U. S. Department of Agriculture. Appreciation is expressed for this cooperation.

10 g. of potassium permanganate until the color due to the permanganate ions disappeared. The resulting manganese dioxide was removed by filtration, washed with acetone and then digested for two hours with 500 cc. of boiling absolute alcohol. The hot alcoholic extract was filtered, concentrated to 40 cc. and allowed to crystallize.

The resulting potassium salt, which weighed 1.5 g., was then dissolved in 100 cc. of water and the solution filtered through norit. The filtrate was heated to boiling, and dilute sulfuric acid was added until an acid reaction to Congo red was obtained. Upon standing overnight the liquid deposited 1.4 g. of rod-like plates, which melted at 220° with decomposition.

The acid was recrystallized from 1.5% boiling aqueous solution, from which it separated as clear-cut tabular crystals and rods which melted at 221° with decomposition (corr.). The substance has inclined extinction, positive elongation and the following indices of refraction: n_α, 1.530; n_β, indeterminate, and n_γ, 1.640; both ±0.003.

Anal. Calcd. for $C_{23}H_{22}O_{11}$: mol. wt. 474.3; OCH_3 (2), 13.1; C, 58.21; H, 4.68. Found: acid equivalent (2 COOH), 472; OCH_3, 13.1; C, 58.37; H, 4.73.

Summary

1. Deguelin, m. p. 171°, and a compound melting at 198°, were isolated from the leaves of *Cracca vogelii*, derris root and the roots of *Lonchocarpus nicou* (Cubé root).

2. These two substances form a mixture which is difficult to separate by fractional crystallization and which appears to be the material designated by Hanriot as *tephrosin*.

3. It is proposed that the name tephrosin should be retained for the compound with the melting point of 198°.

4. Tephrosin is a dimethoxy lactone, $C_{23}H_{22}O_7$, which, under the influence of certain dehydrating agents, loses one molcule of water, forming dehydrodeguelin.

5. It is suggested that tephrosin is a hydroxydeguelin.

6. The action of potassium permanganate upon tephrosin results in the formation of a dicarboxylic acid, $C_{23}H_{22}O_{11}$.

ROTENONE.
XI. THE RELATION BETWEEN ISOROTENONE AND ROTENONE

BY H. L. HALLER

RECEIVED NOVEMBER 20, 1930 PUBLISHED FEBRUARY 9, 1931

Rotenone on catalytic hydrogenation with one mole of hydrogen yields a mixture of dihydrorotenone and rotenonic acid.[1] Rotenonic acid on hydrogenation is reduced to dihydrorotenonic acid, which can also be obtained by the hydrogenation of dihydrorotenone.[1]

Isorotenone,[2] an isomer of rotenone, is obtained by dissolving rotenone in a solution of glacial acetic acid and concentrated sulfuric acid and then adding the resulting cherry red solution to water. In its chemical behavior isorotenone exhibits most of the typical reactions of rotenone. It yields a dehydro derivative, a diketone, isoderritol and isotubaic acid. The only marked difference is in its behavior on catalytic hydrogenation. Whereas rotenone is readily reduced with catalytic hydrogen to an acid, and a dihydro derivative, isorotenone is reduced only with great difficulty and so far it has not been possible to obtain from it an acid corresponding to rotenonic acid.

Isoderritol and isorotenol are not reduced to acids under the conditions employed for the reduction of derritol and rotenol.

Tubaic acid,[3] which is obtained on boiling an alcoholic potassium hydroxide solution of rotenone, is readily reduced to a dihydro derivative.

Isotubaic acid[4] (rotenic acid), which is obtained on isomerization of tubaic acid, is not easily hydrogenated but can be reduced under certain conditions, as has been shown by Butenandt and Hildebrandt[5] and by Takei, Koide and Miyajima.[6]

Tubaic acid is optically active, whereas isotubaic acid is optically inactive. Dihydroisotubaic acid is a racemic mixture. It has been resolved[5,6] into its enantiomorphs and the levo form has been found to be identical with dihydrotubaic acid. Thus it is definitely established that the isomerization of tubaic acid into isotubaic acid is due to the migration of a double bond.

The facts that isorotenone yields isotubaic acid under the same conditions that rotenone yields tubaic acid and that tubaic acid can be isomerized

to isotubaic acid, lead to the conclusion that the same groupings are involved in the isomerization of rotenone into isorotenone as in the transformation of tubaic acid into isotubaic acid.

On oxidation with permanganate, tubaic acid yields acetic acid, whereas isotubaic and dihydrotubaic acid give isobutyric acid.[7] Takei and Koide[8] have obtained a methyl ketone on ozonization of tubaic acid. The presence of an isoallyl group in tubaic acid and in rotenone is therefore definitely established; isotubaic acid, dihydrotubaic acid and isorotenone, on the other hand, contain the isopropyl group.

As it has been shown that the double bond in tubaic acid which is readily reduced is in the isoallyl group and that isotubaic acid does not reduce readily, it appears fairly well established that the double bond from the isopropylene group in tubaic acid is the one which migrates on isomerization.

The fact that rotenone readily yields an acid on catalytic hydrogenation, whereas isorotenone does not, indicates that there is a close relation between the lactone ring and the migratory double bond, and that the cleavage of the lactone ring by hydrogenation depends upon the position of the unsaturated bond. It has not yet been possible to fix the position of the lactone ring, but in a recent paper it has been shown that acid derivatives obtained by hydrogenation of rotenone do not yield tubaic acid, but that the hydroxyl group resulting from the hydrolytic opening of the lactone ring is necessary for its formation.[9]

In an attempt to isomerize rotenonic acid to isorotenonic acid with glacial acetic and sulfuric acids, a product insoluble in alkali was obtained. It is not a mixed anhydride since it was recovered unchanged on refluxing in methyl alcohol solution, but is isomeric with rotenonic acid and dihydrorotenone. It will be called β-dihydrorotenone. It is probably a saturated lactone formed by the migration of a double bond with subsequent ring closure. As is well known, unsaturated acids can be transformed into saturated lactones by means of acid.

The formation of β-dihydrorotenone is further evidence that there is a close association between the lactone ring and the migratory double bond.

Jacobs and Scott[10] have recently shown that γ- and 6-lactones which contain a double bond in the β, y- or γ,δ-position readily yield desoxy acids on catalytic hydrogenation. When the double bond is in the α,β-position the ring is not opened but, instead, saturated lactones are obtained.

It is possible that when rotenone is isomerized to isorotenone, the double bond from the isopropylene group migrates to an α,β-position to the lactone

[8] S. Takei and M. Koide, *Ber.*, 62, 3030 (1929).

[9] H. L. Haller and F. B. LaForge, THIS JOURNAL, 52,4505 (1930).

[10] W. A. Jacobs and A. B. Scott, *J. Biol. Chem.*, 87,601 (1930).

group and that the double bond becomes part of a conjugated system, which rearrangement might explain why isorotenone does not yield an acid on hydrogenation and why it is reduced only with difficulty.

The isomerization of rotenonic acid to a saturated lactone may be explained by rearrangement, accompanied by the disappearance of the double bond. No such change is possible in the case of dihydrorotenonic acid because the double bond in the isoallyl group has been reduced.

β-Dihydrorotenone is optically active. In alcohol solution it reduces Fehling's solution. It is not reduced with platinum oxide and hydrogen in ethyl acetate solution. On refluxing in alcoholic potash solution, an acid isomeric with dihydrotubaic acid is obtained. The same acid is obtained on fusion with potassium hydroxide. Like rotenone, β-dihydrorotenone yields a yellow dehydro compound on mild oxidation, and with stronger oxidizing agents, a diketone. Dehydro-β-dihydrorotenone on boiling with alcoholic potash and zinc adds two moles of water to form an acid corresponding to dihydro-dehydrodihydroxyrotenonic acid (dihydroderris saure, Butenandt) which has been termed dehydrodihyroxy-β-dihydrorotenonic acid. This acid also yields derric acid on oxidation with hydrogen peroxide in alkaline solution.

Experimental

β-Dihydrorotenone.—Five grams of rotenonic acid was dissolved with gentle heating in a solution of 16.5 cc. of concentrated sulfuric acid and 60 cc. of acetic acid. The cherry red solution was slowly poured into 500 cc. of water with constant stirring. The precipitate was filtered off, washed with water and dissolved in ether. The ether solution was washed with 5% potassium hydroxide, then with water and then dried over sodium sulfate. The substance readily crystallized after most of the ether was distilled off. It melted at 156". In alcohol solution it reduced Fehling's solution; in chloroform, $[\alpha]^{34}_{D}$ −26.5° (C = 5.86).

Anal. Subs., 0.0790, 0.0782, 0.0987: CO_2, 0.2000, 0.1984, 0.2522; H_2O, 0.0432, 0.0416, 0.0531. Subs., 0.0220, 0.0214; AgI, 0 0268, 0.0261. Calcd. for $C_{23}H_{24}O_6$: C, 69.69; H, 6.06, $2OCH_3$, 15.65. Found: C, 69.08, 69.20, 69.68; H, 6.08, 5.92, 5.96; OCH_3, 16.08, 16.09.

One gram of β-dihydrorotenone was dissolved in 50 cc. of methyl alcohol, and the solution was refluxed for three hours. It was then concentrated to about half its volume and cooled. The substance which readily crystallized proved to be unchanged β-dihydrorotenone. The melting point was 156°. β-Dihydrorotenone in ethyl acetate solution with platinum oxide catalyst absorbed no hydrogen.

β-Dihydrotubaic Acid.—Five grams of β-dihydrorotenone was dissolved in a solution of 5 g. of potassium hydroxide in 50 cc. of alcohol and 5 cc. of water. The solution was refluxed for three hours and then poured into 500 cc. of water. The acid was isolated by the procedure described for the preparation of tubaic acid.[11] It melted at 175–176° with decomposition. In alcohol it gave a purple color with ferric chloride. It contained no methoxyl.

Anal. Subs., 0.0844, 0.0827: CO_2, 0.2002, 0.1946; H_2O, 0.0467, 0.0469. Calcd.

[11] H. L. Haller and F. B. LaForge, THIS JOURNAL, 52,3207 (1930).

for $C_{12}H_{14}O_4$: C, 64.86; H, 6.31. Found: C, 64.70, 64.16; H, 6.15, 6.31. 0.0245 g. of subs. required 1.10 cc. of N/10 KOH; 0.242 g. of subs. required 1.10 cc. of N/10 KOH. Calcd. mol. wt., 222. Found: 223,220.

Alkali Fusion of β-Dihydrorotenone.—Two grams of β-dihydrorotenone was intimately mixed with 18 g. of powdered potassium hydroxide and 1 cc. of water in a nickel crucible. The reaction mixture was heated with constant stirring in a metal-bath at 225° for twenty-five minutes. After cooling, the fusion mass was dissolved in water and the acid isolated by the procedure previously described.[10] The acid proved to be identical with the acid obtained by the action of alcoholic potash on β-dihydrorotenone.

β-Dihydrorotenone.—Four grams of β-dihydrorotenone was dissolved in 120 cc. of glacial acetic acid, and the solution was heated to boiling under a reflux condenser. During the course of three hours, 8 g. of chromium trioxide in 200 cc. of glacial acetic acid was added. The solution was then concentrated to half its volume. On cooling fine yellow needles crystallized out which decomposed at about 310°.

Anal. Subs., 0.0808, 0.0804: CO_2, 0.1982, 0.2001; H_2O, 0.0351, 0.0349. Subs., 0.0223, 0.0223: AgI, 0.0247, 0.0248. Calcd. for $C_{23}H_{20}O_7$: C, 67.61; H, 4.93; $2OCH_3$, 15.20. Found: C, 66.90, 67.88; H, 4.83, 4.82; OCH_3, 14.62, 1468.

From the mother liquors obtained in the oxidation described above a minute quantity of acid was isolated which was found to be identical with the acid obtained by the action of alcoholic potash on β-dihydrorotenone.

Dehydro-β-dihydrorotenone.—One gram of β-dihydrorotenone was dissolved in 50 cc. of boiling 95% alcohol. A solution of 1.8 g. of potassium fenicyanide and 0.27 g. of potassium hydroxide in 15 cc. of water was added to the boiling solution. The reaction mixture was allowed to stand overnight. Water was then added and the resulting crystalline precipitate was filtered off, washed with water and then with alcohol. It melted at 269°.

Anal. Subs., 0.0823, 0.0884: CO_2, 0.2100, 0.2250; H_2O, 0.0419, 0.0441. Calcd. for $C_{23}H_{22}O_6$: C, 70.00; H, 5.58. Found: C, 69.62, 69.47; H, 5.70, 5.58.

β-Dihydrorotenolone.—One gram of β-dihydrorotenone was dissolved in a solution of 2.5 g. of potassium acetate in 50 cc. of absolute alcohol. To the hot solution 0.8 g. of iodine dissolved in 50 cc. of absolute alcohol was slowly added. On cooling, a cream-colored product crystallized. It was recrystallized from chloroform–ethyl alcohol. It melted at 274". The compound was an hydroxy derivative of β-dihydrorotenone.

Anal. Subs., 0.0855, 0.1009: CO_2, 0.2109, 0.2495; H_2O, 0.0441, 0.0511. Subs., 0.0212, 0.0219: AgI, 0.0248, 0.0255. Calcd. for $C_{23}H_{24}O_7$: C, 67.00; H, 5.82; $2OCH_3$, 15.05. Found: C, 67.27, 67.44; H, 5.73, 5.63; OCH_3, 15.45, 15.37.

On boiling with alcoholic sulfuric acid, β-dihydrorotenolone yielded a yellow compound which was identical with the dehydro compound obtained by oxidation of β-dihydrorotenone with potassium ferricyanide.

The filtrate from the β-dihydrorotenolone was concentrated to dryness and water was added. The undissolved substance was filtered off, dried and recrystallized from 95% alcohol. It melted at 224°. Analysis indicated it to be the acetyl derivative of the hydroxy compound obtained above.

Anal. Subs., 0.0945, 0.0907: CO_2, 0.2288, 0.2195; H_2O, 0.0473, 0.0464. Calcd. for $C_{25}H_{26}O_8$: C, 66.08; H, 5.75. Found: C, 66.03, 66.00; H, 5.56, 5.68.

Dehydrodihydroxy-β-dihydrorotenonic Acid.—Eight-tenths gram of dehydro-β-dihydrorotenone was refluxed with 5 cc. of 40% potassium hydroxide, 20 cc. of ethyl alcohol and 2 g. of zinc dust for one and one-half hours. The zinc was removed by filtration and the solution was acidified with dilute sulfuric acid. After adding water to the solution it was cooled and extracted with ether. The ether extract was washed with water and dried over sodium sulfate. The ether was removed and the substance was crystallized from butyl ether. It melted at 149°.

Anal. Subs., 0.0927: CO_2, 0.2177; H_2O, 0.0506. Calcd. for $C_{23}H_{26}O_8$: C, 64.16; H, 6.09. Found: C, 64.05; H, 6.11.

Oxidation of **Dehydrodihydroxy-β-Dihydrorotenonic Acid** to Derric Acid.—One gram of acid was dissolved in 12 cc. of 5% sodium hydroxide solution. The solution was gently heated and 3 cc. of 30% hydrogen peroxide was gradually added. The solution was finally heated to boiling for a few minutes, then cooled and acidified with dilute sulfuric acid. The solution was extracted with ether, the ether extract was washed with water and dried over sodium sulfate. After removal of the ether the substance was crystallized from butyl ether. It melted at 167° and was found to be identical with derric acid.

Summary

Rotenonic acid in glacial acetic acid and sulfuric acid is isomerized to a substance which is insoluble in alkali and appears to be a saturated lactone. This compound has been named β-dihydrorotenone.

β-Dihydrorotenone gives the typical reactions of rotenone. It yields a dehydro compound which adds two moles of water to form an acid. It gives a diketone. With potassium hydroxide it yields an acid isomeric with dihydrotubaic acid.

A possible explanation is given of the fact that rotenone is readily reduced and isorotenone is not, and a relation between the two is indicated.

THE SPECTROCHEMISTRY OF FURAN AND ITS DERIVATIVES[1]

BY EVERETT C. HUGHES AND JOHN R. JOHNSON

RECEIVED NOVEMBER 21, 1930 PUBLISHED FEBRUARY 9, 1931

Absorption spectra and molecular refraction have proved to be of considerable value in attacking chemical problems from a physical standpoint. In the furan series no extensive study has been made of these optical properties, although a number of observations are reported in the literature. The present work was undertaken with the object of making a rather extensive study of furan derivatives with the idea of discovering any general relationships which might prove useful in elucidating the structure and behavior of furan and its derivatives.

Preliminary observations of absorption spectra showed that furan and its simpler derivatives do not exhibit selective absorption in the visible and ultraviolet regions (to 2200 Å.). It was hoped that there would be a difference in the absorption spectra of the isomeric alpha- and beta-sub-

---

[1] This article is an abstract of a thesis submitted to the Faculty of the Graduate School of Cornell University by Everett C. Hughes, in partial fulfilment of the requirements for the degree of Doctor of Philosophy, June, 1930.

stituted furans that would be of value in distinguishing between them. Even in the case of the carboxylic acid derivatives, which do exhibit a characteristic absorption, there was not observed any regular or sufficient difference that would be of value in distinguishing between isomeric compounds. The only real difference lies in the molecular absorption coefficients (Fig. 2), which are consistently higher for the alpha-derivatives than for the beta-derivatives. These differences are directly related to the differences in optical dispersion; the latter, as will be shown below, prove to be of value as a criterion for distinguishing between the alpha- and beta-substituted derivatives.

Early investigations of the refractive index of compounds containing the furan ring have shown that the law of refraction equivalence is not strictly followed.[2] From theoretical considerations of molecular refraction as presented by Lorentz and discussed by later investigators[3] it appears that no absolute agreement between the calculated and observed values can be expected.

It was found, however, that the furan derivatives under examination could be divided into two categories on the basis of the differences between the observed and calculated values. Furthermore, the exaltations of the dispersion of compounds of the furan series may furnish information bearing upon the fundamental question of the structure of the ring and the position of substituents.

In order to provide data for study, furan and twenty furan derivatives were prepared in a high state of purity, and their refractive indices and densities were determined. These data, together with a number of values taken from the literature, are shown in Table V. The calculations made from these observations are collected in Table I.

An examination of the results indicates that these furan derivatives can be divided into two categories: one in which the value EMR is negative, and another in which this value is positive.

In the first class are found furan and all of the derivatives (Table I, 1–13) in which the substituents do not contain a double bond on the atom immediately attached to the ring in the alpha-position.[4] These compounds

[4] Ethyl pyrotritarate (2,5-dimethyl-3-carbethoxyfuran) is an exception to this statement. If the above constitution is correct, there is present a cross-conjugated system, the effect of which is uncertain—due to the lack of a sufficient number of known examples for examination. The only other available example of cross-conjugation is **2-methyl-3-carbethoxyfuran,** which is not an exception to the general statement given

[a] $EMR_D = MR_D$ observed − MR_D calculated. The revised values of Eisenlohr were used for the atomic refractions [Landolt-Bornstein, "Physikalisch-chemische Tabellen," Julius Springer, Berlin, 5th Ed., Vol. II, 1923, p. 985]. The furan ring was considered to have two ethylenic double bonds and an ethereal oxygen atom.

[b] $E_{\Sigma\beta-\alpha}$ is calculated from the specific refractions according to the empirical formula of Auwers (see below).

[c] **Nasini** and **Carrara**, *Gazz. chim. ital., 24, I,* 271 (1894); [d] **Brühl**, ***Ann.*, 235,** 1 (1886); [e] **Auwers, *Ber.*,** 44, 3690 (1912); [f] Bruhl, **J.** *prakt. Chem., [2]50,* 142 (1894); [g] Gennari, *Gazz. chim. ital., 24, I,* 253 (1894).

might be termed normal furan derivatives. The differences in the group, for the D line, vary from −0.134 to −1.078 and the average difference is −0.479. It is of interest to point out in this connection that the tetrahydro derivatives of furan show much less difference in the values of EMR than do the furan derivatives; e. g., five typical tetrahydrofuran derivatives showed differences from −0.31 to +0.03.[5]

In the second class are found all of the furan derivatives in which the side chain contains a double bond forming a conjugated system with the ring (Table I, 14–26). The differences in the group, for the D line, vary from $0.814 to +5.523. This result is not surprising in view of the many observations of optical exaltations caused by the presence of conjugated

---

[5] Tetrahydrofuran. −0.13; 3-methyltetrahydrofuran, +0.03; **tetrahydrofurfuryl** alcohol, −0.16; **tetrahydrofurfural**, −0.31; **tetrahydrofuroic** acid, −0.11.

systems. Since all of these compounds exhibit absorption in the near ultraviolet region, the exaltations are probably caused by the proximity of this absorption band. It has previously been demonstrated that the refractive index increases rapidly as an absorption band is approached and apparently rises to infinity at the center of the band. The absorption spectra of a number of the furan derivatives used in this investigation are shown in Figs. 1 and 2.

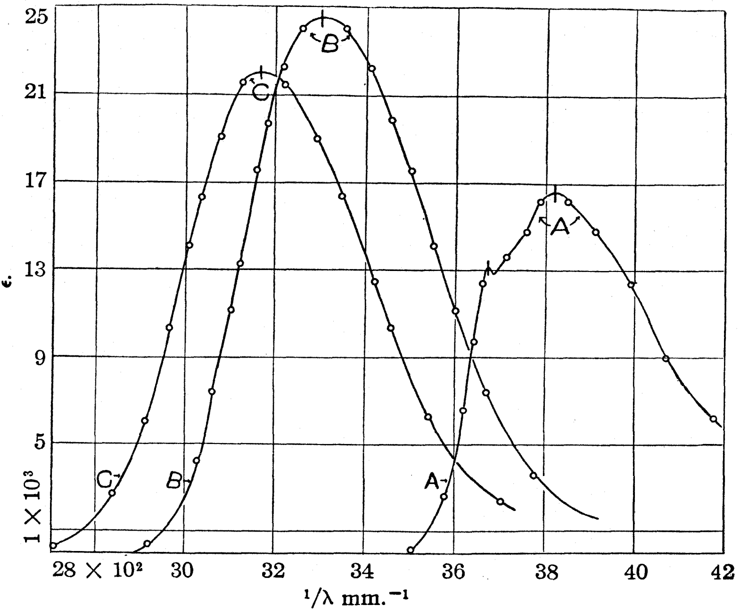

Fig. 1.—A, Furylethylene; B, ethyl furylacrylate; C, furylbutenone; solvent, ethyl alcohol.

In an effort to obviate the effect of the ultraviolet absorption bands it seemed of interest to make use of a proposal of Hunter.[6] He suggested that if the Sellmeir equation for dispersion (1) be used to calculate a value for the refractive index at a wave length sufficiently removed from the major absorption bands to be uninfluenced by them, the observed and calculated values would agree better than at visible wave lengths. By the use of three simultaneous equations, the constants for the following form of the Sellmeir dispersion formula were calculated for a number of furan derivatives.

$$n^2 = \frac{M}{\lambda^2 - \lambda_0^2} + C + 1 \qquad (1)$$

In this equation λ is the wave length of light used in the determination of n, λ_0 is the free vibrational period of the electron which is responsible

---

[6] Hunter, *J. Chem. Soc.*, 123, 434, 1671 (1923).

for the refraction and also for the absorption of light, and M is an intensity factor. The value of λ_0 should represent an absorption band in the ultraviolet; that it does so has been verified experimentally for five of the compounds used (Table II). The calculated and observed values for the absorption bands were found to differ by only 250 Å., an effect which can be attributed to the influence of the solvent (alcohol).

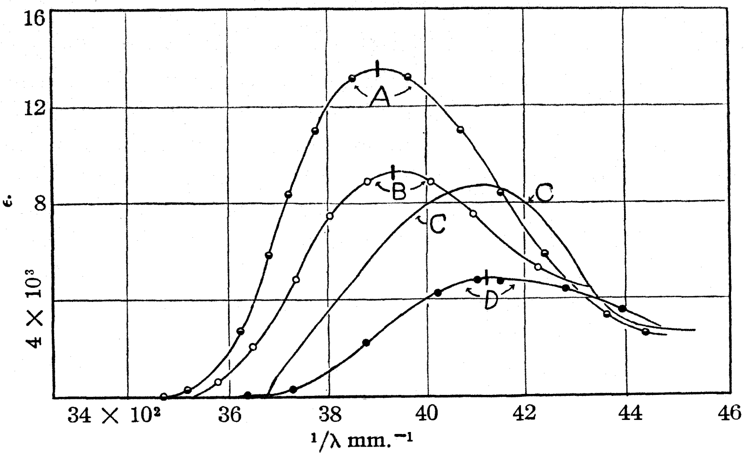

Fig. 2.—A, 5-Chlorofuroic acid; B, 3-chlorofuroic acid; *C*, 2-furoic acid; D, 2-methyl-3-furoic acid; solvent, ethyl alcohol.

TABLE II

ABSORPTION SPECTRA MAXIMA FOR FIVE DERIVATIVES OF FURAN

	Compound	Molecular extinction coefficient	Maxima in Å.	Sellmeir equation constant λ_0
1	Furylethylene	16600	2600	2325
2	Furylbutenone	22000	3100	2967
3	Furylpentenone	22800	3100	2888
4	Ethyl furylacrylate	24500	3000	2754
5	Furfural pinacolone	20500	3200	2983

In the above equation the first term will vanish if λ is taken to be infinite, and the square root of $(C + 1)$ will be the refractive index at infinite wave length. The exalting effect of the ultraviolet absorption band should therefore be at a minimum. The values obtained from these calculations at infinite wave length are shown in Table I. The results show that the differences are somewhat less than those at visible wave lengths but they are far too great to constitute any improvement in the situation.

The most satisfactory application of an empirical relation derived from refractive indices, to the study of structural problems has been made by

Auwers.[7] He uses the following calculation of the percentage exaltation of dispersion (E)

$$E = \frac{(\Sigma_\gamma - \Sigma_\alpha)\text{obs.} - (\Sigma_\gamma - \Sigma_\alpha)\text{calcd.}}{(\Sigma_\gamma - \Sigma_\alpha)\text{calcd.}} \times 100\%$$

$$\Sigma = \text{specific refraction} \times 100$$

This method was tried in the furan series for four pairs of isomeric alpha- and beta-substituted compounds. The values of E, listed in Table I, show that there is a very large difference between the alpha- and beta-isomers, and that the value for the alpha compound is always larger than that of the beta-compound. A comparison of the densities, boiling points, refractive indices and other properties indicates that the exaltation of the dispersion is unique in showing a marked difference between the isomers.[8] Although the differences in the percentage exaltation of the dispersion constitute a satisfactory means of distinguishing between the alpha- and beta-isomers, this method has the serious limitation of requiring that both isomers be available for comparison.

It was also observed that the constant M of the Sellmeir equation differs quite markedly in the alpha- and beta-derivatives of furan (see Table I). This constant is a value which, by deduction, represents the intensity of the vibration producing the absorption band and is directly related to the exaltations of the dispersion. In the compounds examined, the value of M was always higher for the alpha-isomer. This evidence of higher vibrational intensity in the alpha-isomers might be interpreted to mean that the alpha-derivative would be more reactive than the beta-derivative. With the present incomplete knowledge of the relative reactivity of substituents in the alpha- and beta-positions this interpretation cannot be confirmed from the chemical standpoint. This conclusion is in agreement with the observation that a halogen atom in the beta-position is less reactive than one in the alpha-position.

In its chemical behavior, in general, the furan ring occupies a position intermediate between the unsaturated aliphatics and the typically aromatic benzene ring. A comparison of the exaltations of the dispersion of corresponding benzene and furan derivatives (Table III) indicates a similarity in the compounds that have simple substituents (Cl, Br, CH_3). The effect of a substituent containing a double bond in the α,β-position of the side chain is much more marked in the furan series than in the benzene series. This result appears to parallel the unusual chemical behavior of furan derivatives with a double bond in the α,β-position of the side chain;

[7] Auwers, Ber., 43,806 (1910); *Ann.*, 408,212 (1915); 422,160 (1921).

[8] The generalization made here is based on a comparison involving only a few pairs of alpha- and beta-isomers. It is our intention to synthesize a number of other beta-substituted furan derivatives in order to test the validity of this general statement.

these compounds readily undergo a scission of the ring, accompanied by an unusual rearrangement.[9]

Table III

Percentage Exaltation of Dispersion in Benzene and Furan Series

$E_{\Sigma\gamma} - \Sigma_\alpha$

Substituent	$-H$	$-Cl$	$-Br$	$-CH_3$	$-COOC_2H_5$	$-CH{=}CH_2$	$-CH{=}CH-COOC_2H_5$	$-CH{=}O$
Benzene series[a]	7	10	11	11	26	45	105	49
a-Furan series	−6	12[b]	10[b]	10	48	79	227[c]	110[c]

[a] The data for the benzene series are those of Auwers [*Ber.*, **45**, 2769 (1915); *Ann.*, **408**, 212 (1915)]. [b] Values for the 8-substituted furan derivatives are Cl, −3.77; Br, −12.4. [c] The values for the furan series are much higher than those of a simple ethylenic series. In the series, $CH_3CH{=}CH-$, the values are $-CH{=}O$, 55; $-CH{=}CH-COOC_2H_5$, 128 [Auwers and Eisenlohr, *J. prakt. Chem.*, [2] **84**, 34, 108 (1911)]. The effect of ring closure on spectrochemical properties has been studied by Auwers [*Ann.*, **415**, 98 (1918); 422, 133 (1921)].

It is of interest to note that the model of benzene suggested by Dupont[10]. and by Latimer and Porter,[11] can be applied also to furan and other five-membered heterocyclic rings of aromatic character, such as thiophene, pyrrole and glyoxaline. The essential feature of this model is a "centric" system of six electrons, which in the benzene ring may be considered to be formed by a contribution of one electron from each carbon atom of the ring. In the case of furan the "centric" system is also one of six electrons, four of which may be considered to be contributed from the four carbon atoms and two from the oxygen atom (Fig. 3, I). The system in furan may then be represented by equilibria of the following types of electronic arrangements.

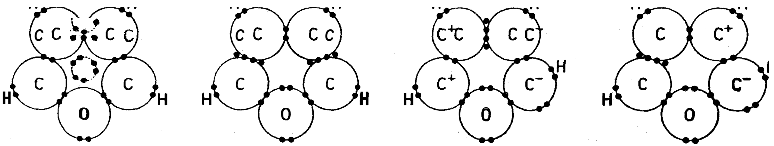

Fig. 3.—Electronic formulas fpr furan: I, centric formula; II, ethylenic formula; III, active form for 1,4-addition; IV, active form for 1,2-addition.

Active forms of furan may be postulated to explain either 1,2- or 1,4-addition (Fig. 3, III and IV) by use of the general conceptions of Carothers concerning the double bond.[12] A consideration of 1,4-addition to the furan ring will be presented in a later publication dealing with the mechanism of rearrangements in the furan series.[13]

Experimental

The furan derivatives used in this investigation were prepared with only minor deviations from methods which previously have been described in the literature. The final purifications were always carried out with consideration only of purity of the product, and not of yield. In Table IV are given the physical constants and references to the methods of preparation.

TABLE IV

PHYSICAL CONSTANTS OF COMPOUNDS

No.	Compound	Reierence	Boiling point, °C.

The method employed in the examination of the absorption spectra was that described by Orndorff, Gibbs and McNulty,[14] using a Hilger spectrograph in conjunction with a Hilger sector photometer. The light source was a high tension spark between brass electrodes under water.

The refractive indices were measured at five wave lengths and three dif-

---

[14] Orndorff, Gibbs and McNulty, THIS JOURNAL, 47, 2767 (1925).

ferent temperatures, using a water-jacketed Pulfrich refractometer. The densities were determined in carefully standardized pycnometers of two and five cc. capacity. In Table V the numerical results are summarized and tabulated. In addition to these values, certain previously recorded values from the literature were used in making the calculations given in Table I.

Summary

1. The densities and refractive indices (in the visible region of the spectrum) have been measured for furan and twenty furan derivatives. The absorption spectra of eight furan derivatives are reported.

2. From the molecular refractions and the exaltations of the dispersion, calculated from these data, certain generalizations have been made concerning the effects of various types of substituents in the furan ring.

3. It has been shown that isomeric alpha- and beta-substituted furan derivatives may be distinguished from each other by spectrochemical means. The exaltations of the dispersion for the alpha-isomers are invariably higher than for the beta-isomers.

4. It has been shown for five furan derivatives that the wave lengths

of the absorption maxima (in the near ultraviolet) calculated from the Sellmeir dispersion formula are in agreement with the wave lengths of the absorption maxima actually observed.

5. Electronic formulas for the furan ring have been proposed and discussed briefly from the standpoint of interpretation of reactions of furan derivatives.

SOME ARSONIC ACIDS OF FLUORENE AND ITS DERIVATIVES

BY F. E. CISLAK[1] AND CLIFF S. HAMILTON

RECEIVED NOVEMBER 21, 1930 PUBLISHED FEBRUARY 9, 1931

In an attempt to find arsenicals which might be of value from the standpoint of chemotherapy, it seemed desirable to make a study of arsonic acids of fluorene and of some of its derivatives[2]

Bart's[3] method of preparing arylarsonic acids was adapted to the preparation of 2-arsonofluorene (I), 2-arsonofluorenone (II) and 2-acetamino-7-arsonofluorene (III). In the preparation of (III) the steps taken are indicated graphically below; the yield of (III) from (VI) was extremely low.

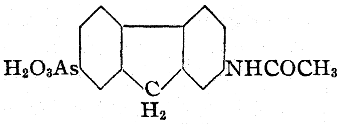
[1] This article is an abstract of Part II of a thesis submitted to the Graduate School of Northwestern University by F. E. Cislak in partial fulfilment of the requirements for the degree of Doctor of Philosophy. The work was made possible by a grant from Parke, Davis and Company.

[2] Some of the compounds described in this article are being tested pharmacologically at the University of Wisconsin under the direction of Dr. **A.** L. Tatum, **but** no data are available at this time.

[3] Bart, Ann., **429,** 55 (1922).



III

2-Amino-7-nitrofluorene (IV) was first prepared by Diels.[4] By the nitration of 2-acetaminofluorene in glacial acetic acid, he obtained a mixture of 1-nitro-2-acetaminofluorene and 2-acetamino-7-nitrofluorene. This mixture could not be separated, but after hydrolysis the nitroaminofluorenes could be separated with difficulty. Because of the difficulty in obtaining any quantity of 2-acetamino-7-nitrofluorene by this procedure, a method was devised for the preparation of the desired substance in yields of 90–95% of the calculated amount.

The compounds, 2-acetamino-7-nitrofluorene, 2-acetamino-7-aminofluorene, as well as arsonic acids of fluorene have not been reported previously in the literature.

Experimental

2-Nitrofluorene and 2-Aminofluorene.—These compounds were prepared by the methods devised by Diels.[5]

2-Arsonofluorene.—Fifteen grams of 2-aminofluorene was mixed with 550 cc. of water, treated with 20 cc. of concd. hydrochloric acid solution and heated to boiling. The resulting clear solution was cooled (40°) rapidly, thereby causing the precipitation of the hydrochloride of 2-aminofluorene. While stirring this mass, a saturated aqueous solution of 6 g. of sodium nitrite was added dropwise. The hydrochloride of 2-aminofluorene then disappeared and a clear brownish yellow solution resulted. This solution was gradually heated to 60°, filtered hot and the filtrate cooled to 20°, causing the precipitation of golden yellow needles of fluorene diazonium chloride.

Thirteen grams of sodium meta-arsenite and 1 gram of copper sulfate were dissolved in 300 cc. of water. This solution was stirred during the entire course of the arsonation. In small portions, the mixture of solid fluorene diazonium chloride and its saturated solution was added to the arsenitc at room temperature. At once a vigorous evolution of nitrogen occurred. Sufficient 6 N sodium hydroxide solution was added from time to time to make this arsenite solution just alkaline. When all of the diazo compound had been added, the solution was stirred for fifteen hours. The mixture was then heated to 90° and stirred for three-quarters of an hour. It was filtered hot, and the filtrate acidified with 10 cc. of concd. hydrochloric acid solution, thereby precipitating 2-arsonofluorene. This precipitate was removed by filtration, washed with water, dissolved in a dilute solution of sodium carbonate, reprecipitated with hydrochloric acid and again separated by filtration, washed and dried; yield 4.5 g.

Anal. Calcd. for $C_{13}H_{11}O_3As$: As, 25.86. Found: As, 25.71, 25.81.

2-Nitrofluorenone and 2-Aminofluorenone.—The preparation of these compounds has been described by Diels.[6]

2-Arsonofluorenone.—Ninety cc. of concd. hydrochloric acid solution was added to one liter of water and the solution heated to 80°. Thirty grams of 2-aminofluorenone

---

[4] Diels, *Ber.*, 35, 3284 (1902).

[5] Diels, *ibid.*, 34, 1758 (1901).

[6] Diels, *ibid.*, 34, 1864 (1901).

was added to the hot solution and while stirring this mixture, it was heated to 97° until all of the solid dissolved. The resulting golden-colored solution was quickly cooled to 50°; at this temperature, the golden needles of 2-aminofluorenone hydrochloride crystallized from the solution. While stirring this mixture, a saturated aqueous solution of 14 g. of sodium nitrite was added drop by drop. After all of the nitrite solution had been added, the mixture was stirred for fifteen minutes more and then cooled to 15°.

Twenty-five grams of sodium meta-arsenite and 2 g. of copper sulfate were dissolved in 400 cc. of water. While stirring the arsenite solution, the solution of fluorenone diazonium chloride was added in small portions. A vigorous evolution of nitrogen occurred. The procedure from this point was the same as outlined under 2-arsonofluorene; yield, 10 g.

Anal. Calcd. for $C_{13}H_9O_4As$: As, 24.67. Found: As, 24.60, 24.53.

2,7-Dinitrofluorene.—For the preparation of this compound the directions given by Morgan and Thomson[1] were followed.

2-Amino-7-nitrofluorene.—To a solution of 1800 cc. of 95% alcohol and 200 cc. of concd. ammonia was added 30 g. of 2,7-dinitrofluorene. This solution was maintained just below its boiling point and a stream of hydrogen sulfide was passed in for four hours. At the end of the first hour the solution changed its original yellow color to a deep red and a red solid began to crystallize from the solution. At the end of the four-hour reduction period, 250 cc. of water was added to the mixture and the latter cooled to about 10°. The red precipitate formed was removed by filtration. The 2-amino-7-nitrofluorene was isolated from this precipitate by boiling the latter with 16 liters of water to which had been added 1500 cc. of concd. hydrochloric acid solution. This solution was filtered hot, the filtrate cooled and then made alkaline by the addition of an excess of ammonia solution. The precipitated orange-red 2-amino-7-nitrofluorene was filtered, washed with water and then with 100 cc. of alcohol. It was dried at 100°; yield, 90–94%. Crystallization from alcohol gave a product melting at 228–229° (corr.).

When this compound was mixed with some 2-amino-7-nitrofluorene prepared by the method of Diels,[4] there was no change in melting point.

2-Acetamino-7-nitrofluorene.—Forty-five grams of 2-amino-7-nitrofluorene was dissolved in 400 cc. of hot glacial acetic acid. To this solution were added ten 25-cc. portions of acetic anhydride, the solution being stirred after the addition of each portion. When all of the acetic anhydride had been added, the solution was refluxed for eight hours and filtered hot, thereby removing a slight amount of dark brown sediment which had formed. To precipitate the bright yellow acetylated product, the filtrate was poured into four volumes of water. It was removed by filtration, washed with 25 cc. of hot glacial acetic acid, and dissolved in 600 cc. of hot glacial acetic acid. The acetic acid solution was boiled with decolorizing carbon, filtered and the resulting filtrate diluted with 50 cc. of water and cooled to about 10°. The 2-acetamino-7-nitrofluorene crystallized from this solution. It was removed by filtration, washed several times with water and finally with two 100-cc. portions of 95% alcohol; yield, 75% of the calcd. amount. Crystallization from alcohol gave a product melting at 250–253° (corr.).

Anal. Calcd. for $C_{15}H_{12}N_2O_3$: N, 10.46. Found: N, 10.18, 10.23.

2-Acetamino-7-aminofluorene.—Thirty grams of 2-acetamino-7-nitrofluorene was dispersed in 700 cc. of 95% alcohol. To this were added 50 cc. of water, 100 g. of zinc dust, and a solution of 5 g. of calcium chloride in 20 cc. of water. This mixture was refluxed for five hours under mechanical stirring and filtered hot to remove the excess

---

[7] Morgan and Thomson, *J. Chem. Soc.*, 691 (1926).

zinc. This zinc was washed on the filter paper with 20 cc. of hot alcohol and then boiled with 200 cc. of 95% alcohol and separated from the alcohol by filtration. All the filtrates were combined and added to four volumes of water, thus precipitating white 2-acetamino-7-aminofluorene, which slowly acquired a gray color. This compound was removed by filtration and washed with water. In order to purify the resulting product, it was dispersed in I liter of hot water (90°) and to this was added 15 cc. of concd. hydrochloric acid solution, thus causing nearly all of the substance to go into solution. The mixture was filtered hot and the 2-acetamino-7-aminofluorene was reprecipitated from the filtrate by the addition of an excess of ammonia solution, filtered, washed with water and dried; yield, 60–65% of the calcd. amount. Upon recrystallization from alcohol, the compound decomposed at 188–192° (corr.).

Anal. Calcd. for $C_{15}H_{14}N_2O$: N, 11.74. Found: N, 11.66, 11.78.

2-Acetamino-7-arsonofluorene.—No satisfactory method has been found for preparing this substance. The method described below gave only small yields.

One liter of water was heated to 70° and to it was added 75 cc. of concd. hydrochloric acid and while stirring this solution, 15 g. of 2-acetamino-7-aminofluorene was added. The stirring at 70° was continued for fifteen minutes. Then the solution was cooled to 30° and while stirring, an aqueous solution of 6 g. of sodium nitrite was added drop by drop. After all of the nitrite solution had been added the solution was stirred for thirty minutes.

Fifteen grams of sodium meta-arsenite and a crystal of copper sulfate, the size of a pea, were dissolved in 200 cc. of water. The arsenite solution was stirred mechanically while the diazo solution was added in small portions. A copious evolution of nitrogen took place. After each portion of the diazo solution was added, the arsonation mixture was rendered just alkaline to litmus by the addition of 6 N sodium hydroxide solution. The solution was stirred for an hour and then the temperature was raised to 70–75°, and the stirring continued for another hour. At the end of this time the mixture was made strongly alkaline by the addition of 30 cc. of 6 N sodium hydroxide and filtered. The filtrate. upon acidification, gave a light brown precipitate, which was filtered off, dissolved in 300 cc. of a dilute sodium carbonate solution, filtered, acidified with concd. hydrochloric acid solution and the precipitate then formed removed by filtration and dried at 60°; yield, 2–2.5%; color; dull yellow.

Anal. Calcd. for $C_{15}H_{14}NO_4As$: As, 21.61. Found: As, 21.80, 21.49.

Summary

1. 2-Arsonofluorene, 2-arsonofluorenone and 2-acetamino-7-arsonofluorene have been prepared for the first time.

2. A method of preparing 2-acetammo-7-nitrofluorene in considerable amounts with good yields has been developed.

EVANSTON, ILLINOIS

THE ACETOACETIC ESTER CONDENSATION. II. THE REACTION OF ALIPHATIC ESTERS WITH SODIUM

BY JOHN M. SNELL AND S. M. MCELVAIN

RECEIVED NOVEMBER 26, 1930 PUBLISHED FEBRUARY 9, 1931

In a previous communication[1] from this Laboratory it was pointed out that in any study of the synthetic phase of the acetoacetic ester condensation the choice between sodium and sodium ethoxide as condensing agents was an important consideration for the reason that the metal reacts with the type of ester used in the condensation to form a distinctly different type of compound, *viz.*, the sodium derivative of an acyloin. The acyloin and related substances may be the major if not the sole products of reaction of certain esters with sodium. The results reported at that time showed that no such complications accompany the use of sodium ethoxide as a condensing agent.

Although a number of earlier investigators had observed that certain esters react with sodium to give compounds other than the acetoacetic ester type, it was Bouveault and Locquin[2] who first formulated the reaction as being two molecules of the ester and four atoms of sodium with the formation of the sodium salt of an acyloin which was converted by hydrolysis into the acyloin

$$2RCOOR' + 4Na \longrightarrow RC(ONa) = C(ONa)R + 2NaOR'$$

$$RC(ONa) = C(ONa)R \xrightarrow{H_2O} RC(OH){=}C(OH)R \longrightarrow RCHOHCOR$$

Bouveault and Locquin carried out the reaction between sodium and the ethyl esters of acetic, propionic, butyric, caproic, isobutyric and trimethylacetic acids at 0° in ether as a solvent. They obtained, after allowing the reaction to proceed for several days, quite good yields (in most cases approximately 80% of the theoretical) of the acyloins. There was generally a small amount of the diketone, RCOCOR, and some higher-boiling material obtained from the reaction. It was thought that the former compound resulted from the oxidation of the sodium derivative of the acyloin, and that the latter was produced from the acyloin during distillation. The only explanation of the mechanism of the reaction that was offered by these investigators is the one shown above. In 1920 Scheibler and Voss[3] offered an explanation for the formation of acyloins which postulated an intermediate formation of the sodium salt of the enol form of the ester. They stated that under the reaction conditions (0°) of Bouveault and Locquin the hydrogen which was given off during the formation of the enolate

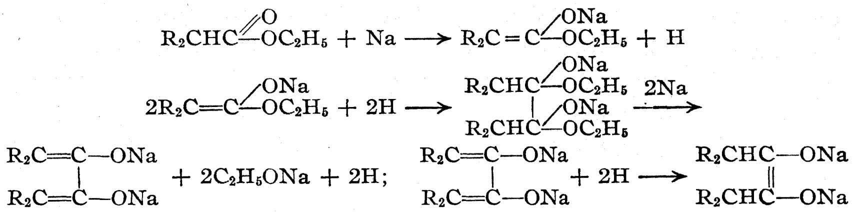
---

[1] McElvain, THIS JOURNAL, 51, **3124** (1929).

[2] Bouveault and **Locquin,** Bull. *soc. chim.,* [3] 35, 629 (1906).

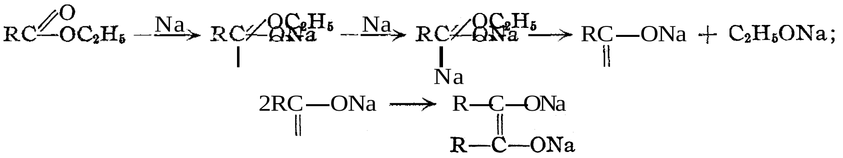
[3] Scheibler and **Voss,** *Ber.,* 53, **388** (1920).

salt was utilized to reduce this salt to the acyloin, but that at the temperature (the boiling point of ether) at which they prepared the salts of the enol forms of esters the hydrogen was evolved as such before it could cause the reduction of the enolate. This explanation hardly seems reasonable, since the results reported below show that excellent yields of the acyloins may be obtained at the temperature of boiling ether. Later, in 1923, Scheibler and Emden[4] reported a study of the formation of the acyloins and proposed the following mechanism for the reaction



It is seen that this mechanism also postulates the intermediate formation of a salt of the ester enolate. No reason was given for the necessity of assuming alternate addition and loss of hydrogen in the process.

One grave weakness[5] in this mechanism is that it will not explain the formation of an acyloin from such an ester as ethyl trimethylacetate which has no hydrogen on the carbon atom adjacent to the carbethoxy group and consequently cannot form an ester enolate. Scheibler and Emden handle such a case by postulating a special mechanism for this type, as follows



Such esters must go through a different mechanism, it is pointed out, on account of the slowness and incompleteness of the reaction.

Scheibler and Emden explained the presence of small amounts of the diketone, RCOCOR, which often accompanies the acyloin as resulting from the oxidation of salt of the di-enolate of the acyloin by air and pointed

---

[4] Scheibler and Emden, *Ann.,* 434,265 (1923).

[5] Another may be noted. Scheibler and Emden point, in a footnote, to an observation of Bouveault and Blanc that only esters which have at least one hydrogen on the α-carbon atom may be reduced by sodium and alcohol to the corresponding alcohol as further substantiation of their mechanism. This "generalization" is based, apparently, on the behavior of ethyl benzoate and has the common defect of such "generalizations," *viz.*, that it is not generally applicable. For example, Courtot [*Bull. soc. chim.,* 35, 121 (1906)] has reported the reduction of ethyl Δ^3-2,2-dimethylbutyrate, $CH_2{=}CHC(CH_3)_2COOC_2H_5$, to the corresponding alcohol and his results have been confirmed by Folkers and Adkins in this Laboratory, who obtained a 61% yield of this alcohol by the reduction of the above ester with sodium and alcohol.

out that the potassium salts were much more susceptible than the sodium salts to such oxidation.

Recently Corson, Benson and Goodwin[6] described a general procedure for the preparation of a number of aliphatic acyloins. They obtained yields, approximately 50% of the theoretical, of products with 25° boiling range using boiling ether as a solvent. They noted the formation of the higher-boiling products which they felt were derived in part, at least, from the acyloins during distillation and also the diketones the formation of which they ascribed, as did Scheibler and Emden, to the oxidation of the salt of the di-enolate of the acyloin.

In the work which is now reported a study has been made of the reaction between sodium and the following esters: ethyl acetate, ethyl propionate, ethyl butyrate, ethyl isobutyrate and ethyl trimethylacetate. Ether, benzene and an excess of the ester were used as solvents. The temperature of each reaction was determined by the boiling point of the particular solvent used. In the cases when the two inert solvents were used one mole of the ester was allowed to react with two atoms of sodium. A number of different procedures for the decomposition of the sodium salts in the reaction mixture were tried, and it was soon discovered that considerable attention had to be given to this point if consistent and comparable results were to be obtained. The procedure finally adopted used the calculated amount of 35% sulfuric acid for the decomposition of these salts. This amount and concentration of sulfuric acid, besides destroying the alkalinity of the reaction mixture rapidly, converted all of the sodium which had been used into the solid $Na_2SO_4 \cdot 10H_2O$ from which the supernatant liquid could be directly decanted. The products of each reaction were separated into an acidic and neutral fraction by extraction of the former with a sodium carbonate solution. These two portions were then dried and subjected to fractional distillation.

Experimental Part

Materials Used.—The esters, ethyl acetate, ethyl propionate, ethyl butyrate, ethyl isobutyrate and ethyl trimethylacetate were carefully purified and dried by the procedure previously described (Ref. 1) in the first paper of this series. The ether and benzene (thiophene free) were distilled from phosphorus pentoxide before use.

General Procedure.—Two gram atoms of sodium was powdered by heating and vigorous stirring under xylene in a 3-liter flask fitted with a stirrer, reflux condenser and a dropping funnel. The xylene was then cooled and decanted from the sodium. The sodium was washed several times with dry ether to remove the xylene and finally covered with 600–800 cc. of ether. To this ether suspension of sodium 1 mole of the ester was added and the mixture stirred and refluxed until the reaction appeared to be complete.

There was a very noticeable difference in the reactivity of the various esters with powdered sodium in ether. In the case of ethyl acetate twenty-four hours of refluxing was required to complete the reaction. Ethyl propionate reacted quite completely

---

[6] Corson, Benson and Goodwin, THIS JOURNAL, 52, 3988 (1930).

after about two hours of refluxing. In the case of ethyl butyrate, ethyl isobutyrate and ethyl trimethylacetate, the reaction was so vigorous that it could not be controlled if the ester were added in a single portion. For this reason the ester was added gradually from a dropping funnel at such a rate as to keep the ether boiling vigorously. The reaction of each of these three higher esters appeared to be complete in one to one and one-half hours. The reaction converted the sodium into a voluminous, amorphous, yellow, insoluble solid. A very noticeable feature of the reaction of ethyl trimethylacetate was that considerable sodium remained unreacted even after two hours of refluxing, while with each of the other esters practically all of the sodium was used up. The reaction, however, was complete so far as the ester was concerned for practically no unchanged ethyl trimethylacetate was recovered from the reaction mixture.

After the reaction was finished the calculated quantity of 35% sulfuric acid for neutralization of the sodium that had been used was added from the dropping funnel. During this addition the Bask was cooled with ice and the contents vigorously stirred. It required about five or ten minutes to complete this neutralization. The sodium sulfate with its water of crystallization readily separated and solidified in the bottom of the reaction flask. The supernatant liquid was decanted, the precipitate washed with 200 cc. of ether and the combined ether solutions extracted with a 20% solution of sodium carbonate. The carbonate extract was then acidified with sulfuric acid and extracted several times with ether. After drying, the ether extract of the acidic products and the original ether solution of the reaction products were fractionated.

A procedure similar to that outlined above was followed with benzene as the solvent instead of ether. Under these conditions of reaction the esters showed the same variation in reactivity that they did in the ether solution. Ethyl acetate was not used with benzene as the solvent on account of the rather uncertain results which it gave in ether solution. A considerable amount of unreacted sodium remained after the reaction of ethyl trimethylacetate in benzene as was the case in the ether solution.

The amounts and types of reaction products obtained from the reaction of these esters with sodium in the inert solvents, ether and benzene, are summarized in Table I. A ferric chloride test applied to a portion of the ether or benzene solution of reaction products before distillation indicated that small amounts of β-ketonic esters, resulting from an acetoacetic ester condensation, had been formed from ethyl acetate and ethyl propionate, but after distillation there was no evidences of such products in any of the fractions. Presumably the distillation had destroyed their identity so far as the ferric chloride test could determine and converted them into higher-boiling materials through condensation with other products of the reaction. The acidic products shown in the last two columns were obtained from the sodium carbonate extraction of the ether or benzene solution of the reaction products after the sodium salts of the reaction mixture had been decomposed and the $Na_2SO_4 \cdot 10H_2O$ filtered off. The calculations of the percentage yield of the diketone and acyloin are based on the amount of ester which was put into the reaction.

A very noticeable difference in reactivity of these esters with sodium was noted when an excess of the ester was used as the solvent. In these cases four to five moles of the ester was reacted with **23** g. (1 atom) of powdered sodium. The sodium could be covered directly with ethyl ace-

Trimethylacetate	50	Benzene	5	15	20	63	..	3	...

[a] This fraction was composed of material boiling higher than the ester and lower than the acyloin and represented approximately a 40° range. The major portion of this fraction in the case of ditrimethylacetyl boiled over a 10° range. It had the deep yellow color characteristic of the 1.2-diketones.

[b] This fraction had a boiling range of 5–10°. The highest boiling acyloin boiled under 100" (15 mm.).

[c] This fraction represents the material boiling higher than the acyloin and which had not reacted with sodium carbonate. It boiled as high as 200" (15 mm.). A small amount of undistillable residue was obtained from the ethyl acetate and ethyl propionate reactions.

tate or ethyl propionate and very little reaction appeared to take place until heat was applied. The reaction in either case was in no sense vigorous and it was necessary to reflux the ester for about two hours before the sodium had disappeared. The reaction mixture appeared quite homogeneous. With the three higher esters it was necessary to add the sodium in small portions to the ester. This was done by dipping the powdered sodium which was kept covered with dry ether with a dipper having a perforated bottom (constructed from a Gooch crucible) and allowing most of the ether to drain off before the addition of the sodium to the ester. The heat of reaction was sufficient to sustain refluxing until all of the sodium had reacted. The reaction mixture appeared as a thick pasty mass. The reaction products were isolated as described above and are summarized in Table II. The calculations of the yields of the various products were based on the amount of sodium *(23* g. in each case) that was put into the reaction.

Some Properties of the Diketones and Acyloins. The Diketones.—With the exception of ditrimethylacetyl, the diketones were obtained in quite small yields from the above reactions. They are characterized by their deep yellow color. They generally boil about 20–25° lower than the acyloin and about the same amount higher than the esters from which they are derived.

TABLE II

THE PRODUCTS OF REACTION OF SODIUM WITH AN EXCESS OF CERTAIN ALIPHATIC ESTERS

Trimethyl acetate	...	...	42	98	..	..	6	46	45	..

[a] Percentage yield calculated on the basis of 2Na producing 1RCOCOR. [b] Percentage yield calculated on the basis of 4Na producing 1RCHOHCOR. [c] Percentage yield calculated on the basis of 1Na producing $1RCOCHR'COOC_2H_5$. When, however, the alcohol was distilled out of the reaction of ethyl acetate and sodium a 72% yield of acetoacetic ester was obtained. [d] Percentage yield calculated on the basis of 1Na producing 1RCOOH. [e] Colorless, water-white liquids. [f] Deep yellow-colored liquids.

They are readily polymerized and rearranged by sodium ethoxide, as is shown by the following experiment. A solution of 9 g. of dibutyryl in 50 cc. of benzene was heated for two hours on a water-bath with 5 g. of sodium ethoxide. The reaction mixture was then acidified with sulfuric acid and separated into a neutral and acidic portion by extraction with sodium carbonate. The former portion yielded on fractionation 1 g. of unchanged dibutyryl and 4 g. of higher-boiling material. The acidic portion was separated by fractionation into 2 g. of butyric acid and 1 g. of di-n-propylglycolic acid,[7] m. p. 76°, neutral equivalent 166. Di-isobutyryl showed a similar behavior except that about 2 g. (18% of the calcd.) of di-isopropylglycolic acid,[8] m. p. 108–110°, neutral equivalent 163, was obtained. A similar experiment using 10 g. of ditrimethylacetyl yielded 7.5 g. of unchanged diketone, 1 g. of trimethylacetic acid and 1 g. of an undistillable tar.

The Acyloins.—The acyloins which are reported in Tables I and II were collected over a 5–10' boiling range. Acetoin boiled at 140–150°, propionoin at 160–170°, butyroin at 85–95' (12 mm.), isobutyroin at 175–180°, pivaloin (hexamethylacetoin) 80–90° (15 mm). The latter compound solidified on cooling and melted at 80–81°. All of the acyloins as obtained from the reaction show a yellow coloration which is much less intense than that characteristic of the diketones. This color is no doubt due to the presence of small quantities of the diketone.

In contrast to the diketones the acyloins are hardly affected by sodium

ethoxide; for example, 8 g. of isobutyroin was recovered unchanged when 10 g. of this acyloin was refluxed with 5 g. of sodium ethoxide in benzene solution. These reaction conditions, it was pointed out above, readily polymerized and rearranged the diketones with the exception of ditrimethylacetyl.

Bouveault and Locquin[2] thought that the higher-boiling products of the reaction were derived from the acyloin by polymerization during distillation. However, samples of propionoin, butyroin and isobutyroin after one and one-half hours of boiling under a reflux condenser were found to distil completely over the temperature range at which they had originally boiled. It would seem quite certain from this fact that the higher-boiling products owe their origin to some other source.

The Higher-Boiling Products.—Very little investigation was made on the nature of these products. With the exception of those obtained from ethyl acetate and ethyl propionate when an excess of the ester was used as the solvent (Table II), these products all possessed the yellow color suggestive of the diketone structure. The product from ethyl propionate (Table I) did not show any appreciable reduction with hydrogen in the presence of either catalytic platinum or nickel (propionoin was reduced quantitatively with the latter catalyst at 50° and under 150 atmospheres of hydrogen[9] to the 3,4-hexanediol). The product from ethyl propionate reacted with acetic anhydride in the ratio of 307 g. of the former to one mole of the anhydride. With the similar product from ethyl butyrate the ratio was 500 g. to one mole of the anhydride. They showed no reaction with semicarbazide but with phenylhydrazine a red viscous liquid was formed.

The Acidic Reaction Products.—The origin of that portion of the acidic reaction products representing the acid, the ester of which was used in the reaction, is discussed below. From the higher-boiling acidic products there were obtained, in the cases of ethyl butyrate and ethyl isobutyrate, small yields of di-n-propylglycolic acid and di-isopropylglycolic acid. These acids were obtained by recrystallization of fractions which boiled at 140–170° (15 mm.). After this fraction was removed the bulk of the higher acidic portion remained as an undistillable residue. This residue was no longer soluble in alkali. The dialkylglycolic acids are formed, as shown above, from the rearrangement of the diketones with sodium ethoxide and this reaction is, no doubt, responsible for their presence in the reaction mixtures obtained from ethyl butyrate and ethyl isobutyrate. The undistillable residue after the removal of the dialkylglycolic acid, since it was insoluble in alkali, was quite probably a lactide resulting from the heating of the α-hydroxy acids.

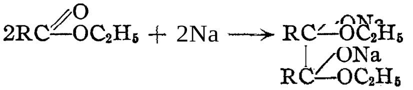
[9] This work was done by Mr. Karl Folkers under the direction of Professor Homer Adkins in this Laboratory.

Discussion of the Experimental Results and the Mechanism of the Reaction between the Esters and Sodium

An inspection of the data presented above shows that there is no perceptible difference in the rate at which the three esters, ethyl butyrate, ethyl isobutyrate and ethyl trimethylacetate react with sodium nor is there any great difference in the completeness with which they react in the inert solvents to form diketones and acyloins. The need, therefore, of a special mechanism to account for the slowness and incompleteness of reaction of those esters which cannot enolize does not exist, for ethyl trimethylacetate reacts somewhat more completely and just as rapidly as the other two. Corson, Benson and Goodwin[6] made a somewhat similar observation on the behavior of ethyl dimethylethylacetate. Since the only group capable of reaction that these three esters have in common is the carbethoxy group it is logical to conclude that the reaction of sodium with such esters involves only this particular group. The postulate of Scheibler and Emden that the reaction proceeds, when possible, through the salt of the enol form of the ester, or, when this is not possible, through an entirely different mechanism, has no experimental support and would seem to be quite unnecessary, if not erroneous.

It is also evident from the experimental data presented in Table I that the diketone is an intermediate product in the formation of the acyloin rather than the result of an oxidation of the acyloin as previous investigators of the reaction have thought. Egorova[10] arrived at a similar conclusion in his study of the action of sodium on the chloride of trimethylacetic acid. It would be difficult to explain the relatively high yields of the diketone in the case of ethyl trimethylacetate in Table I on the basis of atmospheric oxidation when the reaction conditions were practically identical to the conditions used with the other esters and ***unreacted*** sodium ***remained*** in the reaction mixture. The fact that dibutyryl and di-isobutyryl are readily polymerized and rearranged by sodium ethoxide while the ditrimethylacetyl is quite stable to this reagent is not without significance and indicates that the low yield of the former two is due to their partial destruction by the sodium ethoxide produced in the reaction.

It would seem, therefore, logical and consistent with the experimental facts to represent the reaction between sodium and such aliphatic esters as taking place in two steps. First, the formation of a diketone–sodium ethoxide addition product by the reaction of two molecules of the ester with two atoms of sodium

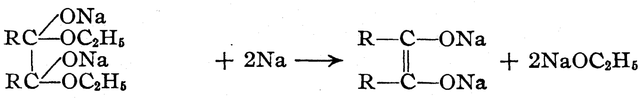


$$2RC(=O)OC_2H_5 + 2Na \longrightarrow \begin{array}{l} RC(ONa)OC_2H_5 \\ | \\ RC(ONa)OC_2H_5 \end{array}$$

---

[10] **Egorova,** ***J. Russ. Phys.-Chem. Soc., 60,*** 1199 (1928); ***Chem. Abstracts,*** 23, 2935 (1929).

This reaction may involve the intermediate formation of a free radical, $R\underset{\overset{|}{\cdot}}{C}(OC_2H_5)ONa$, such as Blicke[11] noted in the reaction of benzaldehyde, phenyl benzoate and ethyl benzoate and sodium. This diketone–sodium ethoxide addition product is then converted by two more atoms of sodium into the sodium salt of the acyloin and sodium ethoxide



$$\begin{array}{l} RC{\diagup}^{ONa}_{OC_2H_5} \\ \ | \\ RC{\diagup}^{ONa}_{OC_2H_5} \end{array} + 2Na \longrightarrow \begin{array}{c} R—C—ONa \\ \| \\ R—C—ONa \end{array} + 2NaOC_2H_5$$

Whether or not the addition product reacts directly with the sodium or first loses sodium ethoxide to allow the free diketone to react with the sodium cannot be decided from any experimental data now available. Egorova[10] has shown that the latter reaction (between the diketone and sodium) does take place with ditrimethylacetyl.

The mechanism of Scheibler and Emden, it might be pointed out, allows for the intermediate formation of diketone–sodium ethoxide addition product in those cases in which the ester involved may enolize. Their mechanism, however, for the reaction of such esters as ethyl trimethylacetate, from which the intermediate formation of the diketone is so apparent in Table I, does not involve this intermediate, and is obviously inadequate.

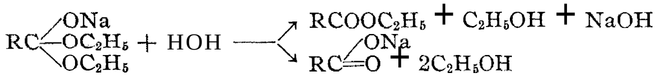
Table II shows that with an excess of ester as the solvent the acetoacetic ester condensation takes place with ethyl acetate and ethyl propionate. Judging from the color of the reaction products, no products of the diketone or acyloin type were formed. With ethyl butyrate very little of the diketone and acyloin, but considerable higher-boiling material with the characteristic yellow color of the diketones is produced. With ethyl isobutyrate the combined yield of di-isobutyryl and isobutyroin is only about 13% lower than those obtained when benzene was used as the solvent but it is seen that the amount of higher-boiling material is correspondingly higher. The very high yield of the acyloin and the absence of any diketone in the case of ethyl trimethylacetate must be due to the favorable conditions for the reaction when the ester is used as the solvent.

The source of the higher-boiling materials is a matter of speculation. It is the opinion of the authors that they are not derived from the acyloin during distillation for the reason, mentioned above, that the acyloin appears to remain practically unchanged after a period of boiling. The fact that the diketones are readily polymerized and rearranged by sodium ethoxide indicates that they are responsible, to some extent at least, for the presence of the higher-boiling materials in the reaction mixture. It is significant that very little or no higher-boiling products are obtained from ethyl trimethylacetate, the diketone of which is quite stable to sodium ethoxide. Added to this probability is the possibility of Claisen condensa-

[11] Blicke, THIS JOURNAL, 47, 229 (1925).

tions between an ester molecule and the diketone or acyloin induced by the sodium ethoxide formed in the reaction in the cases of those esters possessing a structure (two hydrogens on the a-carbon atom) capable of undergoing such a condensation. The fact that ethyl butyrate in Table II shows higher-boiling products almost to the exclusion of the acyloin while ethyl isobutyrate and ethyl trimethylacetate produce quite high yields of the acyloin type would seem to lend support to this latter suggestion.

The high yields of the acids, RCOOH in Table II, are striking. Previous investigators have noted the formation of such acids. Egorova[10] thought that the trimethylacetic acid which he obtained from the action of sodium on trimethylacetyl chloride resulted from the decomposition of the intermediate diketone, ditrimethylacetyl, by alkali. The data in Table II, particularly for ethyl trimethylacetate, show that such an explanation is insufficient for it is seen that practically all (98%) of the sodium put into the reaction was used in the formation of the acyloin and that no diketone could have been present. Still a 45% yield of the acid was obtained. Scheibler and Marhenkel[12] suggested that the acid resulted from one type of hydrolysis of the salt of the ortho ester thus



$$RC\begin{cases}ONa\\OC_2H_5\\OC_2H_5\end{cases} + HOH \longrightarrow \begin{cases}RCOOC_2H_5 + C_2H_5OH + NaOH\\ RC\begin{cases}ONa\\O\end{cases} + 2C_2H_5OH\end{cases}$$

This explanation involves the reaction of the sodium ethoxide produced in the reaction with a portion of the ester which is in excess of that required for the primary reaction and is supported by the fact that high yields of the acid, RCOOH, were obtained in each case when an excess of the ester was used as the solvent. In order to check this possibility, 68 g. of sodium ethoxide was refluxed with 380 g. of ethyl butyrate for thirty minutes. The reaction mixture after cooling was treated with the calculated amount of 35% sulfuric acid as was done in each of the above experiments. A yield of 49 g. (56% based on the sodium ethoxide) of butyric acid was obtained from the sodium carbonate extract.

It is apparent from the data presented above that sodium produces two distinct types of reaction with aliphatic esters, the acetoacetic ester condensation and the acyloin type of condensation. Whether or not the metal is directly responsible for the former type of reaction cannot be definitely decided from any experimental facts now known. There is no doubt, however, that the metal is the direct cause of the acyloin condensation and the simultaneous production of sodium ethoxide. It is quite probable that it is this latter compound that is responsible for any acetoacetic ester type of condensation which may take place. Obviously the alcohol produced in this latter condensation would react with the metal to produce more of the active condensing agent. Such a functioning of the sodium has been

---

[12] Scheibler and Marhenkel, *Ann.*, **458**, 8 (1927).

previously suggested by Higley.[13] Some significance, therefore, may be attached to the fact that those esters, ethyl acetate and ethyl propionate, which are the most sluggish in their reaction with sodium in the inert solvents, react through the acetoacetic ester condensation when an excess of the ester is the solvent.

Summary

1. The reaction of ethyl acetate, propionate, butyrate, isobutyrate and trimethylacetate with sodium has been studied under various conditions.
2. The mechanisms which have been proposed for the formation of acyloins are discussed on the basis of the experimental results obtained.

[COMMUNICATION NO. 449 FROM THE KODAK RESEARCH LABORATORIES]

A HEAT COAGULABLE PROTEIN FROM GELATIN

BY S. E. SHEPPARD, J. H. HUDSON AND R. C. HOUCK

RECEIVED DECEMBER 1, 1930 PUBLISHED FEBRUARY 9, 1931

In a report on the specification of a standard gelatin[1] attention was called to the desirability of specifying the permissible amount of heat coagulable protein in a standard gelatin. The presence of albuminous substances in gelatin has been frequently indicated, especially in articles dealing with its manufacture and purification.[2]

The following is an account of some preliminary work on the estimation, separation, and analysis of the heat coagulable protein from a number of different gelatins.

The results are insufficient to decide whether the substance is a single homogeneous protein or a mixture. They do, however, definitely establish its nature, in gelatin, as a foreign impurity of different constitution and composition.

Experimental

In separating the coagulable protein from gelatin it is found necessary first to adjust the P_H of the gelatin, with acetic acid, to near the isoelectric point of gelatin. Fifty grams of a gelatin with a P_H range of 5.9 to 6 dissolved in 800 cc. of water will require about 5 cc. of glacial acetic acid to bring the P_H to 4.7. Heating overnight on a steam-bath at a temperature of 80 to 100° is sufficient to hydrolyze the gelatin and allow the protein to

coagulate. Fifty grams of a de-ashed gelatin (PH4.9) in 800 cc. of water is treated with only 0.5 cc. glacial acetic acid and heated to effect coagulation.

The clear gelatin solution is decanted off through a coarse filter paper and the coagulum is broken up in the beaker by a stream of hot water, after which it is washed into the filter. Washing with hot water is continued until all the gelatin solution is removed from the coagulated protein. The protein is finally collected in the cone of the filter and then transferred, with a stream of water, to a weighing bottle. The water is evaporated off and drying completed in the oven at 105 to 110°. The amounts of coagulable protein were determined in various gelatins and the protein was analyzed for nitrogen.

TABLE I

ASH AND WATER FREE BASIS

Gelatin	Protein, %	Percentage N on protein	Origin
X1	0.37	14.6	Domestic calfskin, dc-ashed
X2	.63	14.6	Same

Isoelectric Point of Coagulated Proteins.—The material is obtained in coarse flocks, which are insoluble in water and in weakly acid and alkaline solutions Methods of determining the isoelectric point by desolvation are not, therefore, applicable. Neither was the form of the material suitable for cataphoretic determinations, although it is believed that we have now available a method for rendering it suitable, and this will be tried in later work. The method used was that of electro-endosmose, the inverse of electrophoresis. In this process, liquid is moved under the influence of a potential instead of the particle. A porous plug is formed of the material and brought between the two electrodes. Solutions of known PH are put in contact with the plug and the direction of flow of liquid through the plug is observed under an applied potential difference. The plug assumes a charge on coming into contact with the solution, the nature of the charge, positive or negative, depending on the PH of the solution and the isoelectric point of the material. The liquid in contact becomes oppositely charged, an electrical double layer being set up. By setting up a potential across the plug this layer is disturbed and liquid flows in one direction or the other; if on the alkaline side of the isoelectric point it flows toward the cathode, and if on the acid side toward the anode.

The apparatus employed was similar to that described by Briggs, Bennett and Pierson.[3] It is shown diagrammatically in Fig. 1, but it differs from that of Briggs in that the part which contains the plug is separable from the rest of the apparatus. This was found to be necessary because of the nature of the material used, since a satisfactory plug could not be obtained by filtering, as was done by Briggs and his co-workers. It was also desired to remove any doubt which might be cast on the results as being due to the presence of cotton or glass wool supporting the plug.

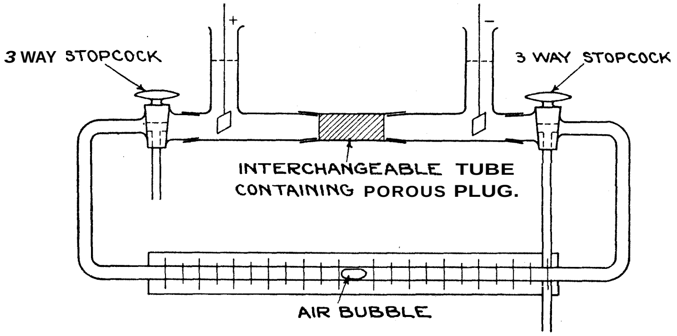

Fig. 1.—Electro-endosmose apparatus.

Accordingly the center portion of the apparatus was made an interchangeable unit in a centrifuge tube; the plug was formed by centrifuging, and then the plug along with the supporting tube was placed in the endosmose apparatus. Satisfactory plugs were obtained in this manner. The material was stirred up with the buffer to be used before centrifuging.

The plug having been formed and placed in position, the buffer of known PH, with which the material had been stirred before centrifuging, was poured into the apparatus and all air bubbles were removed by tilting the apparatus. A loose plug was then tested for by closing both stopcocks and pouring in more buffer on one side and watching the levels in the anode and cathode compartments. If the levels remained stationary the experiment was continued. If not, a new plug was formed. The stopcocks were opened and after the levels had become stationary the current was turned on. In most of the experiments a potential of 110 volts was applied across the plug. The direction of flow was observed and in cases where possible

---

[3] T. R. Briggs, H. S. Bennett and H. L. Pierson, *J. Phys. Chem.*, **22**, **256** (1928)

the rate of flow determined. The direction of the current was then reversed and direction of flow and rate checked.

TABLE III

ISOELECTRIC POINT OF EGG ALBUMEN COAGULATED BY HEAT

Pa of buffer	Direction of flow through plug	Rate of flow, cm./min.
5.4	Cathodic	0.74
5.0	Cathodic	.10
4.8	Cathodic	.007
4.6	Anodic	.006
4.2	Anodic	.30
3.8	Anodic	.51

Clark and Lubs buffers, potassium acid phthalate with varying amounts of hydrochloric acid or sodium hydroxide, were employed. The *PH* values of a number of these were checked electrometrically and found to be satisfactory.

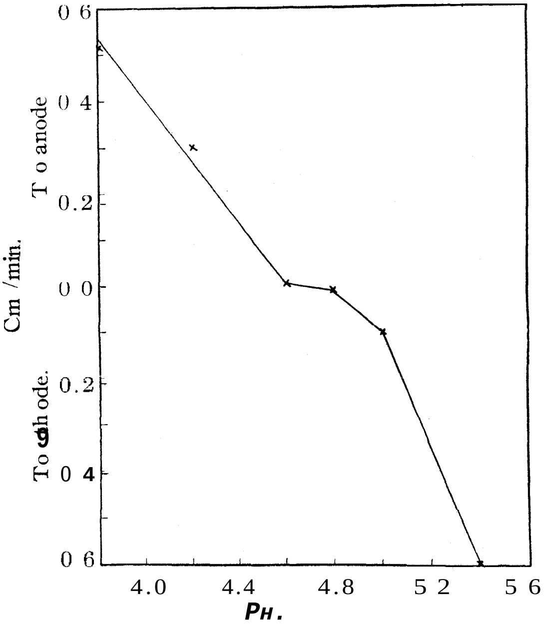

Fig. 2—Isoelectric point of egg albumen denatured by heat.

Egg Albumen.—The results obtained with egg albumen denatured by heat are shown by Table III and Figure 2.

The egg albumen was precipitated by heating from a 4% solution of dialyzed material.

The results indicate a value of *PH* 4.7 as the isoelectric point of egg albumen denatured by heat. The values of the isoelectric point of genuine egg albumen vary: from a *PH* of 4.7 as found by Loeb[4] and by Reinders and Bendien,[5] to a *PH* of 4.8 as found by Svedberg and Tiselius,[6] and to a PH of 4.95 as found by Abramson[7] and by Prideaux and Howitt.[4]

---

[4] J. Loeb. "Proteins and the Theory of Colloidal Behavior," Chapt. 8, "Membrane Potentials," McGraw-Hill Book Co., New York, 1922, pp. 120–150. Prideaux and Howitt, *Proc. Roy.* Soc. (London), 126, 126 (1929). (Calculated from Loeb's figures of membrane potentials.)

[5] W. Reinders and W. M. Bendien, *Rec. trav. chim.*, 47, 977 (1928).

[6] T. Svedberg and A. Tiselius, THIS JOURNAL, 48, 2272 (1926).

[7] H. A. Abramson, *ibid.*, 50, 390 (1928).

Thus, it seems fairly safe to say that the isoelectric point of egg albumen is not appreciably changed by being denatured by heat.

Protein Coagulated from Gelatin Sols by Heat.—The isoelectric point of the material coagulated from gelatin by heat was determined in a similar manner. The results are not quite as good as with egg albumen, as it seemed impossible to obtain rates of flow. The results obtained showed the *isoelectric point of this material to be at a PH of 3.9 to 4.2,* depending on the gelatin employed. The experimental results are shown by Tables IV and V.

The isoelectric point lies between PH 3.85 and 4.0.

Discussion

The analyses of the material for nitrogen, although not concordant for different gelatins, were in good agreement for the same make. The nitrogen content is in every case much lower than that of gelatin itself (*ca.* 18%) and approaches that of albumins. On the other hand, the total sulfur and labile sulfur contents definitely distinguish it from serum albumin and egg albumen. The lower isoelectric point is in agreement with the lower nitrogen content, although there is no necessity of this following, since it depends, *e. g.,* upon proportion of diamino to monamino acids.

In some properties the material resembles keratose, as described by Wilson, but the low sulfur content is in disagreement with this. More complete analyses are required before the constitution can be established.

Relation to Fractionation of Gelatin.—A so-called "insoluble gelatin fraction" was separated by Knaggs, Manning and Schryver,[8] and their work was extended by Kunitz and Northrop.[9]

The coagulable protein from gelatins appears to be identical with the "insoluble fraction of gelatin" found by Kunitz and Northrop.[9] In their procedure the isoelectric gelatin is dissolved to a 2% solution and kept at a constant temperature of 23° for five or six days. The gelatin solution turns milky, thickens and finally breaks up into clots and precipitates.

---

[8] J. Knaggs, A. B. Manning and S. B. Schryver, Biochem. J., 17,473 (1923).

[9] M Kunitz and J. H. Northrop, *J. Gen. Physiol.,* 12, 379 (1929).

After separating the coagulum from the solution it is redissolved and the procedure repeated twelve or fifteen times. A water-insoluble fraction is obtained at the end amounting to only about 1% of the original amount.

A similar substance was obtained by Kunitz and Northrop when they hydrolyzed a 5% solution of gelatin in $M/10$ hydrochloric acid at 90°.

If the "insoluble gelatin fraction" separated by Kunitz and Northrop is actually no constituent of gelatin at all, but a protein impurity, it seems unlikely that it is essential to the swelling mechanism, as suppose by them. We have obtained a gelatin which had merely a trace of this material, but which showed all the usual swelling properties of gelatin, and equal jelly strength and viscosity. We are continuing investigations on this foreign protein and its removal from gelatin.

Summary

It is found that gelatin prepared from calf-skins usually contains a small amount—less than 1%—of a heat coagulable protein as an impurity. The protein approaches albumin (egg albumen and serum) in nitrogen content (around 14%). Its organic sulfur content is considerably higher than that of gelatin (0.8 compared to 0.24%). Its isoelectric point lies at about PH 4.0. It is suggested that the so called "insoluble" gelatin of various investigators is identical with this protein impurity.

THE CONSTITUTION OF HOMOMESITYL OXIDE[1]

BY S. G. POWELL AND C. H. SECOY

RECEIVED DECEMBER 1, 1930 PUBLISHED FEBRUARY 9, 1931

The homomesityl oxide derived from 2-butanone has been prepared by numerous investigators.[2] Earlier workers made no attempt to determine its structure, while later investigations produced some evidence that it has the formula $C_2H_5(CH_3)C{=}CHCOC_2H_5$.

Since 2-butanone reacts with aldehydes to give compounds of the type $RCH{=}C(CH_3)COCH_3$, one would expect the structure $C_2H_5(CH_3)C{=}C(CH_3)COCH_3$, and as the evidence in favor of the other formula was not conclusive and involved some contradictions, this investigation was undertaken to determine definitely the constitution of the homomesityl oxide.

---

[1] This paper is an abstract of a thesis offered by C. H. Secoy in partial fulfilment of the requirements for the degree of Master of Science in the University of Washington.

Chem. Soc.*, 121, 1303 (1922); (h) Ekeley and Howe, THIS JOURNAL, 45, 1917 (1923); (i) Franke and Köhler, *Ann.*. 433,314 (1923).

The formula of the homomesityl oxide from 2-butanone was conclusively shown to be $C_2H_5(CH_3)C{=}CHCOC_2H_5$ by hydrogenating it and identifying the resulting octanone as 5-methyl-3-heptanone. Guerbet[3] prepared 5-methyl-3-heptanone and reported the melting point of its semicarbazone as 96°, whereas Bodroux and Taboury reported 102° as the melting point of the semicarbazone of the octanone obtained from homomesityl oxide. As Guerbet's evidence for the structure of his ketone is not very complete, 5-methyl-3-heptanone was prepared by the oxidation of the 5-methyl-3-heptanol obtained by the Grignard synthesis from 1-bromo-2-methylbutane and propionaldehyde. The semicarbazone of this 5-methyl-3-heptanone melted at 96°, as did that of the octanone obtained by hydrogenating homomesityl oxide, contrary to the findings of Bodroux and Taboury. In addition, the properties of the octanol resulting from reduction of homomesityl oxide corresponded with those of the 5-methyl-3-heptanol mentioned above.

As further evidence, the octanone was oxidized and the resulting acids identified as acetic (by conversion to the *p*-bromophenacyl ester) and *sec.*-butylacetic (by comparison of the amide with the amide of known *sec.*-butylacetic acid).

Furthermore, a homomesityl oxide with the structure $C_2H_5(CH_3)C{=}C(CH_3)COCH_3$ would yield on reduction 3,4-dimethyl-2-hexanone. A ketone with this constitution was prepared by the hydrolysis of ethyl *sec.*-butylmethylacetoacetate and was found to differ from the octanone obtained from homomesityl oxide.

Of the previous attempts to determine the structure of homomesityl oxide, that of Becker and Thorpe is the only one that furnished any positive evidence. They treated it with sodio ethyl malonate, hydrolyzed the resulting product to an ethyldimethyldihydroresorcinol and oxidized this to β-ethyl-β-methylglutaric acid, a product which could only arise from a homomesityl oxide with the formula $C_2H_5(CH_3)C{=}CHCOC_2H_5$. Franke and Kohler assumed this structure because they failed to obtain a positive iodoform reaction, which they offer as evidence that the grouping CH_3CO- is absent. In this investigation it was found that chloroform was readily produced by treatment of the homomesityl oxide with sodium hypochlorite and that in the presence of sodium iodide a small quantity of iodoform was also produced. This apparently contradictory evidence is readily explained if preliminary hydrolysis to two molecules of 2-butanone is assumed.

Experimental

Homomesityl Oxide.—This was prepared by a method that is essentially that of Bodroux and Taboury.[4] It was found that more satisfactory results could be obtained

---

[3] Guerbet, *Compt. rend.*, 150, 183 (1910).

[4] Bodroux and Taboury, Bull. *soc. chim.*, [4] 3, 831 (1908).

by substituting small muslin bags filled with powdered barium oxide for the lumps of calcium carbide of the original method. In a typical run, 500 g. of 2-butanone yielded 85 g. of homomesityl oxide, b. p. 164–166°, d_4^{21} 0.8633, n_D^{21} 1.4445.

The 2,4-dinitrophenylhydrazone[5] melted at 46°. Chloroform was readily obtained by warning homomesityl oxide with sodium hypochlorite solution, and a small amount of iodoform was produced when sodium hypochlorite solution was slowly added to a well shaken mixture of homomesityl oxide and sodium iodide solution.

Preparation of the Saturated Ketone.—The reduction was carried out as described by Adams and his students,[6] using 0.4 g. of platinum oxide, 31.5 g. (0.25 mole) of homomesityl oxide, and 150 cc. of 95% alcohol. The initial hydrogen pressure was 40 lb.; time of reduction nine minutes; yield of saturated ketone, 94% of the theoretical; b. p. 158°; d_4^{24} 0.829; n_D^{24} 1.412.

The semicarbazone after recrystallization from dilute methanol melted at 96°.

Oxidation of the Saturated Ketone.—Twenty-five grams of the ketone was refluxed for six hours with a mixture of 40 g. of sodium dichromate, 53 g. of sulfuric acid and 200 cc. of water. The whole was then distilled until the residue became quite thick. The distillate was neutralized with sodium hydroxide solution and again distilled until no more unchanged ketone passed over. The residue was acidified and distillation continued, collecting three equal-sized fractions. By refractionation the acids more volatile with steam were concentrated in the first fraction, and the least volatile in fraction 3.

Fraction 1 was extracted several times with ether, the ether solution dried with calcium chloride, the ether removed and the residue distilled. The acid was converted by treatment with thionyl chloride to the acid chloride, which was added drop by drop to concd. aqueous ammonia. The amide which separated on cooling was recrystallized from boiling water and melted at 123°. The amide prepared in the same manner from *sec.*-butylacetic acid (obtained by the ethyl malonate synthesis) also melted at 123°,[7] as did a mixture of the two.

Fraction 3 was neutralized with sodium hydroxide and the solution evaporated to dryness; 0.3 g. of the dry salt was converted into the p-bromophenacyl ester according to the directions of Judefind and Reid.[8] The ester melted at 85° as reported by Judefind and Reid for *p*-bromophenacyl acetate.

Fraction 2, treated in the same manner as fraction 3, proved to contain only acetic acid.

Preparation of the Saturated Alcohol.—Homomesityl oxide was reduced with sodium and moist ether by the method previously described by one of us for the reduction of butylidene ethyl methyl ketone.[9] From 25 g. of homomesityl oxide there was obtained 10 g. of the saturated alcohol boiling at 155°, d_4^{24} 0.8425, n_D^{24} 1.433.

5-Methyl-3-heptanol.—This was prepared by the Grignard synthesis from 36 g. of magnesium, 192 g. of 2-methyl-1-bromobutane, and 100 g. of propionaldehyde. The boiling point, density and refractive index corresponded with those of the saturated alcohol obtained from homomesityl oxide. This is evidently the same alcohol as that obtained by Guerbet[3] by heating 2-butanol with sodium.

5-Methyl-3-heptanone.—Eighteen and one-half grams of 5-methyl-3-heptanol was added drop by drop with constant stirring to a mixture of 15 g. of sodium dichromate, 20

g. of sulfuric acid and 70 cc. of water, keeping the temperature at about 50°. Stirring was continued for thirty minutes after all of the alcohol had been added, and the mixture then distilled until no more oil passed over. The oil was separated, dried with calcium chloride and distilled. The boiling point, density and refractive index were the same as those of the saturated ketone obtained from homomesityl oxide.

The semicarbazone melted at 96°.

3,4-Dimethyl-2-hexanone.—This was prepared by hydrolyzing ethyl *sec.*-butylmethylacetoacetate by the regular procedure. Ninety grams of ethyl acetoacetate yielded 90 g. of crude ethyl methylacetoacetate, which in turn gave 62 g. of pure ethyl *sec.*-butylmethylacetoacetate. The ketone was obtained by refluxing the ester with 300 cc. of 15% aqueous sodium hydroxide; b. p. 158°, d_4^{22} 0.8295, n_D^{22} 1.412.

The semicarbazone melted at 124–126°.

Summary

1. An improved method for the preparation of homomesityl oxide has been described.
2. The structure of homomesityl oxide is definitely established as $C_2H_5(CH_3)C{=}CHCOC_2H_5$.

THE CHEMISTRY OF LIGNIN. V. THE DISTILLATION OF ALKALI LIGNIN WITH ZINC DUST IN AN ATMOSPHERE OF HYDROGEN

BY MAX PHILLIPS

RECEIVED DECEMBER 4, 1930 PUBLISHED FEBRUARY 9, 1931

Considerable difference of opinion prevails among investigators of the chemistry of lignin as to whether this substance belongs to the aliphatic, aromatic, hydroaromatic or heterocyclic series.[1] Among the earliest constitutional formulas for lignin may be mentioned the Keto-R-hexene formula of Cross and Bevan[2] and that proposed by Green.[3]

Willstatter and Kalb,[4] as the result of their work on the reduction of lignin with hydriodic acid and red phosphorus, conclude that lignin is structurally related to the carbohydrates. However, none of the products which they obtained were homogeneous, and they were unable to identify any definite chemical substance.

---

[1] An excellent résumé of the literature up to 1926 dealing with the constitution of lignin is given by K. Kiirschner in his monograph, "Zur Chemie der Ligninkörper," p. 141, published in F. B. Ahrens' "Sammlung Chemischer und Chemischtechnischer Vortrage," Vol. 28, Ferd. Enke, Stuttgart, 1926, and in the monograph by W. Fuchs, "Die Chemie des Lignins," Julius Springer, Berlin, 1926, p. 277.

[2] Cross and Bevan, "Cellulose," Longmans, Green and Co., London, 2d ed , 1895, p. 137; Vol. III, 1912, p. 104.

[3] Green, *Z. Farben* Textilchemie, 3, 97 (1904).

[4] Willstatter and Kalb, *Ber.*, 55, 2637 (1922).

Jonas[6] and Marcusson[6] contend that lignin is not aromatic but is made up of furan nuclei.

Schrauth[7] assumes that the fundamental unit of the lignin molecule is formed by the condensation of three molecules of 5-hydroxymethylfurfural. The unit so formed consists of a compact condensed ring system, of which three of the outer rings are furan nuclei and the other three outer rings and the central ring benzene nuclei.

The constitutional formulas for lignin, which at various times have been advanced by Klason,[8] all contain at least one aromatic nucleus, generally some coniferyl derivative coupled with a heterocyclic nucleus.

Kürschner,[9] as the result of his investigations on the sublimation of lignin, advanced the hypothesis that lignin is a polymer of the glucoside coniferin. Freudenberg, Belz and Niemann[10] have recently come out in favor of an aromatic structure for lignin. In a more recent publication Freudenberg, Zocher and Dürr[11] advanced the hypothesis that lignin is a condensation product of a-vanillyl-glycerine and a-piperonyl-glycerine.

The present investigation was undertaken with the hope of obtaining degradation products of lignin that would help to clear up even in part the structure of this substance. It was felt that a zinc dust distillation of lignin in an atmosphere of hydrogen might lead to definite degradation products which would throw some light on the chemistry of this compound.

The only work reported in the literature on the zinc dust distillation of lignin is that by Karrer and Bodding-Wiger.[12] They heated lignin with zinc dust at red heat and obtained an oil which they fractionated. None of the fractions were oxygen free, nor did they appear to be homogeneous, nor did these authors identify any definite chemical substance in their distillation product.

In the present investigation three phenolic substances were isolated, two of which were identified as catechol and guaiacol. The third phenol gave a crystalline dinitrobenzoyl derivative melting at 110° and contained the methoxyl group but was not further identified. It was probably a homolog of guaiacol. It is believed that the results obtained in this investigation tend to give support to the hypothesis that at least one aro-

matic nucleus exists in the lignin molecule.[13] The presence of other nuclei in addition to the aromatic nucleus is however not excluded.

In all of the experiments, considerable amounts of carbon dioxide were evolved during the distillation. This may be explained on the assumption that lignin contains either a lactone, carboxyl or esterified carboxyl group. Van der Haar[14] has recently shown that only those substances which contain two oxygen atoms attached to the same carbon atom, that is to say, carboxylic acids and their esters and lactones give off carbon dioxide when subjected to a zinc dust distillation in a current of hydrogen. Ketones, aldehydes, alcohols, phenols, quinones, purine derivatives and pyrones do not give off carbon dioxide under these conditions.

Experimental

The apparatus used in these experiments is illustrated in Fig. 1. It consisted of a glass tube, B, 3.5 cm. outside diameter and 45 cm. long. This tube was constricted at one end and bent at a right angle in the form of an adapter. This was attached to a vertical condenser F, to which, in turn, was attached a 300-cc. Erlenmeyer flask, G, the inner tube of the condenser reaching to within about one centimeter of the bottom of this flask. The latter was connected in series to two other 300-cc. Erlenmeyer flasks, G′ and H. Flasks G, G', which served as receivers for the distillate, were immersed in an ice-bath. Flask H contained barium hydroxide solution to collect any carbon dioxide that might come over. The glass tube was inserted into an asbestos-covered metal tube (A) 8.6 cm. in diameter, which served as an air-bath and was held in place by transite end pieces C. This tube was heated by means of three fishtail burners J. The temperature of the bath was determined by means of thermometer D. Dry hydrogen was led into the system through tube E.

The glass tube (B) was filled as follows. A plug of glass wool was placed at the constricted end of the tube. This was followed by a 10-cm. layer of pumice about the size of peas which had been impregnated with zinc dust. The coating of the pumice with zinc dust was accomplished as follows. A paste was prepared by rubbing up 100 g. of zinc dust with 30 cc. of water. The pumice was added to this and the mixture stirred until the pumice was well covered with the zinc dust paste. The pumice was then removed from the paste and dried.

After the pumice–zinc dust layer was placed a mixture consisting of 50 g. of alkali lignin[15] and 150 g. of zinc dust to which had been added some pumice impregnated with zinc dust. Finally a 5-cm. layer of pumice–zinc dust was added.

The distillation experiment was begun by passing through the system a fairly rapid stream of dry hydrogen until all of the air was replaced. The current of gas was then diminished so that only about three bubbles per second passed through. Heat was

---

[13] It may be of interest to point out in this connection that phenol ethers had previously been found in the oil obtained by the destructive distillation of lignin (W. Fuchs, "Die Chemie des Lignins," Julius Springer, Berlin, 1926, p. 151).

[14] Van der Haar, *Rec. trav. chim.*, 48, 1170 (1929).

[15] The lignin used in these experiments was isolated from corn cobs following the method described in a previous communication [THIS JOURNAL, 51, 2420 (1929)]. It was purified by dissolving in alcoholic sodium hydroxide solution, filtering, distilling off the alcohol and precipitating the lignin with hydrochloric acid. It was washed free from chlorides and dried in *vacuo* at 80°.

then applied under the front and rear ends of the tube containing the layers of pumice–zinc dust. Finally the mixture of lignin and zinc dust was gradually heated until the temperature of the air-bath was 400°. Throughout the experiment the temperature was not permitted to exceed 400°. At first a considerable amount of gas was evolved, including carbon dioxide which was indicated by the barium hydroxide solution first becoming milky and by the subsequent deposition of a precipitate of barium carbonate. Carbon dioxide was given off in all of the experiments.

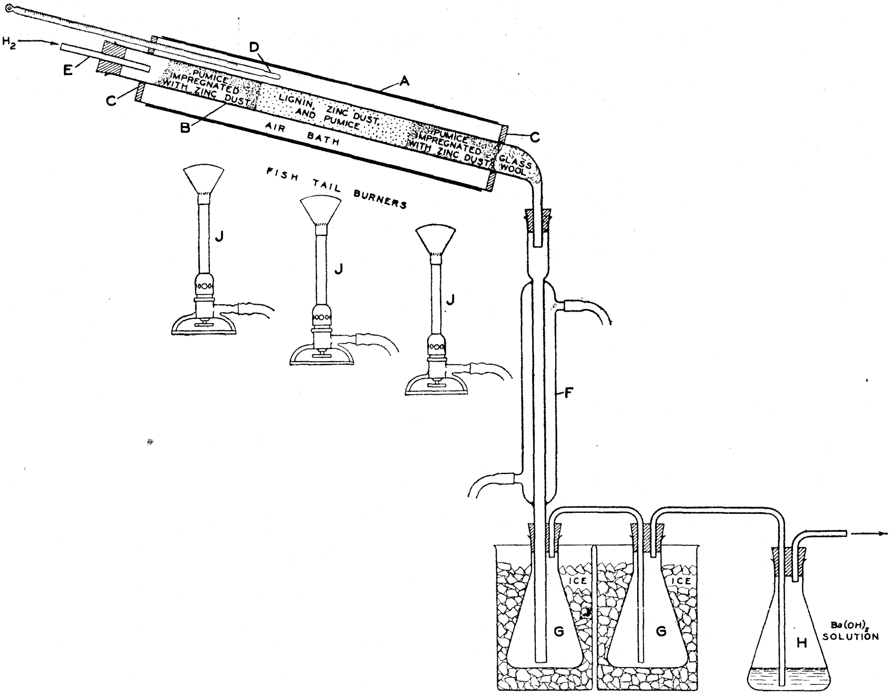

Fig. 1.—Apparatus for distillation of lignin with zinc dust in atmosphere of hydrogen.

Examination of the Distillate.—The distillate consisted of an aqueous portion together with an oil. The combined distillates from five experiments representing a total of 250 g of lignin were combined and worked up. The aqueous portion was separated off, shaken with activated charcoal (Darco) as recommended by Stritar and Zeidler,[16] filtered and the filtrate made up to 500 cc. The oily portion was dissolved in an equal volume of ether, dried over anhydrous sodium sulfate and filtered. Upon removal of the ether by distillation, a brown oil was obtained. The yield was 40 g., equal to 16% of the weight of the lignin used.

Examination of the Aqueous Portion.—The acid in the aqueous distillate was determined by titration with standard alkali and amounted to 0.24% (calculated as acetic acid and on the basis of the weight of lignin used).

The acetone was determined by the Messenger[17] method, which was carried out as

---

[16] Stritar and Zeidler, Z. *anal.* Chem., 43, **387** (1904).

[17] Messenger, ***Ber.***. 21, **3366** (1888).

described in a previous communication.[18] The acetone amounted to 0.36% of the weight of the lignin used.

Two 5-cc. samples were analyzed for methanol by the method of Stritar and Zeidler.[16] The weight of silver iodide obtained amounted to 0.1087 g. (mean of two determinations) which corresponds to 1.48% of methanol in the total distillate and equals 0.59% of the weight of lignin used.

The aqueous distillate gave with ferric chloride solution a green coloration which became red on the addition of sodium carbonate. It gave all the other characteristic tests for catechol.[19]

The aqueous distillate gave no test for furfural with aniline acetate paper and none of the tests for ω-hydroxymethylfurfural.[20] Fuchs[21] obtained ω-hydroxymethylfurfural on the distillation of technical pinewood lignin with powdered silver in an atmosphere of carbon dioxide.

Examination of the Oil.—The oil was dissolved in an equal volume of ether and the ether extracted with 5% sodium hydroxide solution. The alkaline extract was then acidified with hydrochloric acid and the oil separated mechanically from the aqueous portion. This was extracted with ether and the phenolic oil previously separated was added to the ether solution. This solution was dried with anhydrous sodium sulfate, filtered and the ether removed by distillation. A dark brown oil was obtained which amounted to 22 g. (equal to 55% of the weight of the original oil). This oil was distilled in a current of steam, and a light yellow oil was obtained which amounted to 11 g. (equal to 27.5% of the weight of the original oil). This oil was first distilled under ordinary pressure and the distillate fractionated under the same pressure. Two fractions were obtained, namely, 200–210" and 210–220°. The amount of each fraction was 4 g. and 3.5 g., respectively. Each fraction gave a greenish color with ferric chloride in alcoholic solution. A portion of fraction 200–210° (1 g.) was added to a solution of 2.3 g. (0.01 mole) of 3,5-dinitrobenzoyl chloride in 20 cc. of pyridine, and the solution heated at its boiling point under the reflux condenser. The solution after cooling was poured into cold dilute sulfuric acid. The yellow and rather viscid substance which separated out was dissolved in ether, the ether solution extracted with 5% sodium hydroxide solution and the ether removed by distillation. A solid crystalline substance was obtained. This was crystallized from 95% ethanol and recrystallized from methanol and ligroin when a substance melting constantly at 141° (corr.) was obtained. The 3,5-dinitrobenzoyl derivative of pure guaiacol was prepared, and the same melting point was obtained. When the two compounds were mixed the resulting mixture was also found to melt at 141°. Fraction 200–210°, therefore, consisted principally of guaiacol. The 3,5-dinitrobenzoyl derivative of a portion of fraction 210–220" was prepared following the method above described. The product, after several recrystallizations from ethanol, methanol and ligroin, melted at 110°. The melting point, however, was not sharp and even after three other recrystallizations it was not possible to obtain a product having a sharp melting point.

Anal. Subs., 0.0800: required 2.50 cc. of 0.2 N acid. Subs., 0.0374: AgI, 0.0223 Found: N. 8.75; OCH_3, 7.88.

The percentages of nitrogen and methoxyl in the dinitrobenzoyl derivatives of guaiacol and creosol are, respectively: N, 8.80, 8.43; OCH_3, 9.74, 9.34. Fraction 210–220° consisted of some undetermined phenol, possibly some homolog of guaiacol.

[21] Fuchs, Bar., 60, 957 (1927).

The residue in the flask after the steam distillation of the phenols was a black tarry substance and amounted to 4 g. It was distilled under 15 mm. pressure, and practically all distilled over at 150–190°. Nothing definite, however, was obtained from this fraction.

The ether solution of the oil which had been extracted with 5% sodium hydroxide solution was washed with water and then dried with anhydrous sodium sulfate, filtered and the ether removed by distillation. A dark brown oil was obtained. This amounted to 10 g. (equal to 25% of the weight of the original oil). It was distilled under ordinary pressure, whereupon it all distilled over at 200–220°. The distillate was a light yellow oil.

Anal. Subs., 0.1002, 0.1460: CO_2, 0.2770, 0.4027; H_2O, 0.0705, 0.0981. Found: C, 75.38, 75.22; H, 7.87, 7.51. Subs., 0.0774; AgI, 0.0971 = 16.57% OCH_3.

This neutral substance is therefore an ether containing approximately one-half of its oxygen of the form of methoxyl. It did not react with acetic anhydride or benzoyl chloride nor with hydroxylamine or phenylhydrazine. Hydroxyl and carbonyl groups are therefore not present in this substance, and the residual oxygen exists probably in some ring combination.

Estimation of the Amount of Carbon Dioxide Given Off in the Zinc Dust Distillation of Lignin.—Although van der Haar[13] in applying the zinc dust distillation method for the quantitative determination of carboxyl groups has shown that the method invariably gives low results, it seemed nevertheless of interest to determine the approximate amount of carbon dioxide given off it? the zinc dust distillation of lignin. Accordingly, three experiments were conducted in which 5 g. of lignin and 50 g. of zinc dust were used in each case. The distillation was conducted with the apparatus and under the experimental conditions previously described. The carbon dioxide given off was absorbed in a barium hydroxide solution contained in flask H (Fig. 1). The barium carbonate formed was filtered off and washed with water, free from carbon dioxide, until the wash water was no longer alkaline. The carbonate was dissolved in warm dilute hydrochloric acid and the barium determined as the sulfate. From the weight of barium sulfate obtained the quantity of carbon dioxide was calculated. The results obtained were as follows:

$BaSO_4$, g.	CO_2, g. (calcd. from $BaSO_4$)
1.0756	0.2027
1.0520	.1983
1.0807	.2037

Mean 0.2015 $\approx$ 0.2060 g.–COOH = 4.12%

Assuming that the composition of corn cob lignin may be represented by the formula $C_{40}H_{46}O_{16}$[22] and on the basis of one carboxyl group, the calculated value is 5.75% of COOH.

Summary

1. Alkali lignin, isolated from corn cobs, was distilled with zinc dust in an atmosphere of hydrogen. The distillate consisted of an aqueous portion and an oil. The aqueous distillate contained methanol, acetone and an acid (determined as acetic acid) to the extent of 1.48, 0.36 and 0.24%, respectively (calculated on the basis of the weight of lignin used). Catechol was shown to be present in the aqueous distillate. The yield of

---

[22] Phillips, THIS JOURNAL, 49,2037 (1927).

oil obtained amounted to 16% of the weight of the lignin used. Fifty-five per cent. of the oil was alkali-soluble, and in this fraction guaiacol was definitely identified. A phenol containing the methoxyl group and yielding a 3,5-dinitrobenzoyl derivative melting at 110° was also obtained but was not further identified.

2. The isolation of catechol and guaiacol as degradation products of lignin is believed to lend support to the hypothesis that lignin contains an aromatic nucleus.

3. The evolution of carbon dioxide in the zinc dust distillation of lignin in an atmosphere of hydrogen indicates that, in all probability, the lignin molecule contains at least one carbon atom directly united to two oxygen atoms. This may indicate the presence of either a carboxyl group, free or esterified, or a lactone group in the lignin molecule.

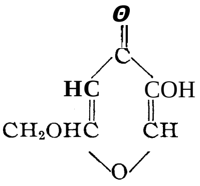
[185TH CONTRIBUTION FROM THE COLOR AND FARM WASTE DIVISION, BUREAU OF CHEMISTRY AND SOILS, U. S. DEPARTMENT OF AGRICULTURE]

THE PRODUCTION OF KOJIC ACID BY ASPERGILLUS FLAVUS

BY O. E. MAY, A. J. MOYER, P. A. WELLS AND H. T. HERRICK

RECEIVED DECEMBER 5, 1930 PUBLISHED FEBRUARY 9, 1931

In the course of a survey of the action of a number of fungi on solutions of xylose and dextrose it was observed that the culture liquors from a strain of *A. flavus* on both sugars gave a deep red coloration upon the addition of ferric chloride solution. Continuous extraction of these cultures with ether yielded a quantity of material crystallizing as colorless needles, soluble in water, methanol, ethanol and ethyl acetate. It was identified as kojic acid by its melting point (152.6' (corr.); Yabuta, 152°; Mauer, 152°; Kinoshita, 154°), by the melting point of the mono-bromo derivative (161° (corr.); Yabuta, 159–160°), and by analysis of the insoluble copper salt (found, average of six determinations, 22.40% CuO. Calcd. for $Cu(C_6H_5O_4)_2\cdot{}^1/_2H_2O$, 22.44%; Mauer found 22.12% CuO). The crystalline products obtained from the xylose and dextrose solutions were identical in all their properties.



Kojic acid was first isolated by Saito[1] from mycelia of *A. oryzae* which had been cultured on steamed rice. He thought it to be identical with β-resorcylcarboxylic acid. Shortly thereafter Yabuta[2] undertook an extensive investigation of the substance, gave it the name kojic acid and.

finally, in 1924, definitely established its constitution. Traetta-Mosca reported the formation of the same compound by A. *glaucus* from sucrose, levulose, dextrose and glycerol and also noted that it was fermented to ethanol by yeast.[3] Wijkman, using an unnamed strain of Aspergillus and employing quartz or paraffined glass vessels as culture flasks, consistently obtained the acid from sucrose.[4] Kinoshita has observed that a deficiency in the supply of nutrient nitrogen resulting from the use of cobalt ammines as nitrogen sources caused an increased production of kojic acid by a strain of A. oryzae. Thus, when cobalt purpureo chloride in a concentration of 0.5% was used as the source of nutrient nitrogen, 33% yields by weight were obtained from 10% sucrose solutions in twenty-five days.[5] Tamiya found that a P_H of 5.5 was most favorable to the formation of the acid by *A.* oryzae and later reported the production of the compound from sucrose by the following Aspergilli: oryzae, *flavus* var., *gymnosardae*, *awamori*, *candidus*, *clavatus*, fumigatus and *giganteus*.[6] Challenger, Klein and Walker pointed out that, from the standpoint of molecular structure, since dextrose yields kojic acid, arabinose might by analogy be expected to give rise to pyromeconic acid. To test this hypothesis, they cultured a strain of A. oryzae on solutions of highly purified arabinose and xylose. Kojic acid was the only pyrone compound found in the culture liquors. Moreover, they recovered it from the pentose cultures in yields of the same order of magnitude as those obtained from dextrose.[7] Katagiri and Kitahara found the optimum conditions for the formation of kojic acid by *A.* oryzae to be in 5% dextrose solutions containing 0.05% ammonium sulfate, at P_H 2.4.[8] Corbellini and Gregorini made a study of the formation of the acid from various carbon sources by different strains of A. *flavus* and concluded that the pyrone nucleus was synthesized from substances containing a chain of three carbon atoms resulting from the fragmentation of larger molecules such as the pentoses and hexoses.[9] Starting with acetobromoglucose, Mauer has recently succeeded in synthesizing kojic acid, confirming the structure established for the natural product by Yabuta.[10]

Continuous extraction with ether of a ten-day culture of *A. flavus* No. 3538 on 15% solutions of commercial dextrose yielded 22.69 g. of pure kojic acid per 100 g. of pure dextrose originally present in the culture solution. The comparatively high yield obtained in this short period of culture led

to an investigation of some of the more important variables affecting the fermentation, such as nutrient salts, temperature and concentration of dextrose, with a view to increasing the yields to a point which would make **the** process of industrial interest and stimulate a search for uses for this hitherto unavailable pyrone.

Experimental

The organism (No. **3538)** was secured from the collection of Dr. Charles Thom, where it had been kept in continuous culture since 1914. Its appearance was typical of the *flavus–oryzae* group and its mycological characteristics are to be described in a forthcoming publication.

For the most part, the experiments were carried out in 200-cc. pyrex glass Erlenmeyer flasks as culture flasks. The dextrose was of commercial grade and contained approximately 91.5% dextrose, 8.0% water, 0.5% dextrin and other non-reducing carbohydrates. Nutrient salts were added in the following concentrations, except when stated otherwise.

	G./liter of dextrose solution
$MgSO_4{\cdot}7H_2O$	0.500
KCl	.100
H_3PO_4	.054
NH_4NO_3	1.125

Seventy-five cc. of culture solution per flask was used to give a surface area/volume ratio of approximately 0.4. The solutions were sterilized for fifteen minutes at 15 lb. steam pressure and after cooling were inoculated with spores of the organism. All cultures were run in duplicate or triplicate.

At the conclusion of the fermentation the contents of the culture flask were heated and filtered with suction through a weighed filter paper. The mycelium was thoroughly washed with three 25-cc. portions of hot distilled water, the washings were added to the culture liquors and the volume of the combined solutions was noted. The filter paper and mycelium were placed in a tarred weighing bottle, dried at 90° for two days and the weight of the dry mat was obtained. Reducing sugar, calculated as dextrose, was determined by the Shaffer–Hartman method, using the citrate–carbonate reagent. In the presence of kojic acid it was impossible to determine the true end-point in the thiosulfate titration when starch was used as the indicator because of the difficulty in discharging the starch–iodine color. For this reason starch was not used, and the typical sharp color change from green to blue was utilized to indicate the disappearance of the iodine. However, in experiments where the concentration of kojic acid exceeded **3** g. per 100 cc. of solution, control titrations indicated that a true end-point was not obtained. In such cases it was necessary to dilute the sample so that the above-mentioned concentration of acid was not exceeded or, where the concentration of sugar was low, to remove the acid as the insoluble copper salt and make the determination on the filtrate. Since kojic acid reduces hot alkaline copper solution, a correction, determined by the quantity of acid present, was applied to the values obtained for reducing sugars. The reduction values of kojic acid in terms of mg. of copper were determined and are given in Table I.

TABLE I

KOJIC ACID REDUCTION VALUES

Kojic acid, mg.	5	10	20	30
Cu, mg.	9.5,	17.0,	35.0,	52.0

The acid was determined by neutralization of an aliquot of the culture liquors with dilute alkali and precipitation of the partially hydrated copper salt with $N/10$ cupric acetate. The precipitate was dried at 100°, weighed and the acid calculated on the basis of $Cu(C_6H_5O_4)_2 \cdot {}^1/_2H_2O$. In the absence of other acids, kojic acid can be estimated accurately by titration with dilute alkali, with alizarin orange R as the indicator. However, in our experiments the culture solutions were invariably colored a deep yellow, which interfered somewhat with the observation of the color change of the indicator.

The yields were calculated as the ratio of the dextrose required to give the quantity of kojic acid formed to the total dextrose originally present in the culture solution.

At the outset of these experiments it became apparent that the source of nutrient nitrogen was of prime importance among the factors governing the formation of kojic acid. The effect on acid production of some nitrogen-containing salts is shown in Table II. Ammonium sulfate was unsatisfactory, and it is of interest that its use almost completely suppressed sporulation. Ammonium nitrate was most satisfactory. The effect of variation in its concentration is given in Table III. Nitrates, while supporting a vigorous vegetative development, were found to have an adverse effect on acid formation when used in conjunction with the standard salt

solution, as noted in Table II, but when type and concentration of the added salts were changed, a decided increase in the quantity of kojic acid produced was noted, as will be observed in Table IV. That this increase was not due to the direct nutritive value or to physical effects of these added salts is evident from the results with ammonium nitrate, where a slightly lower yield was obtained than in experiments where the standard salt solution was used. With both nitrates and ammonium salts, however, in all cases the use of the B solution induced an appreciably greater vegetative development.

Temperature was found to have a decided effect on the quantity of kojic

acid produced. A range from 30 to 35° promoted rapid vegetative development with high yields of acid as shown in Table V. Respiration was apparently much accelerated at the high temperature.

In a range of sugar concentrations from 15 to 33%, inclusive, growth and acid production were satisfactory, the highest yield, based on the sugar originally present, occurring at a concentration of 20%. It is worth noting that the yields obtained in four different concentrations are practically the same when calculated on the basis of sugar consumed. With concentrations above 40% osmotic pressure apparently had an unfavorable effect, since the production of acid dropped off sharply, as indicated in Table VI.

volume of the solution governs, to a large extent, the yields obtained, especially in shorter periods of culture. The maximum quantities of acid were most economically produced in 12-day cultures when this ratio had a value of from 0.3 to 0.5.

The rates of acid production, sugar consumption and vegetative growth on 20% solutions at 35° are given by the curves in Fig. 1. As soon as the supply of sugar is exhausted, the acid is utilized by the organism and slowly disappears with a corresponding diminution in the weight of the mycelium. Whether the decrease in mass of the mycelium is due to a slow autolysis cannot be definitely stated.

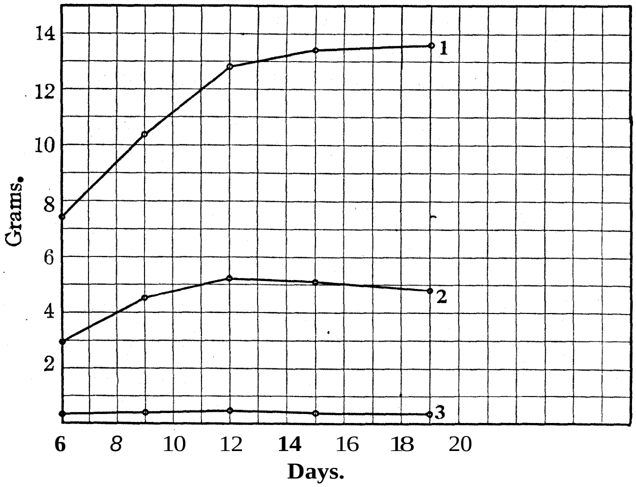

Fig. 1.—1, Sugar consumed; 2, kojic acid produced; 3, dry weight of mycelium.

The formation of this hydroxy pyrone by fungi from carbohydrates in large quantities in a short period of time is a striking phenomenon considering the relatively small quantities of related compounds found in the higher plants. Thus chelidonic acid (2,6-dicarboxy-1,4-pyrone) occurs in the leaves of lily of the valley to the extent of 2% and meconic acid (2,6-dicarboxy-3-hydroxy-1,4-pyrone) is found in opium to the extent of approximately 4%, while maltol (3-hydroxy-2-methyl-1,4-pyrone) is a minor constituent of pine needles and the bark of larches. The fact that pyrones in general react readily with ammonia to form pyridones may have an important bearing on the problem of the origin of pyridine bases found in plants, and the widespread occurrence of flavone compounds in the plant kingdom further emphasizes the importance of the pyrone nucleus in nature. Hence a detailed study of the mechanism of kojic acid formation might throw considerable light on the complete obscurity surrounding the mode of formation of these related substances in the plant cell.

Yabuta[2] thought that the formation of the acid by *A. oryzae* was connected in some manner with the oxidation changes brought about in the reduction of hexoses to the corresponding alcohols, but Kinoshita[5] pointed out that this was not necessarily so, since the organism formed kojic acid when mannitol was used as the sole carbon source. Owing to its close structural relationship to dextrose, Haworth has suggested that kojic acid resulted from the oxidation and dehydration of that hexose,[11] but the yield of acid obtained by Challenger, Klein and Walker from xylose and arabinose, as well as the fact that it is formed when levulose is used as the carbon source, casts doubt on such a mechanism. Moreover, kojic acid has been reported as being produced by Aspergilli from the following additional compounds: starch, inulin, sorbitol, dulcitol, sucrose, mannose, galactose, glycerol, glycero-&phosphate and gluconic acid. Corbellini and Gregorini[9] believe that the pyrone nucleus is synthesized from molecules containing three carbon atoms by a reaction analogous to that brought about by the enzyme carboligase of yeast. They suggest that glyceraldehyde condenses with a molecule of another oxidation product of glycerol to give a product which by dehydration goes over to kojic acid.

The ready formation of pyrone compounds through the dehydration of appropriate acyclic polyketones is well known. Thus dimethylpyrone is formed from diacetylacetone through simple and even spontaneous loss of water at ordinary temperatures and likewise the dehydration of acetonedioxalic acid gives rise to chelidonic acid. If an analogous reaction were postulated as the final step in the formation of kojic acid, the immediate precursor of this hydroxypyrone would be 1-hydroxyacetyl-3-formyl-3-hydroxyacetone ($CH_2OHCOCH_2COCHOHCHO$). Whether this compound could result from reactive oxidation products of either methylglyoxal, glyceraldehyde or acetaldehyde is not known. The results obtained up to the present point to a synthesis of kojic acid from some reactive substance, as yet not isolated, containing two or three carbon atoms, and evidence is slowly accumulating that definitely indicates the production by fungi of such compounds of low molecular weight. The formation of acetaldehyde in the metabolism of several molds has been demonstrated,[12] but its biological significance is not yet clear. As a result of a study of this aldehyde in the citric acid fermentation induced by *A. niger,* Bernhauer concluded that there was no relation between it and the formation of the acid, as the quantity of acetaldehyde produced was entirely too small.[13] Nevertheless, the biological formation of citric acid from widely different carbon sources seems to indicate a distinct synthetic reaction. Yuill has

[12] C. Cohen, *Biochem Z.,* 112, 139 (1920); C. Neuberg and C. Cohen, *ibid.,* 122, 204 (1921).

[13] K. Bernhauer, *ibid.,* 202, 169 (1928).

reported the formation of appreciable quantities of ethanol but no kojic acid by a strain of *A. flavus* cultured on sucrose solution in the usual manner,'* and the recent work of Butkewitsch and Fedoroff has established the importance of ethanol and acetic acid as intermediate substances in the reactions leading to the formation of succinic and fumaric acids by *Mucor stolonifer.*[15] From the fact that in his experiments identical fats were produced from dextrose and xylose by a strain of *Penicillium,* Barber concluded that these sugars are broken down by the organism into smaller molecules from which the fats are then synthesized.[16] It is worth noting, moreover, that up to the present no organism has been found which produces citric or kojic acids from four or seven carbon sugars or sugar alcohols. It is entirely possible that there is a single reactive substance formed by these organisms through the degradation of sugars and other carbon sources which is the starting point for the synthetic reactions brought about through their agency. Whether this substance is acetaldehyde, which serves so well in accounting for the products of yeast and bacterial fermentations, or a closely related compound, remains to be established.

Summary

The effects of variation in nutrient nitrogen, temperature, concentration of sugar and depth of culture solution on the production of kojic acid by *A. flavus* have been investigated. With 20% dextrose solutions, this organism, under favorable conditions, was found to be capable of transforming more than 45% of the dextrose present and 55% of that consumed into kojic acid in twelve days from the time of inoculation from spores.

THE FURTHER FRACTIONATION OF YEAST NUTRILITES AND THEIR RELATIONSHIP TO VITAMIN B AND WILDIERS' "BIOS"

BY ROGER J. WILLIAMS AND ELIZABETH M. BRADWAY

RECEIVED DECEMBER 8, 1930 PUBLISHED FEBRUARY 9, 1931

Different so-called strains of *Saccharomyces cerevisiae* have diverse requirements for their growth stimulation as is evidenced by the contradictory results of many workers[1] and the experimental study made in this Laboratory.[2] In this publication it was reported that yeast of the type "Gebriide Mayer" (wholly unlike several others) is stimulated almost as effectively by extracts which have been shaken with fuller's earth as by untreated extracts. Similar results had been obtained previously on yeast autolysate by Eddy, Kerr and Williams,[3] when they cultured "Gebriide Mayer" yeast.

We have tried numerous means to purify this yeast nutrilite which is not adsorbed by fuller's earth, but with only moderate success. No adsorbent has been found which will remove it from solution effectively and not one of the numerous precipitants tried, precipitates the substance in question satisfactorily. The most potent preparations obtained by us were made by using various adsorbents and precipitants in sequence and in each case rejecting the precipitated or adsorbed material We have thus obtained material approximately ten times as potent as the original material which was extracted directly from rice polish. Experimental details regarding this work will not be presented at this time because we feel that our efforts have been rewarded with comparatively little success and it will be better to wait until we have made further progress on the problem.

On several occasions we tested preparations to ascertain whether we had separated two factors which might be ineffective when introduced singly but which might supplement each other. We have no indications that this is the case and so far as present evidence is concerned the yeast nutrilite which stimulates the growth of Gebriide Mayer yeast may be a single substance. Our results on this are in agreement with those of Eddy and his co-workers[3,4] who have worked with Gebriide Mayer yeast and have never reported a supplementary action between their preparations. Peskett and O'Brien,[5] who are probably working with this same (baker's)

---

[1] It is not appreciated by all investigators in this field that commercial yeast propagation is not necessarily a fixed and immutable process, and that improved strains of yeast may be introduced from time to time. Hence the term "bakers' yeast," for example, does not have a definite meaning when used in connection with these studies.

yeast, have found no evidence that their "bios" is a complex. Narayanan,[6] who has studied a yeast presumably of the same type, says "No evidence to support the complex nature of 'bios' has been obtained."

The description of "bios" originally given by Wildiers was that of a substance which was not precipitated by any of the ordinary precipitants. In fact its properties seemed to be very much like those of the nutrilite which stimulates Gebriide Mayer yeast. We thought it worth while to study further the question as to the identity of the Gebriide Mayer nutrilite and the "bios" of Wildiers. For this purpose we were fortunate in obtaining from Professor M. Ide of Louvain, Belgium, a culture of the yeast with which Wildiers' original work was done. The yeast culture as received was labeled Strain of *Sacch.* Cerev. *1* Hansen, Saccharomyces *Wildiersii.* For convenience we shall refer to this as Wildiers' yeast.

Wildiers' yeast, like Gebriide Mayer, is stimulated nearly as well by yeast extracts which have been treated with fullers' earth as by untreated extracts. This is shown by the results given in Table I. The tests were carried out and the determinations of yeast crops made in accordance with the technique outlined in previous publications[2,7,8] from this Laboratory. The yeast extract was prepared by extracting dry yeast with eight times its weight of hot 60% methanol, evaporating the filtrate to dryness and making up to one-half of its original volume with water. Its PH was adjusted to about 5, and a 50-cc. portion was shaken for ten minutes with 2.5 g. of fuller's earth and filtered.

In this and other experiments which are not reported in detail, some activity is removed by fuller's earth treatment and by the use of a sufficient amount of fuller's earth a considerable amount of activity may be removed. However, we have no evidence that the nutrilite which functions for Wildiers' yeast is any different from that which stimulates the growth of Gebrüde Mayer yeast. While we have had some slight indications in this direction, we must say that we have no proof either from our work or that of others that Wildiers' "bios" is other than a single substance. While preparations made in different ways aid in the stimulation of this yeast, evidence as to a supplementary relationship between them is largely lacking. Later experiments may prove that Wildiers' "bios" is multiple in nature.

We have what seems to be conclusive evidence that the yeast growth stimulants, with which W. Lash Miller[9,10] and his associates in Toronto have been working, are entirely different from Wildiers' "bios." Through the kindness of Dr. Miller we have been furnished with a culture of the yeast with which his experiments have been carried out.

We have been able to show that unlike any other of the seven representative yeasts tested in our laboratory, W. L. Miller's yeast is stimulated in its growth to an appreciable extent by highly purified inositol. In this respect Miller's yeast behaves entirely unlike Wildiers' yeast, as is shown in Table II. This is one of two separate experiments which gave similar results. It will be noted that our method of testing shows a very definite response on the part of Miller's yeast to inositol alone when as much as 1 mg. is added to 12 *cc.* of medium. This response is definitely lacking in the case of Wildiers' yeast.

TABLE II

EFFECT OF INOSITOL ON W. L. MILLER'S AND WILDIERS' YEASTS

Addition to synthetic medium	W. L. Miller's yeast Galv. reading	W. L. Miller's yeast Mg. of yeast	Wildiers' yeast Galv. reading	Wildiers' yeast Mg. of yeast
1 cc. of H_2O	31.25	0.74	35.35	0.38
1 cc. of H_2O	31.85	.69	36.6	.27
1 mg. of inositol in 1 cc. of H_2O	23.7	1.59	36.7	.27
1 mg. of inositol in 1 cc. of H_2O	24.05	1.55	36.9	.26
Seeding, cells	1,300,000		1,600,000	

Even more striking evidence that the nutrilites for Miller's yeast are quite different from Wildiers' "bios" is based upon the effects of tea extracts on these two yeasts. We find, in confirmation of the work of Miller and Eastcott, that tea is a good source of the nutrilites for Miller's yeast. For this purpose our sample of tea was about the equivalent of our rice polish. However, for Wildiers' yeast and all of the other yeasts which we

---

[9] W. L. Miller, Science, 59, 197 (1924).

[10] E. V. Eastcott, *J. Phys. Chem.*, 32, 1094 (1928).

have tested, the rice polish was much richer than the tea. The contrast between these two materials is especially striking in the case of Wildiers' yeast, as is shown in Table III. In one experiment which is not reported in detail tea was distinctly superior to rice polish as a source of nutrilites for Miller's yeast. It seems fair to conclude that the growth-stimulating substances which are abundant in tea are quite distinct from Wildiers' "bios," since they do not stimulate Wildiers' yeast. This conclusion is in line with the fact that Miller and his co-workers have repeatedly and without difficulty fractionated their material into supplementary fractions, whereas attempts on our part to do so with the nutrilite which is effective for Wildiers' yeast have failed repeatedly to yield any such results.

TABLE III

EFFECTS OF RICE POLISH AND TEA EXTRACTS ON W. L. MILLER'S AND WILDIERS' YEASTS

	Yeast crop W. L. Miller's yeast			Yeast crop Wildiers' yeast		
Addition to synthetic medium	Galv. deflection	Mg. of dry yeast	A over blank	Galv. deflection	Mg. of dry yeast	A over blank

Seeding	1,200,000 cells			1,550,000 cells		

It appears, therefore, that Miller and his associates should be credited with the discovery of a new series of yeast nutrilites, at least one of which is abundant in tea. These appear to be entirely distinct so far as present evidence indicates from the "bios" described by Wildiers.

The requirements (for growth stimulation) of old process bakers' yeast (with which the senior author's first experiments were carried out), yeast 578 of the American Type Culture collection and Untergarige Hefe K, seem to be more complex than those of Wildiers' yeast. They can readily be resolved into a number of interdependent growth stimulants of which the "bios" of Wildiers may be one, since one of the factors appears to have properties and occurrences similar to those of Wildiers' "bios."

The growth stimulants for the yeasts listed above appear to be different from those concerned in the growth stimulation of Miller's yeast, since these yeasts are not affected appreciably by inositol and we have been unsuccessful in fractionating the nutrilites by the same means used in the Toronto laboratories.

Our work on these yeasts has recently been concerned largely with yeast 578, partly because a considerable amount of work was done with it when the old process culture was not available and partly because it seems to give relatively regular and reproducible results.

Previous work published in 1927[11] has shown that yeast 378 xequires for growth stimulation two substances (or groups of substances) which can be separated by, adsorption of fuller's earth and which have little effect when introduced into the medium singly. More recently[12] it was shown that the crystalline antineuritic vitamin as prepared by Jansen and Donath is extremely potent as a yeast growth stimulant when used in conjunction with the residue of a yeast extract which is not adsorbed by fuller's earth. It was also shown, however, that the antineuritic vitamin of Jansen and Donath is not the only substance which can function in this manner.

Previous publications from this Laboratory have shown, therefore, that for the stimulation of the growth of yeast 578 (and old process yeast) there is required (1) material not adsorbed from yeast extract by fuller's earth plus (2) the antinemitic vitamin of Jansen and Donath or (3) other material which has many precipitation reactions in common with the Jansen and Donath vitamin but is not identical with it. In other words, at least three distinct and separable nutrilites may be involved in the growth stimulation of certain yeasts.

We shall now present evidence to show the existence of a fourth separable nutrilite which is concerned in the stimulation of the growth of yeast 578.

A highly concentrated preparation which was obtained from rice polish extract by adsorption on fuller's earth, precipitation with phosphotungstic acid, precipitation with silver nitrate and baryta, precipitation with chloroplatinic acid in absolute alcohol, using the method of Jansen and Donath, we shall for convenience designate as "A." It had a potency determined in accordance with a previous publication[12] of 125–200. A preparation of material from rice polish extract which was adsorbed by and extracted from fullers' earth, we shall designate as F. E. S. (fullers' earth solids). It has a potency of 2.5–3.

As a supplement to material which is not adsorbed from yeast extract by fuller's earth (U. R. Y.), "A" is (in accordance with their potencies) about 60 times as potent as "F. E. S." However, as a supplement to unadsorbed material from rice polish extract (designated as U. R. R.), "A" was shown to be only 20 times as potent as "F. E. S." This decideddiscrepancy which was obtained more than once led us to suspect that a new factor was present in the unadsorbed residue from yeast extract and in the "F. E. S.," but not to an appreciable extent in the unadsorbed residue from the rice polish extract.

The suspicions were confirmed when we prepared from the fuller's earth solid a preparation "F. E. S.$_5$" which supplements "A" plus "U. R. R." F. E. S.$_5$ was obtained by precipitating some of the fuller's earth solids with phosphotungstic acid in the presence of sulfuric acid and by subsequent removal of the excess acids and evaporation of the *filtrate*. Simultaneously

[12] R. J. Williams and R. R. Roehm, *J. Biol. Chem.*, **87**, 581 (1930).

we decomposed the precipitated material with baryta and freed it from excess baryta. The precipitated material in this experiment is designated as "F. E. S.$_6$"

The behavior of the "F. E. S.$_5$" preparation in supplementing either "A" plus "U. R. R." or "F. E. S.$_6$" plus "U. R. R." is shown in Tables IV and V. The results obtained in these experiments were in each case confirmed by separate experiments which are not reported in detail.

TABLE IV

SUPPLEMENTARY ACTION OF "F. E. S.$_5$" ON "U. R. R." PLUS "A" (YEAST 578)

Addition to synthetic medium	Yeast crop Galv. deflection	Yeast crop Mg. of dry yeast
1 cc. of H_2O	37.65	0.26
8 mg. of "U. R. R." (in 1 cc. of H_2O)	31.65	.68
8 mg. of "U. R. R." + 0.005 mg. "A"	27.55	1.0
8 mg. of "U.R.R." + 0.2 mg. "F. E. S.$_5$"	29.8	0.87
8 mg. of "U. R. R." + 0.005 mg. "A" + 0.2 mg. "F. E. S.$_5$"	16.75	2.70

Seeding about 950,000 cells.

TABLE V

SUPPLEMENTARY ACTION OF "F. E. S.$_5$" ON "U. R. R." PLUS "F. E. S.$_6$" (YEAST 578)

Addition to synthetic medium	Yeast crop Galv. deflection	Yeast crop Mg. of dry yeast
1 cc. of H_2O	35.3	0.36
8 mg. of "U. R. R." (in 1 cc. of H_2O)	26.3	1.26
8 mg. of "U.R.R." + 0.1 mg. "F. E. S.$_5$"	25.1	1.38
8 mg. of "U.R.R." + 0.1 mg. "F. E. S.$_6$"	10.8	4.07
8 mg. of "U.R.R." + 0.1 mg. "F. E. S.$_5$" + 0.1 mg. "F. E. S.$_6$"	7.5	5.37
8 mg. of "U.R.R." + 0.2 mg. "F. E. S.$_5$"	25.25	1.37
8 mg. of "U.K.R." + 0.2 mg. "F. E. S.$_6$"	9.55	4.52
8 mg. of "U. R. R." + 0.2 mg. "F. E. S.$_5$" + 0.2 mg. "F. E. S.$_6$"	4.4	8.05

Seeding about 1,360,000 cells.

It will be noted in both cases that the addition of "F. E. S.$_5$" alone to "U. R. R." has very little effect but that its addition to (U. R. R. + F. E. S.$_6$) or (U. R. R. + A) has a very appreciable effect. Presumably the preparation "F. E. S.$_5$" contains the new factor relatively free from other known factors, but "F. E. S.$_6$" and other preparations probably contain some of the new factor and thus prevent the results from being as clear cut *as* they would otherwise be.

What the character of this new factor is or what relationship it may have to some of the components of vitamin B is largely conjecture. In view of the fact that the antineuritic vitamin may function as a yeast growth stimulant, it is entirely probable that other yeast growth stimulants of a similar nature may have some function in animal nutrition. It is certain that the study of yeast nutrilites and attempts to isolate them are not interesting alone from the standpoint of the yeast itself but also from the standpoint of higher organisms, since substances which stimulate yeast growth are present in practically all plant and animal tissues and may be presumed to have some function in these tissues.

We wish to acknowledge gratefully the support received for this research from the Research Council of the University of Oregon and from Standard Brands, Inc., Successors to the Fleischmann Company, etc.

Summary

1. Experiments with Wildiers' original yeast culture shows that his "bios" is not readily absorbed by fuller's earth and appears to be the same as the nutrilite which stimulates the growth of Gebrüde Mayer yeast. No conclusive evidence of its multiple nature is available.

2. The yeast nutrilites studied by W. L. Miller and his associates are shown to be distinct from the "bios" of Wildiers. The Toronto workers should be credited with the discovery of a new series of yeast nutrilites.

3. Yeast No. 578 of the American Type Culture Collection and old process baker's yeast appear to have more complex requirements than Wildiers' yeast. Evidence is presented for the existence of a fourth distinct nutrilite concerned in the growth stimulation of yeast No. 578. It seems reasonable to suspect that several of the nutrilites for this yeast may be components of "vitamin B," since the antineuritic vitamin has previously been shown to affect its growth very strikingly.

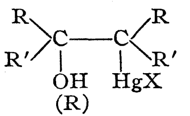
THE STRUCTURE OF THE COMPOUNDS PRODUCED BY THE ADDITION OF MERCURIC SALTS TO OLEFINS. II

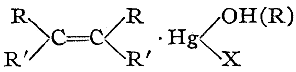
BY ESTHER GRIFFITH AND C. S. MARVEL

RECEIVED DECEMBER 15, 1930 PUBLISHED FEBRUARY 9, 1931

Some time ago a communication[1] from this Laboratory described optically active isomers of an addition product of an olefin of the type RR'C=CRR' with a mercuric salt. The conclusion was drawn that the existence of these isomers furnished evidence for believing that such addition products should be represented by ordinary structural formulas (I) rather than as molecular addition products (II).



I



II

---

[1] Sandborn with Marvel, THIS JOURNAL, 48, 1409 (1926).

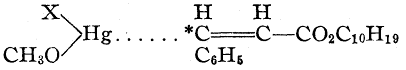
The particular products which have been described previously are two optically active isomers of *l*-menthyl β-methoxy-α-bromomercuri-hydrocinnamate (III) and two optically active isomers of I-menthyl β-methoxy-a-iodomercuri-hydrocinnamate (IV).

$C_6H_5CH(OCH_3)CH(HgBr)CO_2C_{10}H_{19}$ III $\qquad$ $C_6H_5CH(OCH_3)CH(HgI)CO_2C_{10}H_{19}$ IV

These products were prepared by adding mercuric acetate to I-menthyl cinnamate in methyl alcohol solution and converting the acetoxymercuri derivative thus obtained to the corresponding halide Since there are two asymmetric carbons produced by the addition of the methoxy and acetoxymercuri groups to the cinnamic ester, it is theoretically possible for four optically active forms of each of these addition products to exist. However, as is often the case in such addition reactions, all of these theoretically possible isomers were not obtained.

Although the isolation of two active isomers of each compound seemed sufficient to establish the fact that these substances were compounds whose structures could be represented best by ordinary valence bonds, it has seemed worth while to attempt to prepare other addition products which might yield the theoretical number of isomers. In the work described in this communication the unsaturated compounds studied were the I-menthylamide of cinnamic acid, d- and *l-sec.*-octyl cinnamates and d-bornyl cinnamate Only the last of these gave stable crystalline derivatives useful for the separation of isomers. However, here, as in the case of the *l*-menthyl cinnamate, only two optically active isomers were obtained.

Reference should be made to a suggestion by Piccard[2] in which he has pointed out that another assumption can be made which will account for two optically active isomers of such addition products without assuming that the mercury derivatives are of the ordinary valence type. This unusual assumption is that the addition product is represented by formula V.



$$\begin{array}{l} X \diagdown \\ \qquad \rangle Hg\ldots\ldots{}^*\overset{H}{C}=\overset{H}{C}-CO_2C_{10}H_{19} \\ CH_3O \diagup \qquad\quad \underset{}{C_6H_5} \end{array}$$

V

The carbon marked with the asterisk is a coordination center of a molecular addition product and may be optically active.

The work in this paper does not support or detract from this last suggestion but is further evidence of the fact that the addition products of mercuric salts and olefins are capable of optical isomerism.

Experimental Part

I-Menthylamide of **Cinnamic** Acid.—A solution of 16 g. of cinnamoyl chloride in 50 cc. of dry benzene was added slowly and with shaking to a solution of **31** g. of *l*-menthyl-

---

[2] Piccard, private communication. See also Pfeiffer, *Naturwissenschaften,* 14, 1100 (1926).

amine in 100 cc. of dry benzene. The rate of addition was regulated so as to avoid marked increase in temperature. 2-Menthylamine hydrochloride separated from the solution. When the reaction was complete the mixture was filtered with suction and the precipitate of amine hydrochloride was washed with a little dry benzene. The benzene was evaporated from the filtrate and the amide was recrystallized from methyl alcohol. The yield was 13 g. (47% of the theoretical amount) of a product which melted at 158–159°.

Anal. Subs., 1.0010, 1.0010: 47.35, 47.2 cc. of $N/14$ HCl. Calcd. for $C_{10}H_{27}ON$: N, 4.9. Found: N, 4.73, 4.7.

Specific rotation. Solvent, methyl alcohol; subs., 0.5380, 0.5579; volume of solution, 15 cc.; length of tube, 1 dm.; temperature, 25°; **a**, −2.96°, −3.09°; $[\alpha]_D^{25}$ −82.3°, −82.9".

When the amide in methyl alcohol solution was treated with mercuric acetate, a compound containing mercury was obtained, but its instability rendered it unsuitable for fractional crystallization.

d- and *l*-2-Octyl Cinnamates.—A mixture of 11 g. of d-octanol-2 and 14 g. of cinnamoyl chloride was heated for two hours over a low flame. The resulting brown liquid was distilled under reduced pressure. There was thus obtained 16 g. (73% of the theoretical amount) of a product which boiled at 174–177° (5 mm). In the same way 13 g. of 1-octanol-2 and 18 g. of cinnamoyl chloride gave 12 g. (50% of the theoretical amount) of the levo isomer, b. p. 175–180° (6 mm.).

Analysis of the dextro isomer. Subs., 0.1611: CO_2, 0.4626; H_2O, 0.1337. Calcd. for $C_{17}H_{24}O_2$: C, 78.40; H, 9.29. Found: C, 78.31; H, 9.28.

The specific rotations were determined in ethyl acetate solution. d-Ester. Subs., 0.5645; volume of solution, 15 cc.; length of tube, 1 dm.; temperature, 30°; **a**, +1.6°; $[\alpha]_D^{30}$ +42.4°. I-Ester. Subs, 0.5164; volume of solution, 15 cc ; length of tube, 1 dm ; temperature, 27°; **a**, −1.49"; $[\alpha]_D^{27}$ −43.3°.

When either of the esters was treated with a methyl alcohol solution of mercuric acetate, reaction occurred, as shown by the absence of mercuric ions at the end of nine days. The addition products proved to be very low melting and were not isolated and purified as they were unsuited for extensive fractional crystallization. The addition products were treated with alcoholic sodium bromide but the bromo compounds were also too low melting to be satisfactory for fractional crystallization.

***d*-Bornyl Cinnamate.**—This ester was prepared in 85% yields from *d*-borneol and cinnamoyl chloride. The product thus obtained boiled at 200–202° at 6–7 mm. Minguin and Bollemont,[3] described the product as a solid melting at 33°. Hilditch[4] described it as a yellow liquid boiling at 226–230° at 27 mm. with a specific rotation of +29.05° in chloroform solution and +29.10° in acetone solution.

Specific Rotation. Solvent, methyl alcohol; subs., 1.4252, 1.3383; volume of solution, 15 cc., 20 cc.; length of tube, 1 dm., 2 dm.; temperature, 27°; **a**, +3.13°, +4.4°; $[\alpha]_D^{27}$ +32.8°, +32.9°. Solvent, ethyl acetate; subs., 2.2256; volume of solution, 20 cc.; length of tube, 2 dm.; temperature, 27°; α, +7.18; $[\alpha]_D^{27}$ +32.3°.

d-Bornyl β-Methoxy-α-acetoxymercuri-hydrocinnamate.—A solution of 10 g. of *d*-bornyl cinnamate in 20 cc. of absolute methyl alcohol was added to a solution of 11 g. of mercuric acetate in 100 cc. of absolute methyl alcohol. The reaction was complete after eight days at room temperature, The methyl alcohol was evaporated and the residue was washed with water and dried. The crude product was then analyzed and found to be the desired addition product.

---

[3] Minguin and Bollemont, Compt. rend., 136, 238 (1903).

[4] Hilditch, J. Chem. *Soc.*, **93**, 7 (1908).

Anal. Subs., **0.1948:** Hg, **0.0667.** Calcd. for $C_{22}H_{30}O_5Hg$: Hg, **34.82.** Found: Hg, **34.24.**

The product thus obtained behaved like a mixture. After crystallization from methyl alcohol or petroleum ether the product melted over the range 90–100°. When the material was fractionated, samples were obtained which melted at 98–100°, **92–98°, 89–92°.** However, these fractions had almost the same specific rotations (+11.3°, +13.4° and 10.8°, respectively), and mixed melting point determinations showed that they were mixtures. Apparently the isomers of the acetate compound were not separated by crystallization.

***d*-Bornyl β-Methoxy-α-bromomercuri-hydrocinnamate.**—A solution of **20** g. of d-bornyl cinnamate in **50** cc. of absolute methyl alcohol was added to a solution of **22** g. of mercuric acetate in **250** cc. of absolute methyl alcohol. After two weeks the mixture was filtered to remove a small amount of precipitate and the methyl alcohol was evaporated under reduced pressure. The white solid was washed with water to remove acetic acid and mercuric acetate and dried. The yield of crude acetate was **45** g. This product was dissolved in about **200** cc. of absolute methyl alcohol and treated with a solution of **10** g. of sodium bromide in the same solvent. Crystals began to separate in a very short time. The first crop of crystals was filtered after one day. After recrystallization from petroleum ether this product melted at 131–132° (A). The next fraction to be isolated from the methyl alcohol was recrystallized from petroleum ether and it melted at 120–124°. Finally a third fraction (weighing **13** g.) of the addition compound was obtained. After recrystallization from petroleum ether it melted at 147–148° (B). A mixture of the first and third fractions melted at 120–125°. No further material separated from the reaction mixture even after standing for six months. About one centimeter of brown oil remained after the alcohol was evaporated.

The two bromo compounds were analyzed and rotations were determined.

Compound (A), m. p. **131–132°.**

Anal. Subs., **0.2484:** Hg, **0.0832.** Calcd. for $C_{20}H_{27}O_3HgBr$: Hg, **33.7.** Found: **33.5.**

Specific rotation. Subs., 0.1505; volume of solution, **15 cc.;** solvent, ethyl acetate; length of tube, 1 dm.; temperature, 25°; **a,** +0.17°; $[\alpha]^{25}_{D}$ +17.3°.

Compound (B), m. p. 147–148°.

Anal. Subs., **0.2332:** Hg, **0.0771.** Calcd. for $C_{20}H_{27}O_3HgBr$: Hg, **33.7.** Found: Hg, **33.1.**

Specific rotation. Subs., **0.1050;** volume of solution, **15** cc.; solvent, ethyl acetate; length of tube, **1** dm.; temperature, 25°; **a,** +0.10°; $[\alpha]^{25}_{D}$ +14.9°.

Summary

1. Two optical isomers of d-bornyl β-methoxy-α-bromomercuri-hydrocinnamate have been characterized.

2. The l-menthylamide of cinnamic acid and the d- and *l-sec.*-octyl esters of cinnamic acid have been characterized. The mercuric acetate addition products of these compounds were found to have physical properties which made it impractical to attempt to separate them into isomers by crystallization.

THE POTENTIALS AND THE DECOMPOSITION REACTIONS OF ORTHO QUINONES IN ACID SOLUTION

BY LOUIS F. FIESER AND MARY A. PETERS[1]

RECEIVED DECEMBER 18, 1930 PUBLISHED FEBRUARY 9, 1931

With the development of a method of measuring accurately the potentials of unstable oxidation–reduction systems,[1a] it seemed desirable to apply this new method to a re-examination of some of the systems for which the reported values are in the nature of approximations. It is particularly difficult to characterize the systems from the ortho quinones by simple electrometric titration, because of the great instability of the oxidants. We have thus made use of the method of discontinuous titration in a further study of the ortho quinones derived from benzene, naphthalene and phenanthrene, and we have attempted wherever possible to establish the course of the reactions leading to the destruction of the oxidant.

β-Naphthoquinone

The instability of dilute solutions of this substance in alcoholic hydrochloric acid was noted by Conant and Fieser,[2] who reported the results of titrations of the oxidant and some preliminary observations concerning one of the decomposition products. In extending these results we first established the normal oxidation–reduction potential of the system by the discontinuous titration of pure β-naphthohydroquinone, with the results given in Table I. Solutions of the material were treated with varying quantities of an oxidizing agent and the initial potential in each experiment was established by extrapolation of the time–potential curve. The oxidizing agent employed was potassium molybdicyanide. With this reagent the potentials of the organic and inorganic systems are so close together

[1] This communication is in partial fulfilment of the requirements for the degree of Master of Arts at Radcliffe College.

[1a] Fieser, THIS JOURNAL, **52,** 4915 (1930).

[2] Conant and Fieser, *ibid.,* **46,** 1858 (1924).

that the oxidation of the hydroquinone does not go to completion and in calculating the correct ratio of oxidant to reductant (Column 4) the amount of unreacted reagent present (Column *3)* must be taken into consideration, as explained in the first paper cited. On account of this overlapping in potentials, no end-point can be obtained in acid solution. The β-naphthohydroquinone solution was thus compared with the molybdicyanide by titration in a neutral alcoholic buffer solution, for here the potential of the inorganic system is considerably higher than that of the other system. β-Naphthoquinone was found to be perfectly stable in this solution and we were thus able to use the continuous method of titration.

The velocity constants given in the last column of the table were calculated for a monomolecular reaction; they are numerically equal to the decrease in potential per minute. It may be noted that the decomposition of the oxidant was much slower than in the earlier work in which impure β-naphthoquinone was employed.

In order to study the products of the decomposition of β-naphthoquinone, we dissolved a quantity of the pure quinone in the alcoholic buffer solution and allowed the decomposition reaction to proceed to completion (about three hours). This solution was found to contain the oxidant of a stable system and the reductant of another, unstable system. The oxidant could be titrated with titanous chloride, hut the titration of the reductant presented a more difficult problem. Some indication of the normal potential of the unstable system was furnished by rapid titrations of the reductant with tetrabromo-o-benzoquinone The value found (0.576 v.) was very close to that of the β-naphthoquinone system (0.5760 v.), and the velocity of decomposition was identical with that noted. It was not possible, however, to carry out a discontinuous titration with molybdicyanide in just the manner described above, for on attempting to determine the end-point in neutral solution it was found that this oxidizing agent attacks the oxidant of the other stable system present. The same disturbing reaction prevented the use of ceric sulfate, which has a high enough potential to give an end-point in acid solution. Tetrabromo-*o*-benzoquinone is free from this objection, and has a sufficiently high potential, but the compound is not stable enough in solution to permit its use in the time-consuming discontinuous titration.

In order to make an evaluation of the normal potential which would be more reliable than that furnished by rapid titration, the following expedient was adopted. Portions of the solution of the decomposition products were treated with varying amounts of molybdicyanide solution and the initial potentials, velocity constants and the fraction of unreacted molybdicyanide (m) were obtained in the usual manner (Table II). The approximate value for the normal potential of 0.576 v. was then used to calculate from these results values for the ratio [Oxid]/[Red], and from these figures

[a] Solvent: See Table I.

values were obtained for the theoretical end-point of oxidation. The average end-point was then used to calculate values for the normal potential (next to last column). The constancy of the results, and the agreement with the approximate value, justifies this interpretation.

The normal potential found is the same as that for β-naphthoquinone (0.5760 v.), but it is also not far from the potential reported[2] for a known product of the acid decomposition of this quinone, namely, dinaphthyldiquinhydrone. A special study of this compound (see below) showed that the potential is indeed close to that found here, but that the compound is perfectly stable under the conditions of the experiment and that it is thus excluded as a possible product. On the other hand, a comparison of the values given in Tables I and II for both the normal potentials and the velocity constants leaves little doubt but that the reductant produced in the decomposition of β-naphthoquinone is β-naphthohydroquinone.

There remained the identification of the oxidant which is produced, and the determination of the relative amounts of the two decomposition products. The plan of attack was to reduce the oxidant and then to titrate in succession the reductant of each system with the same oxidizing agent. The reagent chosen was tetrabromo-o-benzoquinone. In each of the experiments listed in Table III a 20-cc. portion of the solution of the decomposition products was first titrated to an end-point with titanous chloride. This gave the value for the normal potential of the stable

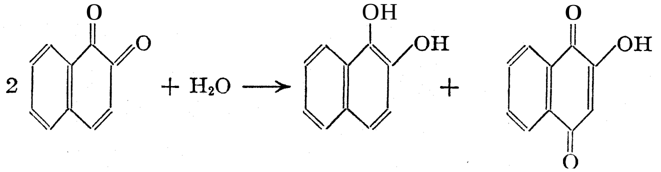
[a] Solvent: See Table I.

system listed in Column 1 of the table. A somewhat more reliable evaluation of the same potential was obtained when the reductant was then titrated with tetrabromo-o-benzoquinone, Column 2. At the conclusion of this titration a certain quantity of the oxidizing agent was quickly added and the potential was followed and extrapolated to zero time, giving the initial potential of the unstable system (Column 5). From this potential and the normal potential of the system the amount of oxidizing agent required for complete oxidation was calculated (Column 6). It is obvious that the amount of reagent consumed in the titration of the reductant of the stable system (Column 3) gives a measure of the quantity of the oxidant of that system which was originally present. It will be observed that the end-point of the titration is not the same in each experiment. This is because solutions of tetrabromo-o-benzoquinone in the alcoholic buffer are not altogether stable. A fresh solution was made up for each experiment, and in warming the solvent to effect dissolution, a certain variable quantity of the reagent was always destroyed. While separate experiments are thus not comparable, the titer of the quinone solution does not change appreciably in the short amount of time required to carry out the two separate titrations in each solution and the two end-points are strictly comparable. A comparison of the figures in Columns 3 and 6 thus gives a measure of the relative amounts of the two decomposition products formed, and this is indicated in the last column of the table. It is clear that the substances are produced in equimolecular proportion.

The potential of the more stable of the two systems (av., 0.3567 v.) suggests that the oxidant in question is 2-hydroxy-1,4-naphthoquinone. The value of 0.356 v. has been reported[2] for this compound, and we have found the average value of 0.3570 v. from a further series of determinations.[3] Any doubt as to the identity of the substance was dispelled by the isolation of hydroxynaphthoquinone from the solution.

The Mechanism of the Decomposition

The above results show that β-naphthoquinone in dilute alcoholic solution decomposes into equimolecular amounts of β-naphthohydroquinone and 2-hydroxy-1,4-naphthoquinone. While the final result thus represents a dispropdrtionation, there is further evidence which shows that the reaction does not follow the simple course:



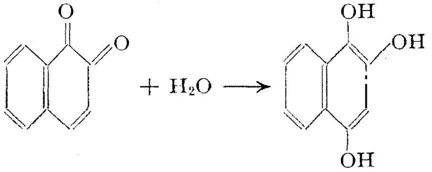
---

[3] The quinone was hydrogenated and titrated with potassium molybdicyanide. Individual results agreed within 0.1 mv.

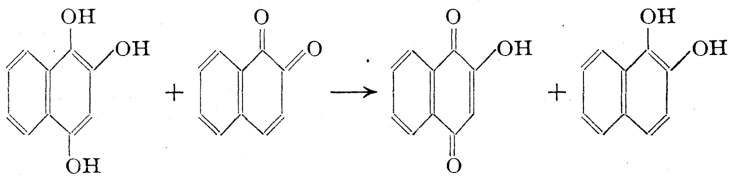
Such a reaction, in an aqueous–alcoholic medium, would be bimolecular. The reaction velocity measurements summarized in Tables I and II show, on the other hand, that the reaction is strictly monomolecular. The values obtained for the monomolecular constant agreed well in each individual experiment, as well as when the concentration of β-naphthoquinone was varied. A mechanism which postulates the intermediate formation of dinaphthyldiquinhydrone is likewise excluded, for this would be a bimolecular reaction.

The only mechanism which fits all of the facts is that β-naphthoquinone first adds a molecule of water as in I, and that the trihydroxynaphthalene

I (Slow)



II (Fast)



thus formed is oxidized at once by unchanged β-naphthoquinone, as in II. Oxidation–reduction reactions of the type of II are extremely rapid, and the speed of the first reaction thus controls the velocity of decomposition. Hydration of the ketonic substance is thus responsible for the final disproportionation in the present case. It may be noted that our results do not preclude the possibility that it is alcohol rather than water which adds to the quinone. If this reaction took place, it would lead to the formation of 4-ethoxy-1,2-naphthoquinone, a substance which would be hydrolyzed and isomerized to give 2-hydroxy-1,4-naphthoquinone under the conditions of the experiment.[4]

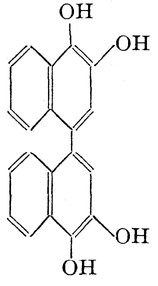
It is a well-known fact that β-naphthoquinone can be converted almost quantitatively into dinaphthyldiquinhydrone by the action of mineral acids, and yet no trace of this material was detected in the present experiments. The difference is easily accounted for. When a small amount of β-naphthoquinone is dissolved in a large amount of alcoholic acid, as in our experiments, the monomolecular reaction consumes the material. The reaction is slow and it is not accelerated by increasing the concentration of the reactant. Thus when a large amount of the quinone is stirred into a relatively small quantity of acid, the speed of the monomolecular reaction remains unchanged, while the condensation of two molecules of the quinone

[4] Fieser, This Journal, 48, 2922 (1926).

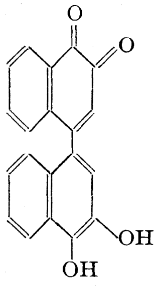
to give dinaphthyldiquinhydrone, being a bimolecular reaction, is greatly accelerated.

Dinaphthyldiquinhydrone (IV) and Dinaphthyldiquinone (V)

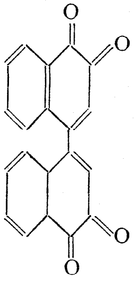
Since the compounds named are ortho quinones, they are appropriately included in this study. When dinaphthyldiquinhydrone, III, was titrated in alcoholic acid solution with ceric sulfate, a curve was obtained having two distinct inflections, as shown in Fig. 1 The reactants present appeared to be perfectly stable and no drift in the potentials was observed except at the very end of the titration. This drift is attributable to an oxidation of the solvent alcohol by ceric sulfate when an excess of the latter is present. The lower half of the curve refers to the potentials of the system formed by the reductant, III, and the monoquinone, IV, for a similar curve was obtained by the titration of the latter substance with titanous chloride. The upper half of the double curve obviously refers to the equilibrium between the monoauinone and the diquinone, V. The complete curve has a distinct end-point, and the "end-point" of each single curve can be taken as half of this value; but it is not permissible to take as the normal potentials of the two systems the mid-points of the two curves, for the normal potentials lie so close together that at almost



III



IV



V

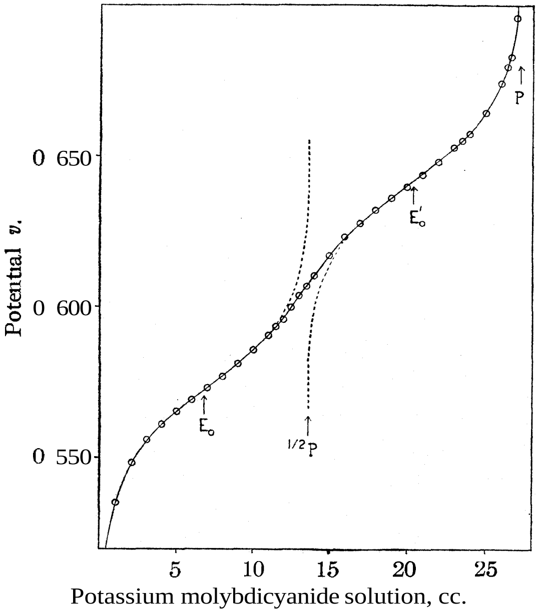


Fig. 1.—The titration of dinaphthyldihydroquinone.

any potential level all three of the organic substances are present in finite concentration. Such approximate values for the normal potentials were, however, employed in calculating more reliable figures in the following manner. From each of the potentials of the lower system, and the approximate normal potential of the upper system, we calculated the amount of diquinone present, and thus the true ratio of the monoquinone to its reductant. This permitted a calculation of the normal potential of the lower system from each observation. The process was then reversed, and the normal potential of the upper system was calculated. A summary of a few calculations from the results which are reported graphically in Fig. 1 is given in Table IV. In Fig. 1 the dotted lines represent the theoretical potentials of the two systems if each were free to function independently; it is obvious that the experimental curve is the resultant of these two.

3,4-Phenanthrenequinone

The normal potential of the unstable system formed by morphol and its oxidation product was determined in exactly the same manner as in the case of β-naphthohydroquinone. The explanation given of Table I thus applies equally well to the results listed in Table V. The normal potential

of this system is so close to that of the molybdicyanide system (0.6760 v.) that at the mid-point of the titration as much as 10% of the molybdicyanide fails to react and remains in the equilibrium mixture. The correction which must be applied to give the true ratio of organic oxidant to reductant is thus large and there is more uncertainty about the value found for the normal potential than in the previous cases studied. In order to obtain the most reliable results possible, we thus confined our experiments to measurements at the lower potentials.

The decomposition products of 3,4-phenanthrenequinone were studied by the method described in connection with Table III, above, and the results are included in Table VI. In the present case it was found that when the oxidant of the stable system was titrated with titanous chloride, the electrode equilibrium was not good and the values thus found for the normal potential are less reliable than those obtained in the back titration and they are not reported. A further variation from the other procedure was that we employed a single series of measurements for the calculation of the normal potentials, as well as of the relative concentrations, of the two decomposition products This was possible because all the indications were that the reductant which is produced in the decomposition is morphol. We thus used the normal potential found for the system from this compound in calculating from each initial potential for the unstable system the amount of oxidizing agent which would be required for complete oxidation. These figures are given in Column 6, and *a* comparison with the end-points in the titrations of the stable reductant (Col. 2) gives the relative proportion of the two decomposition products (Col. 7). Having established the ratio between the concentrations of these products, the titer of the stable reductant could be regarded as a standardization of the tetrabromo-o-benzoquinone solution in each experiment. The ratio of the

components of the unstable system was then calculated from the expression: [Oxid]/[Red] = (oxid. agent added)/[(titer of stable Red) × 1.11 − (Oxid agent added)]. The normal potential was then calculated from these values (see last column).

The normal potential of 0.3974 v. found for the more stable of the two systems is sufficiently close to the value of 0.396 v. reported for 3-hydroxy-1,4-phenanthrenequinone[5] to show that one of the decomposition products of the ortho quinone under consideration is the corresponding hydroxy-*p*-quinone. The potential of the unstable system agrees well with that found for the system morphol/3,4-phenanthrenequinone. The identity of the two decomposition products thus seems clear. There is one point of difference, however, from the results obtained with β-naphthoquinone. The amount of the hydroquinone is in excess of the amount of the hydroxyquinone. The experiment reported in the last line serves to account for this difference. It shows that when the solution was allowed to stand for over a day, the relative proportion of the hydroxyquinone was even less than in the experiments carried out in succession on a solution prepared twelve hours in advance. It is known that 3-hydroxy-1,P-phenanthrenequinone undergoes cleavage very readily in alkaline solution,[6] and that it differs in this respect from hydroxynaphthoquinone. It now appears that acid cleavage is also possible. A certain quantity of the material was destroyed by cleavage during the time allowed for the completion of the decomposition reaction; a further amount had been destroyed during the thirty-hour period.

This interpretation of the experiments leads to the conclusion that the mechanism of the decomposition of this ortho quinone is exactly like that of β-naphthoquinone.

It is worth noting that the value found for the normal potential of the 3,4-phenanthrenequinone system by a method which involves a rather large correction factor (Table V) is well confirmed by the results of Table VI, in which no such correction was required. The value of 0.621 v. thus may be accepted as a reliable constant to replace the approximate figure of 0.615 v. reported by one of us.[5]

1,2-Phenanthrenequinone

Since there is apparently a considerable error in at least one of the earlier, admittedly approximate, determinations, it seemed advisable to reinvestigate other ortho quinone systems by the discontinuous titration method. The results for one of these are given in Table VII. The potential here is so high that potassium molybdicyanide cannot be used as a titrating agent, and tetrabromo-o-benzoquinone is not stable enough to use

in the discontinuous titration method. We consequently used ceric sulfate even though the reaction of this substance with alcohol near the end-point of the titration introduces a slight uncertainty regarding the end-point. The new value, however, is certainly more reliable than that previously reported.[5]

Ortho Benzoquinone

Since ortho benzoquinone and catechol are soluble in water, this solvent was used in carrying out titrations of catechol so that ceric sulfate could be used as the oxidizing agent without any disturbing reaction of this reagent with the solvent. The results given in Table VII do not differ materially from those which have been obtained with other systems. There is a slight trend in the uncorrected values for the normal potential and it is in such a direction as to indicate an association between the oxidant and the. reductant. A correction factor, c, was consequently applied in the manner explained before.' The velocity constants correspond well with the requirements for a monomolecular decomposition reaction. We did not investigate the reaction further, because we were unable to find a satisfactory method of establishing the normal potential of the probable decomposition product.

Conant and Fieser[2] carried out rapid titrations of ortho benzoquinone with titanous chloride and obtained the values of 0.786 v. and 0.776 v. for 0.1 N and 1 N hydrochloric acid solutions, respectively. The present results show that these early figures are much too low. There does appear to be some slight increase in the potential with decreasing acidity of the solution. The potential of the system in neutral buffer is probably somewhat greater than 0.794 v. In a neutral alcoholic solution a potential about ten millivolts higher would be anticipated. Thus the value of 0.810 v. which was estimated by one of us[7] by a purely indirect method does not appear to be very far in error.

Experimental Part

Materials.—From a review of the literature it seems clear that neither β-naphthoquinone nor its reduction product has been prepared in completely pure form. After many trial experiments we concluded that the most promising source of such samples was 1,2-diacetoxynaphthalene. In preparing this compound by the reductive acetylation of ordinary samples of β-naphthoquinone[8] a certain amount of dinaphthyldiquinhydrone was always formed and this itself underwent acetylative reduction. The amount of the by-product may be reduced to a minimum by adding the quinone in small portions to a mixture of sodium acetate, acetic anhydride and zinc dust and by adding fresh portions of zinc dust as required to insure the rapid decolorization of the quinone. The crude product obtained was always oily. It was treated with ether, which left a residue of the solid tetra-acetate of dinaphthyldihydroquinone. The ethereal solution was washed well with sodium carbonate and dried over calcium chloride. Evaporation of the ether left a greenish-black oil which is not easily purified by crystallization. The material distils well, however, at diminished pressure, and after two distillations a colorless product was obtained. The 1,2-diacetoxynaphthalene formed small, colorless crystals from alcohol; yield 50%; m. p. 109.5° (Korn, 102-104°).

For the hydrolysis of the diacetate in the absence of oxygen, and for many similar operations, we have found the following simple apparatus to be of great service. The reaction vessel was a three-necked flask, carrying through one opening a tube for the admission of purified nitrogen. Through the central opening a tube was inserted which ordinarily served as the outlet for nitrogen but which could be pushed to the bottom of the flask when it was desired to transfer a solution to another piece of apparatus under

---

[8] Compare Korn, Ber., 17, 3025 (1884).

pressure of nitrogen gas. The third tubulature carried a separatory funnel for the admission of solution. In order to sweep this solution free of oxygen, a tube extending to the bottom of the funnel was connected to the nitrogen outlet by a length of rubber tubing. The glass tube passed through a large tube which was inserted in the stopper of the funnel, and through which, by means of a side-T, the nitrogen escaped. The advantage of the arrangement is that different reagents may be freed of oxygen rapidly and introduced in succession to the reaction flask.

For the preparation of pure *β-naphthohydroquinone* 10 g. of 1,2-diacetoxynaphthalene was dissolved in 75 cc. of alcohol, the solution was swept with nitrogen and treated with a solution of 8 g. of sodium hydroxide in 50 cc. of water. When the hydrolysis was complete the faintly yellow solution was acidified with 130 cc. of 1 M hydrochloric acid, and diluted with about 400 cc. of oxygen-free water. The material crystallized on cooling in the form of large colorless plates melting at 105.5° (4 g.). The melting point of 60° reported for samples of this compound prepared by reduction of the quinone[9] indicates that this is not a satisfactory method of preparation. By adding an excess of ferric chloride to the mother liquor from the above crystallization, the remaining material was converted into an excellent sample of crystalline β-naphthoquinone (2.6 g.).

Pure **β-naphthoquinone** may be obtained by oxidation of the pure hydroquinone under carefully controlled conditions. Five-tenths g. of β-naphthohydroquinone was dissolved in 10 cc. of alcohol and a mixture of 10 cc. of concentrated hydrochloric acid and 25 cc. of water was added. The solution was cooled to 0° and poured into a cooled solution of 100 cc. of 1 M ferric chloride solution also at 0°. The quinone soon began to separate in the form of small orange needles and crystallization was complete in about ten minutes, when the material was collected and washed well with water. In its crystalline character, orange color and freedom from all traces of foreign material, this product differs markedly from the samples obtained by the usual method of preparation. While our attempts to hydrogenate ordinary samples of the compound were no more successful than those of Skita and Rohrmann,[10] the pure quinone was found to be easily reduced by this method.

The preparation of pure morphol[11] and 3,4-phenanthrenequinone[6] have been described. An improved method of preparing *1,2-dihydroxy-phenanthrene*[12] was as follows. The corresponding quinone was reduced in glacial acetic acid solution with zinc dust and the colorless solution was filtered by suction into water. The gray product which separated was distilled in vacuum, thereby removing most of the color. Crystallization from benzene–ligroin gave colorless needles melting at 178". The sample did not darken on storage.

Details of the Measurements.—The solutions of the hydroquinone used in carrying put the titrations reported in Tables I. V and VII were prepared by placing the weighed solid in the three-necked flask referred to above, and adding the oxygen-free buffer solution after removal of all of the oxygen from the flask. The solution was then transferred to a protected reservoir buret of the type described by Cohen,[13] but modified by providing a tip below the lower stopcock through which the solution can enter the buret. This eliminates much delay in drainage. It is convenient to prepare 250 cc. of a solution of such concentration that 20 cc. contains 0.0003 mol. eq, of the reductant. In each experiment this amount was measured into 200 cc. of the buffer solution contained in the electrode vessel and swept free of oxygen.

[11] Fieser, Ref. 6. Further details will be published elsewhere.

[12] Fieser. THIS JOURNAL. 51, 1896 (1929).

[13] Cohen, *Ind. Eng. Chem.*, 20,1238 (1928).

Aqueous solutions of potassium molybdicyanide and solutions of ceric sulfate in either 1 N or 0.5 N sulfuric acid were employed. The tetrabromo-*o*-benzoquinone was dissolved in the buffer solution with which it was to be used.

Solutions of the decomposition products were prepared by adding the appropriate quinone to the oxygen-free buffer solution. The mixture was shaken well to prevent the formation of any saturated solution during the process of dissolution, and the solution was allowed to stand for five to twelve hours in an atmosphere of nitrogen. During this time the solution of β-naphthoquinone lost its original deep amber color and became pale yellow. The solution of 3,4-phenanthrenequinone remained somewhat red to the end. The solutions were made up to contain approximately 0.0003 M of the quinone in 20 cc., the amount used in each experiment.

Hydroxynaphthoquinone was isolated from the solution prepared from β-naphthoquinone by extracting the diluted solution with ether, washing the ether well with water and then extracting with sodium carbonate solution. The soda-soluble material was recovered by extraction of the acidified solution with ether. The product, which melted with decomposition at 194°, was identified by conversion into the ether, m. p. 183.5°, and comparison of an authentic sample, mixed m. p. 183.5°.

For details concerning the potential measurements and the interpretation and calculation of results reference may be made to the first paper cited for no changes in the general procedure were introduced. The values found for the normal potentials of the molybdicyanide system in 70% alcoholic solutions were as follows: 0.5 M acid, 0.6760 v.; 1 M acid, 0.6867 v.

Summary

By means of potentiometric analysis it has been found that β-naphthoquinone decomposes in dilute acid solution to give equal parts of β-naphthohydroquinone and hydroxynaphthoquinone. Since the reaction is monomolecular, it is concluded that the first step in the disproportionation is the addition of the elements of water to the quinone. 3,4-Phenanthrenequinone behaves in a similar manner, and it is presumed that the reaction is characteristic of all of the unsubstituted ortho quinones.

The method of discontinuous titration has been used in obtaining values for the normal oxidation–reduction potentials of the ortho quinones derived from benzene, naphthalene and phenanthrene, and the results are considered to supplant the earlier, less reliable, determinations.

REACTIONS OF HETEROCYCLES WITH PHENOLS. STUDIES IN THE REACTION OF ETHYLENE OXIDE WITH PHENOL

BY RICHARD A. SMITH AND JOSEPH B. NIEDERL

RECEIVED DECEMBER 20, 1930 PUBLISHED FEBRUARY 9, 1931

A survey of the literature to date reveals the following reports of interactions of phenols with heterocyclic compounds: (1) ethylene oxide, the simplest oxygen heterocycle, under the influence of heat combines with phenol to yield (β-hydroxy-ethyl)-phenyl ether. The same phenoxy compound can be obtained from ethylene chlorohydrin and sodium phenoxide.[1] Epichlorohydrin and phenol under the influence of heat yield the analogous phenyl ether.[2] (2) In the field of nitrogen heterocycles, reactions have been reported with diazomethane,[3] isatin[4] and alloxan.[5] Ethylene-imine and its homologs, as being structurally related to the ethylene oxide studied in this paper, are under investigation.

In the following investigation ethylene oxide was caused to react with phenol in the cold and in the presence of sulfuric acid to form, not an ether, as would be indicated by the work cited, but a substituted phenol. This product appears to be o-vinylphenol, for which the following proofs of structure are offered. (1) The explanation here given for a reaction mechanism appears to be well justified; it may be assumed that the first step in the reaction is the addition of sulfuric acid to ethylene oxide to form ethanol sulfuric acid according to the equation

$$\overset{O}{CH_2—CH_2} + H_2SO_4 \longrightarrow CH_2OHCH_2OSO_2OH$$

The resulting compound then reacts with phenol to form (β-hydroxy-ethyl)-phenyl ether with the elimination of sulfuric acid

$$CH_2OHCH_2OSO_2OH + HOC_6H_5 \longrightarrow H_2SO_4 + CH_2OHCH_2OC_6H_5$$

Inasmuch as ethylene oxide and phenol under the action of heat and pressure form this compound, it is plausible to assume the formation of it here, as an intermediate, with the sulfuric acid acting in the capacity of a catalyst. Phenolic ethers with a negative group in the side chain, as in the foregoing case, rearrange readily in the presence of mineral acids to form substituted phenols. We assume this to be the case here with the formation of *o*-hydroxyphenylethyl alcohol

$$CH_2OHCH_2OC_6H_5 \longrightarrow CH_2OHCH_2C_6H_4OH$$

[4] Baeyer and Lazarus, *ibid.*, 18, 2641 (1895); Liebermann and Danaila, *ibid.*, 40, 3593 (1907).

[5] Bohringer, German Patents 107,720 and 115,817.

The presence of concentrated sulfuric acid causes dehydration with the formation of o-vinylphenol

$$\overset{\text{OH}}{\text{CH}_2}\text{—}\overset{\text{H}}{\text{C}}\text{HC}_6\text{H}_4\text{OH} - \text{H}_2\text{O} \longrightarrow \text{CH}_2{=}\text{CHC}_6\text{H}_4\text{OH}$$

As a modification of the foregoing mechanism, dehydration of the phenoxy glycol may precede rearrangement. It has been shown that unsaturated ethers of the type which would thus be formed rearrange very readily to give ortho substituted phenols.[6] (2) The physical and chemical constants of the compound obtained corresponded with those given in the literature for o-vinylphenol. For further identification, two derivatives, the $3,5,1^1,1^2$-tetrabromo-2-hydroxyethylbenzene and the o-vinylphenoxyacetic acid, were prepared; the physical properties of these also agreed with those given in the literature.

In order, however, to substantiate more fully the reaction mechanism offered, the o-vinylphenol was synthesized by a different method as follows.

Ethylene chlorohydrin was treated with potassium phenoxide and the corresponding (β-hydroxy-ethyl)-phenyl ether obtained; this same ether can also be obtained by the action of ethylene oxide on phenol. The ether was then treated with concentrated sulfuric acid in a manner analogous to that used in the phenol–ethylene oxide condensation. The product was worked up as before and proved to be o-vinylphenol with the same physical constants and yielding the same derivatives. This indicated that the rearrangement and dehydration assumed in the proposed mechanism are allowable. The reaction is also of general interest as it substantiates the explanation offered in the condensation reactions taking place in the cold between unsaturated compounds (hydrocarbons, alcohols, esters, ethers, aldehydes, acetals, ketones, acids, nitriles, amines and halides) with phenols in the presence of concentrated sulfuric acid.[7]

Experimental

(1) Vinylphenol from Ethylene Oxide and Phenol.—A fifth mole of concentrated sulfuric acid was slowly added with cooling to a solution of molar quantities of phenol and ethylene oxide. The action during addition was vigorous. The containing flask was then closed with a stopper containing a calcium chloride drying tube and allowed to stand for one week. The product was washed with cold water to remove phenol, ethylene oxide, sulfuric and sulfonic acids and other water-soluble by-products. o-Vinylphenol is slightly soluble in water. The resulting liquid was distilled in vacuo. Redistillation yielded pure o-vinylphenol in about 65% yield. It was found that hydroquinone was a good inhibitor to polymerization. The rate of reaction as well as the yield of product can be controlled by the amount of sulfuric acid used. Pure o-vinylphenol melts at 29–29.5° (corr.) and boils at 56° under a pressure of 4 mm. The boiling point given by Fries and Fickewirth of 108° at 15 mm. is incorrect for the pure product,

[7] Niederl and Natelson, THIS JOURNAL, 53, 272 (1931).

which at that pressure boils at 77°. Upon distilling o-vinylphenol from the polymerized product a temperature approximating that given by Fries and Fickewirth is noted.[8]

(2) **3,5,1^1,1^2-Tetrabromo-2-hydroxy-ethylbenzene.**—*o*-Vinylphenol, as prepared above in a chloroform solution, was treated with an excess of bromine with cooling. After the action had subsided, the hydrogen bromide, excess bromine, and chloroform were driven off with heat and the remaining solid purified by recrystallization from benzene. The final product melted at 105°, which is in agreement with the literature.

(3) o-Vinylphenoxyacetic Acid.—Molar quantities of o-vinylphenol, as prepared above, and bromoacetic acid were allowed to stand at room temperature in an alkaline solution for a few hours. The solution was then acidified and the resulting product purified by recrystallization from benzene or dilute alcohol. Prisms melting at 137° were obtained. This also was in agreement with the literature.

(4) **(β-Hydroxy-ethyl)-phenyl** Ether.—Molar quantities of potassium phenoxide and ethylene chlorohydrin were heated at 150° for six hours, and after cooling and filtering the liquid was distilled in vacuo. The fraction boiling at 163–167° at 80 mm. was retained as being the desired phenoxy glycol.

(5) o-Vinylphenol from **(β-Hydroxy-ethyl)-phenyl** Ether.—A molar quantity of the phenoxy glycol was allowed to stand for one week at room temperature with a fifth molar quantity of concentrated sulfuric acid. The product was washed with water and distilled in vacuo. o-Vinylphenol with the same boiling point as previously given was obtained; it formed the same bromine and acetic acid derivatives, proving that the compounds prepared by the two different methods were identical.

Summary

1. Ethylene oxide reacts with phenol in the cold in the presence of concentrated sulfuric acid to yield an ortho substituted phenol.

2. A probable mechanism for the above reaction has been advanced and reasons substantiating it have been given.

3. Two new methods for the preparation of o-vinylphenol have been discussed.

NEW YORK, N. Y.

NOTES

The Optical Activity of Cystine Preparations Used for Animal Experimentation.—Marston and Robertson[1] have recently expressed the opinion that much of the confusion in the literature dealing with cystine metabolism might have been avoided by determining the optical activity of the preparations used and have severely criticized certain studies on this account.

For several years we have been using cystine, prepared from human hair, in animal feeding experiments. Most of our preparations, as well as a number of student preparations subsequently reprecipitated by the author,

[8] Fries and Fickewirth, *Ber.*, 41, 370 (1908)

[1] Marston and Robertson, "The Utilization of Sulfur by Animals," Commonwealth of Australia, Council for Scientific and Industrial Research, Melbourne, 1928, Bulletin No. 39, 51 pp.

have been tested for their optical activity. All of these preparations were made for use in animal experimentation, and not for the determination of precise physical and chemical constants. It occurred to the writer that this information might furnish a rough index of the validity of Marston and Robertson's criticisms.

The method of isolation was essentially that outlined by Morrow.[2] The isoelectric precipitations were controlled with Congo red and litmus papers. The student preparations had been precipitated only once from the more or less successfully decolorized solutions, and varied considerably in color and tyrosine content. These preparations were subsequently reprecipitated by the author.

After drying, 1 g. of each of the above preparations was made up to 100 ml. in N hydrochloric acid, analyzed for sulfur and polarized at 21°. The accompanying table shows the results obtained.

Sample	S, %	$[\alpha]^{21}_{D}$	Remarks
158	26.02	$-212.3°$	Author's preparation
159	26.02	$-212.3°$	Student preparation
160	26.34	$-210.4°$	Student preparation
161	25.91	$-208.4°$	Student preparation
162	26.14	$-207.4°$	Student preparation
163	26.53	$-185.9°$	Student preparation
164	26.40	$-210.0°$	Student preparation
177	26.48	$-216.6°$	Author's preparation

It is obvious that the variations in specific rotation cannot be explained on the basis of sulfur content. It is highly probable that any of these samples, with the exception of No. 163, is suitable for animal feeding unless it is assumed that inactive cystine is highly toxic. Subsequent treatment of Sample No. 163 indicated that the above variations in specific rotation are partly due to the prolonged washing of certain samples with hot water in order to remove the tyrosine present.

hyde, propional, heptaldehyde, chloral, furfural, o-chlorobenzaldehyde, 2,4-dichlorobenzaldehyde, anisaldehyde, ethyl acetoacetate, mesityl oxide, cyclohexanone, carvone and benzoylacetone. The products were reddish, viscous oils which did not crystallize at −30°. No reaction seemed to take place with *p*-hydroxybenzaldehyde, piperonal, vanillin and camphor. *p*-Cymylhydrazine cannot therefore be regarded as a good reagent for the carbonyl group.

Experimental.—The frequent appearance of tar, causing varying yields of cymylhydrazine, led to the observation that the acid concentration in the reduction process is very important. The proper acid concentration was obtained by running the sulfur dioxide into the sodium hydroxide solution until it was neutral and then continuing the passage of the gas for a period equal to one-tenth of the time required for neutralization. The free base did not change color in well-stoppered bottles.

Homochromanone.[1,2]—Since phenoxyacetic and β-phenoxypropionic acids can be converted by loss of water into coumaranone[3] and chromanone,[4] respectively, it seemed likely that homochromanone could be obtained in a similar manner from γ-phenoxybutyric acid. It was found in this investigation that γ-phenoxybutyric acid did yield homochromanone, although, as might have been expected, the formation of the 7-membered ring did not take place as smoothly as that of the 6-membered ring in chromanone. In fact, the yields were so poor that proper purification of the product was impossible due to the small quantity obtained.

Attempts to dehydrate y-phenoxybutyric acid with phosphorus pentachloride and with thionyl chloride were unsuccessful. Treatment of the acid with thionyl chloride and then with anhydrous aluminum chloride yielded no homochromanone. It was found that the best results were obtained by dehydrating the acid in small portions (1g.) with phosphorus pentoxide.

Although no pure homochromanone was obtained, the semicarbazone and oxime were prepared and purified.

Homochromanone.—One gram of y-phenoxybutyric acid dissolved in 15 cc. of benzene was treated with 1 g. of phosphorus pentoxide following the method described by one of us[4]" for the preparation of chromanone. On evaporation of the benzene a few drops of a lemon-yellow, highly refracting oil remained. Attempts to induce crystallization were unsuccessful, and even after combining the product from several runs, not enough was obtained to carry out a distillation. The oil was readily soluble in ether, benzene, petroleum ether and alcohol. A drop dissolved in concd. sulfuric acid gave a red solution on warming.

Semicarbazone.—This was prepared in the same manner as chromanone semicarbazone. It crystallizes from alcohol in white needles, m.p. 228–229° (uncorr.).

Anal. (Kjeldahl). Subs., 0.0980, 0.2231: HCl (0.0969 N), 14, 31.04 cc. Calcd. for $C_{11}H_{13}O_2N_3$: N, 19.2. Found: 19.4, 18.9.

Oxime.—This was prepared in the same manner as chromanone oxime. It crystallizes from petroleum ether in white plates, m. p. 99°.

COMMUNICATIONS TO THE EDITOR

COAGULATION OF FERRIC OXIDE HYDROSOLS

Sir:

In a recent communication [THIS JOURNAL, 52, 4170 (1930)] N. R. Dhar suggests that "the results of Judd and Sorum [THIS JOURNAL, **52,** 2598 (1930)] are not in agreement with previous work and need confirmation." The "previous work" referred to is that of Dhar and his collaborators, particularly that reported by Dhar and Gore [J. Indian Chem. *Soc.*, *6*, 31 (1929)], in which the conclusion is drawn that "even highly purified sols of ferric hydroxide containing very small amounts of chloride ion follow the general rule that the greater the concentration of the sol the greater is the amount of electrolyte necessary for coagulation irrespective of the valency of the coagulating ion."

If the two papers in question are compared it will be obvious that Dhar's own results, when properly analyzed, fall in line with the very conclusion with which he seems to take issue. Figure 4, page 2601, in the paper by Sorum and Judd represents graphically the influence of the addition of ferric chloride on flocculation values. If the increase in chloride content, as represented by millimoles of ferric chloride added per liter, is greater than 0.0095 g. per liter, the sol behaves as did Dhar's, i. e., the flocculation value with sodium chloride increases with increased sol concentration. It is only when the added chloride is less than 0.0095 g. per liter that the sol follows the Burton–Bishop rule. An examination of Dhar's results will show that in no case is the chloride content of the purified sol anywhere nearly as low as that represented by the above figure. The best figure is 0.0936 g. per liter, ten times the critical value represented in Figure 4 cited above. As such it would seem that Dhar's criticism is not very well founded.

DERIVATIVES OF OPTICALLY ACTIVE TRIARYLCARBINOLS AND THEIR HALOCHROMIC SALTS

Sir:

In a recent article published in the Proceedings of the National Academy of *Sciences* [**16,** 215 (1930)], I described a method for preparing an optically active triarylcarbinol in the form of its thioglycolic acid derivative. *l*-Phenylbiphenyl-α-naphthylmethylthioglycolic acid, $(C_6H_5C_6H_4)(C_{10}H_7)$-$(C_6H_5)C$—$SCH_2COOH$ (hereafter designated as **A**), has the following specific rotation in carbon tetrachloride, $[\alpha]^{20}_{D}$ $-13.63°$. Experiments with this substance show that it forms halochromic salts. Concentrated sulfuric acid, perchloric acid, and mercuric chloride unite with it, forming deep violet halochromic compounds, which on pouring into ice water yield the carbinol, $(C_6H_5C_6H_4)(C_{10}H_7)(C_6H_5)C—OH$, in its optically inactive form. A solution of titanium tetrachloride in chloroform when added to a chloroform solution of **A** produces a deep violet halochromic salt which on decomposition with water yields A in its racemic form. However, when a solution of ferric chloride in glacial acetic acid is added to a chloroform solution of A, the deep violet halochromic salt so formed, on pouring into ice water, produces the original *l*-phenylbiphenyl-α-naphthylmethylthioglycolic acid with no racemization.

The fact that the halochromic salt with ferric chloride on decomposition with water gives the original optically active thioglycolic acid derivative with no change in specific rotation is compelling evidence against quinoid formulation for the explanation of color. A detailed account of these experiments will be published shortly.

THE VELOCITY OF ADSORPTION PROCESSES AND THE PROBLEM OF PROMOTER ACTION

Sir:

In a recent note [THIS JOURNAL, 52, 5298 (1930)] and in greater detail in a communication to the February issue of THIS JOURNAL, the data relative to the concept of activation energy of adsorption processes has been indicated. In these contributions it was emphasized that the magnitude of the activation energy and, hence, of the velocity of adsorption at a given temperature, is determined not only by the adsorption process in question but also by the nature of the surface area on which the process occurs. We can now record some striking examples of this view which bear fundamentally on the problem of promoter action in catalysis. We have found that on an active manganous oxide catalyst hydrogen is adsorbed immeasurably slowly at 0 and 100°. At 184° the initial rate of absorption in a given adsorption system was 8 mm. per hour. At 305" the velocity of adsorption had risen to 78 mm. per hour, which corresponds to an activation energy in the neighborhood of 10,000 calories. The hydrogen was reversibly adsorbed since it could be recovered quantitatively by evacuation at higher temperatures. To compare these data with a promoted catalyst we have now studied a manganous oxide–chromium oxide catalyst. This again shows an extremely slow rate of adsorption at 0°, but at 184°, in a system comparable to that used with manganous oxide, the velocity of adsorption had risen to approximately 100 mm. per *minute.* The velocity of adsorption had thus increased about 700-fold by reason of the promoter action of the chromium oxide. The promoted catalyst also showed a much increased adsorptive capacity per gram. The gas was reversibly adsorbed. It is evident, therefore, that in considering the mechanism of promoter action consideration must be given not only to extension of surface but also to the velocities with which the activating adsorptions occur.

PUBLISHED FEBRUARY 9, 1931

NEW BOOKS

Die Bedeutung der wissenschaftlichen Tätigkeit Friedrich Wöhlers für die Entwicklung der deutschen chemischen Industrie. (The Importance of Friedrich Wöhler's Scientific Achievements in Developing German Chemical Industry.) By Dr. TH. KUNZMANN. **Verlag Chemie, G. m. b. H., Berlin W 10, Germany, 1930. 90** pp. **15.5 × 23.5 cm. Price, unbound, RM. 4.**

Within the space of ninety pages the author includes those discoveries by Wohler that led to important technical processes, as well as his purely scientific achievements. He presents in thirteen chapters an admirable survey of all this great pioneer did, beginning with a list of Wohler's papers, **223** in all, upon 160 inorganic, 54 organic and 9 biochemical subjects. Those were days when a man was a general practitioner, unconfined to a special field but roaming at will and able to say truthfully, "I am a chemist." In the second chapter is Wohler's biography and in the next four are such technically important discoveries as the isolation of aluminum in 1827, contact production of sulfuric acid in **1852,** explanation of the nature of calcium carbide with suggestions as to its use in 1862, and experiments upon titanium in 1849. Fourteen additional inorganic researches of technical significance appear in the eighth chapter, among the number being the extraction of phosphorus, refining of antimony and oxidation of ammonia.

No book about Wohler would be complete without mention of his announcement in **1828** of the synthesis of urea. In the ninth chapter the author takes up this discovery that has overshadowed much of Wohler's other work. The birth of modern synthetic chemistry dates from this epoch-making experiment that spurred chemists to attempt similar syntheses. The two following chapters call attention to other organic researches by Wohler, such as those upon alkaloids and quinone, the latter leading to the preparation of hydroquinone and quinhydrone. In its subsequent development quinone chemistry has proved a fruitful field of research. His organic experiments led Wohler to devise several ingenious methods, for example, the use of the sealed tube.

The twelfth chapter emphasizes Wöhler's eminence as a teacher. His laboratory was the Mecca of many students of chemistry. The analytical skill he had mastered under Berzelius he insisted upon imparting to his followers and his laboratory became renowned for the exactness of the work done there. Many of his students afterward acquired fame both in academic and in technical circles, among the number being Fittig, Kolbe, Beilstein and many others.

That unique episode in the history of chemistry, namely, the collaboration of Wohler and Liebig, occupies the thirteenth chapter. Working independently, each in his own laboratory, they completed thirteen valuable pieces of work, some of which have become classical examples of chemical research. Three of these researches, namely, those upon the radical of benzoic acid, emulsin, and uric acid, are considered at length. Possibly the general adoption of this method of working might result in fewer but better papers and prevent the waste of many splendid trees.

In the concluding chapter the author summarizes Wohler's chemical career and closes with an appendix upon the influence of the scientific labors of Wohler, Liebig and Schönbein in developing German chemical industry.

W. H. WARREN

Ostwald-Luther. Hand- und Hilfsbuch zur Ausführung physiko-chemischer Messungen. (Physico-Chemical Measurements.) Edited by C. DRUCKER. Fifth, revised edition. Akademische Verlagsgesellschaft m. b. H., Schlossgasse 9, Leipzig C 1, Germany, 1931. xix + 979 pp. 630 figs. 16 × 23.5 cm. Price, unbound, RM. 49; bound, RM. 52.

Only a detailed comparison of the fifth with the fourth edition could make clear the extent of the improvements effected by this latest revision. The text has grown by one hundred and fifty pages, the cuts by seventy. A wealth of references has been added, with adequate recognition of English and American investigators, while increased emphasis is laid upon recent technical books and critical summaries. Each cut is now provided with a suitable legend—an overdue concession to the inexpert. Among the new topics may be mentioned electroplating, preparation of metallic wires, the sputtering of metals, diffusion electrodes, glass membrane electrodes, magnetic measurements. While minor changes appear everywhere, the sections on calorimetry, conductivity, electron tube hookups, x-rays, radioactivity, electrometric titration and electrical temperature measurements have gained the most in usefulness. The alumni of the Physikalisch-Chemisches Institut in Leipzig may feel a passing regret over the disappearance of the course of laboratory exercises once given there. By way of compensation, however, the more important (German) laboratory manuals are listed.

From the very beginnings of modern physical chemistry, "Ostwald-Luther" has embodied and furthered its progress. The latest edition sets a standard of excellence which will be hard indeed to surpass.

G. S. FORBES

Geochemie in ausgewählten Kapiteln. (Selected Chapters in Geochemistry.) By W. J. VERNADSKY. Authorized translation from the Russian, by Dr. E. KORDES, Mineralogical Institute of the University of Leipzig. Akademische Verlagsgesellschaft m.b.H., Schlossgasse 9, Leipzig C 1, Germany, 1930. xii + 370 pp. 15.5 X 23.5 cm. Price, unbound, RM. 23; bound, RM. 25.

The term "geochemistry" is commonly used in two different meanings. Its first and more logical meaning is "chemistry of the Earth," with a capital E; that is, the chemistry of our planet considered as an object, in the sense in which we would speak of the chemistry of an orange or of a micro-organism. Its second and more usual meaning is "chemistry of earth" with a small e, that is, the chemistry of minerals, rocks, and soils, in which sense it is essentially a branch of general chemistry, and consists of facts that could be used, without modification, by the inhabitants of any other planet. Vernadsky's "Geochemistry" is about eighty per cent. of the first kind and twenty of the second. Twenty per cent. is no more than is necessary for a clear understanding of the other eighty, particularly if such reference works as Mellor's Volume VI or Doelter's "Handbuch" are not available. Furthermore, the inclusion of this twenty makes possible the presentation in condensed form of some of the valuable data and conclusions drawn from the experimental researches of the author, who has been a life-time investigator in mineral chemistry, and whose work was long ago recognized by his election as a member of the Russian Academy. A distinguishing feature of the strictly geochemical part of the book is the emphasis placed upon the relations of the activity of living organisms, including Man himself, to the chemistry of the Earth's surface shell. This aspect of the subject has received relatively little attention from earlier writers.

The German translator has confined himself to making a faithful transcript of the author's ideas, basing his translation on the Russian edition of 1927, which in turn was an enlargement of the original French edition of 1924. At the same time the author has rewritten certain chapters, where new experimental knowledge has made a revision desirable.

ROBERT B. SOSMAN

Stereochemie. (Stereochemistry.) By GEORG WITTIG, Lecturer at the University of Marburg. Akademische Verlagsgesellschaft m. b. H., Schlossgasse 9, Leipzig C 1, Germany, 1930. xi + 388 pp. 127 figs. 16 X 23.5 cm. Price, unbound, M. 23; bound, M. 25.

Stereochemistry has considerably expanded during the past few years, not only in the amount of its data but in its scope, and from various sides so much progress has been made that the real ultimate goal—to specify in absolute units the spatial distribution of atoms within molecules—is now clearly visible. This subject is no longer exclusively concerned with certain particular kinds of isomerism, and whatever one's special field as a student or investigator in organic chemistry may be, there are some topics of stereochemistry concerning which it is necessary to be informed.

The problem of finding the needed information now presents no difficulties. For a clear and concise statement of the current status of any particular problem, or for a well-ordered and thoroughly readable account of the entire field, one has only to turn to Dr. Wittig's book. Specialists in stereochemistry may find his discussion of some of their favorite topics disappointingly brief, but if there is any error of judgment in this respect, the error certainly lies in the right direction so far as the general utility of the book is concerned, and for those who are interested in details, copious references to the original literature are supplied. The only topics that have received less emphasis than their importance warrants are ones such as the stereochemistry of sugars that have already been recently reviewed in other books. On the other hand, half the book is devoted to the stereochemistry of other elements than carbon and nitrogen, stereochemistry and crystal structure, and stereochemistry and reaction kinetics, and under the second of these headings one finds discussions of the hypothesis of Reis and Weissenberg, the spatial forms of aliphatic chains, the polymorphism of organic compounds, and the stereochemistry of high polymers. The text is copiously illustrated with excellent figures. The printing is well done and there is a good index. Every organic chemist, no matter what his special interests may be, will find it worth while to own a copy of this book.

WALLACE H. CAROTHERS

Fundamentals of Organic Chemistry. BY HARRY F. LEWIS, Professor of Organic Chemistry, Institute of Paper Chemistry, Appleton, Wisconsin. International Chemical Series, James F. Norris, Consulting Editor. McGraw-Hill Book Company, Inc., 370 Seventh Avenue, New York, 1930. viii + 390 pp. 28 figs. 14.5 X 21 cm. Price, $2.75.

As stated in the introduction, this book is intended to remedy the lack of a recent American text built specifically upon the "Atomic Linking Theory." The various classes of compounds are considered in terms of functional groups, *e.* g., the reactions of an acid are presented as the resultant of the following groups, —C—C, C—H, C=O in presence of OH and OH in presence of C=O.

The book is written in three parts: Part I, The Petroleum Hydrocarbons and their Monosubstitution Products; Part II, The Polysubstitution Products of the Petroleum Hydrocarbons; and Part III, The Ring Compounds.

Emphasis has been placed upon the development made in organic chemistry since the World War, many modern processes being described. There is a goodly assortment of questions and problems and also, at the end of several chapters, references are given for outside reading. However, some of these references would be rather heavy reading for a student in elementary organic chemistry, e. g., "Proteins and the Theory of Colloidal Behavior" by Loeb, "The Physical Chemistry of Proteins" by Robertson, and "Recent Advances in Organic Chemistry" by Stewart.

On the whole, this book should prove to be a usable and interesting text, especially for those teachers interested in the "Atomic Linkage" presentation of organic chemistry.

BEN B. CORSON

Handbuch der biologischen Arbeitsmethoden. (Handbook of Biological Methods.) Edited by Professor Dr. EMIL ABDERHALDEN. Section I. Chemical Methods, Part 2, 2d half, Number 6. Die Verseifung. (Saponification.) By FRANZ BACHÉR, Rostock. Urban and Schwarzenberg, Friedrichstrasse 105b, Berlin N 24, Germany, 1930. 294 pp. 17.5 × 25.5 cm. Price, M. 16.

The present number of Abderhalden's comprehensive "handbook" deals with the saponification of all common types of derivatives of organic acids: anhydrides, chlorides, esters, lactones, nitriles, amides and anilides. It is by far the most extensive and detailed treatment of the subject that is available. By discussion of underlying principles and by very many carefully selected examples the author indicates the most promising methods for solving difficult problems in saponification, like the partial hydrolysis of derivatives of polybasic acids or of polyacid alcohols; the saponification of optically active esters and amides, of esters and nitriles of β-ketonic acids and other similarly unstable compounds, and of substances in which there is a great hindrance to hydrolysis.

Organic chemists as well as the biochemists for whom, presumably, it was primarily prepared will find in this excellent treatise much time and patience saving material.

THE MEASUREMENT OF THE HYDROGEN-ION CONCENTRATION IN UNBUFFERED SOLUTIONS.

II. APPLICATION OF THE HYDROGEN ELECTRODE

BY I. M. KOLTHOFF AND TOHRU KAMEDA[1]

RECEIVED JUNE 9, 1930 PUBLISHED MARCH 6, 1931

It has already been shown[2] that a platinized electrode in a hydrogen atmosphere adsorbs the cation or base from a salt or basic solution, thus yielding a more acid solution in the cell than before the treatment with hydrogen. All experiments described in the former paper have been repeated in a nitrogen atmosphere. There was no adsorption of cation or anion in any case. This proves definitely that the absorbent property of platinized platinum for strong electrolytes is a function of the electrode property (hydrogen or oxygen) of the noble metal (Frumkin).

The fact that the ordinary type of platinized hydrogen electrode adsorbs cations from a solution forms a serious objection to its use for PH measurements in unbuffered solutions. In order to overcome this change of the reaction in a slightly buffered or unbuffered solution, it is evident that the coat of platinum has to be as thin as possible.

H. T. Beans and L. P. Hammett[3] in an important paper arrived at a similar conclusion. They pointed out that the bare platinum electrode is a poor catalyst for the reaction $H_2 \rightleftarrows 2H^+ + 2e$, but that bright metallic deposits of platinum prepared electrolytically act catalytically for the hydrogen-ion reaction, and their life, while not as long as that of platinum black, is sufficient to make their use as hydrogen electrodes possible. Beans and Hammett's results were in the main confirmed by the authors, though there is one important difference between their observations of the adsorbent properties of platinized platinum and those of the authors, which can be attributed to the fact that this property of the electrode is a function of its gas charge. Acids which are adsorbed by the air electrode

[1] From the experimental part of a thesis submitted by T. Kameda to the Graduate School of the University of Minnesota in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] I. M. Kolthoff and T. Kameda, THIS JOURNAL, 51, 2888 (1929)

[3] H. T. Beans and L. P. Hammett, *ibid.*, 47,1215 (1925).

are not adsorbed by the hydrogen electrode and, therefore, can be removed from the electrode by washing out in a hydrogen atmosphere with water. This point is very important with regard to the preparation of an electrode suitable for the measurement of *PH* in unbuffered solutions. Many attempts, a discussion of which has been given in the thesis of T. Kameda,[1] have been made to prepare such an electrode. Finally, it was decided to cover platinum or gold with a bright layer of platinum, as has been suggested already by Beans and Hammett.[3] However, the procedure followed was different from that given by the authors mentioned, since it has been found that adsorbed acid can be removed easily by washing in a hydrogen atmosphere.

Materials

Chloroplatinic Acid.—Pure platinum was prepared according to the directions of Wichers.[4] The metal was dissolved in aqua regia, evaporated several times with hydrochloric acid and then several times with water. This residue was taken up in water so that the resulting solution contained about 2% of platinum as chloroplatinic acid.

Hydrogen.—This was taken from a commercial cylinder and carefully purified by passing through a wash-bottle containing alkaline permanganate over a column of pure copper wire gauze electrically heated at 450–500° and various wash-bottles.

Water.—Conductivity water was distilled over extremely dilute sulfuric acid in order to remove traces of basic impurities, then twice without any addition and finally in a quartz apparatus with condenser. The distillate was collected in a quartz container and protected from contamination by the atmosphere. Usually the final distillate was used the same day as prepared. As will be shown in another paper, this water when made carbon dioxide free has a PH of 7.0 to 7.05.

Potassium Chloride and Potassium Sulfate.—C. P. products were twice recrystallized from water and the crystals ignited for two hours in an electric furnace at 600°.

Ammonium Chloride.—A C. P. product was twice recrystallized from water and dried in a desiccator.

Zinc Sulfate.—A C. P. product was recrystallized seven times from water (for details compare next paper) and dried over deliquescent sodium bromide at a temperature below 23° until the weight was constant.

The Hydrogen Electrode Adapted for Unbuffered Solutions.—A diagram of the cell finally used is given in Fig. 1. All glass parts were made of pyrex glass. A platinum and a gold wire, both about 3 cm. long and 1 mm. thick, were used as electrodes. The wires were fused through a pyrex glass tube and sealed to a thin platinum wire which made the connection with a copper wire. These glass tubes were ground air tight into the upper part of the glass cell. In all cases it was found that the platinum and gold electrodes gave identical readings within 0.3 of a millivolt. It is recommended that platinum wire be used, as it is much easier to handle than the soft gold. Before platinization the electrodes are

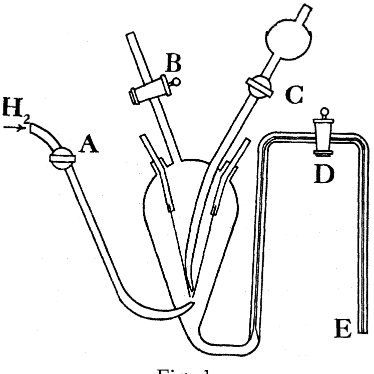

Fig. 1.

---

[4] Wichers, THIS JOURNAL, 43, 1268 (1921).

treated with a solution of potassium dichromate in strong sulfuric acid, washed with water and heated to dull redness. The plating bath contained a solution of pure chloroplatinic acid of a concentration corresponding to 2% platinum. By electrolyzing for two minutes at a current strength of 20 milliamperes, both electrodes are covered with a bright layer of platinum. The current density can be varied within wide limits. Good results are obtained at a current strength between 5 and 30 milliamperes. After the plating, the electrodes are washed well with water and then placed in the electrode cell, which is filled with conductivity water through which hydrogen has been passed for twenty minutes. The passage of hydrogen is continued for about thirty minutes, then the water is forced out of the cell in the hydrogen current. The solution to be tested is washed in hydrogen and introduced in a continuous stream which enters through A by opening stopcock C, closing D and opening B. After a few minutes the solution is again removed and the washing of the electrode in hydrogen is repeated several times. Finally the cell is partly filled with the solution so that about 2 cm. of the electrodes are covered, when the solution is not stirred. The passage of hydrogen is still continued with the stopcocks A and B open. Before taking a reading B is closed, then A, whereupon D is opened. Then the end E of the capillary tube is dipped into a saturated potassium chloride solution contained in a cell as shown in Fig. 2.

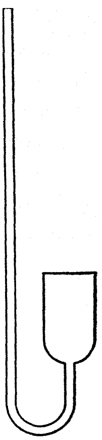

Fig. 2.

The electrodes are easily poisoned in unbuffered solutions. After each set of measurements the electrodes have to be cleaned, replated and treated as described above. Under these conditions reproducible results are obtained even in unbuffered solutions.

Results.—The most difficult problem, of course, is the PH measurement in an unbuffered solution such as potassium chloride. A 0.05 molar solution of this salt was used.

It was not possible to obtain a constant e. m. f.; in the beginning it increased (corresponding to an increase in PH), then it reached a maximum and remained constant for fifteen to thirty minutes, after which the values dropped slowly. Some results are given in the following table.

PH OF 0.05 MOLAR POTASSIUM CHLORIDE WITH THE HYDROGEN ELECTRODE AT 25°

Time in minutes....	15	30	45	55	90
PH..	6.66	6.76	6.75	6.73	6.53

Electrodes Replatinized

Time in minutes....	15	30	40	50	70
PH...............	6.72	6.77	6.77	6.76	6.73

These measurements have been repeated eight times. In all cases a maximum in PH was reached after hydrogen had been passed through for twenty to thirty minutes. If the cell was refilled with fresh potassium chloride solution after one set of measurements, no good results were obtained, the *PH* indicated being much too low. Removing the film of platinum with aqua regia, igniting and replating the electrode was necessary. The *PH* of the potassium chloride solution was also determined colorimetrically with brom thymol blue as indicator (for technique compare next paper). In this way a value of 6.77 was found, the latter being in close agreement with the reading of the hydrogen electrode.

In 0.05 molar potassium sulfate solutions a PH of 7.4 ± 0.05 was found potentiometrically.

Finally, many measurements have been made in solutions of ammonium chloride and of zinc sulfate. The e. m. f. remains constant over a much longer period of time than in the case of potassium chloride solutions and in addition the solutions can be renewed a few times before replating the electrode.

Some results are reported in the following table. The PH values have also been determined colorimetrically with adjusted methyl red as indicator (for technique see next paper). Methyl red is of special utility here on account of its negligibly small salt error.

PH IN AMMONIUM CHLORIDE AND ZINC SULFATE

Solution used	PH (H_2 electrode)	PH (color, methyl red)
0.25 Molar NH_4Cl	4.97	4.96
.01 Molar $ZnSO_4$	6.00	6.00
.02 Molar $ZnSO_4$	5.89	5.90
.05 Molar $ZnSO_4$	5.76	5.77
.1 Molar $ZnSO_4$	5.67	5.66

In more concentrated solutions of zinc sulfate the measurements with the hydrogen electrode were not so well reproducible. Quite generally it may be mentioned that in this tedious work irregularities occur once in a while. These may be due to inadequate platinization, but also it should be remembered that unbuffered solutions like those of neutral salts are very sensitive toward changes of their reaction.

Summary

Use is made of the fact that acid adsorbed by platinum can be removed by washing with water in a hydrogen atmosphere. Directions have been given for the preparation of an electrode coated with a bright layer of platinum, the use of which yields satisfactory results in the measurement of PH in unbuffered or slightly buffered solutions. The electrode is easily poisoned and cleaning and replatinizing are often required, but reproducible results can be obtained even in solutions of potassium chloride.

THE MEASUREMENT OF THE HYDROGEN-ION CONCENTRATION IN UNBUFFERED SOLUTIONS.
III. THE COLORIMETRIC METHOD

BY I. M. KOLTHOFF AND TOHRU KAMEDA[1]

RECEIVED JUNE 9, 1930 PUBLISHED MARCH 6, 1931

I. Acid–base indicators are substances with a weak acidic or basic character and therefore they have a tendency to change the P_H when added to a slightly buffered or unbuffered solution. As the molecular concentration of indicators in colorimetric work is of the order of 10^{-5} or smaller, the "acid" or "base" error will only be noticeable in solutions with extremely slight buffer action. Large errors, however, may occur when the P_H of pure water or solutions of neutral salts in water or extremely dilute solutions of acids and bases have to be measured. I. M. Kolthoff,[2] for example, found that 0.1 cc. of a 0.04% solution of methyl red added to 10 cc. of water (P_H 7.0) gave a color corresponding to a P_H of 5.1. He has already pointed out that in the measurement of P_H in slightly buffered solutions, reliable results can only be obtained if the indicator solution added has the same P_H as the unknown. Edna H. Fawcett and S. F. Acree,[3] who recently published extensive papers on the colorimetric measurement of P_H in unbuffered solutions, call these indicator solutions adjusted or isohydric.

In unknown cases mixtures of the two forms of the indicator in different ratio must be used. If different amounts of the mixture added to the unknown give the same P_H, it is isohydric with the latter. This has been pointed out already by W. H. Pierre and J. F. Fudge,[4] and especially emphasized by Fawcett and Acree.[3]

The color of the indicator in the unbuffered solution is compared with that of the same mixture in an ordinary buffer solution. As the ionic strength of the two may be quite different, a correction must be applied for the difference in activity of the indicator ions in both solutions.[5]

II. Preparation of Adjusted Indicator Solutions.—For the preparation of adjusted solutions, H. T. Stern[6] titrated the indicators with sodium hydroxide and determined the P_H with the quinhydrone electrode. It is

[6] H. T. Stem. *J. Biol. Chem.*, 65, 675 (1925).

claimed that the readings are accurate to within about 0.2 in YH, Pierre and Fudge[4] used a similar technique; however, the results described by these authors are not very convincing. In their table[7] a close agreement between the reading with the hydrogen electrode and the colorimetric ''varying drop method is shown. This agreement, however, is more or less illusory as they neglect the difference in ionic strength between the unknown and the buffer. The correction may amount to 0.2–0.3 in PH.

Fawcett and Acree[3] prepared series of adjusted indicators of known PH more in an empirical way, by noticing the change in color upon addition of an equal volume of a very dilute buffer solution. As a matter of fact, it is not very important to know the PH of the indicator mixture with a high degree of accuracy. As the PH of the solution to be tested is not known, different indicator mixtures must be tried, until one is found which gives the same reading after addition of different amounts of indicator. The color is then compared with that of the same amount of indicator in buffer solutions of known PH. More important is the use of pure indicators in this type of work. Most commercial products show quite a variation in their composition. Therefore, the authors have tried to prepare pure samples of indicators; their purity was tested by a conductimetric titration with sodium hydroxide. If a solution of a sulfonephthalein is titrated, the conductivity drops as in the titration of any strong acid. After the neutralization of the sulfonic group, the conductivity increases and a second break in the conductivity line occurs after the neutralization of the phenol group. Upon further addition of sodium hydroxide, there is a much stronger increase in conductivity. In the titration of phenolphthalein only one break in the conductivity line occurs after addition of two equivalents of sodium hydroxide (neutralization of carboxyl and phenolic group). In the neutralization of methyl red only one break can occur after addition of one equivalent of base.

If pure indicators are available, the composition of mixtures of a definite *PH* can be calculated by means of the equation

$$\frac{[HI^-]}{[I^-]} \quad \frac{(H^+)}{K_1}$$

The most reliable data of the ionization constant K_1 of the indicators have been collected by Kolthoff[S] and the authors have used these figures in their computation.

Indicators Used

Brom Thymol Blue.—A product of Scheting–Kahlbaum was recrystallized from benzene: 1.5% was insoluble; this residue was sodium chloride. The crystals were dried at 190° to remove all water. The conductimetric titration showed that this product was quite pure. The data obtained are summarized in the table.

---

[7] Ref. 4, p. 1260.

[8] I. M. Kolthoff, J. Phys. Chem., 34, 1466 (1930).

Phenol Red.—Commercial products are usually impure. According to W. R. Orndorff and F. W. Sherwood,[9] phenol red is usually contaminated by a dyestuff with weak acid character, which is insoluble in sodium bicarbonate. Therefore, the crude product can be purified by dissolving it in sodium bicarbonate solution and acidifying the filtrate with hydrochloric acid. The phenol red is collected and dried at 130". A product of Schering–Kahlbaum was still impure after this treatment. Further crystallization from acetic acid is necessary to obtain it in a pure state. The authors are obliged to Hynson, Westcott and Dunning,[10] Baltimore, Maryland, for supplying them with samples of pure phenol red, thymol blue and brom thymol blue.

Phenolphthalein.—A product obtained from J. T. Baker Company was recrystallized from methyl alcohol. According to the melting point and the result of the conductimetric titration it was quite pure.

Methyl **Red.—A** commercial product recrystallized from methyl alcohol took after drying the theoretical amount of sodium hydroxide.

A summary of the results obtained in the conductimetric titration of different samples of indicators is given in Table I.

TABLE I

CONDUCTIMETRIC TITRATION OF INDICATORS

Indicator	Origin	Alcohol concn. of soln. titrated, %	1st equiv. point Theoretical	1st equiv. point M. moles, found	2d equiv. point Theoretical	2d equiv. point M. moles, found
Brom thymol blue	Schering–Kahlbaum	20	0.160	0.153	0.321	0.330
Brom thymol blue	Same, purified	20	.160	.159	.321	.322
Brom thymol blue	National Aniline Co.	20	.160	.148	.321	.323
Phenol red	Schering–Kahlbaum	40	.283	.253	.567	.580
Phenol red	Same, purified	40	.283	.263	.567	.588
Phenol red	Same, recryst. from alc.	40	.283	.264	.567	.576
Phenol red	Hynson, Westcott and Dunning	40	.283	.260	.567	.571
Thymol blue	National Aniline Co.	40	.214	.179	.429	.412
Thymol blue	Hynson, Westcott and Dunning	80	.214	.197	.429	.424
Phenolphthalein	Purified	40			.629	.632
Methyl red	Purified	70	.372	.373		
Methyl red	National Aniline Co.	70	.372	.377		

The indicator solutions were prepared from the purified products. As a rule 100 mg. of a sulfonephthalein was dissolved in an equivalent amount of sodium hydroxide, in order to neutralize the sulfonic group. The solution was diluted with water to 100 cc. (solution of monovalent salt). To another 100 mg. of indicator double the amount of sodium hydroxide was added and the solution diluted to 100 cc. (solution of divalent salt). From these two standard solutions indicator mixtures of known PH were prepared

---

[9] W. R. Omdorff and F. W. Sherwood, THIS JOURNAL, 45,486 (1923).

[10] According to our experience the indicators marketed by this company are of the purest obtainable in any country. It is peculiar that in the titration of pure phenol red the first break in conductivity appears before the complete neutralization of the sulfonic acid group.

in the way described above. With phenolphthalein as an indicator it is hard to prepare mixtures of known PH, as the first and second ionization constants are not known exactly and are of the same order of magnitude. Two 0.1% stock solutions of phenolphthalein in 50% alcohol were prepared: one with one equivalent sodium hydroxide (mono-), the other with two equivalents (di-). The right mixture was found empirically. From methyl red a 0.1% solution in 70% alcohol was prepared, and another in 50% alcohol with the same amount of indicator to which one equivalent of sodium hydroxide had been added.

Stability of Indicator Mixtures.—In agreement with the statement of other authors (especially Stern[6]) it was found that partly neutralized indicator solutions cannot be kept for a long time without changing their PH. This, of course, is especially the case with phenolphthalein, as the red quinoid is transformed into the carbonium salt. However, with partly neutralized brom thymol blue, thymol blue and phenol red solutions the authors had a similar experience. Usually the *PH* decreases after a few days' standing. This behavior, of course, has only to be considered in the determination of *PH* in pure water or solutions of neutral salts in pure water. If the solution to be tested has a distinct buffer action, it is immaterial whether the indicator solution used is exactly isohydric with the former.

For the measurement of PH in pure water or any other unbuffered solution, it is recommended that freshly prepared indicator mixtures be used and that these be made up fresh every two or three days. According to the authors' experience, there is no special advantage in keeping a complete series of solutions of an adjusted indicator, each differing 0.2 in *PH* from the other, as Fawcett and Acree recommend. The right mixture must be found in any case by empirical testing, and the series of adjusted solutions is not stable.

III. Technique of the Colorimetric PH Determination in Unbuffered Solutions.—In the *PH* measurement of pure water, neutral salt solutions in pure water and dilute solutions of sodium hydroxide, the liquid has to be protected from contamination by carbon dioxide (and other impurities of acid or basic nature) in the atmosphere. For the measurements described in this paper, the authors used a cell such as is shown in Fig. 1.

A sample of pure water is introduced into the Pyrex glass cell and made carbon dioxide free by passing through purified air which has been thoroughly washed by passing through soda lime, dilute sulfuric acid and several wash-bottles of pure water. After the water is carbon dioxide free (tests must be made after different times of passage of air, until the PH does not change further), a measured amount of the indicator mixture is added quickly from a pipet, by removing the glass stopper of the cell. During the addition of indicator the air is kept flowing through the cell.

Then after the solution is homogeneous, the taps A and B are closed and the color is compared with that of the same amount of indicator in a buffer solution kept in a cell of similar shape (glass stopcocks are not necessary here). After the reading the carbon dioxide-free air is again passed though the sample, and more indicator is added. After the color comparison a third portion of indicator is added. *If the correct indicator mixture is used, the same PH readings are found with different amounts of indicator.* If the *PH* found decreases with increasing amounts of indicator, the mixture is too acid, and if the *PH* decreases, the indicator mixture has too alkaline a reaction.

In the *PH* measurements of solutions of neutral salts in pure water, a measured volume of pure water was introduced into the cell and made carbon dioxide free, whereupon a weighed amount of salt was quickly added. The comparison was then made as described above. Several ***PH*** measurements have been made in extremely dilute sodium hydroxide solutions. It is one of the hardest problems to measure the *PH* of such solutions with any degree of accuracy. The hydrogen electrode is easily poisoned in such an unbuffered solution. The colorimetric method if properly applied gives excellent results, as will be shown in the experimental part.

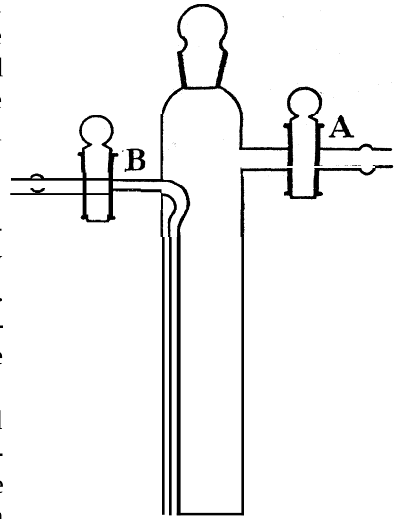

Fig. 1.

The water used was carefully prepared by distilling conductivity water over extremely dilute sulfuric acid to remove traces of volatile bases. The distillation was twice repeated without any addition and finally in a quartz apparatus with a quartz condenser. The first and last quarters of the distillate were discarded. The quartz receiver was protected by means of soda-lime tubes and wash-bottles containing very dilute sulfuric acid from atmospheric contamination. As a rule the water was used on the same day that the final distillation was made. It was siphoned from the quartz receiver into the pyrex cells. At least ten samples of water have been prepared, which after having been made carbon dioxide free showed a ***PH*** of **7.0** to **7.05**. **All** measurements have been made at a temperature of 25 ± 1.0°. Clark and Lubs buffer solutions were used for comparison, the *PH* of these being determined with the hydrogen electrode in a thermostat at 25°.

The *PH* value found with the isohydric indicator mixture must be corrected for the difference in ionic strength between the sample and the buffer solution. According to I. M. Kolthoff[6] a correction of **0.25** to **0.30** should be added to the *PH* found under the conditions mentioned in measurements in solutions with an ionic strength smaller than **0.0001** (water, and extremely dilute sodium hydroxide solutions) with brom thymol blue, phenol red, thymol blue and phenolphthalein as indicators. For methyl red the salt error is negligibly small,

IV. Experimental Results.—Fifteen cc. of water to which the indicated amounts of **0.1%** indicator mixtures were added was used. The water was practically carbon dioxide free when introduced into the cell; the *PH* was constant after passing through carbon dioxide-free air for thirty minutes. Some of the results obtained with mixtures of brom thymol blue and phenol red, respectively, are given in the following table.

TABLE II

COLORIMETRIC DETERMINATION OF *PH* IN 15 CC. OF PURE WATER AT 25°

Indicator	Ratio [HI⁻]/[I⁻]	*PH* for various volumes of indicator[a] 0.1 cc.	0.3 cc.	0.5 cc.
Brom thymol blue	96 : 4	6.62	6.50	6.20
Brom thymol blue	100 : 55	7.03	7.00	7.01
Brom thymol blue	4 : 96	7.93	8.05	8.25
Phenol red	99 : 1	6.70	6.60	6.50
Phenol red	100 : 10	7.03	7.05	7.07
Phenol red	1 : 99	8.55	8.85	9.00

[a] The observed *PH* has been increased by 0.25 to correct for the salt error.[5]

It appears that the mixtures of brom thymol blue, 100:55, and of phenol red, 100:10, are isohydric with the water. The corrected value of PH found in ten different experiments with different samples of water varied between **7.00** and **7.05.** The pure water is very sensitive to traces of carbon dioxide. After the water had been made carbon dioxide free the stopper of the cell was removed for one minute. The *PH* (corrected) dropped from **7.00** to **6.85.** Upon transferring this water–indicator mixture to another cell, the *PH* fell to **6.35.**

TABLE III

COLORIMETRIC DETERMINATION OF PH IN 15 CC. OF POTASSIUM CHLORIDE SOLUTION (AT 25°)

Indicator	Ratio [HI⁻]/[I⁻]	Concentration of 0.1 m.	0.25 m.	0.5 m.
Brom thymol blue[a]	100 : 55	6.77	6.77	6.77
Phenol red[a]	100 : 10	6.78	6.75	6.75
Hydrogen electrode[b]		6.70–6.77		

[a] No correction for salt error has been made. [b] Adapted for unbuffered solution, THIS JOURNAL, **53**, 821 (1931).

The following table gives values found in extremely dilute sodium hydroxide solutions. From the known hydroxyl ion concentration *PH* (theoretical) was calculated: *PH* = **14.00** − p_{OH} (25°). Measurements have been made with phenolphthalein and thymol blue, respectively, as indicators.

TABLE IV

COLORIMETRIC DETERMINATION OF *PH* IN (15 CC. OF) DILUTE SODIUM HYDROXIDE SOLUTION (AT 25°)

Indicator	Ratio $[HI^-]/[I^-]$	PA for various volumes of indicator[n] 0 1 cc.	0.3 *cc.*	0.5 cc	Theoretical
Phenolphthalein	99 : 1	9.30	9.30	9.30	9.22
Phenolphthalein	70 : 30	9.32	9.42	9.50	9.22
Phenolphthalein	60 : 40	9.40	9.50	9.60	9.22
Thymol blue	30 : 70	9.25	9.25	9.25	9.22
Thymol blue	50: 50	9 25	9.15	9.10	9.22
Phenolphthalein		9.30	9.28	..	9.22
Phenolphthalein		9.45	..	..	9.47
Phenolphthalein	...	9.73		..	9.82
Phenolphthalein		9.87	..	..	10.00
Phenolphthalein	...	10.05	..	..	10.12

[a] The observed *PH* has been increased by 0.25 to correct for the salt error.[5]

From these experiments it may be inferred that the PH of extremely dilute sodium hydroxide solutions can be determined with an accuracy of at least **0.1** if isohydric solutions of phenolphthalein or thymol blue are used as indicators and the proper correction for the salt error is added to the experimental figure. Recently J. W. McBain, O. E. Dubois and K. G. Hay, and J. W. McBain, M. E. Laing and O. E. Clark[11] have given data showing that phenol red, o-cresol red, phenolphthalein and thymol blue cannot be used for the colorimetric determination of PH in extremely dilute sodium hydroxide solutions, as the experimental figures differ by more than one to two units from the theoretical ones. From the above it is quite evident that this conclusion is unwarranted if precautions are taken against contaminations by carbon dioxide and if isohydric buffer solutions are used and the proper salt correction is applied.

Finally, it may be mentioned that the PH of pure zinc sulfate solutions has been measured with adjusted methyl red as indicator. At concentrations of zinc sulfate below **0.1** molar the colorimetric readings agreed within **0.01** in PH with the figures obtained with the hydrogen electrode. Details will be given in a paper on the hydrolysis of zinc sulfate.

Summary

1. Commercial indicators were purified by recrystallization and the purity tested by conductimetric titrations with sodium hydroxide.

2. A technique has been described for the colorimetric measurement of PH in pure water, of neutral salts in pure water and of extremely dilute sodium hydroxide solutions.

3. In using isohydric indicator solutions and applying the proper salt corrections, the PH of pure water has been determined with brom thymol blue and phenol red at 25° with an accuracy of 0.05 in PH. With isohydric phenolphthalein or thymol blue solutions, the *PH* of extremely dilute sodium hydroxide solutions has been measured with an accuracy of 0.1 in PH.

THE HYDROLYSIS OF ZINC SULFATE SOLUTIONS, SOLUBILITY PRODUCT OF HYDROUS ZINC OXIDE AND THE COMPOSITION OF THE LATTER PRECIPITATED FROM ZINC SULFATE SOLUTIONS

BY I. M. KOLTHOFF AND TOHRU KAMEDA[1]

RECEIVED JUNE 9, 1930 PUBLISHED MARCH 6, 1931

1. Hydrolysis of Zinc Sulfate.—For two reasons no reliable data on the hydrolysis of solutions of zinc sulfate are given in the literature; in the first place, no careful attention has been paid to the preparation of pure zinc sulfate, and in the second place the accurate measurement of the hydrogen-ion activity in zinc sulfate solutions is relatively difficult. The latter solutions have an extremely small buffer capacity, and on account of the hydrolytic adsorption by platinized platinum described in a former paper,[2] the ordinary type of platinized hydrogen electrode does not give reliable or reproducible results. The use of the quinhydrone electrode too is rather precarious in slightly buffered solutions. The authors have applied this electrode in all measurements described in this paper, but the readings were reproducible no better than to within 0.04 to 0.05 in PH, which was not considered sufficiently accurate for this type of work. Finally, the colorimetric method involves some complications on account of the salt influence upon the color of an indicator at constant activity of the hydrogen ions. In the present work the PH has been determined with a hydrogen electrode adapted to measurements in unbuffered solutions and described in a former paper.[3] The platinum wire was coated with a bright layer of platinum; after each set of measurements it was cleaned with aqua regia, ignited and replated. For details regarding manipulation the reader is referred to the former paper.[3]

The measurements were reproducible to within 0.01 to 0.02 of *PH*. In a former study[4] it had been found that the salt error of methyl red is negli-

gibly small in solutions with an ionic strength smaller than 0.5. For this reason the colorimetric method was applied with adjusted methyl red solutions[5] as indicator. At concentrations of zinc sulfate below 0.1 molar the electrometric and colorimetric methods gave exactly identical results.

Materials Used

Zinc Sulfate.—C. P. zinc sulfate was repeatedly recrystallized from conductivity water, until methyl red added to 0.5 g. of salt dissolved in 15 cc. of water indicated within 0.01 in PH a constant hydrogen-ion concentration. The products from the sixth, seventh and eighth recrystallization showed the same acidity and the salt after the seventh recrystallization was used in this work.

The recrystallization of the zinc sulfate has to be done very carefully; if the salt is boiled with water for some time a scum of basic sulfate is formed, and the crystals obtained in cooling the filtrate have too acid a reaction. In this work the zinc sulfate was added to conductivity water which was kept at about 70° in a larger bath. After the crystals had been dissolved by mechanical stirring, the solution was cooled in an ice-bath, repeatedly stirred and the salt collected by suction.

Water.—The water used as a solvent was obtained from conductivity water by distillation over very dilute sulfuric acid and finally in a quartz apparatus without any further addition. It was protected from atmospheric contamination.[3,5]

Methyl Red.—A product which was 99% pure was recrystallized from methyl alcohol. The conductimetric titrations with sodium hydroxide gave the calculated results. A solution of 100 mg. of indicator in 70% alcohol was prepared. A 0.1% solution of the sodium salt in 50% alcohol was obtained by adding the equivalent amount of sodium hydroxide. From these two stock solutions the adjusted mixtures were prepared.[5]

Buffer Solutions.—Biphthalate–sodium hydroxide buffers with an interval of 0.1 in PH were used. The PH values of these were checked with the hydrogen electrode at 25°. The colorimetric determinations were made at the same temperature.

Results

In Table I the results of the measurements are reported. The first column gives the concentration of zinc sulfate (moles per liter), the second the *P*H measured with the hydrogen electrode, the third the data found colorimetrically. The fourth column gives figures graphically interpolated from measurements made by M. Quintin[6] (using the quinhydrone elec-

trode), and the last column gives interpolated data of H. G. Denham and N. A. Marris[7] (also obtained with the quinhydrone electrode).

The figures obtained by the writers are quite different from those of Quintin.[6] Apparently he used a preparation containing a trace of free acid. The figures of Denham and Marris[7] are irregular; a study of their paper shows that the measurements are not well reproducible;[8] moreover, according to their report the *PH* increases with increasing zinc sulfate concentration, which seems highly improbable.

From the table it will be seen that the electrometric and colorimetric data obtained by the authors agree within 0.01 in *PH* up to a concentration of 0.1 molar. At higher concentrations the colorimetric reading gives a higher PH than the hydrogen electrode indicates. This may be caused by a salt error of the indicator at these high ionic strengths. However, it should be mentioned that at these high concentrations of zinc sulfate the measurements with the hydrogen electrode are not as well reproducible (to about 0.08 PH) as those in more dilute solutions. In order to test the magnitude of the salt error of methyl red at high ionic strengths, electrometric (hydrogen electrode) and colorimetric (methyl red) measurements have been made in 0.01 N acetate buffers in the presence of large amounts of sodium sulfate, magnesium chloride and magnesium sulfate.

TABLE II

SALT ERROR OF METHYL RED AT HIGH IONIC STRENGTH

Concn. of salt in 0.01 N acetate buffer, molar		PH, electr.	Pa, color.	Salt error of methyl red
Na_2SO_4	0.25	5.48	5.59	+0.11
$MgCl_2$	.25	5.38	5.50	+ .12
$MgSO_4$	.25	5.39	5.56	+ .17
$MgSO_4$	.5	5.30	5.52	+ .22

Magnesium sulfate is a salt of the same type as zinc sulfate, and it appears that if added to the acetate buffer the difference between the electrometric and colorimetric reading is of the same order as in pure zinc sulfate solution. On account of the uncertainty in the results obtained with the hydrogen electrode in the latter solutions, no correction has been applied at these higher ionic strengths. Depending upon the strength of zinc hydroxide as a mono-acid or diacid base, the hydrolysis of zinc sulfate can take place according to the reactions

$$Zn^{++} + H_2O \leftrightarrows ZnOH^+ + H^+ \qquad (1)$$

$$Zn^{++} + 2H_2O \leftrightarrows Zn(OH)_2 + 2H^+ \qquad (2)$$

As a matter of fact both reactions can occur simultaneously. From the *PH* values obtained in zinc sulfate solutions, it can be calculated according

---

[7] H. G. Denham and N. A. Marris, *Trans. Faraday Soc.*, 24, 510 (1928).

[8] See Ref. 7. On p. 512 of their paper they mention that the $[H^+]$ at a dilution of 32 is 1.6×10^{-6}; in the table on p. 514 a value of 5.05×10^{-6} is given.

to which equation the hydrolysis takes place. If it occurs according to (1)

$$\frac{[a\text{ZnOH}^+]\,[a\text{H}^+]}{[a\text{Zn}^{++}]} = K_{1\,\text{hydr.}} \tag{3}$$

K should be constant. In the other case the equation

$$\frac{[a\text{Zn(OH)}_2]\,[a\text{H}^+]^2}{[a\text{Zn}^{++}]} = K_{2\,\text{hydr}} \tag{4}$$

should hold. From the experimental figures it appears that the hydrolysis takes place according to (1) and is quantitatively expressed by **(3).** In the calculation of $K_{\text{hydr.}}$ (Eq. *3)* it is assumed that the activity of the ZnOH$^+$ ions is equal to the hydrogen-ion activity $[a\text{H}^+]$. This will be approximately true in the more dilute solutions, at higher ionic strengths the difference between the activity coefficients of both ions probably will be no longer negligibly small. However, we have no means of determining the activity of ZnOH$^+$ ions separately, and therefore this assumption must be made. The activity of the zinc ions ($[a\text{Zn}^{++}]$) in zinc sulfate solutions has been taken from an experimental study of U. B. Bray,[9] assuming that the activities of the zinc and sulfate ions are equal at the same ionic strength. The values of the hydrolysis constant are given in the following table.

TABLE III

HYDROLYSIS CONSTANT (EQ. 3) IN ZINC SULFATE SOLUTIONS AT 25°

Concn. of zinc sulfate. *molar*	$[a\text{H}^+] \times 10^6$	$[a\text{Zn}^+]$	$K_{\text{hydr.}} \times 10^{10}$
0.01	1.00	4.2×10^{-3}	2.4
.02	1.26	6.4×10^{-3}	2.60
.05	1.70	1.1×10^{-2}	2.76
.1	2.14	1.61×10^{-2}	2.84
		Average	2.65

As the PH values in the more concentrated zinc sulfate solutions are rather uncertain, the figures obtained in these solutions have not been used for the calculation of the hydrolysis constant. From the figures given in the table, it appears that $K_{\text{hydr.}}$ is constant within 10% at zinc sulfate concentrations between 0.01 and 0.1 molar. Therefore the hydrolysis according to Equation 2 is negligibly small, and it may be inferred that zinc hydroxide with regard to its first step of ionization behaves like a strong base. Considering the similarity between magnesium and zinc hydroxide, this result could be expected. The second ionization constant of zinc hydroxide

$$\text{ZnOH}^+ \rightleftarrows \text{Zn}^{++} + \text{OH}^-$$

$$\frac{[a\text{Zn}^{++}]\,[a\text{OH}^-]}{[a\text{ZnOH}^+]} = \frac{K_w}{K_{\text{hydr.}}}$$

has been calculated from the hydrolysis constant and the ionic product of water. At 25° $K_w = 1.00 \times 10^{-14}$, and for $K_{\text{hydr.}}$ an average value of

---

[9] U. B. **Bray,** THIS JOURNAL, 49, **2372 (1927).**

2.65×10^{-10} has been found. Therefore the second ionization constant of zinc hydroxide at 25° is equal to **3.8** (± 0.3) $\times 10^{-5}$, which is about twice as large as the basic constant of ammonia.

It may be mentioned that all values of PH have been calculated by using the standard values originally given by S. P. L. Sörensen,[10] and advocated by W. M. Clark.[11] The Sorensen values do not exactly correspond to the activity exponents of the hydrogen ions. Accepting the relation

$$Pa_{H} = P_{H} + 0.04$$

(Pa_{H} is the negative logarithm of the activity of the hydrogen ions and PH is the hydrogen-ion exponent according to Sorensen), it is found that $K_{\text{hydr.}} = 2.2 \times 10^{-10}$ and K_2 of zinc hydroxide is 4.4 (± 0.4) $\times 10^{-5}$. Finally it may be mentioned here that the authors have found no indications whatsoever that the PH of zinc sulfate solutions changes on standing.[12] If kept in pyrex bottles (or Jena glass) the *PH* is unaltered after a few months' standing.

2. Solubility Product of Hydrous Zinc Oxide and the Composition of the Latter Obtained by Precipitation from Zinc Sulfate **Solution.**—Solutions of pure zinc sulfate of various strengths were titrated at 25+ 0.1° with sodium hydroxide, the latter usually having a concentration about ten times larger than the zinc solution. During the titration the PH was measured by means of a hydrogen electrode. The titration cell as shown in Fig. 1 is very suitable for this purpose. Again a platinum wire coated with a bright layer of platinum was used. With an electrode coated with platinum black the results were not quite reproducible, and it is difficult to find the values with an accuracy of 0.1 in PH. With the wire coated with a bright layer of platinum the readings were reproducible to within 0.02. Replating is necessary after each set of measurements.

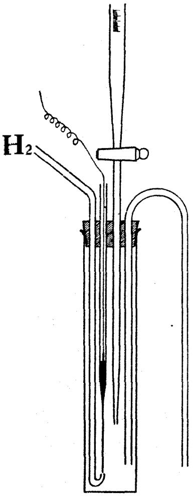

Fig. 1

After the addition of 1 to 2% of the equivalent amount of sodium hydroxide, the hydrous zinc oxide begins to precipitate; from this point on the PH increases very slightly on further addition of sodium hydroxide. In the following table the *PH* values at which the precipitation of the hydrous zinc oxide starts are indicated. As the zinc concentration was known at this point, the solubility product could be calculated. The activity of the zinc ions again was found from the data

$$[a\text{Zn}^{++}]\,[a\text{OH}^-]^2 = S_{\text{Zn(OH)}_2x\text{H}_2\text{O}}$$

given by U. B. Bray? At 25°, $P_{OH} = 14.00 - P_H$. If the solubility of the hydrous zinc oxide at 25° is s, and the saturated solution is completely dissociated into the ions, which practically is the case as may be inferred from the magnitude of the second ionization of zinc hydroxide, then $s = \sqrt[3]{S/4}$.

The values of s expressed in moles per liter are given in the table. It appears that the apparent solubility product is not quite constant, but decreases with increasing zinc concentration in the solution. The product $[c\mathrm{Zn}^{++}]\ [a\mathrm{OH}^-]^2$, in which $[c\mathrm{Zn}^{++}]$ indicates the total zinc-ion concentration, yields a value which is a much better constant than $[a\mathrm{Zn}^{++}]\ [a\mathrm{OH}^-]^2$. The corresponding values are included in the table. The first column gives the concentration of the zinc sulfate solution titrated, the second the P_H values computed on the basis of Sörensen's standard values, the third column the solubility product $[a\mathrm{Zn}^{++}]\ [a\mathrm{OH}^-]^2$, the fourth one the corresponding solubility s, and the last column the product $[c\mathrm{Zn}^{++}]\ [a\mathrm{H}^+]$.[2]

TABLE IV

SOLUBILITY PRODUCT OF HYDROUS ZINC OXIDE

Concn. of zinc sulfate, molar	P_H at precipitation of hydrous oxide	$S = [a\mathrm{Zn}^{++}][a\mathrm{OH}^-]^2 \times 10^{18}$	$s \times 10^6$	$[c\mathrm{Zn}^{++}][a\mathrm{OH}^-]^2 \times 10^{18}$
0.01	6.49	4	1.0	9.5
.05	6.17	2.5	0.85	10.9
.25	5.80	1.0	.64	9.9

H. T. S. Britton,[13] who studied the precipitation of hydrous zinc oxide, found that in 0.025 molar zinc sulfate solution the precipitation started at a P_H of 5.2 (at 18°). This value is more than one unit lower than that found by the authors. Accordingly Britton calculated a solubility product of the order of 10^{-21}, which is about 1000 times smaller than the figure in the above table. Probably some error must have been introduced in Britton's measurements of P_H. From the curve in his paper (p. 2125) it can be calculated that the P_H in 0.025 molar solution of pure (?)zinc sulfate is 3.8, whereas this figure according to our measurements is 5.87!

The figures found by the authors are of the same order of magnitude as those reported by H. G. Dietrich and J. Johnston[14] and Miss de Wÿs.[15] The former calculate a solubility of 2×10^{-6} molar, the latter of 2.7×10^{-6}. The value found by the authors is about 1×10^{-6}, whereas other data reported in the literature are much higher.[16]

As will be discussed below, the hydrous zinc oxide precipitated by sodium hydroxide contains some sulfate in a ratio of about $3\mathrm{ZnO}:1\mathrm{ZnSO_4}$. Die-

trich and Johnston,[11] as well as de Wÿs,[15] used crystalline zinc hydroxide in their work. In order to obtain a better comparison with their data, measurements of PH have been made in zinc sulfate solution saturated with different kinds of zinc hydroxide and zinc oxide. In addition the neutralization curve of zinc chloride (instead of zinc sulfate) with sodium hydroxide has been determined at 25°. The hydrous zinc oxide formed in the latter case contains only a small fraction of chloride. The zinc chloride solution was obtained by adding an equivalent amount of barium chloride solution to zinc sulfate.

Crystalline zinc hydroxide (a) was obtained according to the directions of H. G. Dietrich and J. Johnston by crystallization from an ammoniacal solution. The crystals obtained were kept in a desiccater over deliquescent sodium bromide for two years. The water content determined by ignition in an electric furnace at 800° was 18.18% (calcd., 18.11%).

Another crystalline product (b) was obtained by precipitation of zinc sulfate with an excess of ammonia. The product was carefully washed in a mortar with water, during which time it changed into a definite crystalline compound—zinc oxide. Products a and b were heated in an electric furnace for about three hours at 800°.

0.05 Molar zinc sulfate was saturated at 25° in the hydrogen electrode cell adapted for measurements of unbuffered solutions with the different products of zinc hydroxide and zinc oxide. The data are reported in **Table** V. The figures obtained in the precipitation of zinc sulfate and zinc chloride with sodium hydroxide are also included.

TABLE V

PH OF 0.05 MOLAR ZINC SULFATE SATURATED WITH DIFFERENT KINDS OF ZINC HYDROXIDE OR ZINC OXIDE AT 25°

Zinc hydroxide or oxide	PH	Remarks
Cryst. $Zn(OH)_2$ (a)	6.13	All solutions have a colloidal appearance on shaking with the different preparations.
Cryst. $Zn(OH)_2$ (b)	6.16	
ZnO by ignition of (a)	6.22	
ZnO by ignition of (b)	6.12	
Freshly pptd. by NaOH	6.17	
Freshly pptd. by NaOH in 0.05 molar $ZnCl_2$	6.19	

In all cases the PH measured is the same within 0.05 as in the zinc sulfate solution to which a trace of sodium hydroxide has been added, whereas one would expect individual differences between the different solutions as the solids present in excess have different compositions and crystal structures. However, it seems doubtful whether these different modifications are stable in a zinc sulfate solution; on shaking, all solutions assume a colloidal appearance as in zinc sulfate with a small amount of sodium hydroxide.

In Fig. 2 the change in PH during the titration of 0.01 molar and 0.05 molar zinc sulfate with 0.2 *N* sodium hydroxide and of 0.25 molar zinc sulfate with 1 *N* sodium hydroxide have been given. The abscissa gives the percentage of the equivalent amount of sodium hydroxide added.

In each case the *P*H values have been determined in the hydrogen electrode titration cell usually after addition of 0, 2, 4, 6, 8, 10, 25, 40, 60, 70, 75, 78, 80, 82, 85, 90, 95 and 100% of the equivalent amount of base. Moreover, the curve in the titration of 0.05 molar zinc chloride under similar conditions has been given. **A** jump in potential occurs at a PH approximately between 7 and 10, long before an equivalent amount of sodium hydroxide has been added. This indicates that a basic zinc sulfate or hydrous oxide containing adsorbed sulfuric acid is formed. The location of the jump is almost independent of the concentration of the zinc solutions titrated. Figures are given in Table VI.

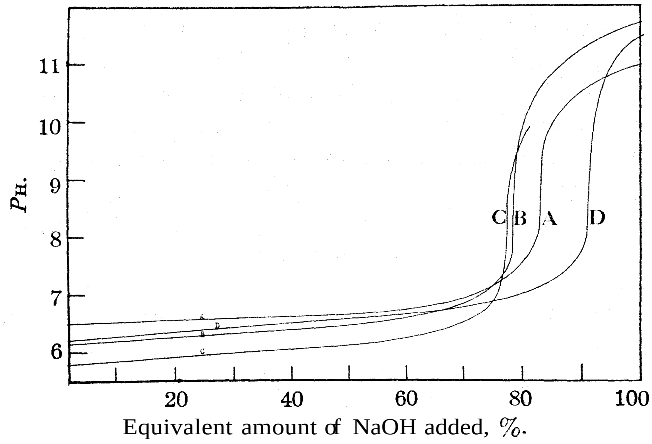

Fig. 2.—Potentiometric titration curves of zinc sulfate with sodium hydroxide. A, 25 ml. of 0.01 M $ZnSO_4$ titrated with 0.1981 *N* NaOH; B, 25 ml. of 0.05 M $ZnSO_4$ titrated with 1.0046 *N* NaOH; C, 25 ml. of 0.25 M $ZnSO_4$ titrated with 1.0046 M NaOH; D, 25 ml. of 0.05 M $ZnCl_2$ titrated with 0.1988 M NaOH.

TABLE VI

END-POINTS IN ZINC SULFATE TITRATION DERIVED FROM POTENTIOMETRIC TITRATION AT 25°

Solution, molar		Jump in potential after addition of NaOH equivalents to
$ZnSO_4$	0.01	83%
$ZnSO_4$	.05	79%
$ZnSO_4$	.25	78%
$ZnCl_2$	.05	92%

The precipitate formed in the titration of zinc chloride is much less basic than that from zinc sulfate. H. T. S. Britton[13] found the precipitation of 0.025 molar zinc sulfate complete after addition of 77.5% of the equivalent amount of sodium hydroxide, which is in good agreement with the data reported.

It seemed interesting to investigate how the composition of the hydrous oxide formed changes during the precipitation. In the titration of aluminum sulfate with sodium hydroxide Miller[17] has found that the hydrous oxide precipitated contains more acid, the less base has been added. As will be shown below, the precipitate formed on the addition of sodium hydroxide to zinc sulfate has a fairly constant composition until quite near the end-point.

In addition it was of interest to see how the P_H of the solution and the composition of the precipitate change on aging. In one set of experiments mixtures of zinc sulfate and sodium hydroxide were shaken for ten days at 25° and thereafter analyzed. In another set mixtures were kept for three hundred days at room temperature and then analyzed. Finally the temperature effect has been studied by heating mixtures of zinc sulfate and sodium hydroxide for ten days at 80°; they were analyzed after cooling.

The experiments were made in the following way. Known amounts of zinc sulfate dissolved in water were mixed with a definite volume of standardized sodium hydroxide. The mixture was immediately diluted with water in a volumetric flask so that the initial concentration of zinc sulfate in all cases corresponded to 0.05 molar. Immediately or after the indicated time of standing the P_H was determined with the hydrogen electrode adapted for measurements of unbuffered solutions. The filtrate was used for the further analysis. In part of the filtrate the P_H was determined colorimetrically with adjusted brom thymol blue as an indicator. The data obtained were not exactly the same as those found potentiometrically. As the salt error of the indicator under the conditions of these experiments is not exactly known, the data found colorimetrically have been omitted in the tables. In another part of the filtrate the zinc concentration was determined by precipitation with o-hydroxyquinoline. The precipitate was weighed or, if the zinc concentration was very small, titrated bromometrically. Both procedures give very accurate results. From the original zinc sulfate content, the amount of base added and the zinc concentration found in the precipitate, the composition of the hydrous oxide could be calculated. However, in order to check the analyses in all cases, the sulfate content in the filtrate was determined by a conductimetric titration with barium chloride in a thermostat at 25°. Details of this investigation will be described elsewhere. It may be stated here that the results calculated from the zinc analysis checked to within 1% with those obtained from the sulfate titrations.

Table VII gives the change of P_H of zinc sulfate solutions to which small amounts of sodium hydroxide had been added. The electrometric measure-

---

[17] Miller, *U. S. Publ. Health Repts.*, **38**, 1995 (1923).

ments were made at 25° immediately after addition of base, after fifteen days' shaking at room temperature and after sixteen days' heating at 80°.

TABLE VII

EFFECT OF AGING UPON P_H OF ZINC SULFATE WITH SMALL AMOUNTS OF SODIUM HYDROXIDE

Concn. of zinc sulfate, molar	Added sodium hydroxide in equivalents	P_H immediately after mixing	P_H after 16 days at 25°	P_H after 16 days at 80°
0.01	5%	6.49	6 42	6.29
.05	5%	6.17	6 09	5.94
.25	5%	5.80	5.80	5.72

In Table VIII a summary of all the analytical results has been given. In all cases the original concentration of zinc sulfate was equal to 0.05 molar. The first column gives the equivalent amount of sodium hydroxide added expressed in percentage, the second column the composition of the precipitate by the ratio $ZnO:ZnSO_4$ as derived from the analysis after immediate filtration. The third gives the same ratio after ten days' shaking at room temperature and the fourth the same after standing for ten days at 80°.

TABLE VIII

COMPOSITION OF HYDROUS ZINC OXIDE BY PRECIPITATION FROM 0.05 MOLAR ZINC SULFATE

Equivalent amount of sodium hydroxide added	Ratio $ZnO:ZnSO_4$		
	Immediately after precipitation	After 10 days at 25°	After 10 days at 80°
25%	3.2:1	3.3:1	5.9:1
50%	3.1.1	3.5:1	5.0:1
75%	3.2:1	3.7 1	4.6:1

Finally, Table IX shows the effect of aging for three hundred days at room temperature upon the composition of the precipitate.

TABLE IX

COMPOSITION OF HYDROUS ZINC OXIDE AFTER 300 DAYS AT ROOM TEMPERATURE

Equivalent amount of sodium hydroxide added to 0.05 molar zinc sulfate	10%	20%	50%	80%	90%
Ratio $ZnO:ZnSO_4$ in precipitate	3.5:1	3.6:1	3.4:1	4.2:1	8.8:1

From the last three tables it may be inferred that the composition of hydrous zinc oxide precipitated from zinc sulfate solution by sodium hydroxide is fairly constant from the beginning to the end of the precipitation, corresponding to the separation of a basic salt $3ZnO \cdot ZnSO_4 \cdot xH_2O$. The jumps in potential in the potentiometric titration discussed before also indicate approximately a similar composition. Pickering[18] concluded that after complete precipitation of all the zinc the precipitate had the composition $4ZnO \cdot ZnSO_4$. However, it seems that just at the equivalence point, where no excess of zinc sulfate is present, the precipitate is no longer

---

[18] Pickering, *J. Chem. Soc.*, 91, 1981 (1907).

stable, as may be seen from the last two figures in the last table. According to Zubkowskaja[19] only the basic salt $3ZnO\cdot ZnSO_4\cdot xH_2O$ is a definite compound. The latter is slowly decomposed by water, as shown by experiments of W. Feitknecht.[20]

From experiments of the latter, one would conclude that the basic salt is only stable in 0.00075 molar zinc sulfate or more concentrated solutions. Therefore, the composition derived from experiments where the precipitation is just complete, has no exact significance. The basic compound is fairly stable at room temperature; even after standing for three hundred days with the supernatant liquid the basicity of the precipitate increases only slightly ($3.5ZnO:ZnSO_4$) whereas the **PH** of the solution practically does not change. However, at higher temperatures the precipitate loses acid and becomes definitely more basic. Accordingly the **PH** of the supernatant liquid decreases, as may be seen from the tables, in which the influence of heating for ten days at SO° has been shown. Though the composition of the precipitate formed at room temperature corresponds to $3ZnO\cdot ZnSO_4\cdot xH_2O$, it is not possible to conclude with certainty from the above experiments whether the latter is a definite compound. The fact that the ratio of $ZnO:ZnSO_4$ is constant during the entire precipitation is an indication in this direction.

Summary

1. An exact study has been made of the hydrolysis of solutions of pure zinc sulfate at 25°. It could be concluded that zinc hydroxide as a monoacid base is very strong; its second ionization constant at 25° is equal to $4.4\ (\pm 0.4) \times 10^{-5}$.

2. The solubility of hydrous zinc oxide precipitated from zinc sulfate is at 25° about 1×10^{-6} molar. This figure is smaller than most data reported in the literature.

3. The PH of a zinc sulfate solution saturated with zinc hydroxide is practically independent of the kind of zinc hydroxide or zinc oxide present as solid.

4. The hydrous oxide formed on the addition of sodium hydroxide to zinc sulfate solutions at 25° has a fairly constant composition during the entire precipitation, corresponding to the formation of a basic salt $3ZnO\cdot ZnSO_4$. The effect of aging at room temperature is small. Heating the precipitate with the supernatant liquid for ten days at 80° changes the composition of the hydrous oxide. It becomes more basic, and the PH of the supernatant solution decreases.

THE CONSTANTS OF THE BEATTIE–BRIDGEMAN EQUATION OF STATE WITH BARTLETT'S P–V–T DATA ON HYDROGEN

BY W. EDWARDS DEMING AND LOLA E. SHUPE

RECEIVED JULY 14, 1930 PUBLISHED MARCH 6, 1931

In two previous papers, Bartlett[1] and his co-workers have published compressibility data for hydrogen, nitrogen and their 3:1 mixture to 1000 atmospheres pressure and from −70 to 400°. These included their own measurements and those from other sources. It is desirable to have a formula that will represent this compressibility data over as wide a range as possible in order that thermodynamic properties may be computed analytically. Accordingly the writers have attempted to find values for the constants in the Beattie–Bridgeman[2] equation of state for these data. The constants for nitrogen have already been published.[3] We here present the values of the constants for hydrogen; and in a later article we hope to present those for the 3:1 hydrogen–nitrogen mixture with a discussion of the scheme for combining the constants of the constituents to derive an equation for a mixture.

The method of determining the constants is a modification of that originally given by Beattie and Bridgeman and it was explained in detail in our paper on nitrogen. In the present work we use specific volumes in cc. per mole instead of cc. per gram; and we decided to use Birge's value[4] 22414.1 cc. for the volume of a mole of an ideal gas at S. T. P., and his value 273.18°K. for the ice point. The "International Critical Tables" (Vol. III, p. 3) give 0.99939 for the ratio of P V at 0° and 0 pressure to P V at 0° and 1 atm. pressure for hydrogen, so we use $22414.1/0.99939 = 22427.8$ cc. as the volume of a mole of hydrogen at S. T. P. This is the factor that converts Bartlett's volumes into cc. per mole. For R we use $22414.1/273.18 = 82.0489$ cc. atm. per mole per degree. In the previous work on nitrogen we used 273.13°K. for the ice point, but we think it is better to adopt Birge's values now. This change is too small to affect the constants in the equation of state because their values are fixed by the positions of certain lines or curves (Fig. 1), and in such work the locations of the curves are often a matter not easy to decide. Further, the ice-point enters mainly through the product RT, that is, through the volume of a mole of an ideal gas at 0° and 0 pressure, for which Birge's value is very

[4] Birge, *Phys. Rev. Supplement*, 1, 1 (1929).

nearly the same as had commonly been accepted prior to his compilation of physical constants, so the use of 273.18° does not have any discernible effect on the values to be determined for the parameters.

Bartlett and co-workers compiled and published compressibility data from all available sources along with their own. For the determination of the parameters in the equation of state we decided to smooth and average all of these data, and at the same time to interpolate to even temperatures.[5] Our method for smoothing and averaging the observations of the different observers listed by Bartlett was to plot $D \equiv mT - PV + I$ against T. m and I are constants for each isobar; I is the intercept and m the slope of a line chosen to approximate PV plotted against T. There is a PV and hence a D for each observation in Bartlett's tables. Smooth isobars were drawn to the graphs of D *vs.* T. Bartlett's points were given the most weight because his observations extend over the greatest range. Values of D were read off these curves at even temperatures; and from them $PV = mT + I - D$ was computed at each temperature and pressure, using the same values of m and I for each isobar that were used in computing the D. These compressibility factors, which are shown in Table I, should be the most reliable yet published for hydrogen. Values at 400° are not shown, because, although Bartlett made determinations at 100, 200, 300 and 400 atmospheres at this temperature, he does not consider them to be reliable.

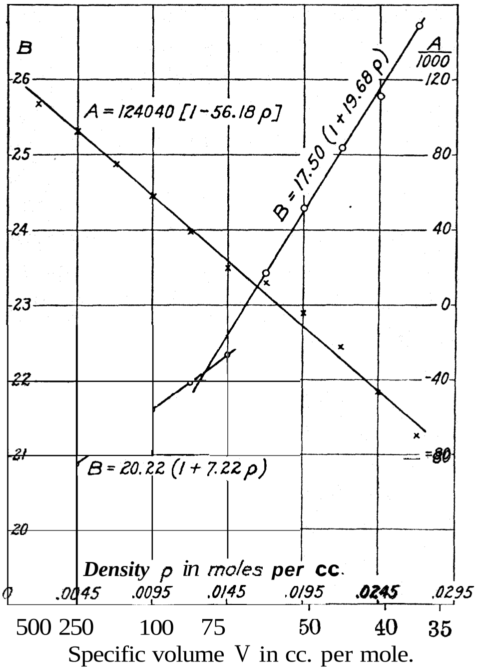

Fig. 1.—Hydrogen, The *A* and B plots.

For determining the constants in an equation of state it is better to have the pressures listed at even temperatures and densities than to have volumes listed at even temperatures and pressures. This change can be

---

[5] In the first reference to Barlett and co-workers, some of the temperatures lacked a few tenths of being integral. Further, after the second reference had gone to the publisher, Dr. Kvalnes advised us that a recalibration of their thermocouple showed the temperatures published as –70, –50, –25° should have been –69.90, –49.93, –24.99°. In our Table I the compressibility factors are computed for integral temperatures.

effected by the following **method.**[6] $A \equiv (PV - RT)V/RT$ is plotted against $\rho = 1/V$ for each temperature and smooth isotherms are drawn. Then A is read off at even densities from each isotherm, and $P = RT(\rho - \rho^2 A)$ is computed for each temperature and volume. In this process the data are further smoothed. Pressures thus derived are listed in Table II at even temperatures and densities. The family of ρ, A isotherms were so regular that extrapolations beyond the highest observed densities seemed justified and, since they are to be desired, were made. We write

$$P + \Gamma = \psi T - \phi \qquad (1)$$

Beattie and Bridgeman put

$$\left.\begin{array}{lll} \Gamma T^2 = \psi c/V & \psi = R(V + B)V^{-2} & \phi = AV^{-2} \\ B = B_0(1 - b/V) & & A = A_0(1 - a/V) \end{array}\right\} \qquad (2)$$

with A,, V_0 a, b, c constants, mentioning the possibility of extending the expressions for A and B to include higher powers of $1/V$. The method that we used for finding the constants was described in the paper on nitrogen.

For the four highest densities, the best values of c are **10.4,** 19.7, 18.9, **23.9** × 10^6. They evidently increase as the density decreases. We adopted $c = 20 \times 10^6$ as the best average value. We then determined what values of ψ and ϕ with $c = 20 \times 10^6$ render the mean square per cent. deviations of the calculated pressures a minimum for each isochore. The values thus found were used to compute $A = \phi V^2$ and $B = (\psi V^2 - RV)/R$ for each density. A and B were then plotted against ρ.

---

[6] Andrews, *Phil. Trans. Roy. Soc.*, 166, 421 (1876); O. C. Bridgeman, THIS JOURNAL, 49, 1130 (1927).

In the A plot, for the representation of compressibility data, a straight line suffices; yet there is an indication of a break at about 0.015 mole per cc. On the B plot two straight lines seem *to* be the only solution. For the representation of data the lines shown in the figure are probably the best that can be drawn; yet for a theoretical discussion the break in the B points comes at a somewhat higher density than is indicated by the intersection of the two lines. It looks as if the location of the breaks on both plots are close to the critical density, which is 0.0154 mole per cc. With the lines as drawn in the figure there will be one set of values for $A,$ and a throughout the entire range of densities, but there will be two sets for B_0 and b, one set for densities below the critical density and another set for densities above it.

Since the points on both the A and B plots from the lowest density to the critical density lie almost perfectly on the lines shown, we can say that the Beattie–Bridgeman equation of state holds almost perfectly up to the critical density.

From the figure it will be seen that $\phi = A\rho^2$ becomes negative at the highest densities. It is customary to regard ϕ as a cohesive pressure. It may be identified with the a/V^2 in van der Waals' equation as it is usually written. It evidently arises from the forces between molecules and will be positive when such forces are attractive. Its sign should change, however, if the forces between molecules become repulsive instead of attractive. The generally accepted working hypothesis for the forces between two molecules predicts that as two molecules come closer and closer together, the force changes from attraction to repulsion. Now at the high densities reached in the experimental work done by Bartlett and co-workers, the molecules of hydrogen may be in such concentration that this change in force is actually brought about, which causes ϕ to decrease and eventually to change sign. This same phenomenon and one allied to it have been noticed with nitrogen and with the **3:1** mixture.

The values for the constants that are determined by the plots in Fig. 1 are

$$\left.\begin{array}{llll} \text{Below the critical density:} & A, = 124040 & B_0 = 20.22 \\ \qquad a = 56.18 & b = -7.22 & c = 20 \times 10^6 \\ \textbf{Above} \text{ the critical density:} & A, = 124040 & B_0 = 17.50 \\ \qquad a = 56.18 & b = -19.68 & c = 20 \times 10^6 \end{array}\right\} \quad (3)$$

Beattie and Bridgeman, in their first paper, gave

$$\begin{array}{llll} A_0 = 197500 & B_0 = 20.96 & a = -5.06 & b = -43.59 \\ c = 50.4 \times 10^4 \end{array} \quad (4)$$

for the values of the constants determined from data published by the Leiden Laboratory, the Reichsanstalt, and Witkowski, in which the highest pressure at each temperature down to −150° was about 100 atm., and in which the temperature range was from −212.74 to 200°. Pressures calculated with the constants of Equations 4 do not agree with the pressures of Table II as well as do the constants in Equations 3, as is shown by the following tabulation of root mean square deviations at the five lowest densities. The second column is anticipated from Table II.

Density	R. M. S. per cent. deviations using Equations 3	Equations 4
0.0020	0.040	0.129
.0045	.048	.398
.0070	.058	1.30
.0095	.100	2.63
.0120	.166	4.25

At higher densities the disparity becomes still more pronounced. On the other hand, the constants of Equations 3 give larger deviations than Equations 4 at the extremely low temperatures at which observations have been made at the Leiden Laboratory. Over the range of density and temperature of Table II the constants in Equations 3 seem to be the best that can be obtained.

Table II lists the smoothed pressures at even temperatures and densities and the comparison with the calculated pressures.

Consideration of the deviations in Table II shows that the constants given in Equations 3 reproduce pressures for hydrogen very well up to 0.0245 mole per cc. inclusive, and with a root mean square error of 1.4% for the five lowest temperatures at 0.0270 mole per cc.

These calculations were made with the two sets of values for B_0 and b, corresponding to the two lines for the B points in the figure. No single set of constants (*i. e.*, no single straight line) will give anywhere near as good agreements between observed and calculated pressures. A parabola cannot be fitted satisfactorily to the B points. The only solution seems to be the two straight lines.

PV values at 400° were calculated and compared with those observed and published by Bartlett, and we find deviations of —1.04, —0.47, —0.62, —0.37% at 100, 200, 300, 400 atm., respectively. This probably confirms Bartlett's suspicion that his observations at 400° may not be reliable, because these are larger deviations than one would expect from an extrapolation of 100" above the interval —70 to 300° at comparatively low pressures. The negative sign of the deviations probably indicates that his measured values of V were too small—perhaps due to gas escaping from or diffusing through the pipet at this high temperature, as was suspected by Bartlett and co-workers.'

We have had the willing coöperation of the staff of the Fixed Nitrogen Research Laboratory and of the authors of the equation of state throughout the course of this work.

Summary

Bartlett and his collaborators have recently extended their P–V–1' measurements on hydrogen to include nine temperatures in the interval −70 to 300°, up to 1000 atmospheres. Their measurements and compilation of data from other sources have been smoothed and averaged and placed in a table (Table I) showing PV at even temperatures and pressures over that range. It is now possible to subject an equation of state for hydrogen to a severe test and to ascertain its limitations. The writers find the constants for hydrogen to be

Below the critical density: $A, = 124040$ $B_0 = 20.22$
$a = 56.18$ $b = -7.22$ $c = 20 \mathrm{X} 10^6$

Above the **critical** density: $A, = 124040$ $B_0 = 17.50$
$a = 56.18$ $b = -19.68$ $c = 20 \times 10^6$

in units of moles, atmospheres and cubic centimeters, for the Beattie–Bridgeman equation of state

$$PV^2 = RT(V + B_0(1 - b/V))\ (1 - c/VT^3) - A_0(1 - a/V)$$

A method of curve fitting was used which insures that trends and measurements be reproduced as faithfully as the formula is capable of doing. With the constants given above, over the temperature range −70 to 300°, the equation reproduces pressures with a root mean square error of 0.251% at 0.0245 mole per cc., the maximum being −0.28% at −25°; and with a root mean square error of 1.38% at 0.0270 mole per cc., the maximum being 2.10% at −70°; and almost perfectly at densities lower than these two. Thus the equation with the above constants reproduces trends and measurements satisfactorily at temperatures as low as −70° up to 0.0270 mole per cc. At densities greater than 0.0270 mole per cc. the calculated pressures (not shown in the table) are invariably too small and the deviations become quite large.

A break between high and low densities comes at about the critical density and is indicated by the intersection of the two lines in the graph of B vs. ρ. It may signify some sort of a change in the properties of hydrogen at this density.

The negative values of ϕ that occur at densities above 0.0180 mole per cc. are evidence for the predominance of repulsive forces between molecules at high densities.

THE ACTIVITY COEFFICIENTS AND THE ADSORPTION OF ORGANIC SOLUTES. I. NORMAL BUTYL ALCOHOL IN AQUEOUS SOLUTION BY THE FREEZING POINT METHOD

BY WILLIAM D. HARKINS AND ROY W. WAMPLER

RECEIVED AUGUST 2, 1930 PUBLISHED MARCH 6, 1931

I. Introduction

Since, when this work was begun, no determinations of the activity coefficients of organic solutes in dilute solution had been made, it seemed important to determine the activities for at least one typical organic solute. Since the activity coefficients are essential for the calculation of the adsorption in the surface of the solution, it was advisable to choose a substance for whose aqueous solutions the surface tension values are known. The substance used, n-butyl alcohol, has the further advantage that it can be purified with relative ease.

In the more concentrated solutions (0.25 molal and above) the results may be compared with those of Jones and Bury[1] on the organic acids, including butyric acid.

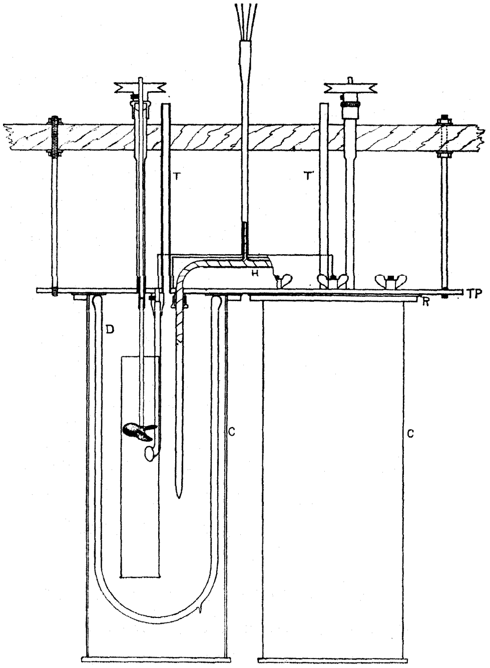

Fig. 1.

II. Freezing Point Apparatus

The freezing point apparatus (Fig. 1) is a modification of that used by Adams[2] and by Harkins and Hall,[3] and resembles that of Randall and Vanselow.[4] Two one-liter Dewar vessels (D) are suspended from a gold-plated brass plate (TP), each in a brass cylinder (C). When in use these brass cylinders were kept immersed in ice in a metal box, which was well insulated thermally by wool felt.

A 24-junction copper–constantan thermel, made in halves of twelve junctions each, was used for the determination of the temperature difference between ice–water in one Dewar, and ice–solution in the other. Five No. 30 double silk covered constantan wires in parallel were soldered to a single No. 35 double silk covered copper

wire. Only extremely uniform constantan wire, as tested by the method of White,[5] was used. The dried thermel was made air tight and waterproof. The equation for the potential difference between its ends is: $E = 957.10\,t - 1.1646\,t^2 + 0.00115\,t^3$ (t = °C.). Its performance was tested by the determination of the lowering of the freezing point produced hy various small amounts of mannite in water, as was done by Hall and Harkins.

A Zeiss laboratory type interferometer, with an all glass 4-cm. cell, and a 2-cm. arid an 8-cm. cell, was used to determine the concentration of the solutions. The interferometer was inclosed in a long thermostat kept at **25** * 0.01". With the 4-cm. cell one interferometer scale division corresponds to approximately 0.00006 molal n-butyl alcohol. For the most dilute solutions the 8-cm. cell was used.

III. Preparation of Materials

The *n*-butyl alcohol was Eastman's best grade. It was first treated with sodium bisulfite. Then it was refluxed with 10% sodium hydroxide for four hours, the alcohol separated from the aqueous layer and washed several times with water to free the alcohol from the base. The remaining base was neutralized with hydrochloric acid, lime was added and the mixture allowed to stand overnight. The partly dried alcohol was again treated with freshly heated lime and refluxed for three hours. The third treatment with lime removed the last traces of water and the alcohol was distilled from the lime and collected in fractions. The alcohol was fractionated twice more, the first time from a distilling column 40 cm. long and finally from a more effective column.

The latter distilling apparatus consisted of a one-liter distilling hulb connected to the fractionating column by a ground-glass joint. The column was 1.6 meters tall and 28 mm. in diameter, and was filled with 6-mm. glass tubing cut in 6-mm. lengths. A layer of sheet asbestos was wrapped around the column, then No. 21 B. and S. gage nichrome wire, five to six turns to the inch, was wrapped over the asbestos. The windings were now covered with a single tightly wrapped layer of asbestos cord. When the heater coil was connected to the 110-volt circuit through a rheostat, the temperature could be controlled so that it just counteracted the heat lost by the vapors in mounting the column. At the top of the column, a small but very efficient condenser was connected by means of a side arm. The ratio of reflux to distillate could be controlled[6] by means of *a* capillary stopcock connected to the side arm. The n-butyl alcohol obtained boiled at 117.70 to 117.74' (corrected).

The ice used in the determinations was frozen in the following manner. Distilled water was placed in a heavily nickel-plated copper vessel, 5 by 51 cm. at the bottom, 7.6 by 51 cm. at the top and 41 cm. high, and boiled for thirty minutes to remove the dissolved air. The tight fitting cover was then placed on the vessel, which was immersed in an ice and salt mixture to freeze. Solutions were made with distilled water that had just been boiled and cooled.

The problem of the air dissolved in the water and the solutions was made difficult in this case since the solute is volatile. The removal of the dissolved air by evacuation of the freezing point apparatus as used by Randall and Vanselow did not give a stable condition of equilibrium. After evacuating for thirty to sixty minutes, the water and the solution both being practically free from dissolved air at the outset, air was admitted through a soda lime tube and after twenty to thirty minutes, readings were taken. The temperature rose in every case and continued to rise slowly for a period of two to three hours, equilibrium never being reached. The method of saturating the solutions with air as used by Rodebush and Hovorka[7] was not applicable, for the solubility of air in the

solutions is different from that in water, especially in the more concentrated solutions. Rodebush and Hovorka[7] make the statement that for salt solutions any error which might arise from this cause is less than the experimental error for solutions of 0.01 molal concentration. The method of removing dissolved air at the outset was adopted as the most advisable procedure.

IV. Experimental Procedure

The distilled water ice was cracked by crushing it through an iron grating. The finely divided ice was removed, leaving pieces from 7 to 10 mm. in diameter. The cracked ice was washed thoroughly with distilled water and finally twice with the distilled water that was used in making the solutions. Approximately 400 g. of ice was placed in each Dewar vessel and boiled distilled water was added so that the surface would be just 4 mm. above the edge of the stirrer tube. The top was placed in position and the apparatus placed in the ice thermostat. The stirrers were started and after about two hours readings were taken until no change in temperature was noted, thus showing that equilibrium had been established. In the meantime, the solution to be used was placed in an ice and salt mixture, where it was allowed to remain until ice started to freeze out. The water in the right-hand Dewar vessel was removed by suction and the solution was added to replace it. Stirring was continued for thirty to sixty minutes before readings on the potentiometer were taken. Thereafter, readings were taken every five minutes until four or five readings showed that equilibrium had been established. A sample of the solution was removed by suction directly into a 100-cc. volumetric flask. Ice water was added to replace the solution removed. By continuing in this manner, it was possible to make the determinations for as many as six to eight different concentrations in a day. As soon as the solutions were removed from the freezing point apparatus, they were brought to the correct temperature and their concentrations determined in the interferometer, thus avoiding any chance for evaporation or change in concentration due to any other cause. The more concentrated solutions were analyzed in two ways. First, they were checked against a solution of approximately the same concentration. Then, they were diluted by weight to a concentration around 0.04 to 0.05 molal and compared against the water used in making up the solutions.

V. Method of Calculation

The method of calculation of the activities is that given by Lewis and Randall.[8] The equation for the activity of the solute is

$$d \ln a_2 = \frac{d\vartheta}{\lambda m} + 0.00057 \frac{\vartheta d\vartheta}{m} \qquad (1)$$

In order to integrate the equation use is made of the quantity j which is defined by the equation

$$j = 1 - \frac{\vartheta}{\lambda m} \qquad (2)$$

which, when differentiated, gives

$$\frac{d\vartheta}{\lambda m} - \frac{\vartheta dm}{\lambda m^2} = -dj \qquad (3)$$

Substituting the value of ϑ/m derived from Equation 2 in Equation 3 and rearranging

---

[8] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," 1st ed., McGraw-Hill Book Co., Inc., New York, 1923, p. 286.

$$\frac{d\vartheta}{\lambda m} = (1 - j)\, d \ln m - dj \tag{4}$$

Substituting in Equation 1 and subtracting d ln *m* from both sides

$$d \ln \frac{a_2}{m} = -j\, d \ln m - dj + 0.00057\, \frac{\vartheta d\vartheta}{m} \tag{5}$$

Integrating from infinite dilution up to a given molality

$$\ln \frac{a_2}{m} = \int_0^m -j\, d \ln m - j + 0.00057 \int_0^m \frac{\vartheta}{m}\, d\vartheta \tag{6}$$

By means of the appropriate graphs, the area under the curves is ascertained and thence the activities.

VI. Discussion of Results

In Table I are given the freezing points for the different concentrations of n-butyl alcohol. The third column gives the molal freezing point lowering ϑ/m. In the fourth and fifth columns are, respectively, the values of j and j/m, while the activities are found in the last column. The values of j/m were obtained from a smooth curve of a plot of j/m against the molality. A graph of the freezing point lowering ϑ/m against the molalities m is shown in Fig. 2.

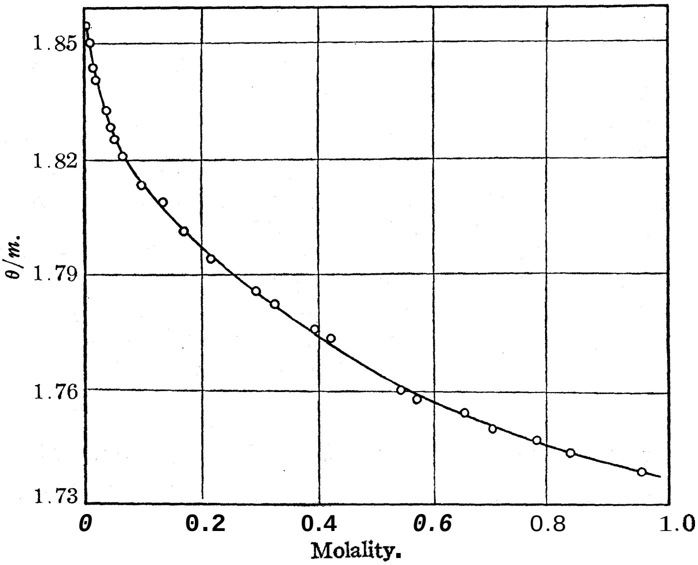

Fig. 2.—Molal freezing point lowering for n-butyl alcohol in water.

In Table II, the values of the activity coefficients are given for rounded values of the concentration. The values of the two integrals and $-j$ of Equation 6 are also given. The integral $\int_0^m - j\, d \ln m$ is designated as A.

The directly calculated values of j/m are given in Figs. 4 and 5. The interpolated values are given above. At concentrations below 0.05 molal the mean difference between the two amounts to a temperature difference of about one fifty-thousandth of a degree.

while B represents the other integral $0.00057 \int_0^m \vartheta/m \, d\vartheta$. The activity coefficients γ, or a_2/m, are given in the fifth column (see Fig. **3** also).

The activity coefficient of butyl alcohol in its 1.0 molal solution (0.82) is approximately that of a 0.07 molal solution of potassium or sodium chloride. If the activity coefficient of butyl alcohol at 1 molal is considered to be unity, then that in a 0.25 *m* solution is 1.101, while the corresponding values of Jones and Bury are 1.160 for butyric, 1.091 for propionic, and 1.015 for formic acid. Thus the value for butyl alcohol is not very different from that for propionic acid. From this comparison it seems

TABLE II

VALUES OF THE ACTIVITY COEFFICIENT (a_2/m) OF n-BUTYL ALCOHOL IN ITS AQUEOUS SOLUTIONS

The values for the activity coefficient in the column marked (I) correspond to extrapolation along the heavy line, and (2) along the light line in Fig. 5.

It has usually been considered that the value of the function j/m is constant below 0.1 molal but Fig. 4 shows that it increases rapidly as the molality decreases, and, on the whole, more rapidly at the lower concentrations. Figure 5 gives the values of j/m at molalities below 0.1 molal. The middle curve represents the smoothed values of j/m, while the upper and lower curves show the deviation produced in j/m by an error of 0.00005° in the temperature measurement. It is evident that the deviations from the mean are in general much less than a twenty-thousandth of a degree, and that below 0.05 molal the average deviation is about one fifty-thousandth of a degree.

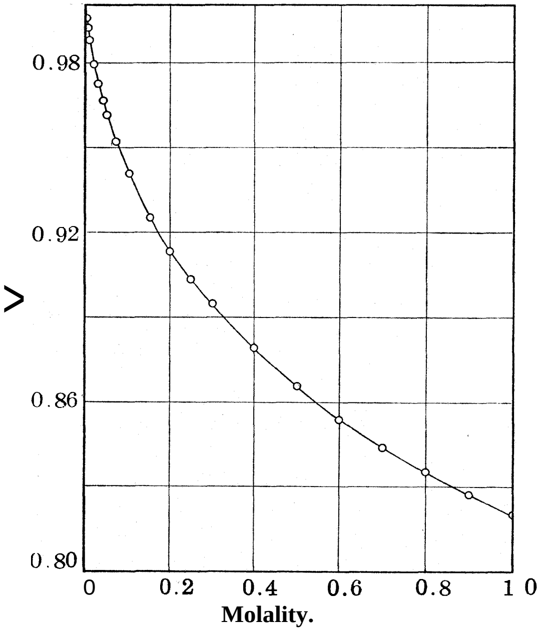

Fig. 3.—Activity coefficient of *n*-butyl alcohol in its aqueous solutions,

In Table II the activity coefficients under (1) represent the extrapolation to zero concentration along the heavy line of Fig. 5, which corresponds better to the data at the lowest concentrations, while those under (2) correspond to extrapolation along the light line, which seems better on the basis of the data at higher concentrations. The maximum difference produced in the activity is only 0.12%.

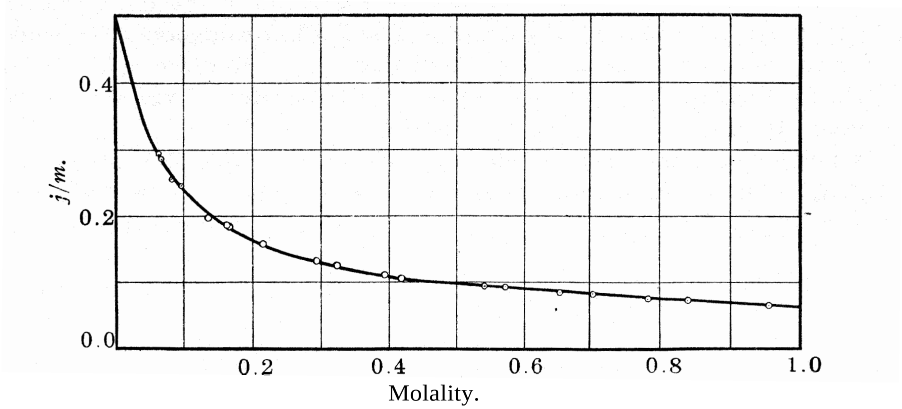

Fig. 4.—Variation of j/m with the molality of butyl alcohol.

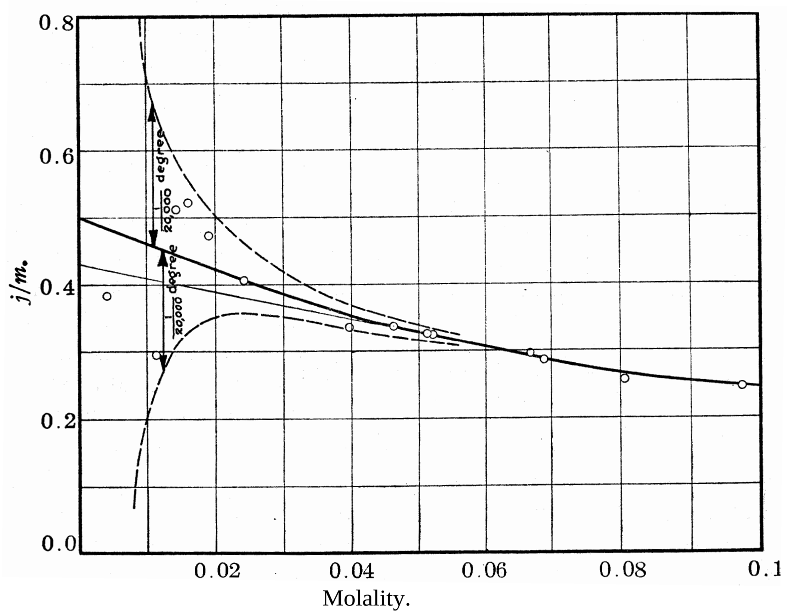

Fig. 5.—Variation of j/m with the molality of butyl alcohol.

VII. The Film of Butyl Alcohol on an Aqueous Solution

The adsorption (u) in the surface region of a solution is supposed to be given by the equation

$$u = -\frac{1}{RT}\frac{d\gamma}{d \ln a}$$

in which γ is the surface tension of the solution, a is the activity of the solute, T is the absolute temperature and R is the gas constant. Figure 6 gives the surface tension values for aqueous solutions of butyl alcohol as determined by King, plotted against the logarithm of the activity of the alcohol in its aqueous solutions as given earlier in this paper. The values for the adsorption, as calculated from these data are given in Table III. At the highest concentration (0.854 molal) the area of the surface per molecule adsorbed is 27.4 sq. Å. units of area.

The area per molecule for normal alcohols in insoluble films on water is about 21.6 sq. Å. units at zero compression. The value per adsorbed molecule of butyl alcohol (27.4) is about one-third larger, and this suggests that the film is monomolecular with respect to butyl alcohol.

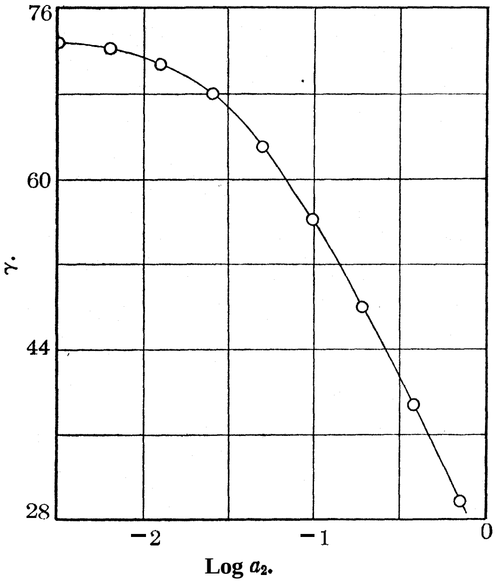

Fig. 6.—Surface tension and activity of butyl alcohol in water.

The value of the adsorption (u) in the above equation gives the number of moles of solute which must be added to the whole solution in order to keep the activity of the solute constant when the area of the surface of the solution is increased by one sq. cm. While it is evident that some solute is present in the surface film of a solution if the adsorption (u) is zero, sufficient attention has not been given to this fact. For example, the value of u for a 0.854 m solution of butyl alcohol is 3.65 × 10^{14} molecules per sq. cm. of increase of surface. It is commonly assumed that this number of alcohol molecules moves into the surface film. However, if the number of molecules of butyl alcohol in the surface were to be determined an infinitesimal time after the formation of the surface, the number would not be negligible. It may be assumed that a plane surface, one sq. cm. in area, inside such a solution would cut 0.56 × 10^{14} molecules of butyl alcohol, since this number is equal to the two-thirds power of the number of alcohol molecules in one cc. of the solution. It will be assumed that this is the number of alcohol molecules "initially" present in the first surface layer. If all of the adsorbed molecules move into this same "layer" the total number present is 4.22 X 10^{14}, and the area per molecule of alcohol present in this layer is 23.7 sq. Å. units, or very nearly that (21.6) exhibited by alcohol molecules in insoluble films. For comparison the surface tension data of Rehbinder and the activity data of Jones and Bury have been used to calculate the corresponding areas for propionic acid and butyric acid (Table IV). The minimum areas are 21.7 and 22.2 sq. Å., respectively. The first surface layer of solute molecules, as defined in this paper, does not include the entire surface region as defined in earlier papers by Harkins. The relation between the first surface layer, sometimes called the surface film, and the surface region, will be discussed in a later paper.

Summary

1. The activity values for solutions of n-butyl alcohol in aqueous solution were determined by the use of a specially designed apparatus for the determination of the lowering of the freezing point. This was a modified form of the apparatus used by Adams, and by Harkins and Hall. It was sensitive to 0.00001° when used with a White double combination potentiometer.

2. The n-butyl alcohol was purified carefully in a specially designed fractionating column. The material used distilled over within a range of 0.04°.

3. The activity coefficient of n-butyl alcohol in its 1 molal solution is 0.8227. At 0.5 M it is 0.8681, and at 0.1 M, 0.9433. Thus the deviation from normal behavior is of considerable magnitude with this organic solute. This indicates that the concentration of the solution cannot be used in place of the activity, in accurate calculations. It may be assumed that the deviations produced by the $-$COOH group are somewhat larger and other active groups of this type give deviations of about the same general order of magnitude.

4. If the "adsorption equation" is correct, the film of butyl alcohol on its aqueous solutions is monomolecular. The area per molecule of alcohol in the film is 23.7 sq. Å., while the well-known value for longer alcohol molecules in insoluble films is 21.6 sq. Å.

THE BEATTIE–BRIDGEMAN EQUATION OF STATE AND BARTLETT'S P–V–T DATA ON A 3:1 HYDROGEN–NITROGEN MIXTURE

BY W. EDWARDS DEMING AND LOLA E. SHUPE

RECEIVED SEPTEMBER 25, 1930 PUBLISHED MARCH 6, 1931

Direct Determination of the Constants

In previous papers[1] the constants for the Beattie–Bridgeman[2] equation of state have been published for the high pressure data obtained at this Laboratory with nitrogen and hydrogen. We now present constants determined by the same method for a 3:1 hydrogen–nitrogen mixture, the experimental data for which were published by Bartlett and his collaborators[3] who record their own measurements from −70 to 300° up to 1000 atmospheres, and a few scattered ones taken from the work of Verschoyle. After comparing the observed pressures in the table with pressures calculated using the constants to be given in Equation 6, we shall study the schemes for combining the constants previously found for hydrogen and nitrogen to devise constants for the mixture.

To settle on a value for the ratio of PV at 0° and 0 pressure to PV at 0° and 1 atm., we took the weighted average of the best values[4] known to us for hydrogen and nitrogen, which are 0.99939 and 1.00046. The weighted average is $(3 \times 0.99939 + 1.00046)/4 = 0.99966$. Using Birge's value[6] 22414.1 cc. for the volume of a mole of an ideal gas at S. T. P. we have 22421.7 cc. for the volume of a mole of the 3:1 mixture at S. T. P. Bartlett expresses his PV with $PV = 1$ at S. T. P., so we multiply his specific volumes by 22421.7 to change them into cc. per mole. We use $R = 82.0489$ cc. atm. per mole per degree, and 273.18°K. for the ice point, as given by Birge.

As we mentioned in our paper on hydrogen, the three lowest temperatures in Bartlett's table should have been published as −69.90, −49.93, −24.99° instead of −70, −50, −25°. We have made these slight corrections and have interpolated to integral temperatures in our process of smoothing.[6] The pressures at integral temperatures and densities derived from Bartlett's publications are listed in the table later on. The extrap-

[6] Described in the preceding paper,

olations beyond 1000 atm. seemed to us reliable, judging from the perfect regularity of the ρ, Δ isotherms after the process of smoothing. The extrapolations were made by extending the ρ,Δ curves. The nearness of the experimental points to these curves, which are greatly magnified deviation curves, attests to the high precision of the experimental work.

Throughout this paper the notation will be the same as that in the papers on nitrogen and hydrogen, and the equations, tables, and figures will be numbered from the last ones in the paper on hydrogen.

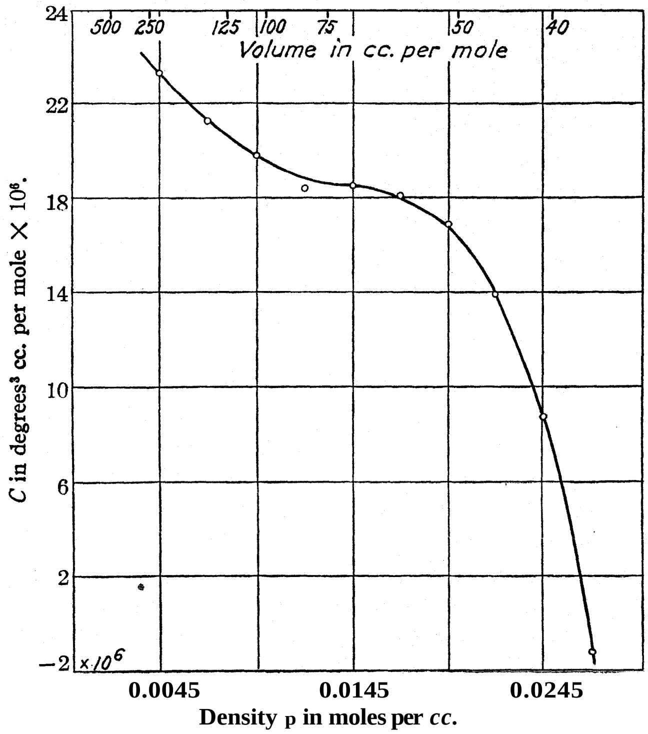

Fig. 2.—The values of c that render $\Sigma[(P_{\text{obs.}} - P_{\text{calcd.}})/P_{\text{obs.}}]^2$ an absolute minimum at each density of the 3:1 hydrogen–nitrogen mixture.

Attempts to find the best value of c revealed immediately some peculiarities of this mixture. The best value of c for $\rho = 0.0270$ mole per cc. turned out to be negative; and the values found for the next three densities were so discordant that we finally computed c for every density. The graph of c vs. ρ (Fig. 2) shows these peculiarities. We chose $c = 16 \times 10^6$ as likely to give the best results over the whole range. The rather long extrapolations beyond 1000 atm. at the low densities and high temperatures are not responsible for the peculiar behavior depicted by the graph;

the calculations were repeated with the extrapolated pressures discarded and the resulting graph showed c to be a trifle more variable than before.

The tendency for c to decrease and finally to become negative as the density increases seems to be related to the similar tendency exhibited by ϕ with hydrogen and to a smaller extent, as will be seen, with this mixture. An explanation for this behavior is found in the existence of repulsive forces that come into play at high densities.[7] The same might have been found true with nitrogen if that work had included higher densities.

The values of ψ and ϕ with $c = 16 \times 10^6$ that render the mean square per cent. deviations of the calculated pressures a minimum along each isochore were found and were then used to compute $B = (\psi V^2 - RV)/R$ and $A = \phi V^2$ at each density. The graphs of A and B as functions of ρ are shown in Fig. **3.** There is little doubt that two lines for each are indicated; the locations finally selected are shown in the figure, and their slopes and intercepts determine A_0, a, B_0, b.

These pairs of lines intersect at 0.0137 and 0.0132 mole per cc. Now this mixture probably has a critical density in this vicinity. In general the critical curve for a binary mixture is fairly smooth between the two components. The "International Critical Tables" give 0.0154 and 0.0111 mole per cc. for the critical densities of hydrogen and nitrogen; so the critical density of the mixture probably lies in the neighborhood of 0.014 mole per cc. The intersections in Fig. **3** are close to this value. We found the same with hydrogen in the preceding paper. It appears that the equation of state has one set of constants below the critical density, and another set above it. This behavior may be common to all gases; our work on nitrogen barely included the critical density, so we cannot predict its behavior. Figure 2 shows a peculiar flattening of the c vs. ρ curve in the interval $0.0120 < \rho < 0.0145$, which may be related to the breaks in the A and B plots. We are indebted to Professor Beattie for pointing out to us the possible connection between the breaks in the A and B plots and the critical density of the mixture.

From Fig. **3**

$$\left.\begin{array}{lll}
\multicolumn{3}{l}{\text{Below the critical density}} \\
A_0 = 3000 \times 10^2 & & B_0 = 25.03 \\
a = 21.36 & b = -15.16 & c = 16 \times 10^6 \\
\multicolumn{3}{l}{\text{Above the critical density}} \\
A_0 = 3489 \times 10^2 & & B_0 = 21.42 \\
a = 28.56 & b = -30.58 & c = 16 \times 10^6
\end{array}\right\} \qquad (5)$$

in units of moles, atmospheres, and cubic centimeters.

Table III lists the smoothed pressures at even temperatures and densities and the comparison with the calculated pressures.

Consideration of the deviations in Table III shows that the equation of

---

[7] Deming and Miss Shupe, an article to appear.

state with the constants of Equations 5 reproduces pressures almost within the experimental error up to 0.0270 mole per cc.; at this density the root mean square deviation is 1.8%.

The Constants Determined by Combination.—A scheme for computing analytically the P–V–T relations of a mixture from those of the constituents would be valuable. In recent papers Beattie and others[8] have given histories of the different devices for making such calculations, and have investigated the result of combining the constants in the equations of state for the constituents to get constants to be used for the mixture. Beattie and Ikehara have made an exhaustive study of this idea using the Beattie-Bridgeman equation of state. They combined a, b, c, $\sqrt{A_0}$ linearly by mole fraction, and compared three methods of combining B_0-linear, Lorentz, and linear square root. We propose here to extend this study to the high pressure data on the 3:1 hydrogen–nitrogen mixture.

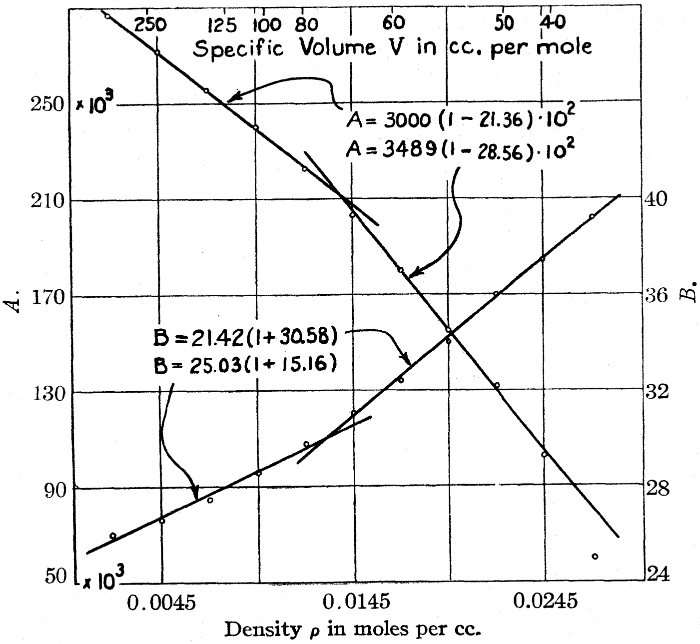

Fig. 3.—The A and B plots for the 3:1 hydrogen–nitrogen mixture.

Suppose B_{oh} and B_{on} are the B_0 constants for hydrogen and nitrogen, and that these two gases are present in a binary mixture to the extent of mole fractions x_h and x_n; then the B_0 constant for the mixture (B_{ox}) will be formed quadratically:

$$B_{ox} = B_{oh}x_h^2 + 2B_{hn}x_hx_n + B_{on}x_n^2 \qquad (6)$$

R. M. S. deviations %[a]		0.179	0.188	0.183	0.112	0.127	0.156	0.171	0.185	0.163	

[a] Density 0.0270 is excluded from these R. M. S. deviations.

The three methods mentioned above apply to the interaction factor B_{hn}, thus

$$\text{By the linear method, } B_{hn} = {}^1/_2(B_{oh} + B_{on}) \quad (7)$$

$$\text{By the Lorentz method, } B_{hn}^{1/3} = {}^1/_2(B_{oh}^{1/3} + B_{on}^{1/3}) \quad (8)$$

$$\text{By the linear square root method, } B_{hn}^2 = B_{oh}B_{on} \quad (9)$$

We shall use subscripts h and n for hydrogen and nitrogen; then $x_h = {}^3/_4$ and x, $= {}^1/_4$, since our specific volumes are in cc. per mole.

If we combine the constants for hydrogen and nitrogen that were found to hold for densities below critical, the synthetic constants cannot be expected to hold above the critical density of the mixture. For nitrogen we found

$$\left.\begin{array}{lll} A,, = 1254 \times 10^3 & & B_{on} = 46.045 \\ a, = 18.68 & b_n = -25.88 & c_n = 61.64 \times 10^6 \end{array}\right\} \quad (10)$$

These have been changed to units of moles, atmospheres, and cubic centimeters. From Equation 3

$$\left.\begin{array}{lll} A_{oh} = 1240 \times 10^2 & & B_{oh} = 19.90 \\ a_h = 56.18 & b_h = -10.72 & c_h = 20 \times 10^6 \end{array}\right\} \quad (11)$$

Combination of 10 and 11 gives

$$\left.\begin{array}{ll} A_{om} = 2889 \ X \ 10^2 & a, = 46.80 \\ b_m = -14.51 & c_m = 30.41 \ X \ 10^6 \end{array}\right\} \quad (12)$$

$$\text{By the linear method, } B_{om} = 26.43 \quad (13)$$

$$\text{By the Lorentz method, } B_{om} = 25.76 \quad (14)$$

$$\text{By the linear square root method, } B_{om} = 25.42 \quad (15)$$

Pressures were calculated with these constants and compared with the observed pressures listed in Table III. The root mean squares of the deviations were taken with respect to temperature, and with respect to density for the five densities below critical. The most comprehensive presentation of these deviations seemed to be the graphical one in Figs. 4 and 5. Root mean square deviations for the pure gases using Equations 3 and 10, and for the 3:1 mixture using Equations 5 are shown for comparison.

The graphs fail to give information in two respects: they do not tell whether the deviations at a particular density are predominantly positive or negative, and they do not tell the extent of variation among the deviations at a particular density or temperature. Two general statements cover these points. At any one density the deviations for any one gas are roughly of the same magnitude, so unless they are nearly zero it is possible to state that they are either predominantly positive or predominantly negative. The deviations at all the densities within the range shown might be expected to be predominantly of the same sign. This is the case; they all turned out to be predominantly negative for all three methods of combination.

Here the linear square root method seems to be a little better than the other two, but none of them are satisfactory except at the lowest densities. The representation of data by the linear square root method of combination for B_0 is almost within the experimental error to densities as high as 0,0070 mole per cc., where, as can be seen in Fig. 4, the R. M. S. deviation is 1.17%.

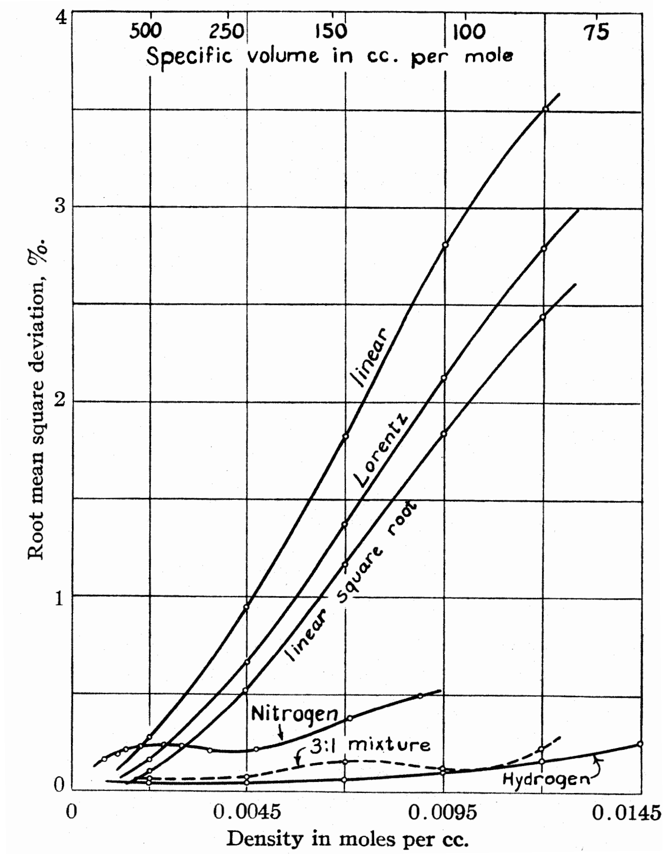

Fig. 4.—Root mean square deviations of pressures calculated by three methods of combining the B_0 constant, taken over the nine temperatures.

This is a different conclusion from that reached by Beattie and Ikehara, who say: "On the whole, linear combination for B_0 was slightly favored over the Lorentz method, while the linear square root relation gave the least satisfactory results. . . . Linear combination for each of the constants R, $\sqrt{A_0}$, a, B_0, b, and c of the Beattie–Bridgeman equation of state gives a satisfactory over-all correlation of the compressibility data on gas mixtures, although in some cases the representation of the data may not be within the experimental error."

A 3:1 hydrogen–nitrogen mixture was only one of many studied by

Beattie and Ikehara; their Fig. 15 shows percentage deviation *vs.* pressure at 0° up to 200 atmospheres for linear and Lorentz combination, using Verschoyle's data. Comparing their results as read from their Fig. 15 with our calculations, we find that our deviations by the linear and Lorentz methods are a little larger than theirs, but our results by the linear square root method are better than either their linear or Lorentz combinations.

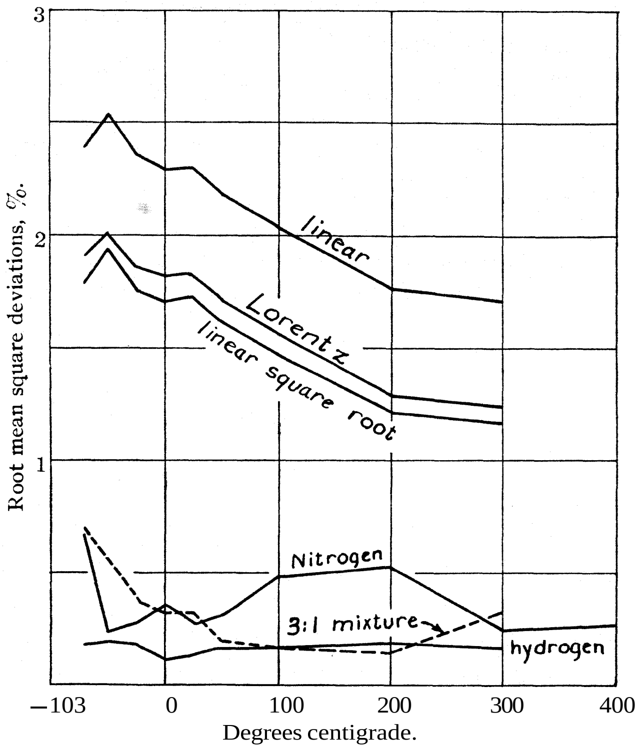

Fig. 5.—Root mean square deviations of pressures calculated by three methods of combining the B_0 constant, taken over the five densities below critical.

One might expect our deviations to be larger since our constants were determined for each constituent up to the critical density at each temperature. The constants that Beattie and Ikehara combined were determined for comparatively low densities, and their combination might be expected to fit the 3:1 mixture quite well at not too high pressures.

It should be noted that the data that we have used for the constituents and their mixture should be consistent, since Bartlett's work was all done with the same apparatus, and his measurements naturally received the most weight in the smoothing and averaging because he covered such a wide range of temperature and pressure.

Summary

Bartlett and his collaborators have recently extended their P–V–T measurements on a 3:1 hydrogen–nitrogen mixture to include nine temperatures in the interval –70 to 300°, up to 1000 atmospheres. A few observations from the work of Verschoyle were used with Bartlett's in a process of smoothing and averaging, in which interpolations and extrapolations were made to even densities from 0.0020 to 0.0270 mole per cc. and at even temperatures from –70 to 300°.

The writers have calculated the constants in the Beattie–Bridgeman equation of state

$$PV^2 = RT(V + B_0(1 - b/V))\,(1 - c/VT^3) - A_0(1 - a/V)$$

by two methods: (1) direct determination, and (2) combination of constants previously found for the constituents of the mixture. As with hydrogen, they find breaks in the plots of A and B vs. p in the region where one would expect the critical density to lie, namely, about 0.0135 mole per cc. By direct determination

$$\left.\begin{array}{lll}
\textbf{Below the critical density} & & \\
A_0 = 3000 \times 10^2 & & B_0 = 25.03 \\
a = 21.36 & b = -15.16 & c = 16 \times 10^6 \\
\textbf{Above the critical density} & & \\
A_0 = 3489 \times 10^2 & B_0 = 21.42 & \\
a = 28.56 & b = -30.58 & c = 16 \times 10^6
\end{array}\right\} \quad (5)$$

in units of moles, atmospheres, and cubic centimeters. Pressures calculated with these constants agree with the observed pressures within a few tenths of a per cent. up to 0.0270 mole per cc.; at this point the calculated pressures are all too low with a root mean square deviation of 1.8%. At any density, the fit is about as good at one temperature as at another.

For studying the combination of the constants of the constituents to derive constants for the mixture, a, b, c, $\sqrt{A_0}$ for hydrogen and nitrogen at densities below critical were combined linearly. The B_0 for each were combined in three different ways, namely, by the linear, Lorentz and linear square root methods. The deviations of pressures calculated with these synthetic constants increase rapidly as the density increases. Of the three, the linear square root method comes the nearest to being satisfactory; it reproduces pressures with a root mean square error of 1.17% at 0.0070 mole per cc., so it can be trusted to reproduce the P–V–T relations almost within the experimental error up to this density.

This conclusion disagrees with that recently published by Beattie and Ikehara, who state that the linear square root method is not as good as the other two. It is pointed out that the conclusions differ because of the different ranges of pressure and temperature that were used for determining the constants of the pure gases.

The peculiarity in the c *vs.* ρ graph (Fig. *2)* exhibiting the tendency for c to decrease and finally become negative as the density increases is believed to be related to the similar tendency of ϕ with hydrogen, and both are evidence for the predominance of repulsive forces between molecules at high densities.

FLAME TEMPERATURES OF HYDROCARBON GASES[1]

BY G. W. JONES,[2] BERNARD LEWIS,[3] J. B. FRIAUF[4] AND G. ST. J. PERROTT[5]

RECEIVED OCTOBER 22, 1930 PUBLISHED MARCH 6, 1931

In a previous report by Loomis and Perrott[6] methods were described and results given for the flame temperatures of methane, propane, carbon monoxide and natural gas. They tried several methods for measuring the temperatures of stationary flames, details of which are given in the report mentioned. The spectral-line reversal method was finally adopted for the measurement of the flame temperatures of combustible gases, because after the apparatus has been properly calibrated and standardized, a large number of determinations may be made easily, accurately and quickly. This method was first used by Kurlbaum,[7] subsequently modified by Kurlbaum and Schulze,[8] and later by Fery.[9] More recently, Henning and Tingwaldt[10] used the method to measure the maximum temperature of the acetylene–oxygen flame, 3100°. Griffiths and Awbery[11] have also described this method and investigated its limitations and factors affecting the accuracy of the results obtained. Tests made by them to determine the influence of flame thickness on the observed flame temperatures showed that within the limits of $^1/_2$ inch to *2* inches, thickness is immaterial to the result, but to ensure sensitivity it is advisable to employ a thick flame. They also investigated the distribution of temperature from base to tip of the flame. The results showed a relatively uniform temperature

in the lower region of the flame, followed by a very rapid decrease from this zone of uniform temperature as the tip of the flame is approached. They used this method for determining the maximum temperatures in gaseous explosions, for the measurement of the temperatures of stationary flames, using carbon monoxide and air at various ratios and rates, also for the measurement of the temperatures of flames of atomic hydrogen. It is of interest to note that values for the maximum flame temperatures of carbon monoxide–air mixtures varied over a range of 100° with the quantity of mixture burned in a given interval of time. The larger the quantity burned the higher the flame temperature for a given air–gas ratio at a given distance above the burner port. This is equivalent to lowering the point of measurement while keeping the rate constant. The temperatures found at the higher rates appear to approach a constant value. It is, therefore, necessary to burn a sufficient quantity of gas in unit time to ensure measuring the maximum temperature at **a** given constant distance above the burner.

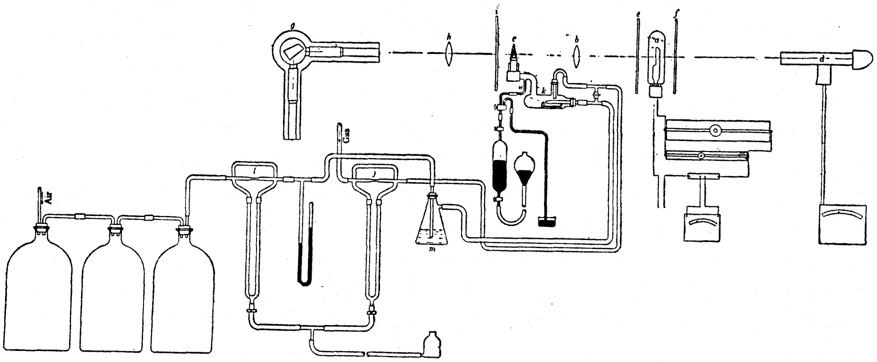

Fig. 1.—Apparatus for determining flame temperatures of gases.

In the spectral-line reversal method employed for obtaining the temperatures given in this report, use was made of a tungsten band lamp as a source of continuous radiation. Figure 1 is a diagrammatic sketch of the apparatus. The tungsten band lamp *a* was heated by a storage battery, the current input being controlled by variable resistances Light from the band lamp was focused by means of the lens b into the center of the flame c just above the tips of the inner cones. The brightness temperature of the band lamp was read by means of the optical pyrometer *d*, of the disappearing filament type, the screens *e* and f permitting radiation to emerge from the same point on the heated band. The optical pyrometer recorded the same temperature (within 5°) on both sides of the band lamp. Furthermore, there was no evidence of a **temperature** gradient one centimeter either side of the center of the band. The image of the heated tungsten band together with the flame was focused on the slit of the spectrometer g by means of the lens h. **A** screen *i* permitted radiation from an area of the flame equal to the area of the band image to reach the spectrometer. The flame was colored by means of sodium, lithium, or thallium salts. The spectral lines (for sodium, the resonance doublet XX = 0.5890–0.5896μ) are seen as bright lines upon the continuous spectrum from the band lamp if the latter is cooler than the flame, but if it is hotter the bright lines are reversed and appear dark upon the brighter background of the continuous spectrum of the band lamp. Final adjustment was made by the observer at the eyepiece of the spectrometer. When the lines are just completely reversed the brightness temperature of the tungsten band lamp is the same as the temperature of the flame. At **this** point the former temperature was determined by means of the optical pyrometer.

Experimental Part

Burners Used **in** Investigation.—Three types of burners were used in our investigation. These are shown in Fig. 2. Type **A** consisted of a small brass box 5.5 by 3.5 by **3.5 cm.** Protruding through the top of the box were fifteen **quartz** tubes arranged in three rows, each having an internal diameter of **5** mm. Holes were drilled into the top plate of the box to admit the lower ends of the tubes, which were sealed in gas-tight with sealing wax. Asbestos paper was wrapped around the tubes **as** shown to prevent the infiltration of secondary **air;** they were also sealed with wax along the bottom and edges.

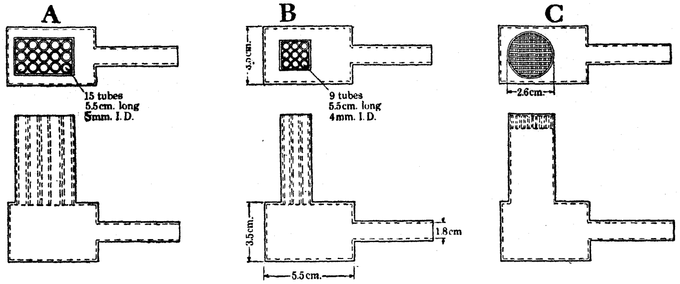

Fig. **2.—Gas** burners.

This burner could not be used with some of the unsaturated hydrocarbon gases, which have rather high flame speeds, due to the flames "flashing back" through the tubes. To handle these gases, type B was prepared similar to the foregoing with the exception that there were nine quartz tubes with an internal diameter of 4 mm. In some cases, even with this burner, it was very difficult to obtain satisfactory flames when the mixture contained oxygen in excess of that required for complete combustion. The flames tended to rise or "float" above the burners, or "flash-back" through the tubes.

Finally, a third burner of the Méker type was prepared. This was made as shown in *C*. The burner head was **2.6 cm.** in diameter and was provided with a nickel grid. Flash-backs were further prevented by installing 40-mesh nichrome screens both above and below the nickel grid when necessary.

Regulation of Flames.—The quantity of gas–air mixture was always regulated so that the inner cones remained close to the top of the burner ports. The quantity **was** then further regulated to give a rather bulky flame which spread out in cross-sectional area equal to the area of the burner ports. Consistent results were possible with any of the burners at a given gas–air ratio, provided that this condition obtained (see results shown in Fig. 4). If the flames tapered off toward the center as they left the burner ports, due to an insufficient amount of mixture being burned, low values were obtained. With some of the mixtures the metal Méker type burner tended to heat up slightly during use; therefore, it was necessary to surround the burner with a thick felt pad which was kept moistened with water. This does not seriously affect the temperature of the flame since any temperature lowering due to heating the burner is practically compensated by the increased temperature due to preheating the incoming gas, barring small losses by convection to the outside atmosphere.

Determination of Gas–Air Ratios.—The combustible gases were admitted to the apparatus either from a 12-cu. ft. gasholder or, in the case of the compressed gases, from tanks through a reducing valve. The quantity of gas admitted was determined by a calibrated flowmeter *j* (Fig. 1) from which the gas passed to the mixing chamber k. The air supply was forced through the apparatus by a Lehman rotary pump, having a by-pass arrangement whereby the air pressure could be maintained at any desired value. This regulation was obtained by a fine adjusting needle-valve. The air was then passed through three large stabilizing bottles, through the calibrated flowmeter *l*, a mercury pressure gage, a humidifier m, and thence through the atomizer in mixing chamber k, whence the gas–air mixture passed directly to the burner *c*. Samples of the gas–air mixtures were taken at *n* by mercury displacement. A small fraction of the sample collected was passed into a collecting tube, and the samples were analyzed in a Bone and Wheeler gas-analysis apparatus

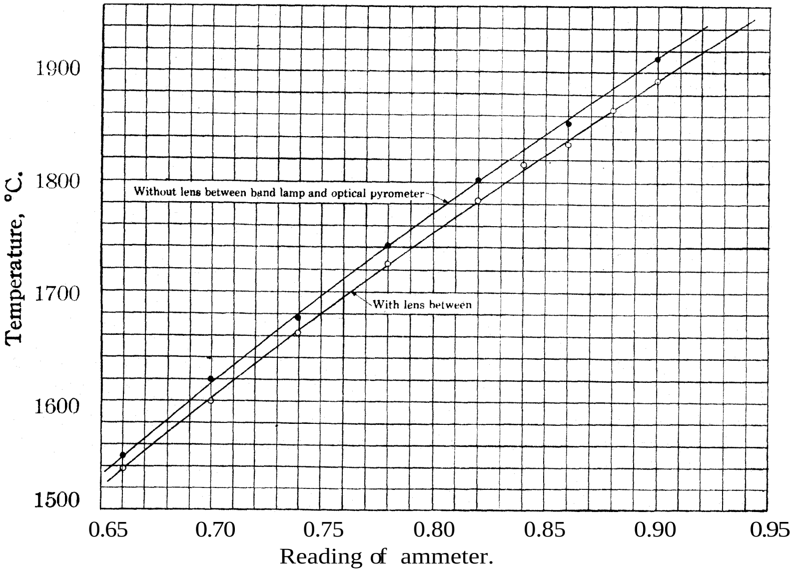

Fig. 3.—Calibration curve for tungsten band lamp and lens.

Calibration of Band Lamps.—General Electric 20-ampere type 4-T-20 tungsten band lamps were used as continuous radiators. Two different lamps were employed during the investigation. Experience with these band lamps showed that the brightness temperature for a given current consumption remained practically constant over long periods In the preliminary work the brightness temperature of the band lamp was read with an optical pyrometer each time an observation was made. However, by calibrating the band lamp with a calibrated optical pyrometer in which brightness temperature is plotted versus current, the time required to make observations was greatly reduced without sacrificing accuracy. The band lamps were calibrated by H. K. Griffin of the Physical Instruments Calibration Section of the Bureau of Mines and a typical calibration is given in Fig. 3.

Calibration of Lens Correction.—As the radiation from the Land lamp passes through a lens before being focused on the flame under investigation, a correction must be applied for the radiation absorbed by this lens. The correction is negative, because, with the

lens absorbing radiation, the lamp must be heated that much hotter before reversal takes place. The values for lens correction are given in Fig. 3. Over the range investigated it varies from 11 at 1600° to 21 at 1950°.

Color Correction.—Tests were made in which the flames were colored with sodium and lithium salts, supplemented by a few tests with thallium salts. As the brightness temperature of the band lamp is measured in the red (λ 0.665μ) and the temperature of the flame in the yellow (sodium salts, λ 0.589μ), red (lithium salts, λ 0.671μ) or green (thallium salts, λ 0.535μ) a color correction is necessary.

The correction for sodium is determined in the following manner. The relation between the true temperature T and the brightness temperature S_λ as derived from Wien's equation, is

$$\frac{1}{T} - \frac{1}{S_\lambda} = \frac{h2.303 \log ex}{C_2} \qquad (1)$$

and

$$\frac{1}{T} - \frac{1}{S_{\lambda'}} = \frac{\lambda' 2.303 \log e_{\lambda'}}{C_2} \qquad (2)$$

where T is black body temperature in absolute degrees; $\lambda = 0.665\mu$ (red light) or 0.0000665 cm.; $\lambda' = 0.589\mu$ (yellow light) or 0.0000589 cm.; e_λ and $e_{\lambda'}$ are spectral emissivities of red and yellow light; C_2 is 1.433 cm. degrees; S_λ is brightness temperature as observed with pyrometer; and $S_{\lambda'}$ is flame temperature (brightness temperature of yellow light). By subtracting Equation 2 from 1 we obtain

$$\frac{1}{S_{\lambda'}} = \frac{2.303}{C_2} [\lambda \log e_\lambda - \lambda' \log e_{\lambda'}] + \frac{1}{S_\lambda} \qquad (3)$$

Data for the spectral emissivities of tungsten as a function of the true and brightness temperature were obtained from Forsythe and Worthing.[12]

From the curves obtained by plotting μ against the spectral emissivity for different temperatures the spectral emissivity for any wave length can be read off for that temperature. Table I was constructed for the temperature range of these experiments.

TABLE I

SPECTRAL EMISSIVITIES FOR SEVERAL TEMPERATURES AT VARIOUS WAVE LENGTHS

True or black body temp., °K.	Brightness temp. in red, °K.	Spectral emissivity 0.665μ	0.589μ	0.671~	0.535μ
2100	1943	0.433	0.446	0.432	0.455
2200	2026	.431	.444	.430	.454
2400	2192	.427	.441	.426	.451
2500	2274	.425	.439	.424	.449

From Equation 3 at 1943°K. (in red), a corresponding temperature in the yellow is calculated. $S_{\lambda'}$ = 1965°K. or 22° higher in the yellow than

---

[12] Forsythe and Worthing, Astrophys. J., 61, 146 (1925).

in the red. Table II contains the color corrections for sodium and lithium[13] over a range of temperatures.

TABLE II

COLOR CORRECTIONS

Temp., °K.	Sodium λ 0.589μ	Lithium λ 0.671μ
1943	+22	−2
2026	+23	−2
2192	+28	−2
2274	+30	−3

To check the accuracy of the calculated color corrections, saturated solutions of sodium and lithium nitrates were used in the atomizer. The flame temperatures were observed with ethane–air mixtures, the air–gas ratios being adjusted to give maximum values. Four different tests were made and the following results obtained.

TABLE III

COMPARISON OF SODIUM AND LITHIUM FOR OBTAINING TRUE FLAME TEMPERATURES

Test	Observed temperature, °C. Using sodium line	Observed temperature, °C. Using lithium line	True corrected flame temperature, °C. Sodium +26	True corrected flame temperature, °C. Lithium −2	Difference
1	1861	1888	1887	1886	− 1
2	1857	1893	1883	1891	+ 8
3	1870	1888	1896	1886	−10
4	1857	1878	1883	1876	− 7

In every case the observed temperatures for lithium salts are higher than those for sodium salts. When corrections are made for color, as previously described, the flame temperatures for both salts show fairly close agreement.

Introduction of Alkali Salts into Flame.—Both dry and wet methods were used to introduce sodium salts into the flames. In the dry method the air was passed through a quartz tube in which were placed three alundum boats containing the sodium salts. The quartz tube was heated in an electric furnace to a temperature sufficient to vaporize the sodium chloride in amounts which would produce a good reversal of the sodium lines in the spectrometer. The sodium chloride entered the burner in the form of a cloud. The air in these tests was not humidified before passing through the furnace, the moisture content being that of the laboratory air used. Considerable difficulty was experienced in maintaining a steady concentration of sodium in the flame, and it was necessary to cool the air back to

---

[13] The reversal of the red lithium line was not as satisfactory as the sodium line. However, it could be employed by adjusting to the point of extinction. With the thallium line, however, it was impossible to obtain a reversal and the point of extinction was very indefinite. Flame temperatures obtained with thallium salts ranged from 100 to 140° below those obtained with sodium or lithium salts. The use of thallium salts is therefore impracticable.

room temperature by passing it through a lead coil immersed in cold water before mixing it with the combustible gas.

A wet method was finally adopted in which a saturated solution of sodium or lithium nitrate was placed in the atomizer chamber k and the salt solution atomized directly into the gas–air mixture. In the wet method the humidifier *m* was used to prevent the salt solution from crystallizing out on the nozzle of the atomizer and causing fluctuations in the rate of flow of air.

The cooling effect of the salt-solution spray was found experimentally by inserting a platinum strip in the non-luminous flame and reading its temperature with an optical pyrometer, with and without pure water being sprayed at the same rate as used in the measurements with the flames. The amount of cooling was found to be 15° for the hydrocarbon flames.[14]

A further series of tests was made with Pittsburgh natural gas–air mixtures in the ratios to give approximately maximum flame temperatures (1870 to 1890°) using both the wet and dry methods. In each case where the gas composition was the same the dry method gave higher results which varied over a rather wide range from 4 to 26°. These results appear to show that a correction for water spray is necessary. As an average value a plus correction of 15° has been added to all the results given in this report in which the wet method was used. The cooling effect of salt in the spray has been shown to be negligible.?

Gases.—Methane was obtained from a natural gas well near Pittsburgh, Pa. Previous tests of the gas from this well showed the combustibles to consist largely of methane. The gas from the well was compressed in steel cylinders by means of a portable compressor.

The natural gas was that supplied at the Pittsburgh Experiment Station, Bureau of Mines, and varies only slightly from day to day.

The ethane, propane, butane, isobutane, ethylene and butylene were all obtained from the Carbide and Chemicals Corporation of New York in steel tanks.

The propylene was obtained from the Ohio Chemical and Manufacturing Company of Cleveland, Ohio. This gas also was supplied in steel tanks.

A fractionation analysis of each of these gases was made at low temperatures and pressures, using a Shepherd and Porter apparatus for the fractionation and a Bone and Wheeler apparatus for the purity of the fraction. The results of these analyses are given in Table IV. All the gases indicate a small percentage of nitrogen. The high degrees of purity of the propane, butanes and butylene agree well with the specifications for these gases. Percentages less than 0.01% are not recorded. The usual combustion

---

[14] The laboratory air was nearly always saturated with moisture so that the cooling effect observed is, in a large measure, due to droplets or a cloud of water picked up in the spray.

analyses in a gas-analysis apparatus give only the percentages of hydrocarbon gases in the gas–air mixtures on a dry basis, so that the percentages of gas given in the results described later are on a nitrogen and moisture-free basis.

TABLE IV

COMPOSITION OF GASES USED IN TESTS

Gas	Composition, per cent. by volume							
	CH_4	C_2H_6	C_3H_8	C_4H_{10}	C_2H_4	C_3H_6	C_4H_8	N_2
Methane	97.8	1.4	0.1	0.1	..	..	..	0.6
Natural gas	86.6	7.9	2.7	1.3	..	..	..	1.5
Ethane	8.4	89.4	0.4	..	..	..	..	1.8

Ethylene	1.0	1.5	.2	0.0	96.6	..	..	.7
Propylene	..	..	.5	..	3.5	93.3	1.1	1.6
Butylene	..	..	..	..	..	0.0	99.9	0.1

Experimental Results

The values found for the flame temperatures of methane, Pittsburgh natural gas, ethane, propane, butane, isobutane, ethylene, propylene and butylene when mixed with varying proportions of air are given in Fig. 4.

Vertical lines are drawn in the graphs representing the composition of the mixture to give complete combustion—that is, just sufficient combustible present to consume all the oxygen in the mixture. A shaded section is also drawn in each graph to show the range in percentage of combustible which has the maximum speed of uniform movement of flame. These values were taken from reports by Wheeler, Coward, Payman and others and represent the speed as measured in a 25-mm. tube for horizontal propagation of flame.

TABLE V

MAXIMUM FLAME TEMPERATURES OF HYDROCARBON GASES WHEN MIXED WITH AIR AND A COMPARISON OF THESE VALUES WITH THE MAXIMUM SPEED OF UNIFORM MOVEMENT OF FLAME

Hydrocarbon	Obs. max. flame temp., °C.	Combustible in air at maximum flame temp., %	Combustible in air necessary to give complete combustion, %	Max. speed of uniform movement of flame, cm./sec.	Combustible in air at max. speed of uniform movement of flame, %	Calcd. max. flame temp., °C.
Ethylene	1975	665–7.00	6.50	165	7.30–7.70	2072
Propylene	1935	4 45–4.90	4.45	100	5.00–5.40	2050
Butylene	1930	3.35–3.45	3.35	97	3.90–4.10	2033
Propane	1925	4.05–4.30	4.00	82	4.60–4.80	1967
Isobutane	1900	3.15–3.25	3.10	. .	.. ..	1973
Butane	1895	3.15–3.40	3.10	83	3.60–3.80	
Ethane	1895	5.70–5.95	5.65	86	6.30–6.60	1949
Pittsburgh natural gas	1890	8.60–9.10	8.60	71	9.10–9.40	1928
Methane	1880	9.45–10.10	9.45	67	9.70–10.00	1918

The variation in the flame temperature given represents the reproducibility that may be expected by this method. In obtaining these temperatures, four different investigators worked on the problem at one time or another, two different tungsten hand lamps were used, three different burners, both sodium and lithium salts, and both the wet and dry method of introducing the salts. The values found when using the different burners are properly noted in Fig. 4. They include corrections for water spray, color and lens, as given above. Table V contains a summary of results.

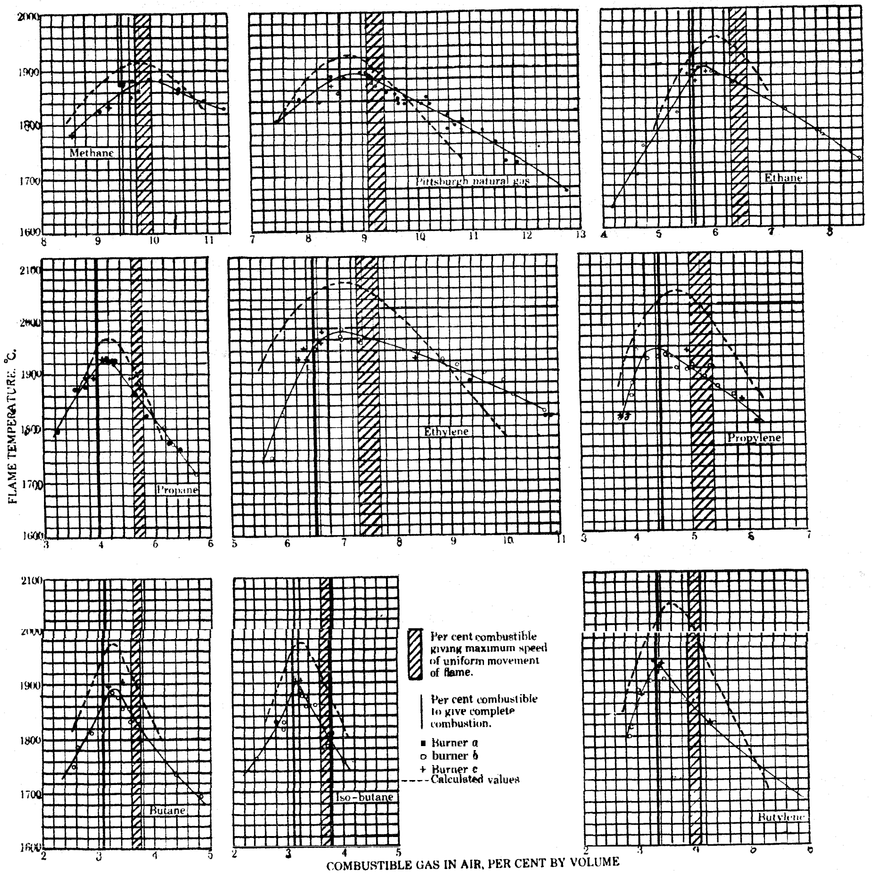

Fig. 4.—Flame temperatures of hydrocarbon gases.

Conclusions

The following conclusions may be drawn. 1. As would be anticipated, the flame temperature is markedly affected by the proportion of combustible gas in air. The flame temperature increases rapidly, starting with a mixture near the lower limit of inflammability and reaches a maximum when the mixture contains combustible slightly in excess of that necessary to consume all the oxygen present. The reason for this slight shift from a stoichiometric mixture lies in the dissociation of the products of combustion at the high temperatures developed. This is borne out by the calculated temperatures, whose maxima, allowing for dissociation, agree well with the observed maxima (refer to Fig. 4). With further increases in percentage of combustible the flame temperature falls again, although not as sharply as for the mixtures containing excess oxygen.

2. The maximum flame temperatures of the gases tested vary from 1880° for methane to 1975' for ethylene; the maximum variation among the different hydrocarbons is less than 100'.

3. The maximum flame temperatures of the unsaturated hydrocarbons are greater than those of the saturated hydrocarbons,

4. In most cases the maximum flame temperature occurs over a very narrow range of gas–air ratios; a slight change in the gas–air ratio at the maximum causes a sharp reduction in the flame temperature. This is especially true for propane, propylene, butane, isobutane and butylene and not so marked for methane, Pittsburgh natural gas, and ethylene.

5. The combustible gas–air mixture which gives the highest flame temperature does not correspond to that which gives the highest speed of uniform movement of flame, except for methane and possibly Pittsburgh natural gas. For all the other hydrocarbon gases the mixtures which give the highest flame temperatures contain less combustible gas than those which give the highest speed of flame.

6. There is a general agreement between the maximum flame temperatures and maximum flame speeds (Table V). Ethylene has the highest maximum speed of uniform movement of flame and also the highest flame temperature. The others are, on the whole, in the proper order in this respect. The variations as between propane, butane, and ethane are too small to draw significant conclusions. The reason for the non-coincidence of the mixtures which give maximum flame speeds and the maximum flame temperatures is not clear. It has been suggested that the maximum flame temperature may have little or nothing to do with the maximum flame speed but that some lower temperature at which the combustion reaches a certain rapidity may be of importance. In spite of the above-mentioned agreement this may well bear further investigation.

An explanation has been advanced by Payman and Wheeler[14a] to account for the disagreement between the maximum flame speed mixture and the stoichiometric mixture. According to them the displacement is due to a mass-action effect whose theoretical maximum occurs on the rich side. On the other hand, the highest calorific effect is produced by a stoichio-

---

[14a] W. Payman and R. V. Wheeler, "Flame Speeds and Their Calculation," Reprinted from *Fuel* in *Science and Practice, 153 (1929).*

metric mixture. This factor will oppose the mass-action effect and will diminish the displacement of the maximum speed mixture caused by the latter. It is found that the temperature factor far outweighs the mass-action factor. The resultant displacement will be governed by the cooling effect of the excess combustible gas; the higher the specific heat of the latter at the temperature developed, the less the displacement will be. The displacement for propane and butane should therefore be less than for methane. Actually, it is slightly greater for propane, whereas for butane it is approximately the same as for methane. For ethylene, whose specific heat may also be expected to exceed that of methane, the displacement is twice as great.

Calculation of Flame Temperatures.—We have attempted to calculate the temperatures attained by the flame for the several mixtures used in this investigation. The agreements with the experimental flame temperatures are, in general, so satisfactory as to justify a brief account of these calculations.

In making the calculations the following assumptions have been made.

1. The initial mixture consists of hydrocarbon gas and air in any desired proportions.

2. The analyses given in Table IV are used for Pittsburgh natural gas and ethane. All other hydrocarbons are considered pure because the small amounts of impurities present introduce only very slight alterations in the final result.

3. The products of combustion consist of carbon dioxide, carbon monoxide, water, hydrogen, oxygen, nitrogen and no hydrocarbons.

4. The products of combustion are in chemical equilibrium at the temperature attained by the combustion. The equilibria considered are

$$\text{(a)}\quad 2H_2 + O_2 \rightleftharpoons 2H_2O$$
$$\text{(b)}\quad H_2 + CO_2 \rightleftharpoons CO + H_2O$$

5. The maximum temperature is reached when the products mixture attains the equilibrium condition. This assumption is not an unreasonable one when the combustion is very rapid.

6. The combustion takes place at constant pressure and one atmosphere.

7. The initial temperature $T_1 = 291°K.$, and the final temperature T_2 is the flame temperature sought.

8. The gases are saturated with water vapor at the temperature of the laboratory before being burned.

9. No heat is lost by radiation or conduction.

Method.—In general, the method employed is that used by Goodenough and Felbeck.[15] The following procedure was used.

---

[15] G. A. Goodenough and G. T. Felbeck, *Bull. Univ. Ill. Eng. Exp. Station*, No. 139, March, 1924.

Initial mixture

1 $C_aH_{2b} = 1$ mole
2 $O_2 = c$ moles
3 $N_2 = d$ moles
4 $H_2O = e$ moles

Final mixture

1 $CO_2 = ax$ moles
2 $H_2O = (b + e)y$ moles
3 $CO = a(1 - x)$ moles
4 $H_2 = (b + e)(1 - y)$ moles
5 $O_2 = c + \frac{e}{2} - \frac{a}{2} - \frac{ax}{2} - (b + e)\frac{y}{2}$ moles
6 $N_2 = d$ moles

$$\text{Total moles} = m = b + c + d + \frac{a}{2} + \frac{3}{2}e - \frac{ax}{2} - (b + e)\frac{y}{2}$$

The number of moles of carbon, oxygen, and hydrogen should check in the initial and final mixture. x = fraction of carbon dioxide undissociated in the equilibrium mixture; y = fraction of water undissociated in the equilibrium mixture.

There are three unknowns—namely x, y, and T_2—and there must be three independent equations from which to determine them. Two are derived from the equilibria mentioned above and the third is obtained by applying the energy equation to the combustion process.

The equations expressing these equilibria are

$$K_{p\mathrm{H_2O}} = \frac{p_{\mathrm{H_2O}}}{p_{\mathrm{H_2}}\sqrt{p_{\mathrm{O_2}}}} = \frac{y}{1 - y}\sqrt{\frac{m}{P\left(c + \frac{e}{2} - \frac{a}{2} - \frac{ax}{2} - (b + e)\frac{y}{2}\right)}}$$

Placing P = 1

$$\log K_{p_{\mathrm{H_2O}}} = {}^1/_2 \log m + \log \frac{Y}{1 - y} - {}^1/_2 \log \left(c + \frac{e}{2} - \frac{a}{2} - \frac{ax}{2} - (b + e)\frac{y}{2}\right) \quad (1)$$

$$K_{p_{\mathrm{wg}}} = \frac{P_{\mathrm{CO}}\, p_{\mathrm{H_2O}}}{p_{\mathrm{CO_2}}\, p_{\mathrm{H_2}}} = \frac{a(1 - x)(b + e)y}{ax(b + e)(1 - y)} = \frac{y(1 - x)}{x(1 - y)} \quad (2)$$

$K_{p_{\mathrm{H_2O}}}$ and $K_{p_{\mathrm{wg}}}$ are the equilibrium constants at constant pressure of the water formation and water-gas reactions.

In deriving the energy equation we apply the first law of thermodynamics and assume that no heat is lost in the combustion process. The following series of changes is assumed in passing from the initial to the final state. The mixture is completely burned at the constant initial temperature T_1; the products, carbon dioxide and water dissociate at the same T_1 until the composition of the mixture is the same as that in the final state of equilibrium; the final mixture at T_1 is heated without change of composition to the final temperature T_2.

The energy equation may be expressed as follows: heat of combustion of hydrocarbon = energy required to dissociate carbon dioxide and water + heat capacity of the final mixture from T_I to T_2. The final equation is

$$H_{\mathrm{HC}} = aH_{\mathrm{CO_2}} - axH_{\mathrm{CO_2}} + (b + e)H_{\mathrm{H_2O}} - (b + e)yH_{\mathrm{H_2O}} + ax\int_{291}^{T_2} C_{p_{\mathrm{CO_2}}}\,\mathrm{d}t$$

$$+ (b + e)\,y\int_{291}^{T_2} C_{p_{2\mathrm{HO}}}\,\mathrm{d}t + a(1 - x)\int_{291}^{T_2} C_{p_{\mathrm{CO}}}\,\mathrm{d}t +$$

$$(b + e)\,(1 - y)\int_{291}^{T_2} C_{p_{H_2}}\,dt + \left(c + \frac{e}{2} - \frac{a}{2} - \frac{ax}{2} - (b + e)\frac{y}{2}\right)\int_{291}^{T_2} C_{p_{O_2}}\,dt + d\int_{291}^{T_2} C_{p_{N_2}}\,dt$$

This can be represented by a linear equation of the type

$$Ax + By = C \tag{3}$$

where

$$A = a\left[\int_{291}^{T_2} C_{p(CO_2 - CO - 1/2\ O_2)}\,dt - H_{CO_2}\right]$$

$$B = (b + e)\left[\int_{291}^{T_2} C_{p(H_2O - H_2 - 1/2\ O_2)}\,dt - H_{H_2O}\right]$$

$$C = H_{HC} - aH_{CO_2} - (b + e)\,H_{H_2O} - \left(\frac{a}{2} + \frac{e}{2} + c + d\right)\int_{291}^{T_2} C_{p_{O_2\text{ or }N_2\text{ or }CO}}\,dt - (b + e)\int_{291}^{T_2} C_{p_{H_2}}\,dt.$$

H_{HC} = heat of combustion of hydrocarbon gas
H_{CO_2} = energy to dissociate one mole of CO_2 to CO and O_2
H_{H_2O} = energy to dissociate one mole of H_2O to H_2 and O_2

By eliminating y in (2) and (3) a quadratic equation in x is obtained

$$A\,(K_{wg} - 1)\,x^2 + x\,[(A + C) + (B - C)K_{wg}] - C = 0 \tag{4}$$

The procedure was modified slightly in the cases of Pittsburgh natural gas and ethane because these gases consisted of a mixture of hydrocarbons. In place of one mole of hydrocarbon a unit containing one mole of carbon was selected. The unit for Pittsburgh natural gas was therefore 1 mole of carbon, 1.85135 moles of hydrogen and 0.012965 mole of nitrogen: then $a = 1$, $b = 1.85135$, and the number of moles of nitrogen $= d + 0.012965$.

Choice of Data.—The heats of combustion of the hydrocarbons were calculated from data given in the "International Critical Tables."[16] The heats given below are in calories per gram mole of hydrocarbon gas forming carbon dioxide gas and water vapor at 18° and a constant pressure of one atmosphere.

TABLE VI

HEATS OF COMBUSTION OF GASEOUS HYDROCARBONS

Formula	Name	Calories per gram mole
CH_4	Methane	189,700
C_2H_4	Ethylene	310,885
C_2H_6	Ethane	336,732
C_3H_6	Propylene	458,532
C_3H_8	Propane	484,076
C_4H_8	Butylene	604,976
C_4H_{10}	Isobutane	630,620

H_{H_2O} at one atmosphere and 18° forming gaseous water = 57830 cal./mole, H_{CO_2} at one atmosphere and 18° = 67960 cal./mole.[17]

---

[16] "International Critical Tables," Vol. V, 1929, pp. 138, 162.

[17] "International Critical Tables," Vol. V, 1929, pp. 176, 181.

The free energy data for the water–gas reaction were taken from Eastman.[18] The equilibrium constants at different temperatures were evaluated from the equation

$$\Delta F = 9800 - 3.06\, T \ln T + 7.912 \times 10^{-3}T^2 - 2.358 \times 10^{-6}T^3 + 3.258 \times 10^{-10}T^4 + I_6 T$$

where $I_6 = 5.60$.

The equilibrium constants for the formation of water were calculated from the expression given by Lewis and Friauf[19]—valid up to 2800°K.

$$\log K_{p_{H_2O}} = \frac{57296}{4.573T} - 0.848 \log T - 1.474 \times 10^{-4}T + 7.78 \times 10^{-8}T^2 - 8.72 \times 10^{-12}T^3 + 0.616$$

The specific heat equations for the various gases are

$$C_{p_{H_2O}}{}^{20} = 8.32 - 6.53 \times 10^{-4}T + 2.70 \times 10^{-6}T^2 - 6.145 \times 10^{-10}T^3$$
$$C_{p_{CO_2}}{}^{21} = 7.70 + 5.30 \times 10^{-3}T - 0.83 \times 10^{-6}T^2$$
$$C_{p_{H_2}}{}^{19} = 6.64 + 4.92 \times 10^{-4}T + 0.319 \times 10^{-6}T^2 - 0.74 \times 10^{-10}T^3$$
$$C_{p_{O_2, N_2, CO}}{}^{19} = 6.73 + 4.08 \times 10^{-4}\, T + 0.486 \times 10^{-6}T^2 - 0.1234 \times 10^{-9}T^3$$

Method.—Given a certain initial mixture of hydrocarbon gas, air and water vapor: a value for T_2 is assumed and A, B and C are evaluated. These are substituted in (4), which is solved for x; y is then obtained from (3). These values of x and y are substituted in the right-hand side of (1) and the value so found is compared with the true value of the equilibrium constant at the assumed temperature. If these do not agree, another temperature is assumed and the calculation repeated until they do agree. Both conditions of equilibrium and the energy equation are then satisfied. The amount of work may be materially lessened by constructing a plot of log $K_{p_{H_2O}}$ vs. T. The values for the right-hand side of (1) (from two temperatures assumed on either side of the true temperature) are entered on the plot. The line of intersection is the true temperature, provided that the two assumed temperatures are not too far removed from each other.

The results of the calculations are plotted as dotted curves in Fig. 4, on a moisture-free and nitrogen-free basis and are comparable with the experimental curves. The maximum temperature for each combustible is listed in the last column of Table V.

Discussion

The character of the agreement between the calculated and observed flame temperatures is evident from an inspection of Fig. 4. Of most significance is the position of the maximum temperatures. These occur

for mixtures slightly on the rich side, as is the case for the observed temperatures. The difference between calculated and observed temperatures is about 100° for the unsaturated and about 40 to 70° for the saturated hydrocarbons. As is to be expected, this difference is greater, in general, the higher the temperature. It should be noted that the calculated and observed curves cross each other in the region of rich mixtures. This is probably due to the infiltration of secondary air which, burning some of the excess hydrocarbon, gives rise to observed temperatures higher than would have been recorded were secondary air absent.

If we assume that the specific heat and free energy data are reasonably correct, the difference is due to radiation losses from the flames.

It is of interest to record that a similar set of calculations assuming the gas to be dry give temperatures 42 to 50° higher than for wet gases.

Acknowledgment.—The writers wish to thank J. S. Brown and H. Seaman, junior chemists, for their assistance in obtaining part of the experimental data and in making temperature calculations.

Summary

The flame temperatures for various hydrocarbon gas–air compositions have been measured for methane, Pittsburgh natural gas, ethane, propane, butane, isobutane, ethylene, propylene and butylene. The spectral-line reversal method was employed using sodium and lithium salt sprays. The flame temperatures reach a maximum when the mixture contains combustible slightly in excess of that necessary to consume all the oxygen present. These range from 1880° for methane to 1975° for ethylene. Comparison with the maximum speeds of uniform movement of flame shows that in general the latter is obtained for mixtures containing more combustible gas than those which give maximum flame temperatures. The flame temperatures of the various combustible gases have been calculated and the agreement is very satisfactory. The calculated maximum temperatures occur slightly on the rich side, as is the case for the observed values. These are higher than the observed values by about 100° for the unsaturated and 40 to 70° for the saturated hydrocarbons, and are in such a direction as to account for the difference by radiation losses from the flame.

THE POTENTIOMETRIC DETERMINATION OF IRIDIUM

BY SHO-CHOW WOO AND DON M. YOST

RECEIVED NOVEMBER 10, 1930 PUBLISHED MARCH 6, 1931

Introduction

In connection with a study of the reduction potential of the chloroiridous–iridic acids[1] it was necessary to develop good volumetric methods for the determination of the concentrations of the metal in its higher state of oxidation. In addition to this it was necessary to prepare solutions of chloroiridous and chloroiridic acids free from other elements of the platinum group and from the baser metals. Owing to the incomplete knowledge of the chemistry of the platinum group elements and the high cost of the iridium itself, both problems presented especial difficulties. In this paper are described a new method and a modified method for the volumetric determination of iridium, and incidentally the procedures used for the preparation of pure solutions of chloroiridous and chloroiridic acids.

The authors are indebted to Professor A. A. Noyes for valuable suggestions given during the course of the work.

Preparation of the Materials

Ammonium Hexachloroiridate.—Fairly pure metallic iridium in a finely divided state was first digested for three hours with a hot mixture of hydrochloric and nitric acids. This treatment removes any organic matter and the base metals as well as some of the platinum, the iridium not being much attacked. The residual metal was next intimately mixed with three times its weight of pure sodium chloride, and the mixture was heated to 650° for one hour in a quartz tube through which was passed a stream of chlorine. All of the platinum metals were converted by this procedure into the double chlorides. The mixture of the chlorides was dissolved in a small volume of dilute hydrochloric acid and the resulting solution was saturated with chlorine and then heated on a water-bath. This treatment resulted in the oxidation of the iridous to the iridic chloride and in the decomposition by heat of any quadrivalent palladium compounds.

To remove the palladium and rhodium, the solution of the chlorides was saturated with ammonium chloride and then cooled in an ice-bath. The precipitate (which contains the iridium) was filtered off and redissolved, and the solution was again precipitated as before. This procedure was repeated several times and yielded a product free from palladium and rhodium.

The resulting ammonium hexachloroiridate was next heated with concentrated nitric acid, fresh acid being added from time to time. To the residue in the flask was added concentrated perchloric acid, and the mixture was boiled until the greater part of the acid had been driven off; then more acid was added and the treatment repeated. Continued application of this procedure caused the complete volatilization of osmium and ruthenium as the tetroxides, leaving the iridium free from all platinum metals except platinum.

The residue was heated nearly to dryness and dissolved in a small amount of water

---

[1] Sho-Chow Woo, THIS JOURNAL, **53**, 469 (1931).

To the solution was added an excess of sodium bicarbonate solution and bromine water, and the resulting mixture was boiled. This caused the precipitation of iridic hydroxide, but not that of platinum. The precipitate was redissolved in hydrochloric acid and subjected again to the bicarbonate precipitation. This tsratment was repeated several times. The final product, iridium hydroxide, was dissolved in hydrobromic acid and, after treatment with nitric and hydrochloric acids to convert the bromides to chlorides, the solution was saturated with ammonium chloride and cooled, and the resulting precipitate of ammonium hexachloroiridate was filtered off. In order to make sure that no sodium salts were present, the ammonium chloride precipitation was repeated several times The resulting ammonium chloroiridatc was washed with ice-cold water and then dried over concentrated sulfuric acid in a vacuum desiccator.

After each separation procedure a portion of the iridium-containing mixture was tested for the element being removed, using the dimethylglyoxime[e] test for palladium and the methods of Noyes and Bray[3] for the other elements. These tests show the presence of 0.3 mg. or less of the elements tested for. The procedures for the removal of osmium and ruthenium give a very complete separation, and the test for palladium is quite sensitive. Therefore the only contaminating elements present to the extent of 0.3% or less are rhodium and platinum, since the purification was always carried out until the tests for the contaminating elements were negative.

Chloroiridic and Chloroiridous Acids.—The ammonium chloroiridate was digested for ten hours with aqua regia upon a water-bath until all of the ammonia had been destroyed, and the nitric acid was then destroyed by repeated digestion with hot concentrated hydrochloric acid. The resulting solution consists principally of a mixture of chloroiridic acid and hydrochloric acid. For use in the electromotive force measurements a portion of this solution was reduced to chloroiridous acid with pure redistilled alcohol, using the procedure described by Delépine.[4] The small quantity of metallic iridium which separated was removed by filtering the solution through a hardened filter after the alcohol had been driven off by heating, and the solution was finally evaporated to dryness in a vacuum desiccator. The residue was dissolved in dilute hydrochloric acid of known strength.

Hydrochloric Acid **and** Other Analytical Reagents.—The best obtainable hydrochloric acid was redistilled and diluted with redistilled conductivity water. The other analytical reagents used were of C. P. grade.

The Methods of Analysis Studied

The iodometric method of analysis that has been described by Delépine[4] was first tested. In this method a hydrochloric acid solution of the chloroiridate is reduced to the chloroiridite by potassium iodide, and the liberated iodine is titrated with thiosulfate with starch as an indicator. In this form the method was not accurate since the color of the solution obscured the end-point; but it was found to give very satisfactory results when benzene was used to determine the point at which all of the iodine had been reduced. The titrations were carried out in 0.1 to 0.2 N hydrochloric acid solutions in a volumetric flask whose volume was such that the benzene layer rose

into the neck when the last portions of thiosulfate were added. This procedure facilitated the determination of the end-point, especially when the narrow column of benzene was observed against a white background.

In the second method studied, titanous chloride was used for the estimation of quadrivalent iridium. This standardized reagent was added to a hydrochloric acid solution, and the end-point was determined electrometrically. During the initial stages of the titration the potential reaches a steady value after a short time, and at the end-point it changes abruptly from 0.65 to 0.4 volt. Some time, however, is required for the electromotive force to become constant near the end-point, and the stage at which the sharp change occurs may be considered to be the end-point only in case the titanous chloride is added very slowly. The addition of sodium chloride to solutions of chloroiridic acid free from other salts was found to increase the sharpness of the end-point. The initial concentration of the hydrochloric acid in the solutions titrated was from 0.1 to 0.2 N, and the total initial volume was 50 cc. The amounts of sodium chloride added to the titration mixtures varied from 2 to 3 g. The other half-cell consisted of a saturated calomel electrode.

For comparison the iridium in the ammonium salt and in the solutions was determined by the well-known gravimetric method of igniting the salt in a current of hydrogen. With the small amounts of material used extreme care was necessary to avoid the small accidental losses that usually accompany this method of analysis. The determinations differed by less than 1% in all cases, usually by not more than 0.5%.

An attempt was also made to determine iridium by precipitating it with strychnine sulfate, but the precipitation was found to be incomplete.

Results of the Test Analyses

In Tables I, II and III are presented, the results of analytical experiments in which the above-described methods were used. The iridium solutions were measured by weighing them in a pipet designed for the

purpose. The thiosulfate used was 0.00623 N. The titanous chloride used was 0.00994 N for the experiments of Table I and 0.009285 *N* for those of Table III.

It is seen from the tables that the two volumetric methods yield concordant results, the maximum deviation from the mean being about 0.3%. Moreover, the amount of iridium in the salt $(NH_4)_2IrCl_6$ as determined volumetrically and gravimetrically is, within a few tenths of one per cent., the same as that calculated from the formula."

Summary

The results (given in Tables I–III) show that the new titanometric method of determining iridium gives results in agreement with those given by the earlier iodometric method, which was refined by using benzene to

---

[5] This tendency to form non-hydrated chloro salts is not found with some other platinum metals. The results of Howe [THIS JOURNAL, 49, 2381 (1927)] and of Crowell and Yost [*ibid.*, 50, 374 (1928)] emphasized this for the case of ruthenium, and at the same time clarified an important question in the chemistry of coordination compounds. Werner, "Neuere Anschaungen auf dem Gebiete der anorganischen Chemie," Vieweg und Sohn, Braunschweig, 1909, 2d. ed., p. 292.

detect the liberated iodine. Both these methods gave results in agreement with the gravimetrically determined amounts of iridium present in the solutions. They show, moreover, that the iridium content of crystalline ammonium hexachloroiridate as determined volumetrically and gravimetrically is the same, within a fraction of one per cent., as that calculated from the formula $(NH_4)_2IrCl_6$.

ACIDITY IN NON-AQUEOUS SOLVENTS. CONDUGTIMETRIC AND ELECTROMETRIC TITRATIONS OF ACIDS AND BASES IN BENZENE

BY VICTOR K. LA MER AND HAROLD C. DOWNES

RECEIVED NOVEMBER 14, 1930 PUBLISHED MARCH 6, 1931

I. Introduction

When we consider the remarkable successes which the theory of Arrhenius achieved in correlating such diverse properties of aqueous solutions as (a) conductivity, (b) osmotic properties, (c) acid and base catalysis, (d) hydrogen electrode potentials, and (e) indicator effects, it is quite natural that the degree of acidity should have been taken as synonymous with the concentration of hydrogen ions behaving osmotically as solute particles independent of the acid ionogen. In other words, it has been tacitly assumed that on passing from one solvent to another the purely thermodynamic properties like (b) and (d) will run parallel to properties like (a) and (c) which depend only indirectly upon thermodynamic relations. On this view the acidity of an acid dissolved in benzene should at best be very small, since its degree of dissociation as judged by conductivity is very minute.

The experimental work of Hantzsch,[1] of Brönsted,[2] and of Hall and Conant,[3] is primarily responsible for demonstrating that this assumed

---

parallelism between thermodynamic and non-thennodynamic properties does not hold. The lines of evidence which they have adduced in support of the view that the classical consideration of acids and bases must be modified if it is to apply to non-aqueous solvents and even certain properties of aqueous solutions as (2) below, are: (1) properly chosen indicators respond promptly to additions of acids and bases when dissolved in solvents like glacial acetic acid[3a,4] or benzene,[2e,1b] whereas the conductivity indicates extremely low ionization; (2) acid (or basic[2"]) catalysis is produced by undissociated acids[Zd] (or bases), the catalysis being dependent primarily upon the facility with which protons can be transferred from catalyst to substrate (or *vice versa);* **(3)** the degree of dissociation[2b,2c] as indicated by the conductance ratio in any given solvent depends not only upon the dielectric constant but also upon the extent of combination of the acid with the solvent acting as a base, yielding a highly dissociated electrolyte popularly called a salt.

As far as we are aware, the possibility of titrating acids and bases electrometrically in solvents like benzene whose role is that of an inert diluent has never been considered. It is obvious if an electrometric titration can be carried out that an important experimental method becomes available since electrometric titration presents in simplest form the essential features of the capacity and intensity factors of acidity.

II. Experimental

A. Conductimetric **Titrations.**—Walden and Gloy[5] have demonstrated that certain salts like the tetra isoamyl ammonium halides, perchlorates, thiocyanates and picrates, (R_4NX), are appreciably soluble (iodide about 0.1 *m* at 72°) in benzene and conduct the current. No corresponding work has been reported for acids and bases.

In order to explore to what extent salt formation may proceed in benzene, we determined the changes in conductivity produced on alternate additions of acids and bases. A very low resistance cell consisting of two platinum electrodes having an area of about 8 sq. cm. held rigidly about 2 mm. apart by glass supports contained the solutions studied. The resistance was measured by noting the deflections on a Leeds and Northrup galvanometer, type 2500, when the cell and galvanometer were placed in series with the 110-volt direct current line. By shunting a variable resistance across the galvanometer, the range of measurement can be greatly extended. Cady and Lichtenwalter,[6] using this method, noted that polarization effects of a few tenths of a volt were present. In our work all

readings were checked by reversing the direction of the current through the cell. We found that the deflections in either direction were sensibly identical and reproducible within the accuracy of the measurement.

In one typical run we employed 1.11 M trichloroacetic acid and 0.834 M diethylamine as the acid and base. The results are plotted in Fig. 1: the ordinates are in reciprocal ohms times 10^{11} and the abscissas in cc. of added base or acid calculated to molar values. The solid dots represent a repetition of the experiment and give a measure of the reproducibility. The arrows indicate the equivalence points where stoichiometrically equal quantities of acid and base were present. The conductivity appears to be unchanged on addition of trichloroacetic acid to benzene, at least up to 0.04 M. At that point diethylamine was added; the conductivity rose sharply, reaching a maximum and then decreasing to a value very little greater than that for benzene, when the equivalence point was reached. The equivalence point in the titration corresponds closely with a region of minimum conductivity.

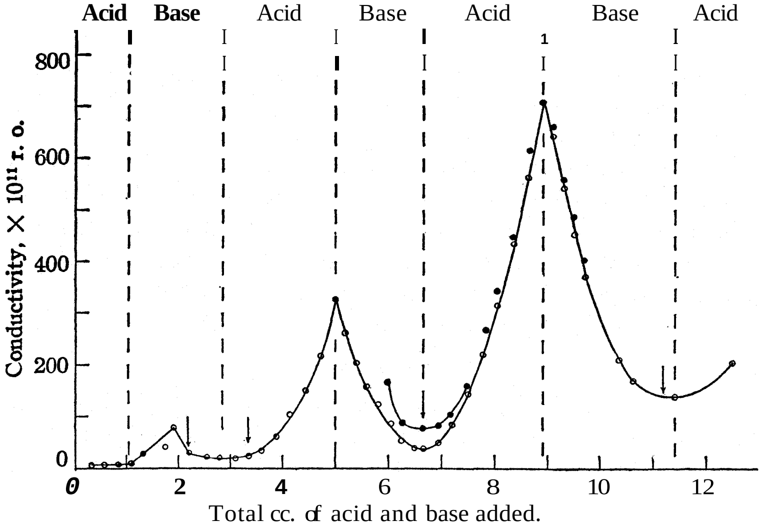

Fig. 1.—**Conductimetric titration** of diethylamine by trichloroacetic acid.

In another run (not shown) where diethylamine was first added to benzene, the conductivity remained sensibly constant (80 X 10^{-11} r. o.) up to about 0.05 M, when it rose sharply to a maximum at about 0.06 M, then decreased to a value which remained constant on addition of trichloroacetic acid until the equivalence point was passed. Further additions of acid then produced relatively rapid increases in conductivity, reaching a value of 1290 × 10^{-11} r. o. for a solution containing 0.220 M acid and 0.08 M base.

Paul Walden[7] states that *"the equivalent conductivity in benzene decreases with increasing dilution."* A plausible explanation for these curious anomalies has been presented by Gross and Halpern[8] in a paper which has received scant attention to date. Their argument may be stated as follows. The addition of an electrolyte like potassium nitrate increases the dissociation of a weak acid like acetic acid in water, by reducing the activity coefficients of the hydrogen and acetate ions by the now well-established mechanism of interionic attraction. In a low dielectric solvent like benzene the dissociation of acids is extremely minute but nevertheless exists, as demonstrated by our own conductivity measurements.

When the electrolyte concentration is increased either by adding excess acid or better by adding base leading to salt formation, the values of the activity coefficients of the dissociated ions of the acids are reduced more than the corresponding conductivity coefficients. Increased equivalent conductance should therefore result.

The Debye–Hückel limiting law predicts that the value $-\log f$ should increase at a rate $(78/2.29)^{3/2} = 200$ times greater in benzene than in water; *i. e.*, the logarithm of the stoichiometric equilibrium constant would be increased 200 times more in benzene than in water at the same ionic strength.

The complete solution of the Poisson–Boltzmann equation given by Gronwall, La Mer and Sandved[9] show, contrary to the case in water, that in a solvent of low dielectric constant the terms of higher order than the first are of sufficient magnitude in the case of uni-univalent salts to completely overwhelm and change the sign of the contribution for ion size yielded by the Debye first approximation since D appears in the denominator to progressively higher powers for each order of approximation.[10] The relative increase in equilibrium constant in benzene as compared to water must be very much greater than any prediction based on the limiting law alone. The general solution consequently strengthens the proposal advanced by Gross and Halpern.

B. Electrometric **Titrations.**—The cell consisted of a Jena glass

[10] Detailed computations by V. K. La Mer on the magnitudes of the contributions of the higher terms and their ability to account for the striking data of Kraus and Seward for the solubility of sodium chloride in isopropyl alcohol D = 16 and the data of A. L. Robinson for various salts in acetone D = 21.3 were presented at the Columbus (April, 1929) Meeting of the American Chemical Society (see V. K. La Mer, "Annual Survey of American Chemistry, 1928–1929," 1930, Vol. IV, p. 12). Bjerrum's hypothesis of ion association yields the same qualitative result but at the expense of an additional and unnecessary hypothesis. For more recent data on solubility in ethyl alcohol, see Seward and Schumb, THIS JOURNAL, 52, 3962 (1930).

crucible with a porous bottom of sintered glass rested in a small beaker. The electrodes were of platinum and placed close to both sides of the glass diaphragm. Even after saturating the benzene with tetra isoamyl ammonium iodide, the resistance of the cell is far too high for the sensitivity of the ordinary galvanometer. The method of discharging a condenser through a ballistic galvanometer as described by Beans and Walden[11] is admirably suited for the purpose. We have found that potential differences could be measured to ±0.1 mv. with a 10 microfarad condenser, using the apparatus as a null point instrument. This procedure does not require the complete charging of the condenser and is almost as rapid as the method using the type 2500 galvanometer. Thiophene-free benzene was employed without any special effort to dry it completely since exposure to air could not be eliminated with a cell of this construction.

A typical cell may be represented as

Pt	Trichloroacetic acid (0.165 m) diethylamine (0.0413 m) tetra isoamyl ammonium iodide (satd.) quinhydrone (a)	trichloroacetic acid (0.165 m) diethylamine (x) tetra isoamyl ammonium iodide (satd.) quinhydrone (a)	Pt

where x is initially 0.0413 M but is increased by addition of base in the course of the experiment; (a) is undetermined but constant. The cell was assembled by saturating a quantity of benzene with tetra isoamyl ammonium iodide, then adding quinhydrone. A measured amount of this solution was put into the beaker and the desired amount of acid–base mixture (2 to 1 ratio of acid to base) added to it. A known aliquot was then pipetted into the crucible compartment which served as the titration vessel.

The saturating salt was washed with ether and recrystallized from benzene. The acid and base solutions were made up in benzene, roughly 1.0 molar and standardized against aqueous sodium hydroxide and hydrochloric acid with continuous shaking until the indicator change occurred in the water layer. The titrating solutions in this experiment were trichloroacetic acid, 1.111 ± 0.002 molar and diethylamine, 0.834 ± 0.001 molar.

Unless the initial potential was zero to within 3 mv., the electrodes were cleaned and the cell reassembled. Diethylamine was then added (about 1.2 milliequivalents at a time) and the potential measured after each addition until a large increase in potential, followed by a relatively slow increase, was observed. In some cases additions of trichloroacetic acid were made to the solution containing excess base. The potential returned to a value approximating the initial one. When the solution was strongly basic the color changed rapidly from pale yellow to red which we attribute

---

[11] H. T. Beans and George Walden, THIS JOURNAL, 50, 2673 (1928); George Walden, Dissertation, Columbia University, 1924,

to reaction with the quinhydrone. It was for this reason that we made up the standard solution by adding a 2 to 1 mixture of trichloroacetic acid and diethylamine rather than adding the pure components. A small amount of iodine dissolved in benzene gave a strong test for iodine with starch, but since the red solution gave no test with starch we could not attribute the color to iodine formed by reaction of the quinhydrone with the iodide. In strongly acid solution the same color change was observed, although it did not proceed as rapidly.

The reaction may be formulated[12] as follows

$$\mathrm{HA} + \mathrm{R_2NH} \rightleftharpoons \mathrm{R_2NH_2^+} + \mathrm{A^-} \tag{1}$$

where HA is trichloroacetic acid and R_2NH is diethylamine. For the quinhydrone electrode where $C_{\text{quinone}} = C_{\text{hydroquinone}}$

$$E = E_0' + RT/NF \ln a_{\mathrm{H^+}} \tag{2}$$

The activity coefficients of quinone and hydroquinone are assumed to be constant during the titration and included in E_0'. The presence of the tetra isoamyl ammonium iodide instead of complicating actually simplifies the theoretical interpretation of the cell since its presence stabilizes the activity coefficients during the progress of the titration by maintaining a more nearly constant environment, and by eliminating junction potential Abundant proof[13] now exists that the addition of an excess of a foreign neutral salt is the simplest way of eliminating these difficulties in aqueous solution, and the same principle should obtain in benzene. Owing to the much greater interionic effects in benzene it is important to reduce these disturbances as far as possible.

When trichloroacetic acid is in excess, the hydrogen-ion activity is most conveniently formulated in terms of its dissociation, hence[14]

$$a_{\mathrm{H^+}} = Ka_{\mathrm{HA}}/a_{\mathrm{A^-}} \tag{3}$$

or

$$E = E_0 + RT/NF \ln a_{\mathrm{HA}}/a_{\mathrm{A^-}} \tag{4}$$

where

$$E_0 = E_0' + RT/NF \ln K \tag{5}$$

Since we have no means of determining the absolute value of E_0' we have arbitrarily taken the potential of the reference electrode (2 trichloroacetic acid : 1 diethylamine) as zero, and plot only the differences in electromotive force as the titration proceeds. The further addition of base (diethylamine) by definition reduces the escaping tendency of protons (hydrogen

---

[12] Although the product is written in ionic form, the number of free ions in benzene solution is extremely small owing to the low dielectric constant.

[12] La Mer and Sandved, THIS JOURNAL, **50**, 2656 *(1928)*. References to earlier work are given on page 2658.

[14] Regarding formulation see W. Mansfield Clark, "Determination of Hydrogen Ions," Williams and Wilkins Co., Baltimore, Maryland, Chap. XXVII, particularly p. 529. Also Brönsted, Ref. 2 g, pp. *238*, 289.

electrode potential) by the process represented by (1). As Fig. **2** shows, the proton potential curve on changing the relative amounts of acids and bases shows a close analogy to the neutralization curves of these acids and bases as ordinarily formulated for aqueous solution. When an amount of diethylamine greater than the stoichiometric equivalent, which is represented by the upturned arrow in Figs. **2** and **3**, has been added, we pass to a new level of acidity which is determined by the ratio of $R_2NH_2^+$ to R_2NH°. The potential is then given by

$$E = E_0'' + RT/NF \ln (R_2NH_2^+)/(R_2NH^\circ)$$

The most convenient means of characterizing the relative acidities (proton escaping tendencies) of the two conjugated systems (HAc°/Ac^-) and $(R_2NH_2^+)/(R_2NH^\circ)$ are by the values of E_0' and E_0'', respectively, which are equal to the respective values of E when the ratio is unity or the systems are at the half neutralization points. Our data are hardly sufficiently accurate or extensive to test the shape of the curves by plotting E against log $(R_2NH_2^+)/(R_2NH^\circ)$ or log (HA°/A^-), but there can be little doubt but that the proton potential of the system diethyl ammonium $\rightleftarrows$ diethylamine is 0.40 volt less than for the system trichloroacetic acid $\rightleftarrows$ trichloroacetate.

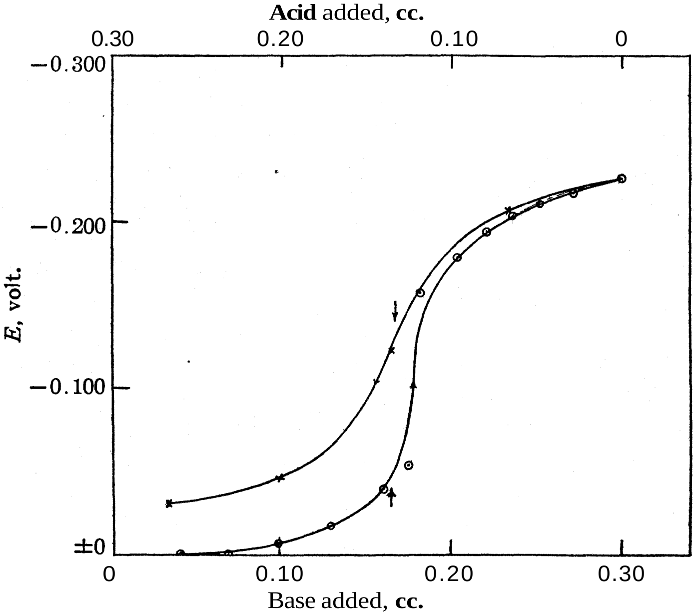

Fig. 2.—Electrometric titration of diethylamine–trichloroacetic acid.

As a test upon the reversibility of the process we added trichloroacetic acid to the solution containing excess base, as shown by the upper curve in

Fig. 1. The curve for this back titration does not correspond exactly to the forward curve. This may be due to possible diffusion through the porous glass membrane or to changing environmental effects during the titration. More work must be undertaken before this point can be regarded as settled. The fact that the equivalence point (downward arrow of Fig. 2) coincides as closely as it does with the point of inflection is strong evidence that acid–base relations in benzene are quite analogous to those in water as far as potential is concerned.

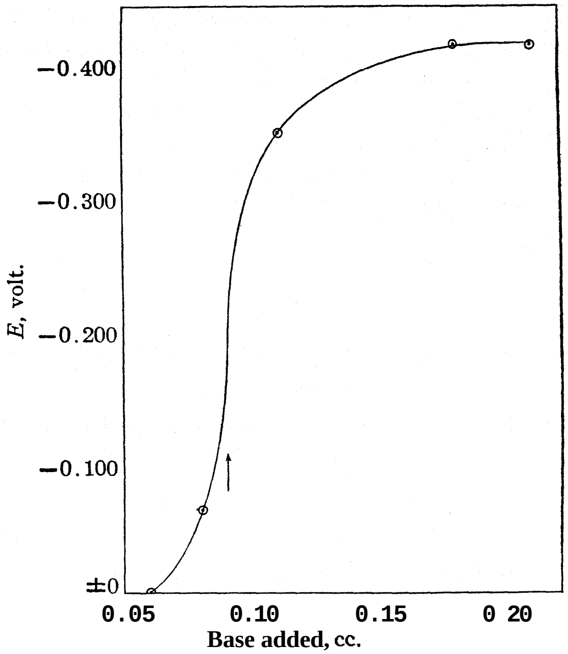

Fig. 3.—Titration of 3 cc. of (0.0266 *M*) trichloroacetic acid in benzene by diethylamine (1 M) in benzene. Equivalent point, 0.08 cc.

The question arises, would these curves be obtained in absolutely dry benzene?" The saturation value for water in benzene is given as 0.57 part per thousand at 20°. It hardly seems likely that the still smaller amount of water in equilibrium with the atmosphere could be entirely responsible for the conductivity and electrometric titration curves. However, we must point out that although indicator changes are immediate and reproducible in moist benzene, one of us (V. K. L.) has observed that this does not always hold true when benzene is dried over sodium. We prefer to leave open the question of the effect of traces of water until a more refined technique has been developed.

We wish to thank Dr. George Walden for placing his electrical instruments at our disposal.

III. Summary and Conclusions

1. An electrometric method is described for titrating acids and bases in benzene using quinhydrone electrodes.

2. The curve obtained when trichloroacetic acid is titrated electrometrically with diethylamine has the same characteristics that are observed in aqueous solution on titrating a strong acid with a strong base.

3. The difference in hydrogen electrode potential (proton escaping tendency) between the trichloroacetic acid system and the diethylammonium acid system is of the order of 400 millivolts.

4. Conductivity titrations of acids and bases in benzene exhibit the anomalous behavior similar to that reported by Paul Walden for salts in benzene. The equivalence points correspond to minima regions in the conductance titration curves.

REACTIONS INVOLVING HYDROGEN PEROXIDE, IODINE AND IODATE ION.

III. THE REDUCTION OF IODATE ION BY HYDROGEN PEROXIDE[1]

By Herman A. Liebhafsky

Received November 29, 1930 Published March 6, 1931

The equations and the free energy data[2] for the reactions

$$2IO_3^- + 2H^+ + 5H_2O_2\,(aq) = I_2(s) + 6H_2O + 5O_2;\ \Delta F^\circ - 118.850\ \text{cal.} \qquad (1)$$
$$I_2(s) + 5H_2O_2(aq) = 2IO_3^- + 2H^+ + 4H_2O;\ AF^\circ = -132{,}050\ \text{cal.} \qquad (2)$$

make it evident that the I_2–IO_3^- couple is capable of catalytically decomposing hydrogen peroxide. The present investigation was begun with an extensive series of experiments on the iodine–iodate catalysis, but the results obtained proved to be so complex that no definite conclusions concerning the mechanism of the catalysis could be drawn from them alone. These data showed, however, that the catalysis was the result of several compensating reactions, of which two--the oxidation of iodine by hydrogen peroxide and the reduction of iodate ion by that same substance—gave hope of being suitable for separate study. In the second paper of this series there have been presented some experimental results on the former

---

reaction (Equation 2). To determine, in so far as is possible by chemical and kinetic methods, the character of the steps underlying the reduction of iodate ion by hydrogen peroxide (Equation 1) is the purpose of this paper.

A reaction system corresponding entirely to the "pure" reduction of iodate ion according to Equation 1 has never been experimentally realized. When peroxide and iodate are mixed in acid solution, the initial formation of a small amount of iodine is followed by the establishment of a "steady state" in which the main reaction is the catalytic decomposition of hydrogen peroxide (cf. Part I). The amount of such catalysis is a complicated function of the concentration of iodine in the system; it seemed almost certain, that by maintaining this iodine concentration as low as possible, the rates of the reactions resulting in catalysis could be reduced. The minimizing of the amount of this catalysis is the first requirement which any experimental method for the study of the reduction of iodate ion must fulfil.

An effective means for meeting this requirement is provided by placing the reaction mixture in contact with carbon tetrachloride and shaking the whole at a rate sufficient to insure rapid extraction of the iodine. Part of the carbon tetrachloride can be withdrawn and replaced immediately by an equal volume of fresh solvent at convenient time intervals; the rate of formation of iodine may be followed by titrating the samples withdrawn. That dI_2/dt thus determined can measure accurately the rate of reduction of iodate ion by hydrogen peroxide will be shown in a later section. Since small amounts of iodine can be determined with relatively high accuracy, and since the reaction is not extremely rapid at the temperatures employed, an accurate value of dI_2/dt can be obtained before the concentration of any of the reacting substances has changed enough to affect this rate beyond the experimental error. The order of the reaction with respect to any substance may be obtained, therefore, from a series of measurements in which only the concentration of that substance is varied.

Experimental Part

C. P. reagents not further purified were used. Permanganate solution standardized against sodium oxalate served for the analysis of peroxide solution, and for the standardization of the thiosulfate solution used in all iodimetric work. The potassium iodate solution was analyzed iodimetrically. Perchloric acid standardized against sodium carbonate was used as the source of hydrogen ion.

Two-hundred cc. glass flasks with conical bottoms were used as reaction vessels; to the acid iodate solution in these flasks 25 cc. of carbon tetrachloride was added, and the whole shaken in an oil thermostat in a dark room at the rate of 120–130 double shakings a minute The hydrogen peroxide was added from a reservoir in the thermostat with a pipet after the attainment of temperature equilibrium; the initial time was taken as that at which the pipet was half emptied; 20-cc samples of the carbon tetrachloride in the reaction mixture were withdrawn as follows The shaker was stopped at a time taken as the time of the sample. After a twenty-second interval,[3] allowed to insure a complete separation of the two layers, the sample was pipetted into a glass-stoppered flask containing water which served both to wash the carbon tetrachloride and to prevent its loss by volatilization. After two further washings in a separatory funnel, the carbon tetrachloride containing the iodine was transferred into a flask containing weakly acid potassium iodide solution, and then titrated with thiosulfate solution of convenient concentration; the most dilute solution of sodium thiosulfate practicable was found to be 0.002 N. For purposes of calculation, all results were expressed in terms of 0.1 N sodium thiosulfate. Experiments in dilute solutions depended upon the titration of amounts of iodine equivalent sometimes to 0.01–0.02 cc. of 0.1 *N* thiosulfate. These titrations were carried out according to a method previously outlined.[4]

Measurements of dO_2/dt were carried out in the usual manner with the aid of gas burets; the time intervals for the readings were so chosen that the presence of the carbon tetrachloride had no disturbing effect due either to the establishment of the equilibrium vapor pressure of carbon tetrachloride, or to the saturation of the carbon tetrachloride with oxygen. The same dO_2/dt was obtained initially from experiments of the same composition when the one reaction mixture was in contact with carbon tetrachloride while the other was not. Since such agreement was obtained repeatedly without considering the vapor pressure of carbon tetrachloride in calculating the volume of oxygen evolved in the first case, all later results were calculated in this way. Accurate measurements of the gas evolution could not be obtained for the experiments in very dilute solutions.

The above experimental method of determining dI_2/dt is subject to several possible inaccuracies; among the most obvious are loss of carbon tetrachloride by vaporization, irregularities in the transfer of iodine from the aqueous to the carbon tetrachloride layers, excessive heat losses due to the vaporization of carbon tetrachloride and of water, inaccuracies incident to the extremely rapid use of pipets, losses of iodine during washings, and iodate contamination in the iodine titrations. The loss of carbon tetrachloride by vaporization was shown to be negligible at 50°, small at 60° and so large at 70° that the temperature of a reaction mixture containing carbon tetrachloride and immersed in a thermostat at 70° could not be maintained above 68°. Accurate experiments at 70° were therefore impossible. Irregularities, for which no better reason could be given than that they were due to corresponding irregularities in the transfer of iodine from the aqueous to the carbon tetrachloride layer, sometimes appeared in the values of dI_2/dt obtained in the course of a run; the value of the over-all average dI_2/dt for such a run was almost always satisfactory, so that these fluctuations could be neglected. Pipet inaccuracies cancel out almost entirely if several samples are taken in the course of an experiment. Iodine losses by contact with aqueous layers, bath during reaction and in the subsequent washing, were approximately compensated by an addition of 3% to the volume of thiosulfate solution used. Iodate contaminations

---

[3] In experiments requiring a sample to be taken every minute, this interval was shortened to five seconds.

[4] Liebhafsky, THIS JOURNAL, 53, 165 (1931).

were practically eliminated by three careful washings. No correction was made for concentration variations occurring during a run. The induction period[6] was never included in the time interval over which the over-all rate for an experiment was calculated.

The detailed data for a regular experiment (No. **023)** and for an irregular experiment (No. 09) are given in Table I.

TABLE I

THE CALCULATION OF RATE CONSTANTS FROM EXPERIMENTAL OBSERVATIONS

Experiment 023 Table III. Concentrations: $(H^+) = 0.0357$; $(IO_3^-) = 0.1001$; $(H_2O_2) = 0.0228$

Time, min.	0.1 *N* $Na_2S_2O_3$, *cc.*	*Cc.* of 0.1 *N* $Na_2S_2O_3$/min
1	0.0123	0.0154
2.5	.0045	.0017
6	.0067	.0020
10	.0080	.0020
28	.0416	.0028
61	.0626	.0020

Over-all average: $$\frac{0.0067 + 0.0080 + 0.0416 + 0.0626 + \frac{0.0626 - 0.0045}{4}}{58.5}$$

$= 0.1334/58.5 = 0.00228$ cc. of 0.1 N $Na_2S_2O_3$/min.

$dI_2/dt = 5(10^{-5}) \times 2.28(10^{-3}) = 1.14(10^{-7})$ moles of I_2/min.

Experiment 09, Table IV. Concentrations: $(H^+) = 0.1438$; $(IO_3^-) = 0.1001$; $(H_2O_2) = 0.746$

Time, min.	0.1 *N* $Na_2S_2O_3$, *cc.*	*Cc.* of 0.1 N $Na_2S_2O_3$/min.
0–0.75	0.15	0.27
0.75–4	.36	.13
4–7	.58	.21
7–10	.84	.30
10–14	.98	.26

Over-all average: $2.97/13.25 = 0.224$ cc. of 0 1 *N* $Na_2S_2O_3$/min.

$dI_2/dt = 11.2(10^{-6})$ moles I_2/min.

In this table and throughout this paper all concentrations will be given in moles/liter at room temperature, and will be indicated by ( ). All rates will be given in moles/min. for a 150-cc. reaction mixture. The temperature of all experiments was 50°, unless otherwise noted. The calculations of the rates for the first two intervals in Experiment 023 were made in the following manner

$$0\text{–}1 \text{ min. } \frac{0.0123 + \frac{0.0123}{4}}{1} = 0.0154; \quad \frac{0.0045 + \frac{0.0045 - 0.0123}{4}}{1.5} = 0.0017$$

---

[6] The initial deficiency of iodine during the induction period will be discussed later. In several experiments at very low (H_2O_2), such as Experiment 023, Table I, formation of a relatively large amount of iodine was observed shortly after mixing the reagents; since this abnormality was variable and unreproducible, it was also disregarded in computing the over-all average.

The factor $\frac{1}{4}$ which appears in the numerator is necessary because 5 cc. of carbon tetrachloride always remained in the reaction vessel when 20 cc. was withdrawn for analysis of the iodine content.

Calculation of the Rate Constants. —Experiments, of the kind just outlined, were carried out to determine the order of the reaction with respect to (H^+), (IO_3^-) and (H_2O_2). Since two of these three concentrations were kept constant in each of the three series, it is possible to obtain three average values of the specific reaction rate by plotting the experiments of each of the three series. The constant concentrations used were (with a few exceptions): $(H^+) = 0.0357$, $(IO_3^-) = 0.1001$, $(H_2O_2) = 0.514$. The data are summarized in Tables II, III and IV; the concentrations and the corresponding values of dI_2/dt are given in the first portions of the tables. The other data will be discussed later.

TABLE II (SEE FIGURE 1)

021	2.498	15.6	32.4	13.7	8.8

In Fig. 1, dI_2/dt of Tables II and III is plotted logarithmically against (IO_3^-), and against (H_2O_2): the logarithmic plot is used in order that the entire concentration range may be included in a plot of convenient size, and in order that the fundamental nature of relative, rather than absolute, changes in the concentrations of reacting substances may be emphasized. The radius of the circles used is equivalent to a 5% change in log dI_2/dt, the approximate magnitude of the average experimental error. The upper limit of the IO_3^- concentration range is fixed by the solubility limit of potassium iodate. The two straight lines show that the reduction of iodate ion is accurately first order with respect to (IO_3^-) over a 120-fold concentration range, and with respect to (H_2O_2) over a 1200-fold concentration range. In a plot of this kind, a set of experimental results must meet two requirements in order that the reaction involved may be first order with respect to the reactant considered: (1) the points must lie on a straight line; (2) the line must have a slope of 45°.[6] The lines in Fig. 1 meet both requirements.

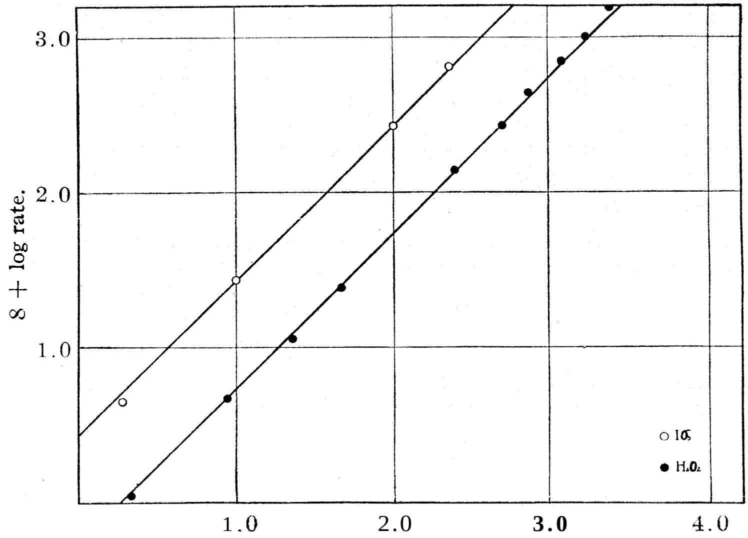

Fig. 1.—Variations of log dI_2/dt with log (IO_3^-) and with log (H_2O_2) (see Tables II and III).

In Fig. 2, dI_2/dt from Table IV for the various temperatures employed is plotted directly against (H^+). The radius of the circles now corresponds to a 5% error, only at (H^+) = 0.05 for the 50° experiments. Given the results from Fig. 1, it is evident that at the constant values of (H_2O_2) and (IO_3^-) employed, dI_2/dt obeys the following rate law at all hydrogen-ion concentrations below 0.14 N

$$dI_2/dt = k_1\,(H_2O_2)\,(IO_3^-) + k_2\,(H^+)\,(H_2O_2)\,(IO_3^-) \qquad (3)$$

The value of k_1 is obtained by dividing the intercept by $(H_2O_2)(IO_3^-) = 0.0514$; the result at 50° is $k_1 = 1.00(10^{-6})/0.0514 = 19.4(10^{-6})$. Simi-

---

[6] The logarithmic method employed in this paper is useful in determining the order of a reaction with respect to any reactant so long as the concentrations of all other substances are (sensibly) constant; the slope of the line in such a plot is numerically equal to the quantity sought.

TABLE IV (SEE FIGURE 2)

VARIATION OF RATE WITH CHANGES IN (H^+) AT DIFFERENT TEMPERATURES

(a) At 50°

Expt.	(H^+)	(IO_3^-)	(H_2O_2)	$\frac{dI_2}{dt}$ (10^6) Meas.	calcd.	"Defect" moles I_2 (10^6)	$\frac{dO_2}{dt}$ (10^5)	Ratio $\frac{dO_2}{dt} / \frac{dI_2}{dt}$	% Yield of I^-
053	Initially neutral	0.1001	0.514	1.18		..	..	..	22
05	0.00716	.1001	.514	1.33		6.5	1.25	9.4	
011	.0214	.1001	.514	2.02		7.0	1.39	6.9	
012	.0357	.1001	.514	2.73		10.8	2.01	7.4	
013	.0439	.1001	.514	3.03		11.9	2.05	6.7	
014	.0572	.1001	.514	3.42		12.4	2.48	7.3	
04	.0715	.1001	.514	4.43		10.8	3.14	7.1	
016	.0929	.1001	.514	4.88		15.1	3.81	7.8	
08	.1072	.1001	.514	6.74		..	4.20	6.2	
015	.1438	.1001	.514	5.52	8.14	..	10.5	19	
06	.7144	.1001	.514	.465	36.4	..	41.4	890

010	.3564	.1001	2.498	33.1	90.9	..	375	113	
028	.2134	.2406	.746	8.77	40.4	..	..	..	

[a] Since the rate is proportional to (H_2O_2), $dI_2/dt = 11.2\ (10^{-6})$ at $(H_2O_2) = 0.746$ corresponds to $dI_2/dt = 7.74\ (10^{-6})$ at $(H_2O_2) = 0.514$; this is the value plotted in Fig. 2.

(b) At 60°: $(IO_3^-) = 0.1001$; $(H_2O_2) = 0.514$

Expt.	(H^+)	$\frac{dI_2}{dt}$ (10^6)	% Yield of I^-
049	Initially neutral	4.22	38
051	0.0214	6.93	
052	.0357	9.47	
050	.0715	14.7	
	(c) At 40°: $(IO_3^-) = 0.1001$; $(H_2O_2) = 0.514$		
056	Initially neutral	0.298	8 8
055	0.0214	.613	
054	.0357	.793	
039	.0715	1.32	
	(d) At 30°: $(IO_3^-) = 0.1001$; $(H_2O_2) = 0.514$		
058	Initially neutral	0.064	8.5
041	0.0357	.200	
057	.0572	.264	

larly the value of k_2 is obtained by dividing the slope of the line by (H_2O_2) (IO_3^-); at 50°, $k_2 = 48.7(10^{-6})/0.0514 = 947(10^{-6})$.

Values of k_2 can be computed from Fig. 1 only if k_1 is known; the calculation for the series in which (H_2O_2) varies will be given. Equation 3 after transposing and after substituting the numerical values of $k_1(IO_3^-)$ and (H^+) becomes: $(dI_2/dt)/(H_2O_2) = [19.4(10^{-6}) + k_2(0.0357)1.1001.$ For any point on the lower line in Fig. 1, the difference between ordinate and abscissa is simply $(\log dI_2/dt) - \log (H_2O_2) = \log (dI_2/dt)/(H_2O_2)$;

its numerical value is 0.743–6. The antilogarithm of this number, 48.7-(10^{-6}), is the ratio $(dI_2/dt)/(H_2O_2)$. Solving the above equation for k_2, we obtain $k_2 = 1005(10^{-6})$.

From the (IO_3^-) plot $(dI_2/dt)/(IO_3^-) = 27.3(10^{-6})$, whence the value $k_2 = 934(10^{-6})$ is calculated.

Since the values of k_2 are in substantial agreement, $k_2 = 965(10^{-6})$ may be taken as a reliable mean, and the value $k_1 = 19.4(10^{-6})$ may be regarded as satisfactory; k_1, however, is less accurate than k_2.

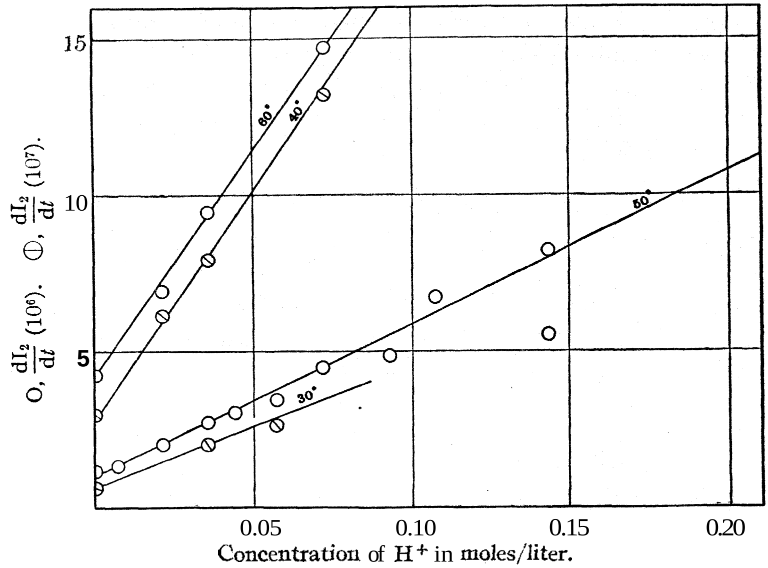

Fig. 2.—Variation of rate with (H^+) (see Table IV).

These constants must finally be multiplied by 2 to change from dI_2/dt to $-dIO_3^-/dt$, and by $6^2/_3$ to change from moles/min./150 cc. to moles/-min./liter. Equation 3 now becomes

$$-d(IO_3)^-/dt = 2.6\,(10^{-4})\,(H_2O_2)\,(IO_3^-) + 129\,(10^{-4})\,(H^+)\,(IO_3^-)\,(H_2O_2) \quad (4)$$

$-d(IO_3)^-/dt$ thus calculated is probably accurate to *5%.

Mechanism of the Reaction.—Equation 3 shows that the first step in the reduction of iodate may occur in the following ways

$$IO_3^- + H_2O_2 \longrightarrow IO_2^- + H_2O + O_2 \quad (5)$$

$$IO_3^- + H_2O_2 + H^+ \longrightarrow HIO_2 + H_2O + O_2 \quad (6)$$

The formation of IO_2^- and HIO_2 as intermediate products resulting from two simultaneous reactions appears to be the only simple explanation of the empirically determined rate law. This mechanism is not intended to exclude the possibility of the formation of intermediate complexes, such as $H_2O_2{\cdot}IO_3^-$ in Equation 5; there is thus no contradiction between this formulation and that of Bronsted for similar reactions.

The relatively rapid follow reactions cannot be postulated with certainty. As guides in selecting them we have the following. (1) Characteristic of iodine chemistry is the relatively rapid establishment of the equilibrium

$$I_2 4 H_2O \rightleftharpoons I^- + H^+ + HIO \qquad (7)$$

(2) Reactions involving the oxidation of hydrogen peroxide are generally first order with respect to that substance. **(3)** The oxidations of hydrogen peroxide by the hypo-halites and their acids are known to be rapid reaction~. (4)~The end-product of the reduction of iodate ion is iodine in acid, iodine and iodide ion in neutral, and iodide alone in basic solution.[7] (5) The reduction of iodous acid by hydrogen peroxide, if it occurs at all, is not very rapid.[8] Reaction between HIO_2 and I^- is very probable.

The reactions in acid solution following those in Equations 5 and 6 may therefore be the following

Formation of HIO_2	$H^+ + IO_2^- = HIO_2$	(8)
Second step in the reduction	$HIO_2 + H^+ + I^- = 2HI0$	(9)
Third step in the reduction	$HI0 + H_2O_2 = I- + H^+ + H_2O + O_2$	(10)
Formation of iodine	$HIO + I- + H^+ = H_2O + I_2$	(11)

Equation 1 is the sum of 6 (or 5 and 8) counted twice, 9 counted twice, 10 counted three times and 11. If the iodine concentration is permitted to build up in the hydrolysis equilibrium, the concentration of intermediate products increases, and the catalytic decomposition of hydrogen peroxide, which depends on the intermediate products such as I–, also increases.

The relative rates of the above reactions as individuals cannot be established. **A** comparison of their velocity as a group with the velocity of the first step is possible if the combined concentration of all iodine compounds intermediate between iodate and iodine is known; for, in a series of consecutive reactions which has reached a steady state, the concentration of an intermediate product is inversely proportional to the specific rate constant for the step in which this intermediate product is consumed.

---

[7] The percentages of iodine obtained as I^- in the various experiments in neutral solution are given in Table IV. **An** experiment in which the initial (H^+) was **3** (10^{-12}) yielded only I–; quantitative work here was futile because of the large loss of hydrogen peroxide due to catalysis decomposition. Since, however, the reaction mixtures initially neutral were distinctly basic at the end of the run, their agreement with the rate law may be taken as an indication that this rate law is valid in moderately basic solution.

While the percentages of I^- at the different temperatures cannot be correlated because (H^+), (I_2) and (HIO) were not always the same, it may be pointed out that larger percentages of I^- at the higher temperatures are to be expected if the hydrolysis equilibrium, Equation **7,** is realized, from the sign of A H for this reaction.

[8] The reduction of iodous acid by hydrogen peroxide and by I^- has been discussed in Part I; it was there concluded that in moderately acid solution the former must be negligible. While this is probably true also for solutions of low acid concentration, there is always the possibility that hydrogen peroxide may begin to reduce either HIO_2 or IO_2^- as the acid concentration is further decreased.

The Induction Period.—At the beginning of every experiment there exists a time interval during which the rate of formation of iodine differs from that given by Equation 3; this time interval is presumably necessary to establish the concentrations of intermediate products required for the reduction of iodate ion. The length of this induction period in acid solution[9] is roughly independent of the concentrations of hydrogen and iodate ions, and inversely proportional to the concentration of hydrogen peroxide; in many experiments it approximates seven minutes. Ordinarily dI_2/dt begins with a small initial value and gradually increases until the expected rate is reached.

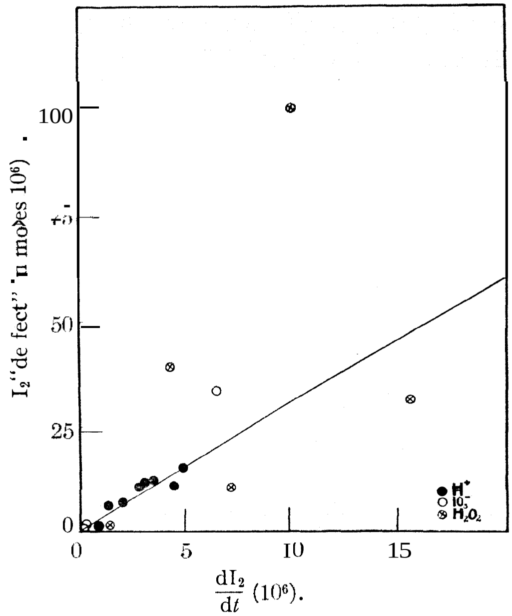

Fig. 3.—Variation of intermediate products with rate.

This induction period furnishes a means for calculating the maximum amount of iodine stored up as intermediate products in the course of any experiment. If the mechanism of the first step in the reduction of iodate is the simple one advanced above, then the rate of this first step is presumably always that calculated from Equation 3; the reduction of iodate ion according to this equation begins as soon as peroxide and iodate are mixed. If this simple picture is correct, the amount of intermediate products—the iodine "defect"—should be the difference between the average dI_2/dt for the experiment, multiplied by the time in minutes of the entire experiment, and the total amount of iodine actually obtained. The "defect" thus calculated is given in Tables II, III and IV, and is plotted against the rate in Fig. 3. Since the values of these "defects" depend upon the determination of very small amounts of iodine, the accuracy obtained is not very great. The legend shows, for any experiment, that substance the variation of whose concentration was principally responsible for the change in rate.

The calculations show, first of all, that the approximate percentage of

---

[9] In neutral solution the induction period lengthened with decreasing iodate The formation here of amounts of I^- very large as compared with the amounts formed in acid solution is the explanation.

iodate stored up as intermediate products is 0.1%; the great speed of the follow reactions as compared to that of the first step in the reduction is thus established. The graph shows further that at low rates, the "defect" is proportional to the rate when (H^+) and (IO_3^-) are varied; the relationship expressed by the straight line is "defect" = 3 × rate. For variations in (H_2O_2) no such definite statement can be made; it may be concluded, however, that the "defect" is not independent of (H_2O_2) variations. The proportional increase of the concentration of intermediate products with the rate is to be expected as the result of any concentration change which increases the rate of the first step in the reduction of iodate without directly affecting the rate of the following reactions. The necessary increase of the absolute rate of the latter must then be brought about by an increase in the concentration of those intermediate products concerned. That the same proportionality which exists for (H^+) and (IO_3^-) does not exist[10] for (H_2O_2) justifies the selection of a reaction between HIO_2 and I^- as the second step in the reduction (Equation 9). If each step in the reduction involved one molecule of hydrogen peroxide, the "defect" should be unaltered when (H_2O_2) is changed.

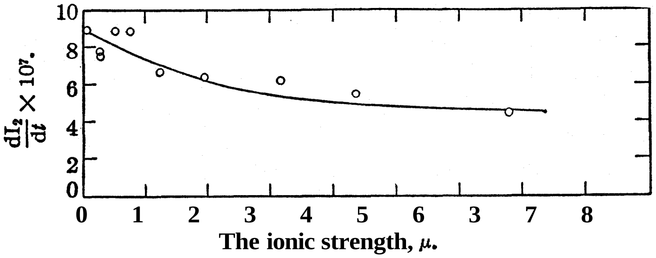

Fig. 4.—The salt effect.

The **Salt** Effect.—In Fig. 4 the result of a series of experiments on the salt effect at 60° is given. The experiments were carried out at (H^+) = (IO_3^-) = 0.038 M and (H_2O_2) = 0.115 M; changes in the ionic strength, μ, were produced by adding sodium nitrate.

We do not wish here to discuss the application of any "activity" theory of reaction rate. That there is a relatively small salt effect which disappears at higher μ is quite apparent; it is apparent further that no simple function of the activity coefficients involved is likely to yield a curve like that in Fig. 4. We must bear in mind, also, that this curve represents two salt effects, superimposed one upon the other, because the reaction has two rate-determining steps. One of these, the one involving only H_2O_2 and IO_3, should have a "linear' salt effect, but for the other the effect should be[11]

---

[10] Experiment 012 serves as a point for all three cases.

[11] See Brönsted "The Velocity of Ionic Reactions," Contemporary Developments in Chemistry, Columbia University Press, 1927.

"exponential." The matter is complicated further by the change in solvent which occurs as the higher ionic strengths are reached, and by uncertainty of the value of activity coefficients under the experimental conditions. As evidence in dilute solution, where the activity rate applications have been most successful, the line in Fig. 1 representing (IO_3^-) variations might be used. There is a change in from **0.038** to **0.267** because of the change in (IO_3^-); but, as the graph shows, there is no salt effect greater than the experimental error.

Variation of Rate Constants with Temperature.—The effect on the rate constants of temperature variation in the interval from **30** to 60° is shown in Fig. **5**; the line of greater slope represents the value of k_1 as determined from the values of the intercepts in Fig. 2; the other line represents the values of k_2 as calculated from the slopes in that figure. From Fig. 5

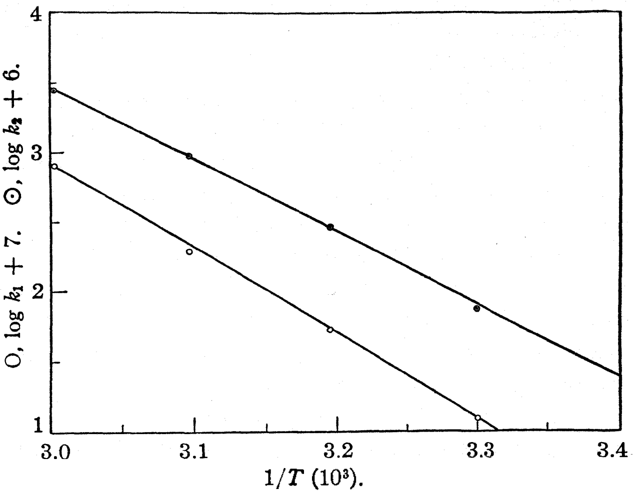

Fig. 5.—Variation of rate constants with temperature.

$$\frac{d \log k_1}{d\,(1/T)} = -6.07(10^3);\quad \frac{d \log k_2}{d\,(1/T)} = -5.20(10^3)$$

the corresponding values of the heats of activation are $Q_1 = 27{,}500 \pm 1500$ calories, and $Q_2 = 23{,}500 \pm 500$ calories. These values have been obtained by subtracting $RT/2$ calories (*ca.* 300 cal.) from the value calculated directly from the temperature coefficients, to correct for the variation of the root mean square velocity of the molecules with temperature. The estimated errors are the differences between the mean value of Q given above and the heats calculated from the lines of greatest and least slopes consonant with each set of experimental results in Fig. 5. **Using** the value of k_1 at 50° and the value of Q_1, the average of the diameters of H_2O_2 and IO_3^- may be calculated by the application of an **equation given** by Tolman;[12] for a heat of activation within the limits given above for Q, the value of the molecular diameter lies between $1(10^{-7})$ and $1(10^{-6})$ cm.

This average diameter is considerably larger than the values, 10^{-8} in order of magnitude, obtained from x-ray measurements; although a hydrated molecule in aqueous solution is probably larger than an ion in a crystal, the above result is larger than we should expect even for such a hydrated molecule. The simplified calculation we have made is, however, only very approximate. The number of moles colliding has been calculated for a gaseous system; if this number is greater for an equally concentrated aqueous solution of the reactants, then a smaller average diameter would be obtained. If, on the other hand, all collisions between molecules whose combined energies equal or exceed the minimum energy required for reaction are not effective, and an "orientation factor" must be introduced, the calculation would lead to an even larger molecular diameter. However, these difficulties will not vitiate the comparison to be made below, since the reactions to be compared are part of the same reaction system.

Using $5(10^{-7})$ as the average diameter, the rate may be calculated at which a bimolecular reaction involving IO_3^- and H_2O_2 with a heat of activation equal to Q_2 should proceed. **A** comparison of the rate thus calculated with that observed for Reaction 6 shows that the former rate is only about ten times the latter. This reaction, therefore, is too rapid to be the result of ordinary triple collisions;[13] it can be regarded simply as a bimolecular reaction in which the substance reacting with H_2O_2 is a complex, $H^+ \cdot IO_3^-$,[14] resulting from loose coupling, perhaps of an electrostatic nature, between the ions. Thus HIO_3, although completely dissociated in a thermodynamic sense, might act as a unit in chemical reactions involving both H^+ and IO_3^-.

The fact that the values of Q_1 and Q_2 are so nearly equal indicates that the activation processes in the two reactions are closely related. The dif-

---

[12] Tolman, "Statistical Mechanics, Etc.," Chemical Catalog Co., 1927, p. 242, Equation 543; no. of mols. colliding/cc./sec. $= 10^{28.4427}\sigma^2 C_1 C_2 \sqrt{T\frac{M_1 + M_2}{M_1 M_2}}$; C_1 and C_2 are concentrations in moles/cc.; σ is the average diameter of the colliding molecules, T the absolute temperature and M_1 and M_2 are the ordinary molecular weights. This total number of moles colliding multiplied by the factor $e^{-Q/RT}$ which is the probability that any collision will have the minimum energy required for reaction, is equated to the experimentally measured rate; the equation is then solved for the value of σ.

[13] Since orientation is assumed to be of relatively greater importance in a triple collision, the introduction of orientation factors into the calculations would strengthen this conclusion.

[14] Another possibility would be complex formation of the type $H_2O_2 \cdot H^+$; this oxonium compound, however, can be present only at very low concentrations, since preliminary transference and freezing point experiments failed to show any evidence for its existence.

ference in the heats of activation, however, exceeds the estimated error. If we postulate the addition compounds, $H_2O_2{\cdot}IO_3^-$ and $H_2O_2{\cdot}HIO_3$, as intermediate steps in Reactions 5 and 6 it is evident that the presence of H^+ in the addition compound lowers the critical energy necessary for the reduction of iodate by 4000 calories. This is equal in order of magnitude to the heat of dissociation of a weak acid, such as HIO_2 by analogy appears to be. The products assumed in Reactions 5 and 6 are IO_2^- and HIO_2, respectively, and the difference in critical energies may thus be related to the energy of the H^+—IO_2^- bond. Whether this suggestion is of value can be determined by applying it, whenever accurate data for temperature coefficients are available, to other similar pairs of reactions, such-as those involved in the oxidation of iodide ion by H_2O_2 (cf. Part I, Equations 6a' and 6a).

Catalysis **and** the Rate Measurements.—Equation 1 suggests that the rate of the reduction involved might be followed by measuring either the rate of formation of iodine, or the rate of evolution of oxygen. In the ideal case

$$-\frac{dIO_3}{dt} = 2\frac{dI_2}{dt} = \frac{2}{5}\frac{dO_2}{dt} = -\frac{2}{5}\frac{dH_2O_2}{dt} \qquad (12)$$

If, however, hydrogen peroxide *oxidizes* any iodine compound present in the reaction system, Equation **3** will no longer be strictly valid; should such oxidation increase until one molecule of hydrogen peroxide reacted thus for every molecule reducing an iodine compound, the main reaction occurring in the system would be the sum of 1 and 2

$$10H_2O_2 = 10H_2O = 5O_2;\quad \Delta F^\circ = -250{,}900 \text{ cal., or}$$

$$H_2O_2 = H_2O + \frac{1}{2}O_2;\quad AF^\circ = -25{,}090 \text{ cal.} \qquad (13)$$

and a steady state analogous in principle to that in the simpler bromine–bromide catalysis[15] would then have been reached. In this event

$$-\frac{dIO_3^-}{dt} = 2\frac{dI_2}{dt} = 0 \text{ (very nearly)};\quad \frac{dO_2}{dt} = \frac{1}{2}\frac{dH_2O_2}{dt} \qquad (14)$$

The criterion for pure stoichiometric reduction of iodate is therefore $(dO_2/dt)/(dI_2/dt) = 5$, while for pure catalytic decomposition of hydrogen peroxide this ratio approaches an infinite value. Any system composed initially of iodate ion and hydrogen peroxide in acid solution must have for its rate-ratio a value included within the above limits. While the pure reduction of iodate has never been experimentally realized, pure catalysis will take place in every reaction system as soon as the steady state concentration of iodine has been built up by the reduction of iodate ion. Since, in moderately acid solution and at low (H_2O_2), this steady state iodine concentration is less than 10^{-6} *M*, it is experimentally impossible to study the reduction of iodate ion under such conditions.

---

[15] Bray and Livingston, THIS JOURNAL, 45, 1251 (1923).

As long as appreciable catalysis does occur, dO_2/dt can never accurately measure $-dIO_3/dt$, for a measurement of oxygen evolved must necessarily include oxygen produced by catalysis. That it is possible to have catalysis and still measure accurately $-dIO_3/dt$ by following dI_2/dt will now be shown. Experimental evidence proves that the reactions underlying Equation 1 must form a consecutive series which depends for its existence upon a series of intermediate iodine compounds; the slowest member of this series (*i. e.*, the one with the smallest specific rate) is the one directly involving iodate ion. If catalysis involving the oxidation of an intermediate compound back to iodate occurs, then some iodate will of necessity take part more than once in this slowest step. Under such conditions no measure of the absolute rate of reduction of iodate is possible, for there is no way of measuring how much of this substance, once reduced to a lower valence, is returned to its original state by the oxidizing action of hydrogen peroxide. Catalysis in which no iodate ion is re-formed, such as that resulting from the oxidation of I^- by H_2O_2, will not sensibly affect dI_2/dt, for it does not affect the *slowest reaction* taking place in the system.

A direct proof that no iodate is formed in the system is impossible. If, however, the amount of catalysis taking place as measured by the ratio $(dO_2/dt)/(dI_2/dt)$ changes from experiment to experiment, then the amount of oxidation involved in this catalysis must also change, as must the concentrations of all the intermediate products concerned. Thus, if the catalysis involves the re-formation of iodate ion, a change in the amount of catalysis will effect a change in the amount of iodate ion formed in the system, with the result that dI_2/dt (which must always measure the net amount of iodate reduced, since the concentration of intermediate products is small) will no longer follow a simple law.

A measure of the relative amount of catalysis in an experiment is the difference between the experimental value of $(dO_2/dt)/(dI_2/dt)$ and 5, its value for the pure reduction of iodate ion. In Tables II, III and IV these ratios are given wherever dO_2/dt was measured; with two exceptions, the values lie between 6.2 and 9.6 for all experiments with $(H^+) < 0.14$. (In the experiments on the salt effect three ratios between 5.9 and 6.6 were obtained.) In this region of acid concentrations, the amount of catalysis varies while dI_2/dt obeys the simple rate law in Equation 3; we conclude, therefore, that in this region the catalysis does not involve the re-formation of iodate ion.

In Table IV, the results of several experiments in more acid solutions are presented; the ratios for these experiments were always larger, 19 to 890, and calculations showed that the experimental values of dI_2/dt were always below those calculated from the simple rate law (see Columns 5 and 6, Table IV). The only simple explanation seems to be that catalysis at these higher acid concentrations involves some re-formation of iodate.

In Experiment 06 (Table IV), in which $(H^+) = 0.7144$, the value **890** for the ratio was obtained in the usual way with carbon tetrachloride; the value 160 was obtained by using mercury to extract the iodine. Since the extraction by means of mercury is more complete, the experiment definitely indicates that, other things being equal, the amount of catalysis depends on (I_2).

In the series of experiments at 50° plotted in Fig. 2, the low results can all be explained as due to catalysis involving IO_3^-. The most striking case is furnished by the two experiments at $(H^+) = 0.1438$ (Experiments **09** and 015, Table IV) which differ only in the magnitude of (H_2O_2). From unpublished work on the catalytic decomposition of hydrogen peroxide by iodic acid, it is known that the steady state (I_2) is proportional to (H_2O_2). That the experiment at the higher (H_2O_2) gives a value of dI_2/dt in agreement with the rate law is thus due to the effective elimination of IO_3^- formation made possible by the higher value of the steady state (I_2). Attempts further to extend the range of (H^+) for which Equation **3** is valid by increasing (H_2O_2) and (IO_3^-), failed.

The close relation of the reduction of iodate ion to the general problem of the catalytic decomposition of hydrogen peroxide by the iodine–iodate couple must now be apparent. A knowledge of the mechanism and the rate of this reduction will be of value first of all in interpreting the induction period for the catalysis, for the reduction of iodate was studied merely by prolonging this induction period indefinitely through the addition of carbon tetrachloride to remove the iodine formed.

In conclusion I desire to thank Professor William C. Bray for his assistance in this investigation.

Summary

1. The rate of reduction of iodate ion by hydrogen peroxide has been measured and found to be given by the expression $-d(IO_3)/dt = 2.6(10^{-4})(H_2O_2)(IO_3^-) + 129(10^{-4})(H^+)(IO_3^-)(H_2O_2)$ to within ±5%.
2. A plausible mechanism for the reaction has been suggested.
3. The induction period has been studied and discussed.
4. A relatively small salt effect has been found for the reaction.
5. The reaction has been studied from **30** to 60°, and the data thus obtained were used to calculate the average diameters of H_2O_2 and IO_3^-; the resulting value was of the correct order of magnitude.
6. The relation of this reaction to the catalytic decomposition of hydrogen peroxide by the iodine-iodate couple has been discussed.

THE INFLUENCE OF P_H UPON THE FORMATION AND DECOMPOSITION OF THE CHLORO DERIVATIVES OF AMMONIA

BY ROBERT M. CHAPIN

RECEIVED DECEMBER 5, 1930 PUBLISHED MARCH 6, 1931

The Chloro-amines under Decreased P_H.—The writer[1] demonstrated that in aqueous solution maximum purity is reached by monochloro-amine (NH_2Cl) above P_H 8.5 and by dichloro-amine ($NHCl_2$) at P_H 4.5–5.0. In Fig. 1 are shown percentage recoveries of available chlorine from such solutions of the chloro-amines, containing an excess of ammonium ion, subjected to decreased P_H. Each atom of constituent chlorine in all three chloro derivatives (including nitrogen trichloride), as in hypochlorite, liberates two atoms of available chlorine under the methods of assay employed.[2] Evidently the P_H ranges of maximum stability coincide with the ranges of maximum purity. Under current hypotheses[3] the curves of Fig. 1 would be explained through the operation of pairs of competing reactions, e. g., $2NH_2Cl + HCl \longrightarrow NH_4Cl + NHCl_2$ and $3NH_2Cl \longrightarrow NH_4Cl + N_2 + 2HCl$, catalyzed by acid. But each of these reactions may be complex; the second, in particular, inasmuch as it is also catalyzed by alkali,[4] leaves the mechanism obscure.

The action of excess hypochlorite upon ammonium ion is known to progress to the formation of nitrogen trichloride. Stoppage of the chlorination at the stage of either chloro-amine demands, first, a limited proportion of the chlorinating agent, and, second, a sufficiently high P_H. Supplementing these established facts, the writer finds two fundamental general hypotheses adequate to account for the various products and decompositions which result from the chlorination of ammonium ion over a wide range of conditions: Hypothesis I. Under the influence of hydrogen ion, all three chloro derivatives of ammonia yield ammonium ion and hypochlorous acid. Hypothesis II. Under the influence of hydroxyl ion, all three chloro derivatives of ammonia yield chloride ion, the consequent oxidation of the residual atoms leading to a variety of associated products.

The first hypothesis was implied by Marckwald and Wille[4] in accounting for the production of nitrogen trichloride from acidified monochloro-amine, data regarding dichloro-amine not being in their possession. The

second is deduced from the apparently invariable presence of chloride ion among the decomposition products of all the chloro derivatives. The associated products include hypochlorite ion, nitrogen, nitrous oxide, nitrite and nitrate, which all have been identified by previous investigators.[5] Hitherto, however, practically nothing seems to have been available in the way of a quantitative study covering the alkaline decompositions of the chloro derivatives as a class.

Under Hypothesis I the formation of dichloro-amine through the acidification of monochloro-amine involves two steps. (A) $NH_2Cl + H^+ + H_2O \longrightarrow NH_4^+ + HClO$, and (B) $NH_2Cl + HClO \longrightarrow NHCl_2 + H_2O$.[6] The acidification of dichloro amine to below PH 4.4 similarly yields nitrogen trichloride. Inasmuch as no loss of available chlorine is indicated in these reactions, further discussion of Fig. 1 will follow a study of the influence of increased *PH* upon the individual chloro derivatives.

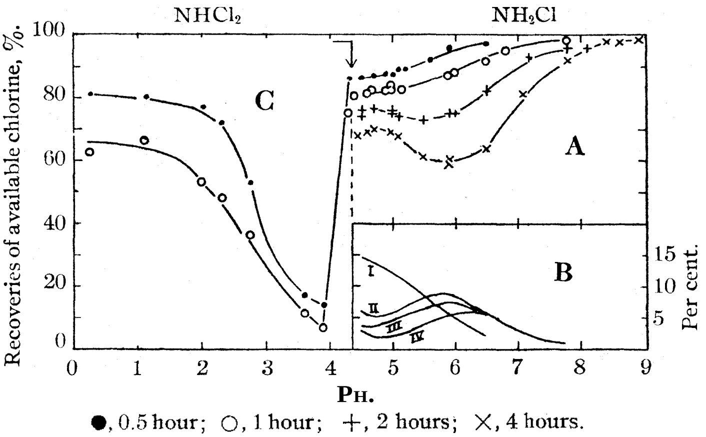

Fig 1. Recoveries of available chlorine at 25° from solutions of (A) NH_2Cl (0.01 N) and of (C) $NHCl_2$ (0.010 – 0.022 *N*) subjected to decreased PH. Fig 1-B.—Rate loss per 0.5 hour; from 1-A.

$NHCl_2$ and NCl_3 under Increased *PH*.—In Fig. 2-A are shown percentage recoveries of available chlorine from solutions of dichloro-amine, containing excess ammonium ion, subjected to increased *PH*. The residual substance above *PH* 9.0 was identified as monochloro-amine through its partition ratio, $C_{CHCl_3}/C_{Aq.}$[1] It was concluded that the principal reaction was (C) $2NHCl_2 + 4OH^- \longrightarrow 3Cl^- + ClO^- + 3H_2O + N_2$, under which 25% of the original available chlorine should be

[5] J. W. Mellor, "A Comprehensive Treatise on Inorganic and Theoretical Chemistry," Vol. VIII, 1928.

[6] Discussion of the electronic mechanism of chlorination being beyond the scope of this paper, the term hypochlorous acid (HClO) is here of comprehensive significance, without regard to possible ionization.

recoverable. But during one hour at *Ph* 9.6 oxy acids of nitrogen were developed equivalent to 3.0 p. p. m. of nitrogen, of which nitrite afforded 1.8 p. p. m. of nitrogen. These quantities are equivalent to 8.2% of the original available chlorine and therefore quantitatively account for the deficient recovery shown. Though the liberated ClO ion would rapidly react with excess ammonium ion present to produce monochloro-amine, there is experimental evidence for its evanescent existence. Thymol blue[7] is rather resistant toward both chloro-amines, but when *a* solution of dichloro-amine is treated with ammonia and thymol blue simultaneously, or in rapid succession, the color quickly fades after a transitory stage of abnormally bright blue.

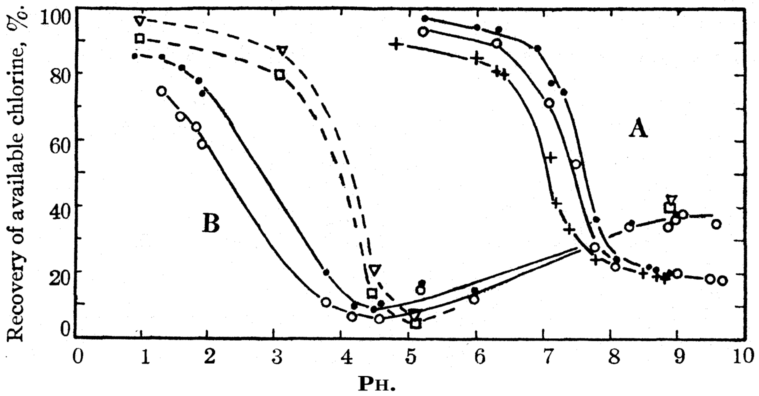

Fig. 2-B.—Nitrogen trichloride. Fig. 2-A.—Dichloro-amine.
At 25": ●, 0.5 hour; ○, 1 hour; +, 2 hours. At 7": V, 0.05 hour; ⊡, 1 hour.

Fig. 2.—Recoveries of available chlorine from solutions of $NHCl_2$ (0.01 *N*) and of NCl_3 (0.013 – 0.018 N) subjected to increased Ph.

Similar experiments on nitrogen trichloride subjected to increased Ph in the presence of ammonium ion are covered by Fig. 2-B, and monochloro-amine was similarly found to be residual at Ph 9.6, together with a small proportion of nitrite. It was concluded that the principal reaction at that Ph was (D) $2NCl_3 + 6OH^- \longrightarrow 3Cl^- + 3ClO^- + 3H_2O + N_2$, under which 50% of the original available chlorine should be recoverable. Failure to attain more than 40% recovery was attributed to rapid decomposition while the preparations were passing through the intermediate *Ph* range during the process of mixing the alkaline buffer with the original solution.

Comparison of Figs. 1 and *2* indicates that the effect of hydroxyl ion

---

[7] Indigo carmine, employed by F. Raschig, *Chem.-Ztg.*, 31, 926 (1907). for the detection of hypochlorite in the presence of monochloro-amine is much less sensitive than either thymol blue or methyl orange,

is adequate to account for the curves shown in Fig. 1. When dichloro-amine is acidified (Fig. 1-C), the loss is not due to direct action of hydrogen ion upon that substance, but to the action of hydroxyl ion upon the resulting nitrogen trichloride. When monochloro-amine is acidified (Figs. 1-A and 1-B) the free liberation of hypochlorous acid under Equation A carries some molecules of chloro-amine through to nitrogen trichloride; consequently the curves represent combined decompositions of both nitrogen trichloride and dichloro-amine under the influence of hydroxyl ion.

In view of the work of Marckwald and Wille, decompositions of monochloro-amine were not studied.

Reason arose for doubting the apparently uncontradicted statement of Anderson[8] that the passage of chlorine into excess aqueous ammonia of varied concentration always affords a considerable proportion of oxygen at all stages. He reported 13.8% in the dried gas evolved from "strongest" ammonia water, but unfortunately gave neither his method of preparation of chlorine nor a test for its purity, nor assurance that the evolved gases were freed from ammonia. Here the chlorine was prepared from hydrochloric acid and specially made manganese dioxide, and showed only a trace insoluble in sodium hydroxide solution. About 75 cc. of the gases evolved from the chlorination of excess ammonia water, after standing for about one hour, was drawn into a gas buret. The confining liquid was normal sulfuric acid tinted with methyl orange. Thorough shaking in the buret left the pink unchanged, insuring absence of both ammonia and chloro derivatives from the gas measured. The absorbing agent for oxygen was alkaline pyrogallol, and the fitness of the absorption pipet was proved through a final assay of outdoor air. "Ammonium hydroxide, C. P., sp. gr. 0.90" was chlorinated at full, half, and quarter strengths, but in each case the gas lost less than 0.2% in the pyrogallol pipet, a proportion within the limits of error of the work. The residue from the evaporation of the ammoniacal liquid afforded a distinct diphenylamine test for nitrate in the run with quarter strength, but none in the run with full strength ammonia water.

Effects of Excess Chlorine.—In Fig. 3 are shown moles of available chlorine lost per mole of ammonium when similarly buffered solutions of known concentrations were mixed. At P_H 9 the mixtures evidently ran through rapid alternate formations of chloro derivatives and decompositions of the latter under the influence of hydroxyl ion, until either ammonium ion or hypochlorite was exhausted and only monochloro-amine and ammonium ion, or hypochlorite, remained, action being found already practically complete in one-quarter hour. Excess hypochlorite was detected after half an hour by the thymol blue test in the

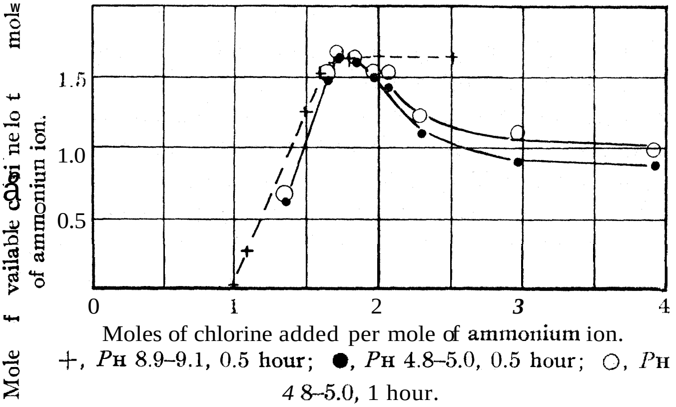
mixture of mole ratio 1.7 but not in that of ratio 1.6. At PH 5 the mixtures ran through a similar series of decompositions up to a mole ratio of close to 1.7, but here excess of chlorine evidently inhibited the decomposition of nitrogen trichloride under the influence of hydroxyl ion. A mixture of mole ratio 3.45 lost only 57% of its potentially ammoniacal nitrogen in half an hour, as shown by concordant determinations after reduction with As_2O_3–HCl and with sulfurous acid.



+, PH 8.9–9.1, 0.5 hour; ●, PH 4.8–5.0, 0.5 hour; ○, PH 4.8–5.0, 1 hour.

Fig. 3.—Moles of available chlorine (Cl_2) lost per mole ammonium ion (0.005 *M*) after admixture at *PH* 9.0 and at *PH* 4.9, at 25°.

When, however, the reaction was effected in much higher concentration at PH 5 by letting a heavily buffered ammonium solution flow[9] into a gas buret charged at atmospheric pressure with pure dry chlorine, the mole ratio 1.5 was found to leave a trace of chlorine in excess. Accordingly, departure from the relation (E), $2NH_3 + 3Cl_2 \longrightarrow 6HCl + N_2$, appears to increase with dilution. In the dilute solutions at both PH 5 and PH 9, about 40% of the departure from the mole ratio 1.5 was accounted for by the formation of nitrate. Only questionable traces of chlorate or perchlorate were detected, so search was made for nitrous oxide.[10] Preparations of 500 cc., containing the equivalent of 0.005 M ammonium chloride, were made by letting solutions of sodium hypochlorite, acetic acid or boric acid, and buffered ammonium chloride, flow successively into a previously evacuated flask. After one hour the gases were pumped from the warmed flask into a mercury buret, washed successively with 1 to 2 cc. of strong sulfuric acid and potash over mercury in pipets, and measured over a little distilled water. Next they were run into an ordinary pipet filled with air-saturated distilled water, and the detached pipet was shaken for five minutes. After measurement, absorption was repeated with fresh

[10] Lord Rayleigh, *Proc. Roy. Soc.* (London), 64, 95 (1898).

water, which took out about one-tenth as much as the first treatment. A third treatment showed no significant change. At mole ratio 1.67, which by tests with methyl orange was sufficient to leave a trace of hypochlorite, two preparations at PH 5 afforded equivalents of 5.2 and 6.9 cc. of water-soluble dry gas at 0° and 760 mm., which quantities, reckoned as nitrous oxide, quantitatively account for the remainder of the available chlorine consumed. But at PH 9 no nitrous oxide was found at mole ratios 1.60 or 1.67, so that under conditions representing the storage of nitrogen trichloride at PH 9 there remains a quantitative deficit.

The formation of the oxy compounds of nitrogen noted above resembles the various decompositions[5] of hyponitrous acid, $H_2N_2O_2$. Accordingly, the following mechanism is suggested. First, the production of chlorohydroxylamines, NHClOH and NCl_2OH, by metathesis, as in Equation (F), $NCl_3 + OH^- \longrightarrow Cl^- + NCl_2OH$; second, the removal of chlorine and hydrogen chloride from these by further action of hydroxyl ion, leaving the nitroyl group, HNO, which finally affords the characteristic decomposition products. Kolotoff[11] found that sodium hypobromite oxidizes hydroxylamine to hyponitrite.

Equilibria of Nitrogen **Trichloride.**—In Fig. 4 are shown values for the partition ratio, $C_{CCl_4}/C_{Aq.}$, of the available chlorine in solutions of varying PH and containing excess ammonium ion, after being held for two hours at 25°. In the one series ammonium chloride was used and hydrochloric acid, with or without potassium chloride, was the acidifying agent below *P*H 1.8; in the other, ammonium sulfate, sulfuric acid and potassium sulfate were used instead. The $HI-Na_2S_2O_3$ method of assay was employed because of its superior delicacy. Evidently the points **A** and **A'** mark maximum purity of the resultant nitrogen trichloride. Incomplete reaction, or reversion to ammonium chloride, begins to appear in hydrochloric acid solutions a little stronger than normal and is nearly complete at 4 *N*, but none is indicated in sulfuric acid solutions up to 7 N, so that it cannot be due solely to low PH. The explanation of reversion given by Seliwanow[12] appears adequate. In aqueous solution nitrogen trichloride is in equilibrium with hypochlorous acid; (G), $NCl_3 + H^+ + 3H_2O \rightleftharpoons NH_4^+ + 3HClO$. In the presence of only sulfuric acid, even of high concentration, the small concentration of hypochlorous acid necessary to stabilize nitrogen trichloride is itself stable, so that reversion is scarcely perceptible; but in presence of sufficient hydrochloric acid the reaction (H), $HClO + Cl^- \rightleftharpoons OH^- + Cl_2$ may so reduce the actual concentration of hypochlorous acid that reaction (G) progresses toward the right to practical completion. It directly follows that chlorine itself is inert toward ammonium ion, chlorination occurring only when the concentration

---

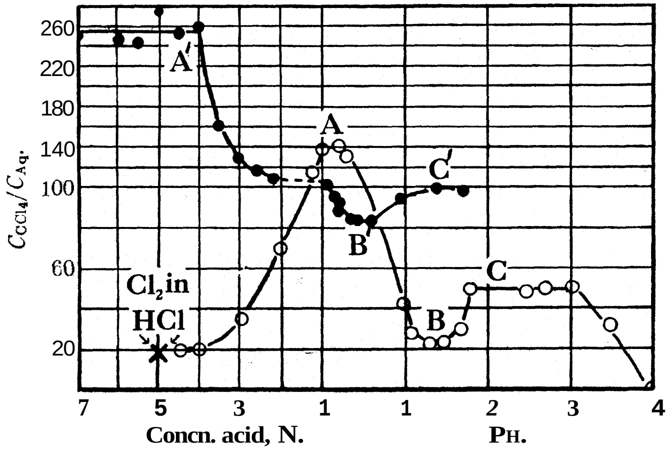
[12] T. Seliwanow, *Ber.*, 27, 1012 (1894).

of chloride ion is sufficiently low and the PH is sufficiently high to permit formation of the necessary concentration of hypochlorous acid.

In opposition to the foregoing, Noyes[13] suggests that the formation of all three chloro derivatives involves direct addition of either chlorine or hypochlorous acid, not to ammonium ion, but to ammonia, according to the scheme $NH_3 + Cl^+Cl^- \longrightarrow NH_3Cl^+Cl^- \longrightarrow NH_2Cl + H^+Cl^-$. Similarly, dichloro-amine would be derived from monochloro-amine, and finally nitrogen trichloride from dichloro-amine; but this scheme appears workable only in presence of free chlorine or hypochlorous acid. The writer does not see how the production of dichloro-amine and nitrogen trichloride from monochloro-amine through mere decrease of PH may be accounted for without violating Noyes' fundamental assumption that each chlorine atom retains its electronic configuration, its positive or negative character, unchanged throughout. Again, Noyes accounts for the effect of strong hydrochloric acid upon nitrogen trichloride by reversing the scheme of formation, thus, $NCl_3H^+Cl^- \longrightarrow NHCl_2 + Cl^+Cl^-$, until, after a similar passage through monochloro-amine, ammonium chloride is finally reached; but these chloro amines, and still more the corresponding chloro-ammonium chlorides, should be so comparatively little soluble in organic solvents that their presence in hydrochloric acid solutions somewhat stronger than *N* should be apparent from the partition data of Fig. 4. Lastly, the theory demands the existence of a significant concentration of ammonia in sulfuric acid solution as strong as 7 N. Altogether,



●, in sulfuric acid; ○, in hydrochloric acid.

Fig. 4.—Partition ratios, $C_{CCl_4}/C_{Aq.}$, of available chlorine in stored aqueous solutions of nitrogen trichloride. Initial chlorine, about 0.02 N.

---

[13] W. A. Noyes, This Journal, 42, 2173 (1920).

the theory of Noyes appears to gain no support from the present experiments.

Returning to the discussion of Fig. 4, when the PH rises from the points A and A', the decreasing partition ratios indicate formation of another substance, but complete analyses of chloroform extracts from several preparations over the range A to C showed only nitrogen trichloride. The substance in question rather persistently resisted repeated extraction by carbon tetrachloride and traces of it powerfully bleached methyl orange. It was assumed to be simply hypochlorous acid, for Hypotheses I and II applied to Figs. 1 and 2 indicate a considerable range below *P*H 4.4 over which both the action of hydrogen ion upon dichloro-amine and the action of hydroxyl ion upon nitrogen trichloride should cooperate to maintain a relatively high concentration of hypochlorous acid.

The distinct dips in the curves at the points B and B' may perhaps be due to the presence of Cl_2O derived from the equilibrium (I) $2HClO \rightleftarrows H_2O + Cl_2O$, recently studied by Roth.[14] He found for Cl_2O the partition ratio $C_{CCl_4}/C_{H_2O} = 2.22$.

Experimental Technique

The buffers were various mixtures of phosphates (acid, middle and alkaline ranges), acetates and borates. The *PH* indicators were those recommended by Clark,[15] except that methyl orange replaced brom phenol blue, while cresol red (acid range)[16] was employed below the acid range of thymol blue. Nitrogen trichloride, when present, was extracted by carbon tetrachloride before the determination of *PH*, and, when necessary. residual bleaching powder was removed by adding to the test in the tube, before the indicator, one drop of potassium iodide solution, followed by 0.1 N sodium thiosulfate to decolorization. All *PH* results reported are those determined at the end of the various processes, and were, in most cases, slightly below the calculated initial PH.

The three chloro derivatives were prepared by rapid admixture of solutions of chlorine or hypochlorite and of ammonium ion, both buffered alike, the former, where practicable, being poured into the latter. Typical formulas were as follows: for monochloro-amine, (a) 15 cc. of 5% ammonium chloride solution, 50 cc. of 0.1 M sodium tetraborate, diluted to 100 cc., and (b) sodium tetraborate the same, 40 cc. of strong chlorine-water, diluted to 100 cc.; for dichloro-amine, (a) 20 cc. of 5% ammonium chloride solution, 32 cc. of 0.5 M sodium acetate, 8 cc. of 0.5 M acetic acid, diluted to 100 cc., and (b) sodium acetate and acetic acid the same, 60 cc. of chlorine-water; for nitrogen trichloride, (a) 20 cc. of 5% ammonium chloride solution, 5 cc. of 0.5 M hydrochloric acid, and (b) 25 cc. of chlorine-water, 20 cc. 0.5 M hydrochloric acid, diluted to 100 cc. The minimum periods of storage before use and the final *PH* were as follows: monochloro-amine, one hour, *PH* 9.0; dichloro-amine, two hours, *PH* 4.6–5.0; nitrogen trichloride, half an hour, *PH* 0.9.

For making changes of *P*H, sufficient solution of the chloro derivative was placed in a glass-stoppered, graduated cylinder in a water-bath, a sample for assay was pipetted out, then the remainder was immediately treated with the necessary acid or alkaline solution.

Available chlorine in the two chloro-amines is determinable by the acid–iodide–thiosulfate method,' but in the presence of nitrite only sufficient acetic acid should be used to reach about PH 4. Dowell and Bray[8] reported neither iodide nor arsenious oxide as satisfactory for use in assaying nitrogen trichloride. Here it was found that about 80% of the total available chlorine of nitrogen trichloride was recoverable through a moderately acid solution of potassium iodide–hydrochloric acid from both aqueous and carbon tetrachloride solutions, and the method was employed in the presence of nitrogen trichloride in the single case of the work covered by Fig. 4. But arsenious oxide was found entirely reliable for all three chloro derivatives provided sufficient hydrochloric acid was present to effect reversion to ammonium chloride and chlorine before direct action upon arsenic trioxide occurred. A final concentration of not less than 20 volumes of the concentrated reagent per 100 of the final mixture appeared sufficient. Excess arsenic trioxide was titrated either by the bromate or the iodate method, depending upon whether the sample was in aqueous or organic solution. Solutions of pure nitrogen trichloride in chloroform afforded results closely in accord with determinations of ammonium and chloride ions made after reduction with aqueous sulfur dioxide.

The total nitrogen converted to oxy acids was determined by Nesslerization after reduction with aluminum.[17] Both sample and blank were first freed from active chlorine by the same proportions of identical solutions of potassium iodide and sodium thiosulfate, then to the blank was added acid or alkaline buffer corresponding to that already added to the sample. Just before the distillation of ammonia, each was treated with an alkaline lead solution to retain hydrogen sulfide arising from the reduction of thio acids. Nitrite nitrogen was determined colorimetrically by the A. P. H. A. method. Active chlorine was first removed by an aqueous solution of arsenic trioxide, after which the blank received the acid or alkaline buffer necessary to bring it into correspondence with the sample. The determinations noted under Fig. 3 were conducted similarly, the solution of ammonium ion there taking the place of the "buffer" referred to above.

Summary

Quantitative experiments lead to the following conclusions:

1. Elementary chlorine is inert toward ammonium ion, requiring conversion to hypochlorous acid before attack occurs.
2. Hydrogen ion induces formation of ammonium ion from each chloro-amine, particularly below a characteristic PH, the resulting hypochlorous acid then reacting to produce a more highly chlorinated derivative.
3. Hydroxyl ion induces formation of chloride ion from nitrogen trichloride or dichloro-amine, particularly above a characteristic PH, with gaseous nitrogen and hypochlorite ion as the principal associated products. With increasing dilution nitrous oxide, nitrite and nitrate also appear. To account for these oxy derivatives it is suggested that hydroxyl ion may first react by metathesis to produce chloro-hydroxyl-amines, which then decompose to afford the nitroyl group, characteristic of hyponitrous acid.
4. The statement that some gaseous oxygen is formed by passage of gaseous chlorine into ammonia water is apparently erroneous.

THE SELENIOUS ACID METHOD FOR THE DETERMINATION OF ZIRCONIUM

BY STEPHEN G. SIMPSON WITH WALTER C. SCHUMB

RECEIVED DECEMBER 18, 1930 PUBLISHED MARCH 6, 1931

The accurate determination of zirconium has always been a matter of considerable difficulty, especially in materials containing a variety of other metals. Many of the methods of analysis which have been proposed give good results when applied to simple zirconium compounds, but fail when certain other elements are present. The two most common methods have been the phosphate method and the cupferron method, both of which have been carefully studied by Lundell and Knowles,[1] who, in their proposed procedures, have made provision for the elimination of all interfering elements. The removal of such interfering elements in samples of moderate complexity, however, involves a very long series of manipulations.

Smith and James[2] have recently shown that the precipitation of zirconium by selenious acid can be applied to the quantitative determination of zirconium. They studied the effect of the presence of only a few interfering elements, however, and as J. W. Marden[3] has pointed out, however promising the method may seem, the effect of such metals as are ordinarily encountered in zirconium ores and alloys must be understood before the method can be generally used.

It was the purpose of this investigation, therefore, (a) to determine the most favorable conditions for the quantitative precipitation of zirconium selenite; (b) to determine what elements other than zirconium are precipitated by selenious acid under the conditions for the most favorable precipitation of zirconium; (c) to determine what elements are adsorbed or otherwise brought down by zirconium selenite in sufficient amounts to interfere with the accuracy of the estimation of zirconium; (d) to devise a reasonably rapid and direct method for eliminating the interfering elements and quantitatively precipitating the zirconium selenite in pure form; (e) to apply the method to mixtures and natural products containing zirconium in conjunction with a wide variety of other metals, especially those which have been found to cause interference.

Previous Work.—The formula of the flocculent precipitate obtained by the addition of selenious acid to solutions of zirconium salts is, according to Nilson,[4] $4ZrO_2{\cdot}3SeO_2{\cdot}18H_2O$. On heating the solution containing the

suspended precipitate with excess selenious acid, the precipitate is slowly converted to the crystalline normal selenite, $Zr(SeO_3)_2$. Smith and James showed that the precipitation is quantitative and recommended that it be made from 500 cc. of solution containing 5% hydrochloric acid. Ignition of the precipitate gives zirconium dioxide and with equal amounts of original zirconium salt the weights of the dioxide are essentially the same as those obtained by the ignition of the corresponding cupferron and ammonia precipitates. Smith and James likewise found that aluminum and the rare earths do not interfere except that cerium must be in the cerous form, and also that the presence of amounts of iron usually present in zirconium ores does not affect the results. Titanium interferes but can be completely held in solution by hydrogen peroxide. Thorium also interferes but the writers state that this element is rarely a constituent of zirconium ores.

Experimental Work

Solutions Used.—A solution of C. P. selenious acid containing 100 g. per liter was prepared for use as a precipitant and several liters of zirconyl chloride solution were prepared of an approximate concentration of 12 g. of $ZrOCl_2 \cdot 8H_2O$ per liter. The zirconium from 25-cc. portions of the latter solution was precipitated (a) by cupferron from 10% sulfuric acid solution, and (b) by 20 cc. of selenious acid from 400 cc. of neutral solution.[5] The ignited precipitates gave the following values.

	Precipitation by cupferron, g. ZrO_2	Precipitation by selenious acid, g. ZrO_2
	0.1200	0.1200
	.1197	.1206
	.1199	.1194
		.1198
		.1200
		.1200
		.1201
Average	0.1199	0.1200

This zirconyl chloride solution was used throughout the entire investigation and its concentration was checked frequently.

Effect of Acid on the Precipitation of Zirconium Selenite.—Since in an ordinary analysis of zirconium it might be desirable to precipitate zirconium selenite from nitric acid or sulfuric acid solution, as well as from hydrochloric acid solution, and since considerable alkali salts might very likely be present from previous neutralizations, the effect of the presence and concentrations of these substances on the quantitative precipitation of

---

[5] One-half milligram of zirconium in 500 cc. of solution acidified with hydrochloric acid gives a visible precipitate with selenious acid. This corresponds to 0.05% Zr in a one-gram sample of ore.

zirconium by selenious acid was next studied. The results are listed in Table I. In all the determinations a total volume of 400 cc. was used, *25* cc. of standard zirconyl chloride solution was present (equivalent to 0.1200 g. of ZrO_2), and the zirconium was precipitated from boiling solution with 20 cc. of 10% selenious acid solution. The precipitate was allowed to stand and was then filtered and ignited.

In these precipitations the use of hydrochloric acid or nitric acid gave immediate flocculent precipitates, which, on long standing (*e.* g., overnight) on the hot-plate, became more crystalline. The precipitates in the presence of sulfuric acid did not appear at once and in some cases did not begin to form before an hour or more. When they did appear, they were entirely crystalline in character and had a great tendency to adhere to the scratches on the beaker, from which they were removed only with difficulty, Furthermore, the two forms of precipitates differed markedly in their lease of solubility in acids. The amorphous form (basic selenite) was readily soluble in 6 *N* mineral acids, while the crystalline form (normal selenite) was difficultly soluble.

TABLE I

ZrO_2 present, 0.1200 g.

Acid	6 *N* acid present, cc.	Acid normality of solution	ZrO_2 found, g.	
HCl	40	0.60	0.1202	0.1199
			.1203	
			.1196	
			.1199	
			.1200	
			.1198	
			.1196	
	50	0 75	.1178	
	60	0 90	.1097	
	80	1.20	.0930

			.1198	
			.1200	
			.1200	
			.1205	
	60	0.90	.0142	
	80	1.20	.0080	

It is seen from Table I that greater acidity in hydrochloric acid can be used than in nitric acid if complete precipitation is to be expected, and that with hydrochloric acid the total acidity should not much exceed 0.6 *N*

(40 cc. of 6 N HCl in 400 cc. of solution). Sulfuric acid is the least desirable acid medium of the three, not only because of the slowness of precipitation and greater difficulty of removing the precipitate from the beaker, but also because a slight increase in acidity over 0.6 N causes a very sharp decrease in the amount of zirconium precipitated.

Incidentally, the statement made by Smith and James[6] that precipitated zirconium selenite cannot be easily redissolved for reprecipitation was found to apply only to the crystalline form. The freshly precipitated flocculent form dissolves in hot 6 N hydrochloric acid without much difficulty.

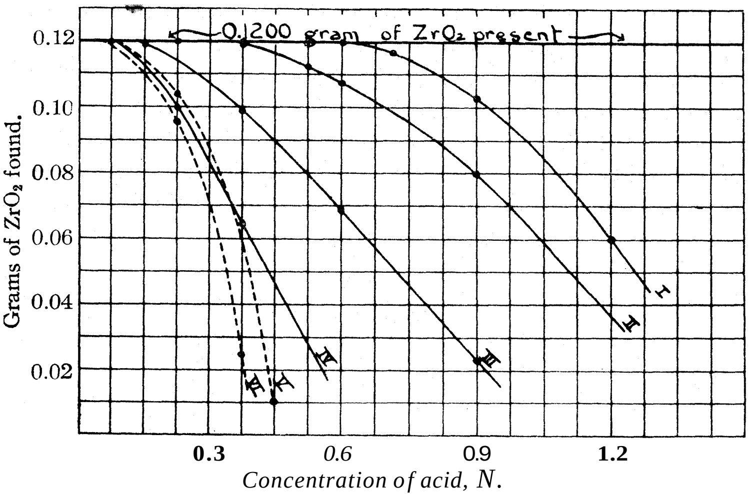

Fig. 1.—I, HCl + 0.5 *g. of* Na_2SO_4; II, *HCl* + **2** *g. of* Na_2SO_4; III, HCl + *5 g.* of Na_2SO_4; *IV,* HCl + *10* **g.** *of* Na_2SO_4; *V,* H_2SO_4 + *0.5* **g.** *of* Na_2SO_4; *VI,* H_2SO_4 + *2 g. of* Na_2SO_4.

Effect of Alkali Salts on the Precipitation of Zirconium Selenite.—Determinations of zirconium with selenious acid in the presence of alkali salts were next made In these experiments, 400 cc. of solution were used, 25 cc. of standard zirconyl chloride (equivalent to 0.1200 g. of ZrO_2) was present and the zirconium was precipitated from boiling solution with 20 cc. of 10% selenious acid. Varying concentrations of hydrochloric acid and of sulfuric acid were used and also varying. amounts of alkali salts. Several determinations using 40 cc. of 6 *N* hydrochloric acid and amounts of sodium chloride, sodium nitrate, ammonium chloride and ammonium nitrate up to 10 g. gave precipitates of zirconium selenite producing on ignition 0.1200 ± 0.0004 g. of ZrO_2. Similarly, the presence of alkali chloride showed no appreciable effect upon the precipitation from sulfuric acid solution. The presence of alkali *sulfate,* however, had a marked effect on the precipitation from hydrochloric acid solution, and an even

---

[6] *Smith and James,* Ref. *2,* **p. 1768.**

greater effect from sulfuric acid solution. These effects are shown in Fig. 1, in which grams of ZrO_2 obtained are plotted against the volume of acid in 400 cc. of solution. From this graph it is seen that *increasing amounts of sulfate require a corresponding decrease in acidity for complete precipitation of zirconium.* Conversely, with *a* solution of desirable acidity in hydrochloric acid *(e. g., 0.6 N) only a small amount of sulfate can be present if complete precipitation is desired.*

In all cases, increasing amounts of alkali sulfate caused a decrease in the rate of precipitation and gave more crystalline precipitates.

Explanation of the Effect of Sulfate.—The explanation of the peculiar effect of the presence of sulfate on the completeness of precipitation of zirconium selenite is probably analogous to that proposed by Ruer in his studies on the precipitation of zirconium oxalate.[7] Ruer found that the addition of oxalate to zirconyl chloride solution gave a precipitate, but the addition of oxalate to zirconyl sulfate solution or to a mixture of zirconyl chloride and alkali sulfate gave no precipitate. He assumed the ionization of zirconyl sulfate to be

$$ZrOSO_4{\cdot}H_2SO_4 \longrightarrow [ZrOSO_4{\cdot}SO_4]^{=} + 2H^+$$

This assumption is borne out by the experimental fact that upon electrolysis of zirconyl sulfate the zirconium migrates to the anode, whereas with zirconyl chloride the zirconium migrates to the cathode.

Applying the same theory to the precipitation of zirconium selenite from sulfate solution, the following equilibria may be written

$$\begin{array}{lcl} [ZrOSO_4{\cdot}SO_4]H_2 & \rightleftharpoons & ZrO^{++} + 2SO_4^{=} + 2H^+ \\ ZrO^{++} + H_2SeO_3 & & ZrOSeO_3 + 2H^+ \\ ZrOSeO_3 + H_2SeO_3 & & Zr(SeO_3)_2 + H_2O \end{array}$$

Application of the principle of mass action to these equilibria shows that an increase in acidity and in sulfate-ion concentration would cause a decrease in solubility of the selenite precipitate. This is borne out by the experimental data. It is likewise apparent that a considerable excess of precipitating agent is desirable.

Metals Precipitated by Selenious Acid.—Solutions of various metal ions were treated individually with selenious acid solution to determine those precipitated by that reagent. In each case, 10 mg. of metal was present in 25 cc. of solution which was also 0.6 N in hydrochloric acid (except that 0.6 N nitric acid was used where an insoluble chloride could be formed). All the common cations were tested for, as well as various members of the rare earth group and of the gold and platinum groups. Thallium, beryllium, molybdenum, vanadium, tungsten, and uranium were also included.

The only elements which precipitated with selenious acid from the acid

---

[7] R. Ruer, Z. *anorg. Chem.*, **42**, 87 (1904).

solution were zirconium, titanium, thorium and ceric cerium. (Ferrous iron and stannous salts precipitated free selenium by reduction of the reagent.)

Although Berg and Teitelbaum[8] have shown that bismuth precipitates quantitatively with selenious acid from solutions which are 0.25–0.33 N in nitric acid, bismuth does not precipitate from this concentration of hydrochloric acid nor from solutions which are 0.60 N in hydrochloric or nitric acid, the latter concentration being the one used in the finally adopted method for zirconium. Ferric iron, silver and mercuric mercury also form insoluble selenites but these are likewise soluble in 0.60 N acid.[9]

Although no experimental evidence has been obtained, the element hafnium undoubtedly behaves like zirconium in its reaction with selenious acid, and if present in the original sample would not be distinguished from zirconium by this method. This is, of course, equally true of all other methods in common use.

Elimination of the Effect of Titanium and Cerium.—Smith and James have claimed that the presence of hydrogen peroxide prevents the precipitation of titanium by selenious acid. Since hydrogen peroxide in acid solution also reduces ceric cerium to the cerous form, which is unprecipitated by selenious acid, it would seem that hydrogen peroxide could be used to cause precipitation of pure zirconium selenite by selenious acid even in the presence of titanium and cerium. Twenty-five cc. portions of the standard zirconyl chloride solution were mixed with solutions of ceric nitrate and titanium chloride, 20 cc. of hydrogen peroxide and 20 cc. of 6 N hydrochloric acid were added. The solutions were heated and diluted to 400 cc. and the zirconium precipitated with 20 cc. of 10% selenious acid. The results were as follows.

ZrO_2 present, g.	Ce^{++++} added, g.	Ti^{++++} added, g.	ZrO_2 found, g.
0.1200	0.050	...	0.1201
.1200	.050	...	.1195
.1200	...	0.050	.1338
.1200	.050	.050	.1341
.1200	.050	.050	.1331

This would indicate that zirconium selenite can be precipitated pure in the presence of cerium if hydrogen peroxide has been added to reduce the cerium to the trivalent state but that zirconium cannot be precipitated pure by one precipitation in the presence of much titanium even in the presence of hydrogen peroxide. Since basic zirconium selenite, if freshly precipitated, can be dissolved in hot 6 N hydrochloric acid, the above

.1200	.050	.050	.1205

Double precipitation by selenious acid in the presence of hydrogen peroxide therefore suffices to precipitate zirconium nearly completely, uncontaminated by cerium or titanium.

Elimination of the Effect of Thorium.—The presence of the element thorium gives greater difficulty in the determination of zirconium by selenious acid, since it is precipitated by the reagent and is not affected by hydrogen peroxide. Smith and James dismissed this difficulty with the statement that thorium is rarely present in zirconium ores, but Dana[10] lists many zirconium ores in which thorium is present in considerable amount.

The two most common methods of separating thorium from zirconium are with hydrofluoric acid and with oxalic acid. Since the former method requires platinum ware and other special forms of apparatus, it was not experimentally applied to this case. Oxalic acid precipitates thorium oxalate from slightly acid solution and leaves zirconium in solution. Since, however, zirconium selenite will not precipitate from solutions containing oxalate, it becomes necessary in this case to remove excess oxalate after filtering off the thorium precipitate. An attempt was first made to destroy this oxalate with concentrated permanganate solution, but, besides introducing a very large amount of manganese into the solution, it was found difficult to destroy all of the oxalate by this method. It seemed best to destroy oxalate by evaporation with sulfuric acid, but since all but a small amount of sulfate must be absent from the solution from which zirconium is precipitated, an additional step is necessary, namely, that of precipitating zirconium with ammonium hydroxide and dissolving in hydrochloric acid before precipitating with selenious acid.

In the following determinations, zirconium (+thorium) was first precipitated with selenious acid from 0.6 N hydrochloric acid solution, the precipitate was dissolved in hot 6 N hydrochloric acid and 40 ce. of hot 10% oxalic acid solution. The solution was diluted to 200 cc. with hot water and made 0.36 N in hydrochloric acid. After standing overnight, the thorium oxalate was filtered off and the filtrate evaporated with 18 N

---

[10] E. S. Dana, "System of Mineralogy."

sulfuric acid until oxalate was completely destroyed. The solution was diluted and made ammoniacal. The precipitate was filtered, washed superficially with water and dissolved in 15 cc. of hot 12 *N* hydrochloric acid. The solution was then treated with 20 cc. of 3% hydrogen peroxide, diluted to 400 cc. and the zirconium was precipitated from the hot solution with selenious acid. The results were as follows.

ZrO_2 present, g.	Th^{++++} added, g.	ZrO_2 found, g.
0.1200	0.050	0.1190
.1200	.050	.1195
.1200	.050	.1191
.1200	.050	.1178

The somewhat low values seemed to indicate the probability of some zirconium precipitating with the thorium. Scott[11] recognizes this possibility and recommends two precipitations of thorium in its separation from zirconium. In the next series of determinations this was done by decomposing the precipitated thorium oxalate by evaporation with 18 *N* sulfuric acid. The solution was diluted, made just ammoniacal and then slightly acid. The thorium was again precipitated with oxalic acid and the filtrates were united before proceeding as above with the precipitation of the zirconium. Erratic results were obtained for the weights of zirconium dioxide, however, some being within 0.3 mg. of the correct value (*i.e.*, 0.1200 g.) while others ran as high as 0.1315 g. It seemed obvious, therefore, that thorium oxalate is incompletely precipitated in the presence of a large concentration of sulfate ion. This was substantiated by a series of determinations in which the thorium in 25-cc. portions of thorium nitrate solution was precipitated with 10% oxalic acid solution from 0.36 N hydrochloric acid solution in the presence of varying amounts of sulfate The thorium oxalate precipitates were ignited to oxide and the results were as follows.

(Gram ThO_2 present = 0.1660)

Gram-equivalents of sulfate present	0.090	0.180	0.360	0.540
G. ThO_2 obtained, g.	.1658	.1656	.1581	.1524

This effect of high sulfate concentrations in preventing the complete precipitation of thorium oxalate is therefore analogous to the effect of sulfate on the precipitation of zirconium oxalate as studied by Ruer. It also explains the erratic results obtained in the above determinations of zirconium when thorium was precipitated twice, for somewhat variable amounts of sulfate were present in the second precipitation of thorium. The obvious remedy for this error is to precipitate the thorium with ammonium hydroxide, after reprecipitating with oxalic acid. This addi-

tional step was therefore included in the method finally adopted and described below.

Experiments on Adsorption.—Since freshly precipitated zirconium selenite can be redissolved in hot 6 *N* hydrochloric acid and reprecipitated from the diluted solution, and since the final proposed method involves three such precipitations, it was felt that any possibility of error due to adsorption of foreign elements would be eliminated. The following experiments were made, however, to verify this conclusion.

The zirconium in 25-cc. portions of the standard zirconyl chloride solution (equivalent to 0.1200 g. of ZrO_2) was precipitated from 400 cc. of solution containing 40 cc. of 6 *N* hydrochloric acid and 0.20 g. of various metal ions. It was found that even with a single precipitation of zirconium the elements manganese, zinc, cobalt, copper, lead, bismuth, iron, aluminum, and rare earth metals are not seriously adsorbed, the maximum adsorption increasing the weight of ZrO_2 obtained to 0.1210 *g*. With two precipitations, the adsorption in each case was negligible, being not greater than 0.2 mg. Uranyl ions were considerably brought down by one precipitation (ZrO_2 found, 0.1225 g.) but not by two precipitations (ZrO_2 found, 0.1202 *g.*). Vanadium as vanadate was greatly adsorbed (0.1415 g. ZrO_2) but on dissolving the precipitate in hot hydrochloric acid, vanadate is reduced to vanadyl ions, which are not brought down by zirconium selenite, and 0.1200 g. of ZrO_2 was obtained. Since in the proposed method hydrogen peroxide is to be added to hold cerium and titanium in solution, any vanadium would be converted to pervanadic acid. Pervanadic acid, like vanadate, is greatly adsorbed by zirconium selenite (in the presence of 0.20 g. of vanadium as pervanadate 0.1294 g. of ZrO_2 was obtained), so in the proposed method of analysis one precipitation of zirconium selenite is made without the addition of hydrogen peroxide and following the addition of alcohol to reduce any vanadate to the vanadyl form.

Proposed Methods of Analysis

Proposed Method for Zirconium when Present in Solution.—To the nearly neutral solution, which should be free from phosphate, sulfate, columbium and tantalum and which should have a volume not much greater than 100 cc., add 20 cc. of 12 N hydrochloric acid and 20 cc. of alcohol. Heat nearly to boiling, dilute to 500 cc., again heat to boiling and add 20 cc. of 10% selenious acid solution. Allow to stand hot until the supernatant liquid is clear enough to filter (preferably not over two hours). Filter and wash superficially with hot water. Puncture the paper and thoroughly flush off the precipitate into the original beaker with a fine stream of hot water, using as little as possible and saving the paper. Add 15 cc. of 12 *N* hydrochloric acid and heat until the precipitate is dissolved (a slight turbidity sometimes persists but may be permitted to remain). Add 20 cc. of 3% hydrogen peroxide, warm, dilute to 500 cc., heat to boiling, and again precipitate with 20 cc. of 10% selenious acid. Filter and wash with hot water. Again puncture the paper and flush off the precipitate.

(A) In a small beaker digest the two filter paper.: with 40 cc. of hot 10% oxalic acid solution. Filter and wash the pulp, and add the filtrate and washings to the zirconium precipitate. Dilute to **200** cc., heat to boiling and add **12** cc. of **6** N hydrochloric acid. Let stand at room temperature for at least ten hours. Filter and wash the precipitate with a solution containing **40** cc. of **6** N hydrochloric acid and **25** g. of oxalic acid per liter. To the filtrate add **30** cc. of **18** N sulfuric acid and start evaporating on the water-bath, covering the beaker with a large watch-glass supported on a glass triangle. (If the oxalate precipitate is large, flush it off into a 400-cc. beaker, add **5** cc. of **18** N sulfuric acid and evaporate on the water-bath until oxalate has been destroyed, as shown by the cessation of the evolution of gas bubbles. Dilute with water, make ammoniacal, filter and dissolve in **12** cc. of **6** N hydrochloric acid. Dilute to **160** cc., heat to boiling, and add **40** cc. of 10% oxalic acid. Let stand for at least ten hours and filter into the main solution.) Evaporate on the water-bath until oxalate has been destroyed as shown by the cessation of the evolution of gas bubbles. Wash down the sides of the beaker and watch-glass and filter any precipitated selenium. If a small amount of red selenium runs through the paper it may be neglected. Make the solution ammoniacal, filter and wash superficially with hot water. Puncture the paper and flush off the precipitate with as little hot water as possible. Pour **15** cc. of hot **12** *N* hydrochloric acid over the paper into the zirconium hydroxide suspension and heat until the precipitate is entirely dissolved. (B)

Add **20** cc. of **3%** hydrogen peroxide and warm. Dilute to **500** cc. and heat to boiling. Add **20** cc. of **10%** selenious acid and filter after the supernatant liquid is clear. Ignite over the Bunsen flame and finally for five minutes over the Méker burner. Weigh as ZrO_2.

In the known absence of thorium, the above method may be shortened. The oxalate precipitation involved in the above directions from (A) to (B) may be omitted. In this case, dissolve the zirconium selenite precipitate obtained at (A) by adding **20** cc. of **12** N hydrochloric acid and heating to boiling. Continue from point (B). Ignite the two filter papers from which the first two precipitates were washed and add the weight of their ash to the final weight of ZrO_2.

Results Obtained by Use of the Proposed Method.—The above proposed method for the determination of zirconium was applied to the following mixtures and the values obtained are shown in the last column. It may be pointed out that the mixtures used are such as to offer greater difficulty than would be encountered in an ordinary analysis.

ZrO_2 present, g.	Th^{++++}, g.	Ce^{++++}, g.	Ti^{++++}, g.	V as VO_3^-, g.	U as UO_2^{++}, g.	Fe^{+++}, g.	ZrO_2 found, g.

Decomposition of Zirconium Ores.—The most satisfactory methods for the decomposition of zirconium minerals are fusion with sodium peroxide or sodium peroxide mixtures, fusion with borax, and fusion with alkali fluorides. Of these, a strong alkaline fusion should serve best in cases where zirconium is subsequently to be determined by the selenite method, for by this fusion the interfering constituents phosphate, columbium and tantalum can be removed most easily. Hillebrand and Lundell[12] state that

---

[12] W. F. Hillebrand and G. E. F. Lundell, "Applied Inorganic Chemistry," John Wiley and Sons, Inc., New York, p. **445.**

phosphate is best removed by fusion of the original material with sodium peroxide and leaching with water. Some columbium and tantalum are removed in this way, but by fusing the residue with potassium carbonate or potassium hydroxide, columbium and tantalum can be practically completely removed. Schoeller and Powell[13] have studied this separation and have worked out a procedure which, according to Hillebrand and Lundell, serves as probably the best method for the removal of these elements. In this connection the authors state that it is preferable to dissolve in acid the extraction residue from the first fusion, precipitate with ammonia and use the ignited precipitate for the second fusion rather than to fuse the residue directly.

Fusion with sodium peroxide is usually carried out in a nickel crucible and for ordinary zirconium ores requires about twenty minutes. A simple procedure for sodium peroxide fusions and one that is complete in a very short time is that devised by Muehlberg.[14] This consists in mixing the sample with sugar carbon and sodium peroxide and igniting, the crucible being kept covered and also immersed in running water during the ignition and subsequent cooling. The melt shrinks when cooling and can be easily removed from the crucible. It has the very great advantage of introducing no nickel from the crucible into the melt. The method has been further studied by Marvin and Schumb,[15] who have determined the exact conditions for the most satisfactory decomposition of refractory substances and have found that all common refractories yield to the treatment, including zircon and other zirconium ores.

The following directions serve as a rapid method not only for decomposing zirconium ores but also for removing phosphate, columbium and tantalum. The method prepares the material for the determination of the zirconium by the selenite method given above.

Proposed Method of Attack of Zirconium Ores.—Place in a 50-cc. nickel crucible about 25 g. of an intimate mixture (made by gently rolling the two constituents in a large dry bottle) of 15 parts of fine sodium peroxide with 1 part of 100-mesh pure sugar carbon. Weigh out 1 g. of the finely ground sample upon this mixture, cover with more fusion mixture and mix intimately at the surface with a spatula. Cover with a liberal layer of the fusion mixture and immerse in cold running water so that the level of the water is slightly above the level of the contents of the crucible. Cautiously start the ignition by means of the glowing tip of a piece of cotton twine and immediately cover the crucible. After fusion is complete and the crucible is cold, remove the contents to a 1-liter beaker, add 300 cc. of cold water, flush out the crucible and wash off the cover. Heat nearly to boiling until the melt has disintegrated, dilute to 900 cc. with hot water, and heat until the supernatant liquid is clear enough to filter. Filter and wash the residue with hot water. Reject the filtrate. (If much phosphate is present or if columbium or tantalum is present in small amounts, treat the residue with hydrochloric acid and without filtering

[15] G. G. Marvin with W. C. Schumb, THIS JOURNAL, 52, 574 (1930).

add excess ammonia. Filter, ignite the residue and repeat the fusion and leaching as above.) Dissolve the residue in hydrochloric acid and filter off any undissolved material. This is essentially carbon but it may contain a very small amount of undecomposed original material (seldom more than one milligram), which can be separately fused with sodium peroxide–carbon mixture and the residue, after leaching with water, dissolved in hydrochloric acid and added to the main solution. To the hydrochloric acid solution add 25 cc of 18 N sulfuric acid and evaporate to fuming. Cool, dilute with water and filter off any silica. Make the filtrate ammoniacal, filter, wash superficially with hot water and dissolve in 15 cc of 12 N hydrochloric acid. The solution is then ready for the determination of zirconium by the method described above.

With moderate or high percentages of columbium or tantalum, treat the residue from the first peroxide–carbon fusion with hydrochloric acid and without filtering add excess ammonia. Filter and wash superficially with hot water. Ignite and fuse for five minutes in a platinum crucible with 20 parts of potassium carbonate. Leach with hot water, filter, and wash with 2% potassium carbonate solution and then with hot water. With high percentages of columbium and especially with high percentages of tantalum fuse the residue again with potassium carbonate. Leach with water; ignite the residue and fuse in the original platinum crucible with potassium pyrosulfate. Extract with 200 cc. of hot water, containing 10 cc. of 18 N sulfuric acid, filter, make the solution ammoniacal, filter and wash superficially with hot water. Dissolve the precipitate in 15 cc. of 12 N hydrochloric acid. The solution is then ready for the precipitation of zirconium as described above.

Results Obtained by the Proposed Fusion Method.—Artificial ores, made by mixing pure ZrO_2 with feldspar, apatite, and Cb_2O_5, when fused according to the directions above and the zirconium precipitated with selenious acid, gave the following values.

ZrO_2, g.	0.0837	0.0973	0.1112	0.1183	0.1091	0.1034

[a] Approximate weights only, as indicated.

Summary

1. Zirconium is quantitatively precipitated as basic selenite by excess selenious acid from solutions the acidity of which should not be greater than 0.6 *N*.

2. Hydrochloric acid is the best acid medium for this precipitation. Sulfuric acid causes a much slower precipitation, presumably of the crystalline normal selenite, and the precipitate is more difficult to remove from the beaker and more difficult to redissolve.

3. The presence of more than a small amount of sulfate prevents quantitative precipitation of zirconium from hydrochloric acid or sulfuric

acid solution. Increasing sulfate requires decreasing acidity for quantitative precipitation. This effect is probably due to the formation of $[ZrOSO_4 \cdot SO_4]H_2$, which provides few zirconium or zirconyl ions.

4. The elements zirconium (with hafnium), titanium, thorium and ceric cerium are the only dements which can ordinarily be present in a zirconium mineral which are precipitated either wholly or in part by selenious acid from 0.6 N hydrochloric acid solution.

5. The precipitate of zirconium basic selenite, if not allowed to stand suspended in hot solution long enough to become crystalline, can be redissolved in hot 6 N hydrochloric acid and therefore can be reprecipitated free from adsorbed elements (*e.* g., vanadate and uranyl salts which are considerably brought down by the zirconium precipitate). Vanadium, if previously reduced to vanadyl salt, is not brought down by the zirconium precipitate.

6. The addition of hydrogen peroxide before the precipitation of zirconium causes reduction of ceric cerium, therefore prevents its precipitation, and holds up titanium sufficiently so that it is eliminated by two precipitations of zirconium selenite.

7. Quantitative separation of thorium can be effected by double precipitation of thorium oxalate in the absence of sulfate and subsequent removal of excess oxalate by evaporation with sulfuric acid.

8. A method for the analysis of zirconium by means of selenious acid is given in detail. This gives satisfactory results even when all of such elements as thorium, ceric cerium, titanium, vanadium, iron and uranium are originally present.

9. A rapid method for decomposing zirconium ores preparatory to making the above analysis is also given. By this method phosphate, columbium and tantalum can be eliminated and the selenite method as given then serves as a satisfactory method for zirconium in any zirconium ore.

TERNARY SYSTEMS. IX. SODIUM IODATE, SODIUM NITRATE AND WATER[1]

BY ARTHUR E. HILL AND JOHN E. DONOVAN

RECEIVED DECEMBER 19, 1930 PUBLISHED MARCH 6, 1931

In the Caliche from which Chile saltpeter is extracted there are present a number of salt-forming ions. Of the many poly-component systems which these may compose with water a number have been investigated but a very large number still remain without published investigation. A short time ago it was decided to investigate some of these three-component and four-component systems at New York University. During the process of this work, there appeared the investigations by Foote and Vance,[2] covering the system sodium iodate, sodium nitrate and water at various temperatures between the ternary eutectic and 35°. Our own work on this system, nearly completed before Foote and Vance's became known to us, contains certain isotherms at temperatures slightly different from those selected by Foote and Vance, and at a duplicate temperature in the case of the 25° isotherm. Our findings are in general accord with those of the earlier publication; the two sets of investigations gave a rather unusually complete set of data for a ternary system. To the earlier isotherms at 0, 8, 25 and 35° we add as new material the isotherms at 5 and at 50°.

Attainment of Equilibrium.—The solubility data on sodium iodate and water, previous to the work of Foote and Vance,[2] were both discordant and misleading, because of confusion as to the degree of hydration of the saturating salt (seven hydrates having been mentioned by various authors[3]) and also doubtless because of difficulties, which we shall point out, in the attainment of equilibrium. The stable hydrates found by us are in agreement with the findings of Foote and Vance, namely, $NaIO_5 \cdot 5H_2O$ below 20°, $NaIO_3 \cdot H_2O$ between 20 and 70°, above which temperature the anhydrous salt is stable in contact with solution. In the matter of attainment of equilibrium we have found the various alkali and alkaline-earth iodates to be extremely slow, as will be pointed out in later publications relative to the magnesium and potassium salts; and where in addition the formation of a hydrate is involved, as in the case of the sodium salt, the quantitative change to that form is also slow, giving most annoying retardation in the attainment of both internal and external equilibrium. We have given some considerable study to this problem and are in possession of the facts even though no remedy has been found outside of an extremely lengthy

---

[3] See Mellor, "Comprehensive Treatise," Vol. II, p. 334.

agitation of the salt with water. The first very important finding is that if experiments are made with use of the anhydrous salt at any temperature at which a hydrate is the stable form, the equilibrium can be approached only from the side of supersaturation; samples treated with cold water and agitated at 25° showed a solubility of the order of 8.79% at the end of three hours, dropping slowly thereafter and remaining for many days above what we believe to be the true solubility for the hydrate. This behavior is undoubtedly owing to the higher solubility of the metastable anhydrous form, and to the fact that with samples of whatever amounts of solid phase were used, the process of solution was much more rapid than the process of hydration. In the endeavor to eliminate this source of error special experiments were conducted with the purpose of providing only pure hydrate as initial solid phase. It was found, however, that samples of supposed hydrate prepared by ordinary recrystallization in the neighborhood of 25° would regularly show the same phenomenon of forming supersaturated solutions, which may be again attributed to the presence of sufficient unhydrated salt to give the high results. It was only after a sample of the supposed hydrate had been agitated with new solvent three times and for a period of about two weeks at each treatment that it could be made to give results which could not be regarded as an approach from supersaturation. The elimination of this source of error, however, did not help with the second, which is the slow attainment of equilibrium. In only one instance have we been able to secure results, from true supersaturation and true undersaturation, which were within the limits of our analytical error, which for the determination of iodate by iodimetry we place at 0.2% as an extreme, and which probably is nearer 0.1%. The following results in Table I are typical.

TABLE I

$NaIO_3 + H_2O$ AT 25° (SOLID, $NaIO_3 + H_2O$)

Time	From undersaturation, %	From supersaturation, %	Difference in, %
3.5 hours	8.561	8.829	3.1
1 day	8 576	8.703	1.5
4 days	8.568	8.694	1.24
11 days	8.560	8.680	1.39
23 days	8.564	8 665	1.21

The two samples have remained more than 1% apart in solubility after twenty-three days, and show no marked trend after the fourth day. Similar results have been found in this Laboratory by Professor S. F. Brown and Mr. J. E. Ricci, in the course of investigations to be reported later. In one instance the solubility approached from supersaturation came down to 8.56% in thirty-five days; we therefore conclude that the figures from undersaturation, obtained after any briefer interval, are more nearly correct than those approached from supersaturation. We are quite unable to agree with Foote and Vance that equilibrium from both directions has been reached, within narrow limits, in four to six hours, and raise the question as to whether their agreement between results from undersaturation and supersaturation at this temperature (8.65 and 8.66%) and at other temperatures may not be due to the use of anhydrous salt and the consequent agreement of two samples both from supersaturation. As a practical experimental matter, however, we have used the anhydrous salt as our original solid (this being necessary for our calculations in the ternary system) and have allowed a time of rotation from one week to two weeks; there is no evidence that longer periods, within reasonable limits, would add materially to the accuracy.

The Binary System, Sodium Iodate–Water.—For this work recrystallized and dehydrated salt in generous amount was put in 40-cc. glass-stoppered pyrex test-tubes and rotated in a water thermostat, constant to within 0.05°, for periods of about two weeks. The results are therefore those obtained from supersaturation, and are given in Table II.

TABLE II

SOLUBILITY OF $NaIO_3$ IN WATER

Temp., °C.	Wt. % of $NaIO_3$	Density of solution	Solid phase
5	3.30	1.028	$NaIO_3 \cdot 5H_2O$
15	5.85	1.051	$NaIO_3 \cdot 5H_2O$
20	7.81	...	$NaIO_3 \cdot H_2O + NaIO_3 \cdot 5H_2O$
22	8.11	1.071	$NaIO_3 \cdot H_2O$
25	8.67	1.077	$NaIO_3 \cdot H_2O$
35	10.58	1.093	$NaIO_3 \cdot H_2O$
40	11.70	...	$NaIO_3 \cdot H_2O$
50	13.95	...	$NaIO_3 \cdot H_2O$

These solubility data agree with those of Foote and Vance within 0.01 to 0.03% up to 40°, leading us to believe that their experiments were also done with the anhydrous salt and therefore represent approach to equilibrium from supersaturation. The densities are approximate figures, obtained by weighing the solution delivered by a calibrated 5-cc. pipet. The intersection of the two solubility curves, shown in Fig. 1, is at 20° within the accuracy of our measurements; this also is in accord with Foote and Vance's figure of 20.3° obtained by careful calculation from the logarithmic curves for the solubility against the inverse of the absolute temperature; their results by the thermal and dilatometric methods are about 0.5° lower. The composition of the hydrate stable at room temperature was determined by analysis for water content after samples slowly formed by isothermal evaporation had been brought to constant weight over the anhydrous form as desiccating agent in miniature desiccators; it gave 8.31% H_2O, 8.34% being required by the formula $NaIO_3 \cdot H_2O$. Difficulties in maintaining desiccators at the lower temperatures for the pentahydrate were such that the crystallized salt was simply centrifuged well and analyzed directly.; samples gave from 32.17 to 32.52% water, where 31.28% is required by the formula $NaIO_3{\cdot}5H_2O$. We confirm the findings of Foote and Vance that these are the only stable hydrates found in the temperature range studied, and that Meerburg's[4] formula $NaIO_3{\cdot}{}^3/_2H_2O$ is not valid.

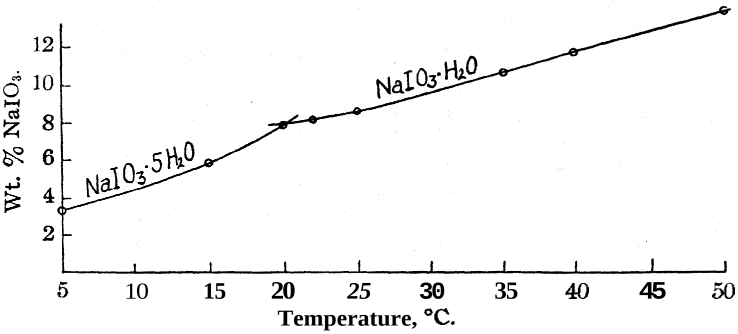

Fig. 1.—Solubility of sodium iodate in water.

The Ternary System.—For the study of the ternary system, good grades of sodium nitrate and sodium iodate were purified by crystallization. Weighed quantities of these salts were treated with weighed amounts of water in pyrex test-tubes and vigorously shaken by hand to prevent caking of the hydrate formed. The tubes were then slowly rotated in a water thermostat at the desired temperature for periods of about two weeks. After the tubes had been allowed to settle, samples were withdrawn into a calibrated pipet fitted with a small filter of absorbent cotton. One sample was weighed and evaporated in a platinum dish to constant weight at 110°, about twenty-four hours being required. From this the water content of the saturated solution became known. A second weighed sample was treated with potassium iodide and sulfuric acid and titrated with sodium thiosulfate solution, previously standardized against pure potassium iodate. The content of sodium iodate being thus established, the sodium nitrate was obtained by subtraction. The data at three temperatures are given in Table III, and plotted in Figs. 2, 3 and 4.

Since data were at hand both for the composition of the phase complex used and for the saturated solution, it was possible to extrapolate graphically or algebraically the line connecting these two points and thus determine approximately the composition of the solid phase, whenever it was a two-component body, by the intersection of this line with the side of the triangle. It was this procedure which first made clear to us, in the study of the 25° isotherm, that the solid phase is a monohydrate and not the more complex hydrate suggested by Meerburg. Following this method, two

points of interest were noted: first, that at 50° the anhydrous sodium iodate is solid phase in the solutions more highly concentrated with sodium nitrate, although the temperature is 20° below the transition temperature for that salt, as found by Foote and Vance; and, second, that at 5° a double salt exists, in contact with solutions of a restricted range of concentrations, as likewise reported by Foote and Vance for S°.

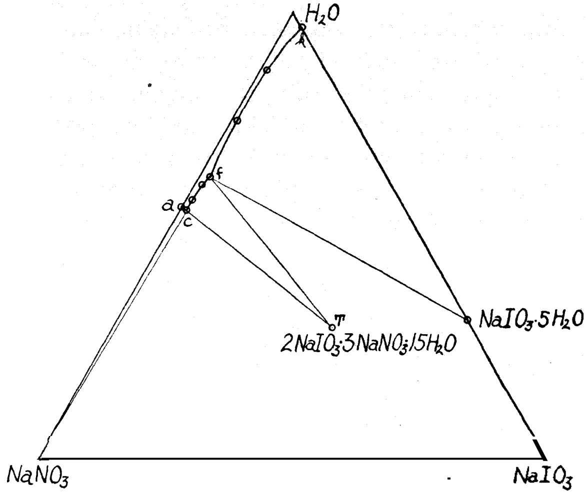

Fig. 2.—5° Isotherm: $NaIO_3$–$NaNO_3$–H_2O.

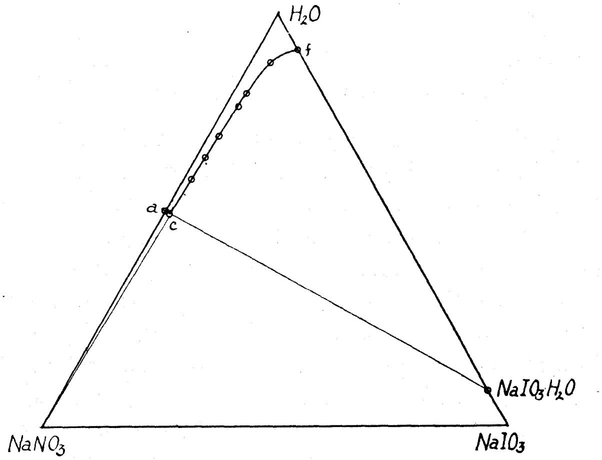

Fig. 3.—25° Isotherm: $NaIO_3$–$NaNO_3$–H_2O.

The Double Salt.—The double salt which appears in the 5° isotherm was prepared for analysis by making a complex of phases which fell within the triangle cTf of Fig. 2, bringing the solids completely into solution by warming, and then allowing the solution to cool quietly to 5° without the formation of solid phase, which was not difficult because of the marked slowness with which precipitation of the iodate (and presumably of the double salt) is known to occur. Upon agitating the tube in the thermostat, however, the first precipitation was of a flocculent character, and must have been either hydrated sodium iodate or an amorphous form of the double salt. After a few hours' stirring the precipitate changed to a well-crystallized product which settled quickly and completely. After four days of stirring the sample was removed, filtered and centrifuged in an environment not above 5°. The sample was then weighed at this temperature, put in a miniature desiccator over a second sample which had been allowed to lose about half its water, and placed in a refrigerator at 7° where it was held for forty days. The solution was also analyzed and found to represent a point on the curve cf. The matter of the analysis of an incongruently soluble ternary compound has been discussed at some length in another place;[5] the essential is that the amount of mother liquor present, which is here widely different in composition from the salt, must be known so that a correction may be applied for the salts deposited upon its drying up. In this case the amount of water of solution lost during the forty days of desiccation was 1.76% of the whole, the composition of the mother liquor 1.40% $NaIO_3$ and 57.74% $NaNO_3$. The sample was analyzed in the usual manner and the results corrected for the amount of mother liquor present; the data are given in Table IV.

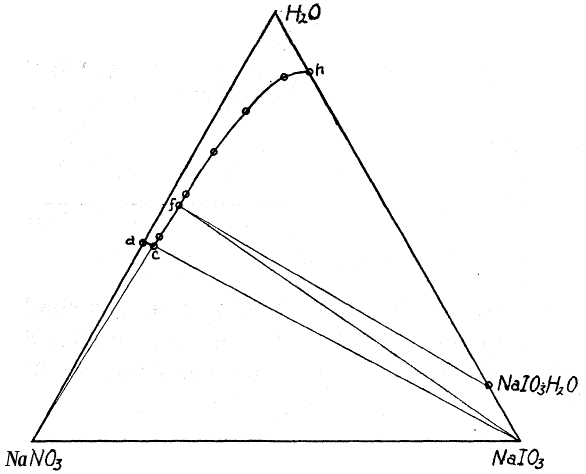

Fig. 4.—50° Isotherm: $NaIO_3$–$NaNO_3$–H_2O.

The result confirms the finding of Foote and Vance, with a somewhat better agreement between analysis and calculation.

TABLE IV

ANALYSIS OF TERNARY COMPOUND

	Uncorrected analysis, %	Corrected analysis, %	Calculated for $2NaIO_3 \cdot 3NaNO_3 \cdot 15H_2O$
$NaIO_3$	42.06	42.60	42.97
$NaNO_3$	28.91	28.00	27.69
H_2O	29.03	29.40	29.34

The upper temperature limit for the ternary compound is at about 9.6°, as found by thermal measurements—in sufficient agreement with Foote and Vance's figure 9.8°, accurate measurements not being possible because of the apparently slow formation of the compound. It is obvious that the existence of this compound will have an important influence upon the separation of sodium nitrate and sodium iodate at any temperature below this point.

Summary

1. Solubility measurements are given for sodium iodate in water between 5 and 50°, and for the three-component system consisting of sodium iodate, sodium nitrate and water at 5, 25 and 50°.
2. The stable hydrates of sodium iodate are the pentahydrate below 20°, and the monohydrate above that temperature to its transition to the anhydrous form.
3. Hydrated sodium iodate does not reach equilibrium with its solution, from both undersaturation and supersaturation, within twenty-six days or more.
4. In the ternary system below 9.8' there exists a double salt of the formula $2NaIO_3 \cdot 3NaNO_3 \cdot 15H_2O$.

TERNARY SYSTEMS. X. MAGNESIUM IODATE, MAGNESIUM NITRATE AND WATER[1]

BY ARTHUR E. HILL AND SAMUEL MOSKOWITZ

RECEIVED DECEMBER 19, 1930 PUBLISHED MARCH 6, 1931

For the work upon this ternary system, knowledge of the two binary systems of a single salt and water are necessary. Investigations of the solubility of magnesium nitrate in water have been conducted by Chodnew,[2] Lescoeur,[3] Ditte,[4] Ordway[5] and Funk;[6] the latter determined that only

two hydrates have stable existence, $Mg(NO_3)_2 \cdot 9H_2O$ from —29 to −18°, and $Mg(NO_3)_2 \cdot 6H_2O$ from −18° to its congruent melting point at 90°. We have not repeated this work. For magnesium iodate and water it was found that the work of Millon,[7] Ditte[8] and Mylius and Funk[9] should omissions, for which reason the work has been repeated.

Magnesium Iodate and Water.—Magnesium iodate was prepared according to the method of Millon,[7] by neutralizing an aqueous solution of iodic acid with magnesium carbonate and evaporating the slightly acidified solution at above 40–50° for four days, which gave a copious crystallization of the tetrahydrate. The crystals were washed with water, air dried, ground and placed in a desiccator; here there developed an outstanding peculiarity of the compound. The tetrahydrate loses only an inappreciable weight of water at room temperature over sulfuric acid or phosphorus pentoxide; a sample of 220 g. lost about 1 mg. per day over concentrated sulfuric acid, and a sample of 67 g. lost about 0.6 mg. per day over phosphorus pentoxide. Samples kept in an oven at 110° lost rapidly for a few days, but could not be brought to an anhydrous condition in a month, the residual water being about 0.5% for finely ground samples and considerably larger for coarse samples. Mylius and Funk report the tetrahydrate as stable at 80°. These results at room temperature and even at the higher temperature are most striking in view of the fact, later shown, that the hydrate has a transition temperature at about 57.5" and therefore has a vapor tension at that temperature equal to that of the saturated solution, which may be calculated by Raoult's law as approximately 128 mm Either the vapor tension curve for this hydrate is astonishingly steep, or the hydrate shows a remarkable degree of metastability with regard to dehydration; we are inclined to accept the latter view as the better interpretation. Samples which had been over the desiccating agent for several weeks were analyzed by titration and found to have the composition $Mg(IO_3)_2 \cdot 4H_2O$ within the errors of titration. This material was later used in the three-component work as of constant and known composition, since efforts to prepare the anhydrous compound by oven treatment had not been successful.

For the solubility determinations, excess salt was treated with distilled water in glass-stoppered pyrex tubes; for the lower temperatures the tubes were rotated in a water thermostat, constant to about 0 03°. For temperatures above 50° the tubes were inserted in an air thermostat and stirred by means of a brass paddle on a mechanical stirrer; a mercury seal served to minimize evaporation. Filtered samples were withdrawn by calibrated pipets at the lower temperatures and weighed to give approximate figures for density; at the higher temperatures the samples were forced through a tube into a weighing bottle by air pressure, crystallization being easily avoided because of the marked metastability. At the lower temperatures, one to three days of stirring were found to give equilibrium from undersaturation, while from supersaturation long periods were needed. Seeding with a crystal of decahydrate was resorted to below 13°. Where the change from the tetrahydrate to the anhydrous form occurs, four days of stirring were required at 80° and two days at 90°; at 70° the solid phase used was anhydrous salt, obtained at the higher temperatures, equilibrium being reached within one day. Analysis of the centrifuged solid phase obtained at 90° was in good agreement with the requirements for the anhydrous form. The results are given in Table I and shown in Fig. 1.

The solubility figures were obtained by titrating with standard thiosulfate the iodine freed by action of the samples upon potassium iodide

solution with sulfuric acid. In the fourth column of the above table, the abbreviation I_{10} is used for the decahydrate, I_4 for the tetrahydrate, I for the anhydrous form; (m) indicates that the solid phase was metastable, by interpretation of Fig. 1. The system is, therefore, found to show the following invariant points: a eutectic at —0.36' found by the usual thermal means, a transition of the decahydrate to the tetrahydrate at **13.3'** (by interpolation), and a transition of the tetrahydrate to the anhydrous form at 57.5'. Because of the great tendency toward metastability, confirmation of these transition points by thermal means was not possible. Whether or not the remarkable behavior of the tetrahydrate is connected with the possible poly-basicity of iodic acid and the constitution of the compound as an acid salt rather than a true hydrate would be mere speculation in the absence of other data.

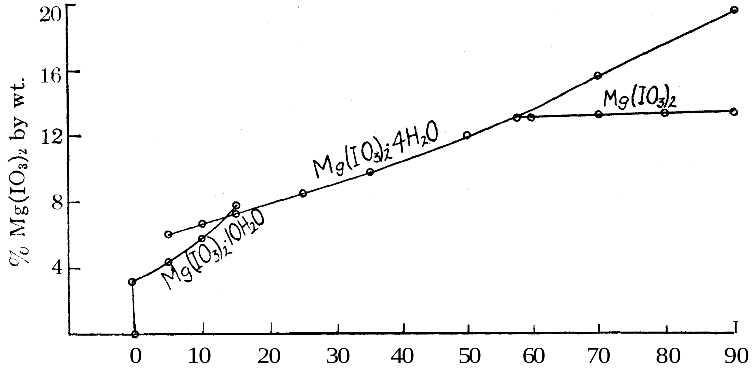

Fig. 1.—Solubility of magnesium iodate.

The Ternary System.—The phase complexes used in the study of the ternary system were made from weighed amounts of magnesium iodate tetrahydrate, water and an analyzed solution of purified magnesium nitrate nearly saturated at room temperature; the latter solution was used since it is impossible to dehydrate crystallized magnesium nitrate without hydrolytic decomposition. In a few instances it was necessary to use magnesium nitrate hexahydrate which had been partially dehydrated, in order to reduce the water content of the complex. The materials were agitated in the thermostat at the desired temperature for periods of one to three days. For the analysis of the ternary solutions, the method of iodimetry was used to give part of the necessary data, but evaporation to dryness for the water content was found impossible for the two reasons stated—incomplete dehydration of the iodate and hydrolysis of the nitrate. **A** determination of total magnesium was therefore necessary for the calculation of the composition of the solutions. Investigation of solutions

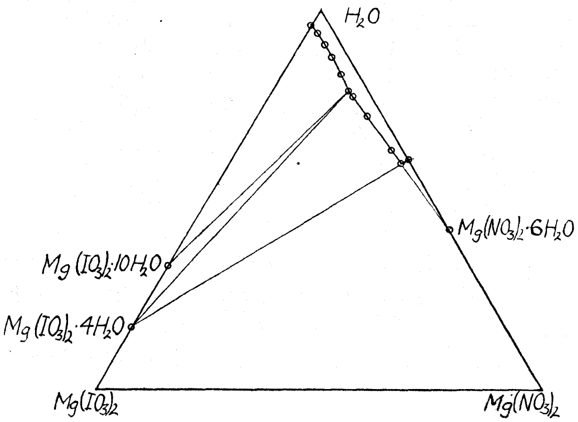

Fig. 2.—5° Isotherm: $Mg(IO_3)_2$–$Mg(NO_3)_2$–H_2O.

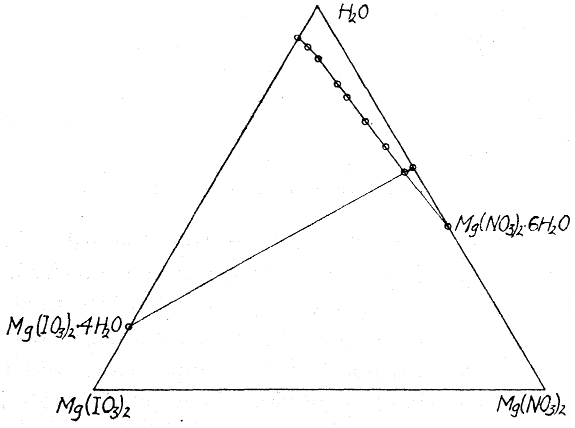

Fig. 3.—25° Isotherm: $Mg(IO_3)_2$–$Mg(NO_3)_2$–H_2O.

of known magnesium content showed that precipitation as magnesium ammonium phosphate and weighing either as the hexahydrate or by conversion to magnesium pyrophosphate gave distinctly high results; the same was true, though to a much less degree, of the values obtained by igniting the salts to form magnesium oxide. The method used, which gave results only 0.25% low with a known solution, consisted in evaporation on a steam-bath with excess sulfuric acid, finally raising the temperature over a burner to a dull red for a brief time, and weighing the residue as $MgSO_4$.

Table II gives the results obtained at 5, 25 and 50°. The curves are plotted in Figs. 2, **3** and 4.

N_6 represents $Mg(NO_3)_2 \cdot 6H_2O$

The solid phases at these three temperatures are determined beyond question by the extrapolation of the tie-lines from the composition of the saturated solution through the composition of the original complex used. At 5° there are found not only the hexahydrated magnesium nitrate and the decahydrated magnesium iodate, but also the tetrahydrated magnesium iodate in those solutions where the vapor tension has been greatly lowered by the highly soluble magnesium nitrate. At 25° only the two salts, each stable in water at this temperature, are found. At 50° the same condition prevails; were it not for the strange behavior of the magnesium iodate tetrahydrate already stated, one would be ready to predict that the anhydrous form should also appear, since the high concentration of magnesium nitrate obviously lowers the vapor tension greatly. The extrapolated tie-lines however point to the tetrahydrate as solid phase in every instance.

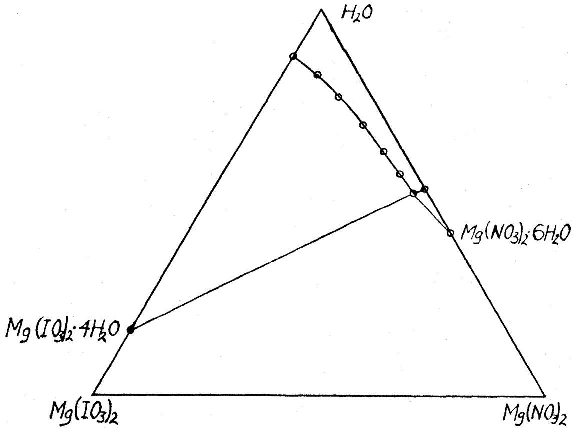

Fig. 4.—50° Isotherm: $Mg(IO_3)_2$–$Mg(NO_3)_2$–H_2O.

Summary

1. It is found that magnesium iodate and water give not only the decahydrate and tetrahydrate previously known, but also an anhydrous form stable in contact with water above 57.5°.

2. The solubility of magnesium iodate in water has been determined from −0.36°, the eutectic temperature, to +90°.

3. Ternary isotherms have been studied for magnesium iodate, magnesium nitrate and water at 5, 25 and 50°. No double compounds have been found.

LITHIUM CHLOROPLATINATE AND THE SEPARATION OF POTASSIUM FROM SODIUM AND LITHIUM BY THE UNMODIFIED ORIGINAL FRESENIUS METHOD

BY G. FREDERICK SMITH AND A. C. SHEAD[1]

RECEIVED DECEMBER 22, 1930 PUBLISHED MARCH 6, 1931

Introduction

The determination of potassium as potassium chloroplatinate is of sufficient historical interest to warrant a somewhat detailed reference to the literature of the subject as a theoretical background to the present paper. The original work of Fresenius on the separation and determination of potassium in presence of sodium and lithium by the chloroplatinic acid process consisted of two contributions.[2,3] Somewhat later there appeared an additional paper[4] by Fresenius consisting of a duplication of the former work. This confirmatory work was necessitated by the intervening revision of the atomic weight of platinum by Seubert[S] as will be explained later. Other important work dealing with Fresenius' process was contributed by Precht,[6] Dupré,[7] Morozewicz,[8] and Fresenius and Brinton.[9]

By the original Fresenius method,[2,3] of 1876–1877, potassium chloride was separated from sodium and lithium chlorides by converting the three chlorides to chloroplatinates, using an excess of chloroplatinic acid followed by the extraction of K_2PtCl_6 from the soluble sodium and lithium chloroplatinates using 80% ethyl alcohol. The value for the ratio $2KCl/K_2PtCl_6$ was found to be 0.3056. This value is the theoretical one based on the early atomic weight 197.18. In 1881 the Seubert[K] revision of the atomic weight of platinum established the value 194.46. Consequently, the German potash industry solicited Fresenius to reinvestigate his process, which was undertaken in 1882.[4] "As a result," Fresenius reported, "of all these determinations not the slightest doubt remains that for the calculation of the potassium chloride from the weight of potassium chloro-

platinate dried at 130°, no other value than 30.56 to 100 is permissible and if the Seubert ratio 0.3069 is employed high results necessarily follow." The inference derived from this statement was that the Seubert revision of the atomic weight of platinum should be confirmed. This was done by Halberstadt,[10] who substantially confirmed Seubert's value. The retention of the Fresenius value for the ratio $2KCl/K_2PtCl_6$ of 0.3056 therefore stamps the Fresenius method as empirical. Further studies of this method by Dupré[7] and Fresenius and Brinton[9] were attempts to clear up the difficulties involved. These failed to indicate methods eliminating the empiricism of the Fresenius method. The present value for the atomic weight of platinum, 195.23, was the result of the work of Archibald,[11] which gives for the theoretical factor 0.3067 as compared to the empirical factor 0.3056.

Variable Factors Influencing the Fresenius Method.—The basic facts accounting for the formation of impure precipitates of K_2PtCl_6 are summarized here. The chloroplatinic acid is often prepared under conditions giving the impurity $H(NO)PtCl_6$. This product results from the incomplete removal of the nitric acid used in the solution of platinum black with aqua regia. The complete removal of this nitric acid using hydrochloric acid results in the accumulation of the impurity $H_2Pt(OH)Cl_5$. Impurity in the precipitated K_2PtCl_6 results from the impure chloroplatinic acid as well as from the presence of water in the 80% alcohol, thus

$$K_2PtCl_6 + HOH = K_2PtOHCl_5 + HCl$$[12]

Absolute alcohol cannot be used to avoid the hydrolysis of K_2PtCl_6 for the reason that sodium chloride is thus formed from the Na_2PtCl_6 present:

$$Na_2PtCl_6 + \text{absolute alcohol} = 2NaCl + PtCl_4$$[13]

All these errors give rise to low results in the determination of the ratio $2KCl/K_2PtCl_6$. The effects of these errors are shown by the many methods for the analysis of K_2PtCl_6. For example, the platinum may be reduced to metal, separated by filtration from the soluble potassium chloride and weighed as such. The filtrate from the platinum determination may be evaporated to dryness and the potassium chloride determined. In this case hydrogen is used to precipitate the platinum. The chloride aside from that combined as potassium chloride can be determined by thermal decomposition with absorption of the hydrogen evolved and precipitation

[12] This reaction has led to the suggestion that K_2PtCl_6 should be separated in the presence of a small amount of hydrochloric acid.

[13] This fact was not recognized by Precht,[6] who proposed using absolute alcohol, but was corrected by Morozewicz.[8] The use of absolute ethyl alcohol is attractive for the reason that it diminishes the solubility of K_2PtCl_6 and is a better solvent for Na_2PtCl_6 and Li_2PtCl_6.

with silver. By the same method the total water can be determined. Water combined in the form $K_2PtOHCl_5$ is determined by ignition in an atmosphere of carbon monoxide followed by the determination of the carbon dioxide formed. Following these methods the exact determinations of the impurities in a precipitate of K_2PtCl_6 were studied by Dupré.[7] Since the dissertation by Dupré was not published in any other form, and since the material is almost inaccessible, a summary of this thesis is given.

Summary and Conclusions from the Work of Dupré

1. The determination of potassium in the form of chloride by the reduction of the platinum with hydrogen, followed by filtration and evaporation of the potassium chloride solution, gives accurate results after taking into account the solubility of K_2PtCl_6 in alcohol. This method of determining potassium chloride is independent of atomic weights, factors and variations in the conditions of the separation. The method is slow, involved and not adapted to routine application.

2. The separation and determination of potassium as K_2PtCl_6 from the direct weight of the precipitate gives good results if the factor for potassium chloride is 0.3056. Precision in the result thus obtained is the only justification for the use of this empirical factor.

3. Potassium chloroplatinate obtained using the Fresenius method does not have the exact composition K_2PtCl_6 but contains more platinum and less chlorine than indicated. The determination of its potassium chloride content is not correct if calculated from the determination of either the platinum or chlorine using either the Fresenius factor or the correct atomic weight for platinum.

4 Precipitates of K_2PtCl_6 obtained by the use of either sodium or lithium chloroplatinates to precipitate potassium chloride solutions, "evidently" likewise contain too much platinum and too little chlorine.

5. The methods for the analysis of K_2PtCl_6 depending upon the calculation of potassium chloride from the weight of platinum by hydrogen, sodium formate or metallic magnesium, all lead to incorrect results. The determination of chlorine using finely divided silver or following ignition at 500–550° using excess of sodium oxalate likewise gives erroneous results.

Lithium Chloroplatinate as Precipitant for Potassium Chloroplatinate.—The present work describes a process for the precipitation of potassium chloroplatinate in the presence of sodium in which the potassium chloride in the precipitate can be calculated from its weight or by determination of the platinum content. The purity of the K_2PtCl_6 thus precipitated is further proved by the fact that it is stable at 260°, whereas the salt precipitated using chloroplatinic acid decomposes at temperatures much above 160°. The preparation of lithium chloroplatinate is described. By this process there is obtained the theoretical factor for the ratios $2KCl/K_2PtCl_6$ and Pt/K_2PtCl_6.

At the time this work was begun the content of the dissertation by Dupré[7] was not familiar to the authors. As a result the process employing lithium chloroplatinate was thought to be original. A copy of the thesis was subsequently obtained and the errors in Dupré's work were studied. He stated that lithium chloroplatinate was unsatisfactory.

It should be pointed out that the present work does not indicate that the platinum process is the best for the separation of sodium and potassium. The separation of potassium from sodium and lithium using perchloric acid has been the subject of an extended series of researches by one of the present authors[14] and it has been shown that the use of perchloric acid for separations and determinations in the alkali group is superior to the platinum process in speed, accuracy and economy.

Experimental Part

Preparation and Purification of Materials

Lithium Carbonate.—An ordinary grade of lithium carbonate was suspended in a large volume of water in a flask and dissolved by conversion to the bicarbonate using a rapid stream of carbon dioxide during a period of several hours. The solution was filtered and the filtrate boiled to dissociate the lithium bicarbonate to the normal carbonate, which was precipitated, filtered and the mother liquor removed by centrifugal drainage. A portion of this product was dissolved and reprecipitated. The products thus obtained were used to prepare lithium chloroplatinate without further treatment. Both fractions were equally satisfactory.

Lithium Chloroplatinate.—Lithium carbonate was dissolved in either a slight excess or slight deficiency of reagent quality chloroplatinic acid, the solution filtered and the filtrate concentrated until upon cooling a slush of crystals and mother liquor was obtained. The crystals of hydrated lithium chloroplatinate ($Li_2PtCl_6 \cdot 6H_2O$) were filtered using a sintered glass filtering crucible and drained centrifugally in the same container. They were dissolved in water and recrystallized in the same way. In case the lithium carbonate had been dissolved in a small deficiency of chloroplatinic acid, a little more of the latter was added to the filtered solution before crystallization. The light yellow crystals of $Li_2PtCl_6 \cdot 6H_2O$ were found to be completely soluble in ethyl alcohol and were dried in a desiccator over anhydrone until ready for use. A yield of 65–70% of the total lithium chloroplatinate is easily obtained by this process. A second crop of 15% of the original quantity was then obtained.

Chloroplatinic Acid.—Crystals as purchased on the market.

Potassium Chloride.—This was from a stock of 100% KCl used in previous work, dried by fusion and proved to be pure by conversion to perchlorate by evaporation with a slight excess of pure perchloric acid. Occluded perchloric acid was removed by dissolving in hot water and evaporating to dryness. The crystals of potassium perchlorate now contained a small amount of occluded water which was removed by heating to constant weight at 350°. The final product gave no test for chloride. The purity of the potassium chloride was proved by the value obtained for the ratio $KCl/KClO_4$. The data are tabulated in Table I.

Alcohol.—Reagent alcohol was refluxed over lime and distilled, giving a 99.6% product.

Sodium Chloride.—From a stock of material comparable to the pure potassium chloride described above.

Procedure Followed in Determining the Conversion Factor $2KCl/K_2PtCl_6$.—Weighed samples of pure potassium chloride were dissolved in water in 150-cc. beakers and a small excess of a solution of lithium chloroplatinate in water added to convert the potassium chloride to chloroplatinate. The precipitated K_2PtCl_6 was dissolved by heating and the greater portion of the water evaporated until upon rapidly cooling the hot solution a finely divided precipitate was obtained. The beaker and moist contents were treated with 25 cc. of absolute alcohol and the K_2PtCl_6 filtered using platinum sponge filtering crucibles. The precipitates were washed by decantation with fresh portions of absolute alcohol and transferred to the filtering crucible. The precipitates were then washed in the crucible by the addition of 10–15 separate small portions of absolute alcohol followed by drying first at 130° for extended periods of time and finally at 260° during two and one-half hours. The results of five consecutive determinations are listed in Table II.

				Average	.3070		
				Calcd.	.30673		

The lithium chloroplatinate used for the conversion of KC1 to K_2PtCl_6 in Table II was made from lithium carbonate which had been twice precipitated from its bicarbonate solution by boiling. The $Li_2PtCl_6 \cdot 6H_2O$ was recrystallized once and dried in a desiccator over phosphorus pentoxide.

Two and one-half grams was dissolved in 25 cc. of water and sufficient of this solution added to give approximately a 20% excess.

The filtrate and washings from the five determinations in Table II varied from 40 to 47 cc. No correction was applied to the values obtained for the weight of K_2PtCl_6 left in the filtrate and washings. Such a correction if applied would result in an average correction to the potassium chloride found of 0.12 mg. Applying the correction would reduce the value found for the conversion factor $2KCl/K_2PtCl_6$ to practically the theoretical value.[15]

The precipitates of K_2PtCl_6 obtained in Table II were dissolved in the filtering crucibles using a minimum quantity of hot water and the filtrates caught in 125-cc. Erlenmeyer flasks for determination of their platinum content. The platinum sponge filtering crucibles were then dried and weighed. Their final weight was compared with the original weight, and a small correction applied for the insoluble impurities accumulated throughout the analyses. This correction averaged 0.25 mg. Failure to have applied this correction would have tended to make the results obtained agree more closely with the theoretical value.

To the K_2PtCl_6 from the experiments of Table II dissolved in water as above described, a little hydrochloric acid was added and the platinum reduced to metal by the use of hydrogen under slight pressure which was kept in contact with the solutions at a temperature of approximately 80° for a period of twelve hours or until the solutions were colorless. The platinum sponge thus obtained was filtered using the same filtering crucibles in which the K_2PtCl_6 had been filtered, washed with hot water, dried and ignited. The results of these analyses are included in Table III.

From examination of Table III it is found that practically the theoretical weight of platinum was obtained from the analysis of the K_2PtCl_6 shown in Table II. The slight error is found to be of the same direction and magni-

---

[15] A second series of results for the ratio $2KCl/K_2PtCl_6$ determined with a new preparation of Li_2PtCl_6 in which the K_2PtCl_6 was dried at 160–170° gave the following values for the factor: 0.30625, 0.30671, 0.30660, 0.30707, 0.30683; mean, 0.30668.

tude as that found in the case of the determination of the factor $2KCl/K_2PtCl_6$. The low values found in the case of the last two experiments of Table III are the only ones obtained in both Tables I and II which **do** not show the trend predicted.

The Stability toward Heat of Potassium Chloroplatinate Precipitated by Lithium Chloroplatinate.—The observation has been made repeatedly and was familiar to Fresenius and all subsequent investigators that the precipitate of K_2PtCl_6 obtained using chloroplatinic acid is not stable much above 130". This temperature was not thought to be sufficiently high to eliminate entirely occlusion of water and the temperature of 160" is sometimes recommended as it was by Dupré.[7] No statement was found which would indicate that precipitates of K_2PtCl_6 obtained following the Fresenius method can be heated at a temperature above 160° without decomposition. A temperature higher than this is never advised.

Potassium chloroplatinate when pure is known to be stable at 400°, as demonstrated by Noyes and Weber.[16] The K_2PtCl_6 used in their work had been prepared from chloroplatinic acid made from platinum black by electrolytic oxidation in the presence of hydrochloric acid as described by Weber.[16] It was thought appropriate, therefore, to determine the various ratios $2KCl/K_2PtCl_6$, Pt/K_2PtCl_6 and $4Cl/K_2PtCl_6$ using chloroplatinic acid from various sources, including acid prepared by the Noyes and Weber process. The data are reported in Table IV.

TABLE IV

VARIOUS CONVERSION FACTORS DETERMINED FOR K_2PtCl_6 USING H_2PtCl_6 FROM VARIOUS SOURCES

Source of chloroplatinic acid	Factor determined	Values obtained					Average	Calcd.	Error, %
Commercial	Pt/K_2PtCl_6	0.40117	0.40067	0.39928	0 40098	0.40083	0.40060	0.40157	−0.25
Commercial	$2KCl/K_2PtCl_6$	.30495	.30540	.30525	.30554	.30613	.30546	.30673	−0.38
B.S. elec. oxid.	$2KCl/K_2PtCl_6$	.30346	.30465	.30440	.30347	.30407	.30401	.30673	−0.89
Recovered Pt + HNO_3 + HCl	$2KCl/K_2PtCl_6$	.30366	.30321	.30283	.30386	.30269	.30342	.30673	−1.08
	$4Cl/K_2PtCl_6$	.28444	.28936	.29074	.28980	.28966	.28980	.29174	−0.63
	Pt/K_2PtCl_6	.39766	.39901	.39606	.39850	.39753	.39775	.40157	−0.95

The determinations of the various ratios of Table IV followed the procedure given for the determinations using lithium chloroplatinate as precipitant. The results in the first two horizontal rows were obtained using 99.6% ethyl alcohol. The remaining results were obtained using 80% alcohol with a solubility correction applied on the basis of one part of K_2PtCl_6 dissolved in 26,400 parts of alcohol, the corrections calculated averaging 1.5 mg. The last sample of chloroplatinic acid in Table IV

---

[16] Noyes *and Weber, Bull. Bureau Standards, 4,345 (1908)*; Weber, THIS JOURNAL, 30. 29 (1908).

was prepared from scrap platinum dissolved in aqua regia and later precipitated as platinum black and again dissolved in aqua regia followed by the removal of the nitric acid by evaporation with hydrochloric acid. It had been made and used in connection with previous work by others published from these laboratories.

It will be noted by examining Table IV that the values obtained using chloroplatinic acid purchased in the usual manner from a reagent supply company gave values for the determination of the Fresenius factor $2KCl/K_2PtCl_6$ which duplicated the value 0.3056 as given by Fresenius. The chloroplatinic acid made from scrap platinum showed the poorest quality and the three factors obtained leave no doubt that the K_2PtCl_6 precipitated using this acid was impure. The errors found were all in the predicted direction, namely, too little platinum and chlorine and a molecular weight of K_2PtCl_6 less than the theoretical.

A point of particular interest lies in the fact that the Fresenius method calls for the use of 80–85% alcohol for reasons cited above, whereas in the absence of sodium, absolute alcohol may be used, thus avoiding a correction due to the solubility of K_2PtCl_6. The correct Fresenius factor was obtained using 99.6% alcohol in the case of the first sample of $H_2PtCl_6\cdot 6H_2O$ of Table IV.

The Separation of K_2PtCl_6 from Na_2PtCl_6 Using Li_2PtCl_6 as Precipitant

In the practical separation of potassium and sodium using lithium chloroplatinate as precipitant two modifications of the procedure previously employed had to be applied. One consisted in using 80% ethyl alcohol in place of 99.6% strength. The reaction $Na_2PtCl_6 = NaCl + PtCl_4$ is known to occur[7] in the latter case. The sodium chloride formed is insoluble. The second modification consisted in restricting the filtrate from the K_2PtCl_6 in order to avoid the necessary correction for its solubility in 80% alcohol. This correction is undesirable since a variable excess of chloroplatinate ion makes the magnitude of this correction uncertain.

The use of the filtrate from the K_2PtCl_6 to transfer the precipitate to the filtering crucible made it possible to limit the filtrate and washings to a volume of 15 cc. That a complete transfer of the precipitate was obtained was shown by washing the beaker with distilled water which, after concentration to a small volume, was colorless. Using lithium chloroplatinate prepared as previously described, 80% alcohol as solvent and weighed quantities of potassium and sodium chloride, a series of separations was carried out using the theoretical factor $2KCl/K_2PtCl_6 = 0.3067$. The theoretical factor was obtained from the data. The K_2PtCl_6 precipitates were dried for an hour at 185° and finally for an hour at 200°. No decomposition resulted, as was proved by their complete solubility in hot water. Results are found in Table V.

TABLE V

			Mean[a]	− .00015	.3064	− .11

[a] Excluding the value for the first entry.

Reference to Table V shows that the theoretical factor for the ratio $2KCl/K_2PtCl_6$, namely, 0.3067, is obtained with an error of −0.1%. This theoretical factor was obtained using the detailed directions of the original Fresenius method with the one alteration, the substitution of lithium chloroplatinate for chloroplatinic acid. To include the value for the first determination of Table V would bring the mean value for the conversion factor closer to the theoretical.

Discussion of Results

In accord with the results obtained by all previous investigators the original Fresenius method using chloroplatinic acid, is found to be empirical. Using chloroplatinic acid purchased from a standard supply house, the Fresenius factor 0.3056 was obtained as compared to the theoretical 0.3067 Chloroplatinic acid from other sources or prepared from platinum residues may be less satisfactory.

The substitution of lithium chloroplatinate for chloroplatinic acid makes possible the use of the theoretical factor. The use of the lithium salt obviously does not permit determination of lithium in the presence of sodium and potassium It introduces lithium chloride into the filtrate from the potassium determination, which complicates the separation and direct determination of sodium. Several methods, however, are available for the separation of sodium from lithium.[14] The direct determination of sodium in the filtrate from the K_2PtCl_6 precipitation is seldom made, which minimizes this objection.

Lithium chloroplatinate to be used in the separation of potassium from sodium should be prepared from lithium carbonate purified by two precipitations from lithium bicarbonate and subsequent conversion to the normal carbonate, which is insoluble in water. An excess of lithium carbonate should be used in its conversion to lithium chloroplatinate using reagent quality of chloroplatinic acid.

The lithium chloroplatinate is twice recrystallized. One recrystallization improves the results but does not correct completely the errors resulting in low values for the'ratio $2KCl/K_2PtCl_6$.

It is of interest to compare the advantages afforded by the use of the chloroplatinate method for alkali metal separations with the disadvantages.

Advantages.—1. The insolubility of K_2PtCl_6 in 80% alcohol. One part of K_2PtCl_6 is dissolved by 26,400 parts of the alcohol

2. The low conversion factors $2KCl/K_2PtCl_6 = 0.3056$ (The Fresenius factor) or 0.3067 (Theoretical) and $K_2O/K_2PtCl_6 = 0.1906$.

3. The chloroplatinate process is a semi-extraction operation since the mixture of alkali chloroplatinates is taken up with alcohol from a concentrated solution in water. Occlusion of sodium and lithium chloroplatinates in the K_2PtCl_6 is therefore practically eliminated.

Disadvantages.—1. The cost of recovery of platinum. Aside from the cost of platinum and the interest on the value invested, the recovery is costly in time and attention.

2. The factor $H_2PtCl_6/2KCl$ is high, greater than 3.5. This value is greatly increased for the reason given in **3.**

3. The necessity for the conversion of NaCl to Na_2PtCl_6. The failure to complete this conversion results in the precipitated K_2PtCl_6 being contaminated by NaCl.

4. The direct determination of sodium in the filtrate from the potassium must follow the separation of platinum from the solution.

5. The method is empirical if H_2PtCl_6 is used.

6. Using H_2PtCl_6, the K_2PtCl_6 must be dried at 130°. Occluded moisture is not expelled completely at this temperature.

The low conversion factor in the original Fresenius method is due to the errors resulting from several sources. Reduction of platinum in H_2PtCl_6 is known to occur in warm alcohol solution. It was shown by Dupré[7] that precipitation of K_2PtCl_6 using a cold alcoholic solution of H_2PtCl_6 gave high results, indicating a low conversion factor $2KCl/K_2PtCl_6$. Presumably the addition of alcohol to the slightly acid solution that results from the precipitation of aqueous potassium chloride by aqueous H_2PtCl_6 also results in the reduction of platinum with the same effect. It is at least noteworthy that the use of lithium chloroplatinate for chloroplatinic acid avoids the formation of hydrochloric acid through precipitation of K_2PtCl_6. The hydrolysis of chloroplatinic acid to form such a product as $H_2PtOHCl_5$ would result in a high value for the ratio $2KCl/K_2PtCl_6$. Nitrosochloroplatinic acid, $H(NO)PtCl_6$, if present in the H_2PtCl_6, would have the opposite effect. The use of lithium chloroplatinate corrects these errors, as previously shown.

Summary

1. The preparation of lithium chloroplatinate suitable for a reagent in the precipitation of potassium has been described.

2. Potassium chloroplatinate of the theoretical composition is precipitated if lithium chloroplatinate is used in place of chloroplatinic acid, with 80% ethyl alcohol as solvent.

3. Precipitates of potassium chloroplatinate formed by the lithium salt are stable at 200–260°, whereas those obtained by the usual process are unstable at temperatures above 160°.

4. A critical discussion has been given of the errors involved in the old process and an explanation offered for the better results obtained by the new procedure.

THE DIELECTRIC CONSTANT OF WATER AS DETERMINED BY A RESONANCE METHOD

BY E. P. LINTON[1] AND O. MAASS

RECEIVED DECEMBER 31, 1930 PUBLISHED MARCH 6, 1931

The object of this paper is not so much the determination of the dielectric constant of water, as an investigation of the adequacy for this purpose of the resonance method when employed in the manner previously described.[2] Certain criticisms have been put forward with regard to this method, the principal one being that when a measurable amount of conductivity can be assigned to the dielectric under investigation, the dielectric constant value obtained is irrelevant. It will be shown in this paper that criticism of the value found for the dielectric constant of water was justified, but that the error involved was due to a cause other than the conductivity of the water and that the method can be used for the measurement of the dielectric constant of water provided its conductivity is below a certain specified value.

It was suspected that any influence of conductivity was to be found in the absorption of the electric oscillations, with consequent distortion of the point of resonance. The set-up previously described was therefore altered to include a radiotron tube of greater power and measurements were made with dielectrics whose conductivity could be varied to a known extent by the addition of a small amount of electrolyte. Apart from this a method was devised for calibrating the tuning condenser. The effect of using the harmonic instead of the fundamental for the point of resonance

[1] Acknowledgment is hereby made of a studentship granted to one of us by the Research Council of Canada.

[2] Cuthbertson and Maass, THIS JOURNAL, 52, 483 (1930).

was also examined. For the determination of the absolute value of the dielectric constant of water a series of intermediate liquids was employed such that for each variation in the number of plates in the dielectric cell three liquids could be used so as to give a double check on the values obtained in each stage.

Changes in Set-Up.—The apparatus and dielectric cell used have been described in detail.[2] As source of oscillations the only important change made was to make it possible to replace the UX171A radiotron tube at will by a UX210 radiotron power tube giving at least ten times the wattage rating and using 368 volts on the plate. In order to keep a constant filament current three 6-volt accumulators in parallel were employed. It was necessary to change both honeycomb and choke coils so as to carry the increased plate current, which could be varied from 15 to 75 milliamperes. Both the variable and fixed oscillators were shielded and care was taken to have a constant temperature environment during the course of related observations, which were all carried out at 25°.

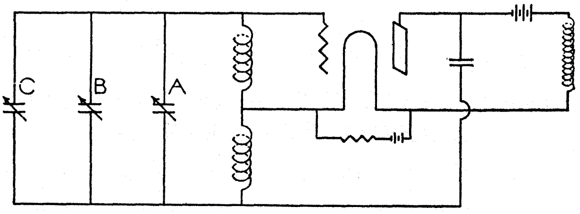

Fig. 1.—Set-up for calibrating tuning condenser **A**.

Calibration of Condenser.—The following procedure is worth describing as a useful method for calibrating the tuning condenser, not as far as its total capacity is concerned (which is of no interest), but in terms of its relative settings along the scale. In Fig. 1, which is similar to the variable oscillator previously described, **A** is the tuning condenser with a mirror mounted at the center of the dial so that scale readings could be read by reflected light on a circular scale four feet in diameter. The vernier control was manipulated by a pulley with 2 cord belt leading to a wheel placed at such a distance that its manipulation could be carried out without bringing in body capacity effects.

C connected in parallel is a variable condenser with the capacity arranged to correspond to a change of about 50 scale divisions on the tuning condenser between two fixed points of C. B also in parallel is a variable condenser with about the same capacity as the tuning condenser. The two fixed points of condenser C correspond to a capacity unaltered by any change in the set-up. By altering B, various parts of the scale readings of the tuning condenser could be calibrated in terms of this arbitrary but reproducible variation in the capacity of condenser *C*. **As** an analogy to this procedure one need only think of the calibration of a capillary tube by measuring the length of a mercury column as it is moved along the tube.

The tuning condenser was found to vary by several per cent. for different parts of the scale, but this variation was found to be perfectly reproducible and could therefore be corrected for in the subsequent measurements which were made. Table I gives a set of readings that were made to show the nature of the variations found.

Initial position on scale	7.0	21.0	36.4	54.5	71.6	93.6	114.2	134.8	159.0	175.9
Scale interval	50.7	51.1	51.4	51.8	52.0	52.1	52.2	52.3	52.2	52.1

With reference to the measurements previously reported which had been made with this same tuning condenser[2] it may be stated that, where a pair of liquids were compared over exactly the same range, the calibration is of course superfluous. Since, however, with two liquids that differ widely in dielectric constant the same range of scale may not be covered, an error may have crept in. Another advantage of the calibration was made evident by the fact that with the corrected scale readings all irregularity in the tuning condenser disappeared and since the dielectric cell condenser was also found to vary in a linear manner, the points obtained fall far better on a straight line.

Dead Space Correction.—As was to be expected, the interchange of the UX171A radiotron tube with the power tube showed no difference in the relative slopes of the curves obtained when two non-conducting media were compared in the dielectric cell. Also, the ratio of the slopes obtained for nitrobenzene and conductivity water when measured first with a 171A tube and then with the power tube agreed within the error of the measurements.

Another source of error which was suspected in the previous measurements was that in using the fundamental for the resonance point a large scale interval exists between the "no-sound" point when approached from the right or the left. If this scale interval has no variation for different settings of the dielectric cell no error may result. When the harmonic is used, which is more readily discerned with the aid of a power tube, this scale interval is reduced to an insignificant amount. In the following table data are given showing the scale readings for the fundamental when approached from the right and when approached from the left, and in the third column the scale readings given when the harmonic was used.

Table II

Scale Readings Giving Slopes

Dielectric cell	Right fundamental	Left fundamental	Harmonic
20	58.9	65 5	27.5
30	89.9	95 3	57.7
40	120.3	125 6	88.2
50	151 4	155 4	118 8
60	182 5	185 8	149 2
70	212.0	214 7	178 5
Slope =	153.1	149 1	151.0

Average, 151.1

It is evident that the "no-sound" scale interval ("dead space") varies with the setting of the dielectric cell. This is indicated by the values for the slopes of the lines given at the foot of each column. It will be observed that the mean of the slopes given by the left and right fundamental "no-sound" points is the same as that of the harmonic in which there is not what may conveniently be termed "dead space." The conclusion is that where the fundamental is used and a large "dead space" exists, the average of the right and left scale readings must be taken to plot the slope. Better still the harmonic should be used when with the aid of the power tube this can be discerned. With liquids having a small dielectric constant the fundamental gives right and left "no-sound" points which are close together and which do not vary appreciably in "dead space" intervals. This had been observed, and the mistake made in the previous results was in assuming that the same would hold for liquids of high dielectric constant.

Conductivity of Medium.—If the conductivity of the medium when at all appreciable distorts the resonance point, then the resonance method is open to unanswerable criticism. To investigate this point a series of experiments was carried out both with a medium having a small dielectric constant (ether) and one having a high one (water) in each of which variation of the conductivity of the medium could be obtained by the addition of electrolytes. In the case of water actual conductivities were measured and corresponding "slopes" determined. In the case of ether carefully purified hydrogen chloride gas was added in known amounts and the slopes of the resulting solution measured. Furthermore, in the case of water the effect of altering the power of the oscillating set and its influence on the slopes of various solutions was examined.

In Table III are given the normalities of hydrogen chloride–ether solutions and the corresponding apparent dielectric constants calculated on the basis of 4.255 for pure ether. The results are plotted in Fig. 2.

TABLE III

RELATION BETWEEN CONDUCTIVITY AND DIELECTRIC CONSTANT FOR ETHER

Normality	Slope	E	Normality	Slope	E
0	56.7	4.255	0.090	59.5	4.47
0.0061	56.7	4.255	.121	60.8	4.57
.013	56.6	4.244	.223	65.6	4.93
.024	56.7	4.255	.314	71.1	5.34
.038	57.3	4.30	.388	101.9	7.65
.052	58.0	4.35			

Conductivities of the ether solution have not been measured, but are roughly proportional to the hydrogen chloride concentration. It will be seen that the true dielectric constant of ether is approached in an asymtotic way with decreased conductivity. It may be safely assumed that provided the conductivity is below a certain value further decrease in conductivity does not measurably alter the value obtained by the resonance method.

The above was still more thoroughly investigated in the case of water. Table IV gives the values of the apparent dielectric constants of the water solutions as calculated from the slopes and based on a value of **79.20** for pure water. Column **A** of the table gives the results obtained with the UX171A tube; column **B** the values obtained with the power tube using a current of 20 m. a ; column C the values obtained with the power tube using 60 m. *a.*

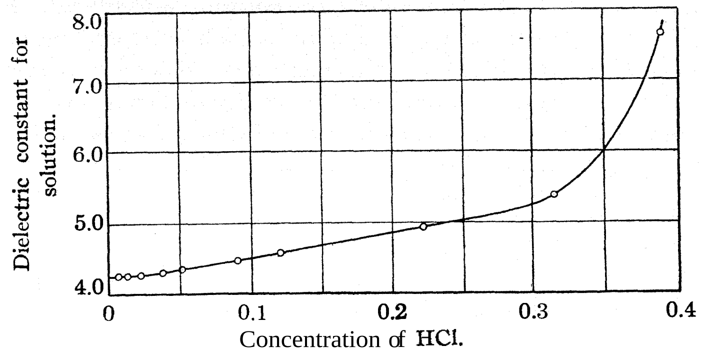

Fig. 2.

TABLE IV

EFFECT OF CONDUCTIVITY ON DIELECTRIC CONSTANT OF WATER AT 25°

	Dielectric constant		
Conductivity mhos 10^6	*A* 171A tube	B UX210 tube 20 milliamp.	C UX210 tube 60 milliamp.
1.31	79.1		
3.3	79.0		
4.0	79.2	79.2	79.2
5.0	80.7		
5.6		80.5	80.5
6.6	82.9	81.8	81.4
7.5	84.5		
8.1		83.5	82.4
9.9	95.5		
12.0	101.8		
13.0		88.2	86.6
24.0		99.8	96.7
34.0		144.0	136.8
44.0			182.0

The results can best *be* correlated by means of Fig. **3,** in which curves are lettered to correspond with the letter of the column in Table IV. It will be noted that in all cases the dielectric constant of conductivity water is approached asymptotically and that below a conductivity of 4×10^{-6} no difference in values is obtained; with increase in conductivity the values obtained alter with conductivity increasing rapidly in magnitude beyond a certain point. The effect of increased power in the oscillator flattens out the curve, decreasing the influence of the conductivity of the medium. It would appear from the nature of the above curves that as long as the conductivity is below a certain value, depending on the power used, a true value of the dielectric constant is obtained. Furthermore, this is not a question of extrapolation such as would be necessary were the curve a straight line. The fact that the curve is apparently asymptotic to the value obtained for the medium when a non-conductor, greatly enhances the validity of making use of the resonance method.

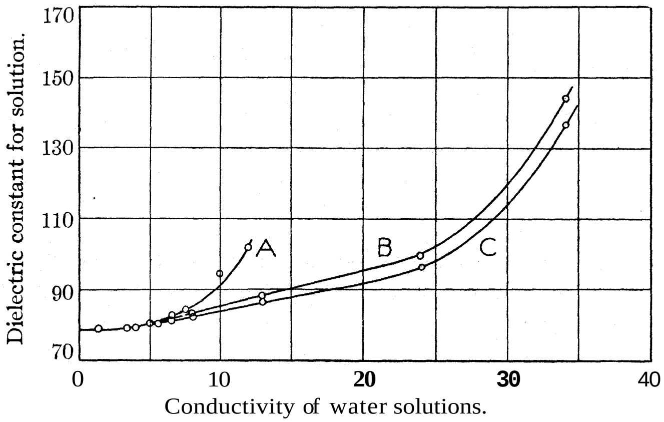

Fig. 3.

The emphasis brought about by recapitulation is perhaps warranted. It is true that the dielectric constant of water calculated from the slopes gives too high a value when the water conducts but the same limiting value is reached (independent of the power) when the conductivity is below 4×10^{-6}. It might be argued that since the purest water obtainable is still a conductor, this affects the value for the dielectric constant. In answer to this the experiments with ether show that with decreased conductivity the value obtained corresponds with that for pure ether, which is presumably a non-conductor. This value for ether, also, is in agreement with that found by other investigators.

Redetermination of the Dielectric Constant of Water.—The conclusion drawn from the above experiments is that the resonance method as described previously is not open to unanswerable objections. On the other hand, errors in the tuning condenser and dead space corrections would make it appear that the previous results referred to[2] need revision. Taking the necessary precaution in this connection the dielectric constant of water was redetermined by making use of benzene, ether, ethylene dichloride and nitrobenzene. The dielectric cell has been described in detail before.[2] This time for each set of stator and rotor' plates three media were used when possible as a counter check, and two series of investigations were made in each of which the dielectric cell was completely rebuilt.

TABLE V

DIELECTRIC CONSTANTS AT 25° OBTAINED IN VARIOUS SERIES FOR DIFFERENT CONDENSERS. EACH SET OF VALUES FOR A REBUILT CONDENSER

	17-Plate condensers	
Air	1.00	1.00
Benzene	2.273	2.270
Ether	4.250	4.258
Benzene average		2.271
	7-Plate condensers	
Benzene	2.271	2.271
Ether	4.255	4.250
Ethylene dichloride	10.38	10.34
Average of all ether values		4.255
	3-Plate condensers	
Ether	4.255	4.255
Ethylene dichloride	10.43	10.40
Nitrobenzene	35.30	35.20
Average of all ethylene dichloride values		10.38
	3-Plate condensers (with twice distance between plates)	
Ethylene dichloride	10.38	10.38
Nitrobenzene	35.1	35.2
Average of all nitrobenzene values		35 20
	3-Plate condensers (smallest capacity)	
Nitrobenzene	35.20	35.2
Water	79.40	78.9
Average for water		79.2

In the table the first substance in each set is taken as standard, the value having been derived from the previous set. Values could be repeated with the accuracy indicated for each condenser set-up. With condensers having a large capacity greater uniformity could be obtained. The three-plate condenser of smallest capacity introduced the greatest error and two extremes are given for the water–nitrobenzene pair. In Table VI the values found for the various substances are tabulated. Each had been carefully purified.

TABLE VI

DIELECTRIC CONSTANTS, T 25°

Liquid.............	Benzene	Ether	Ethylene dichloride	Nitrobenzene	Water
Dielectric constant...	2.271	4.255	10.38	35.20	79.2

Discussion of Results

If the value for water is calculated in different ways by using various pairs of liquids, the greatest divergence is about one per cent. Without again recapitulating the reasons that have been put forward in the first part of the paper, the authors are of the opinion that the resonance method as described can be used to give consistent results for the dielectric constant of a liquid such as water. The setting of the dielectric cell used involved a probable error of one-tenth to one-third of one per cent.; consequently in a series of stages (four in the case of water) the cumulative error may amount to 1%. Either a large number of observations will have to be taken or the dielectric cell improved. The authors are planning to investigate a cell of new design and redetermine the dielectric constant of water and also its temperature coefficient. In view of the results obtained the recalculated value for the dielectric constant of pure hydrogen peroxide at 0° is 93.5. By extrapolation of the dielectric constants of solutions of hydrogen peroxide in ether this value has been confirmed to within 0.5%.

Summary

The resonance method for the measurement of dielectric constants as described by Cuthbertson and Maass has been reinvestigated. A method for calibrating condensers, which vary in a linear manner according to their setting, is described. The effect of the power of the oscillating circuit has been examined and the precautions necessary in dealing with media of high dielectric constants specified, With a high power tube the harmonic is advocated as being better for the determination of the resonance point than the fundamental. The effect of the conductivity of the medium on the resonance point was shown to be negligible provided the conductivity was below 4×10^{-6} (in the case of water). Taking into account the necessary precautions the dielectric constant of water was found to be 79.2 at 25° by a step by step method based on 1.00 for air.

THE PRESSURE-VOLUME-TEMPERATURE VALUES FOR AMMONIA TO ONE THOUSAND ATMOSPHERES FROM 30 TO 200°

BY FREDERICK G. KEYES

RECEIVED JANUARY 3, 1931 PUBLISHED MARCH 6, 1931

The results herewith reported have been obtained from measurements carried out with the assistance of Mr. Robert B. Brownlee in 1913. It has been my intention to repeat the work using the improved apparatus which has resulted from a continuation of the program of measuring physical properties but a reexamination of the old results indicates that they are quite consistent enough to be of practical use. Moreover, it will be some time before new measurements can be made for liquid ammonia. The results are believed to be accurate with a maximum error of one-fourth per cent. The relative precision is much greater.

Apparatus Used.—The method and apparatus have already been described.[1] The pressures were obtained by using a piston gage of the type developed in this Laboratory.[2] The constant of the gage determined in 1911 before the present measurements were made was 4.1351[3] international mm of mercury per gram of weight on the piston. Bridgeman[4] has recently redetermined the constant of the same piston and found 4.1346 mm. using the value 26144.7 mm. for the vapor pressure of carbon dioxide at 0°.

Temperatures were determined by the use of the platinum resistance thermometer. The quality of the platinum available at the time of the measurements was inferior to that now in use in this Laboratory but the temperatures can only differ appreciably from the present scale[5] above 100°. In any case the temperature at 200° probably does not differ from the present scale by more than 0.05.

The volumes of the fluid under pressure are difficult to measure with the same precision as the pressures or the temperatures. Ordinary mild steel was used for the container and data for the elastic constants as a function of temperature were at the time not known. The temperature expansion

[5] The scale in use at this Laboratory at present is that based on the use of 0.1-mm. platinum wire with a mean temperature coefficient between 0 and 100° of 0.0039 or greater. The Callendar formula is employed using a δ value determined from the resistances at the ice, and boiling points of water and sulfur The normal boiling point of the latter is assumed to be 444.6°.

Conversion factors are as follows: (cu. ft./lb.)/(cc./g.), 0.016018; (lb./sq. ft.)/atm., 2116.2; Amagat units/(cc./g.), 0.0007715; (lb./sq. ft.)/atm. × (cu. ft./lb.)/(cc./g.), 33.9. The atmosphere is defined as the pressure per sq. cm. due to a column of mercury 76 cm. long at zero and *g*, 980.665, (the density of mercury being taken as 13.5951 g./cc.).

was likewise but inaccurately known (±3%). Means for determining the temperature dilation of the steel sample were not available. In computing the volumes given in the following tables the best available data have been employed. Nevertheless it is believed that the maximum error had best be assumed to be within one-fourth per cent.

Summary of Experimental Results

Rather than present the experimental results as obtained, it was decided to correlate the experimental data by means of graphs. A total of 191 volume and pressure measurements were available at 17 temperatures. The data were plotted to a large scale using pressure-volume products and volumes as coordinates. Table I gives the *pv* values at the actual temperatures observed for volumes from 1.50 cc./g. to 6 cc./g. In Table II, a table is given for even pressures from 100 international atmospheres to 1100 atmospheres and for each ten degrees of temperature to 200°. All numbers in brackets represent extrapolated values of the corresponding *pv* products.

THE ATOMIC WEIGHT OF IODINE. THE ANALYSIS OF IODINE PENTOXIDE

BY GREGORY PAUL BAXTER AND ALBERT QUIGG BUTLER

RECEIVED JANUARY 6, 1931 PUBLISHED MARCH 6, 1931

Introduction and Summary

In an earlier investigation by Baxter and Tilley[1] the ratio of silver to iodine pentoxide was found to be 0.646225, whereas on the basis of the more probable values of the atomic weights of silver and iodine,[2] 107.880 and 126.932, the ratio should be 0.646251. This puzzling discrepancy is in small part explained by the recent discovery in. this Laboratory by Mr. A. C. Titus[3] that the very porous iodine pentoxide, made by a process of double efflorescence from iodic acid, possesses the property of adsorbing air to the extent of 0.001%. The experimental ratio of silver to iodine pentoxide is thus raised to 0.646231, leaving a discrepancy between this value and that to be expected of 0.003%.

In **the** hope of discovering the cause of the discrepancy, and at the same time of obtaining a direct determination of the ratio of the atomic weights of iodine and oxygen, we have completed a series of analyses of iodine pentoxide by simple decomposition and weighing the iodine. This has already been done by Guichard,[4] but the results of his experiments were less concordant than could be desired and were subject to an uncertain correction for moisture retained by the iodine pentoxide.[5] The outcome of our work was unexpected, for we have found the ratio of iodine to iodine pentoxide to be almost 0.005% smaller than that corresponding to the modern value for the atomic weight of iodine, 126.932. Thus both this investigation and that on the ratio of silver to iodine pentoxide indicate that iodine pentoxide produced by dehydration of iodic acid contains less iodine (and more oxygen) than corresponds to the theoretical formula; for aside from the fact that the modern value for the atomic weight of iodine rests on several well-established ratios to silver and the other halogens, in order to reconcile the experimental values of the ratios of silver and iodine to iodine pentoxide with the theoretical values would necessitate an ***increase*** in the atomic weight of iodine of 0.005 unit in the former case and a ***decrease*** of 0.03 unit in the latter.

The Preparation **of** Iodine Pentoxide.—No pains were spared in the

purification of this substance, and advantage was taken of much experience in this Laboratory in the purification of iodine and iodic acid.

Three kilograms of commercial iodine were distilled in portions from solution in concentrated aqueous potassium iodide. In this way the greater portion of chlorine and bromine were removed. A portion of the product was converted to potassium iodate by boiling with alkaline permanganate, and the iodate was converted to iodide at an elevated temperature. The remainder of the iodine was again distilled in portions from a concentrated solution of this potassium iodide. Thus the purification effected in the first distillation was made more nearly complete since the iodide was purer. Centrifugal rinsing of the product with pure water removed the greater part of any potassium iodide solution which might have accompanied the iodine vapor as spray.

Since iodine which has been purified merely by distillation from aqueous solution leaves a residue of organic matter when sublimed, this impurity was next removed by combustion in oxygen. The iodine was placed in a 20-mm. quartz tube connected at one end with a supply of carefully purified oxygen. Beyond the iodine the quartz tube was constricted to half diameter at two points, in such a way as to provide two compartments several centimeters long. The constrictions were filled with coils of platinum wire. The iodine was then sublimed in a current of oxygen into the first compartment through the first constriction which was heated to redness. A second sublimation followed, from the first to the second compartment, while the second constriction was heated. The twice sublimed material was then melted in the second compartment and poured into a vessel of pure water. The first distillation yielded a small amount of brownish residue, but the second yielded none. The presumption seems justified that organic impurities, even cyanogen, were removed in this treatment.

The iodine was next converted into potassium iodate by oxidation with potassium permanganate which had been twice recrystallized. Since this oxidation proceeds through the iodide, a small amount of potassium hydroxide was added to start the reaction. At first this latter was made by igniting a portion of the purified permanganate; later a portion of the alkaline solution resulting in the main reaction was used. Iodine and permanganate were mixed and boiled with an alkaline solution, sufficient iodine being used to complete the reaction with the permanganate. The solution of the iodate after standing was decanted from the precipitate of manganese dioxide, clarified by centrifugal settling and filtration through a sintered glass filter, and evaporated until saturated with potassium iodate. After the crystals had been removed, the mother liquor was further evaporated and a second crop obtained. All the potassium iodate was then once recrystallized.

The potassium iodate was converted into barium iodate by precipitation with barium hydroxide which had been twice recrystallized. Boiling hot normal solutions of both were used in the precipitation, the hydroxide being very slightly in excess. After standing for some time the precipitate was washed by decantation until the washings were nearly or quite free from alkali. In order to increase the efficiency of each washing the precipitates were centrifugally settled. The precipitate was then dried in platinum over an electric heater, and was found to weigh 2630 g. or about 45% of the theoretical yield from the original 3 kilograms of iodiie.

The final step in the series was the conversion of the barium iodate into iodic acid by metathesis with distilled sulfuric acid. A hot concentrated solution of a slight excess of sulfuric acid was added to the barium iodate suspended in hot water and the mixture was digested for several days in Pyrex flasks. After the supernatant solutions had been decanted, they were evaporated in platinum dishes. The precipitates were washed by decantation and the washings after evaporation in pyrex flasks were added to the main solutions. Since a small amount of suspended barium sulfate still remained, the solutions were filtered through a platinum sponge crucible into platinum dishes and after evaporation on electric heaters, were allowed to crystallize. The ordinary method of fractional crystallization was then followed as indicated in Fig. 1, where the crystal fractions are carried to the left, the mother liquors to the right. Because of the slowness with which equilibrium is established, each crystallization required several days. In the early steps of the process each fraction was divided into two or more portions for convenience and safety. Just before each final crystallization the solution was filtered through platinum sponge, although no insoluble matter could be detected. As soon as the crystallization process was commenced the material came into contact only with platinum.

In spite of these efforts the iodic acid at first possessed the peculiar odor which has been noted elsewhere.[6] This gradually disappeared from the purer fractions and was almost if not quite absent from each final crystal fraction.

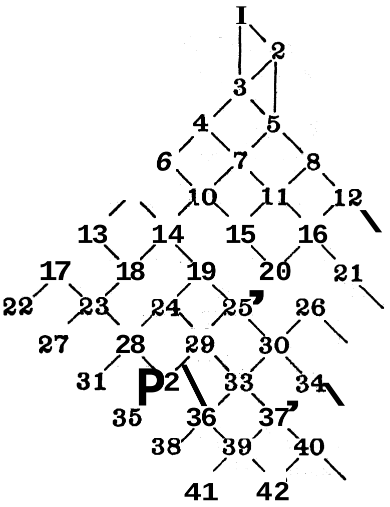

Fig 1.

Since sulfuric acid was present in the original solution, it was important to determine how rapidly this was eliminated in the crystallization. The usual test for sulfate is not sensitive enough for the purpose on account of the large amount of iodic acid necessarily present. A better method was found by heating the iodic acid in a current of air at 200–250° and passing the air through pure water, which was then tested for sulfate in the usual manner. In this way it was found possible to detect with certainty 0.2 mg. of sulfuric acid in 5 g. of iodic acid. Using this method the mother liquor 40 was found to contain 0.05–0.10 g. of sulfuric acid, while none could be detected in mother liquor 42.

Further tests for sulfate were combined with tests for non-volatile matter by decomposing 5-g. portions of the final crystal fractions in weighed platinum or quartz boats and determining the weights of the residues.

Fraction	Boat	Sulfate, mg.	Residue, mg.
41	Pt	0.03	−0.02
41	Pt	0	+ .07
31	Quartz	0	.00
22	Quartz	0	+ .03

Spectroscopic tests in a copper arc, using a Féry quartz spectrograph, failed to indicate the presence of barium except in the first mother liquor.

This evidence indicates that the purification by crystallization proceeded

rapidly and that the final crystal fractions must have been very nearly if not quite pure.

In all the foregoing operations the usual precautions in precise work were taken. Water was doubly distilled, first from alkaline permanganate, then from a trace of sulfuric acid, with tin condensers. Especial care was taken to insure protection from dust and fumes. Crystals were centrifugally drained either in an all porcelain centrifuge or in platinum Gooch crucibles.[1] Pyrex glass vessels were employed in the earlier operations, nothing but platinum during the crystallization of the iodic acid.

The Quantitative Decomposition of Iodine Pentoxide

The method of analysis consisted first in preparing iodine pentoxide for weighing by careful dehydration of iodic acid. The pentoxide was then decomposed by heating to about 400° in a weighed quartz reaction vessel which contained hot silver to prevent escape of iodine, and finally the weight of the iodine was determined. Water retained by the pentoxide was collected in a weighed absorbing tube and subtracted from the weight of the iodine pentoxide, as was also a correction of 0.001% for adsorbed air.

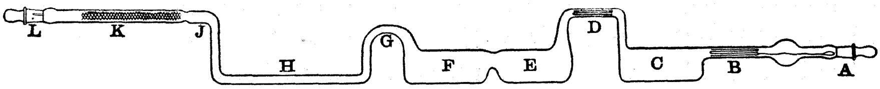

Fig. 2.

Since the possible accuracy of the process was limited by the weight of oxygen liberated, which constitutes less than one-quarter of the weight of the pentoxide, comparatively large quantities of pentoxide were used in each experiment, usually over 40 g. Necessarily the reaction tube was of considerable size and weight. After various preliminary experiments with a reaction tube made of pyrex glass, the final tube of fused quartz was constructed as indicated in Fig. 2. The air current entered through the ground joint A which was provided with a carefully ground stopper. At B was placed a coil of platinum wire which could be heated to redness from the outside. The tube D connecting the decomposition chamber C, 30 × 75 mm., which served to contain the iodine pentoxide during the initial weighing, and the iodine condensation chambers E and F, contained a coil of platinum wire which was heated to redness during an experiment. Condensation of iodine was made as complete as possible in H and the small amount of uncondensed iodine was collected in K upon metallic silver heated to about 600° by means of a removable resistance coil. During an analysis E, F and H were immersed in an ice-bath. A weighed U-tube containing resublimed phosphorus pentoxide was attached by a ground joint at L, which also was provided with a carefully ground stopper. Be-

[1] Baxter, This Journal, 30, 286 (1908).

cause of limitation of space in the balance case the apparatus was bent back on itself at D, G and J, so that the inlet A and the outlet L were not far apart. The weight of the empty system was 143 g. In order to avoid any effect from changing atmospheric conditions between the initial and final weighings, a counterpoise was provided of very nearly the same construction. The weight and volume of the counterpoise were made very nearly the same as those of the tube by adjusting with pieces of platinum and silver wire, and of quartz, the weight of the counterpoise being slightly less than that of the tube. In the early experiments the counterpoise was of pyrex glass, but in the later ones a quartz counterpoise was used.

The method of weighing consisted in hanging the tube and counterpoise on opposite sides of a No. 9 Troemner balance of 500-g. capacity and sensitive to 0.02 mg. or less, and finding the difference in weight necessary to bring the system to the zero point of the empty balance taken directly afterward. The balance room was kept at constant temperature within two degrees so that variations of the ratio of the balance arms were avoided. The balance case was provided with two dishes containing a few milligrams of impure radium bromide to dispel electrostatic charges. During a portion of the time fused potassium hydroxide also was placed in the balance case, although no apparent benefit resulted from this.

In spite of these precautions many difficulties were experienced in weighing the tube, and more time was spent in overcoming these than in the actual analyses. Part of the difficulty undoubtedly resulted from surface effects on the quartz, for this material is notoriously troublesome in this respect. Uncertainty from this source eventually was eliminated by standardizing the preliminary treatment. That finally adopted consisted in wiping the surface with dilute hydrochloric acid, rinsing with water and wiping with a damp cloth just before placing on the balance. The counterpoise was wiped with a damp cloth at the same time. The weighing was carried out only after some hours, usually twelve to fourteen.

A far more troublesome irregularity was eventually traced to diffusion of water vapor from the outside into the tube, thus displacing the heavier air and causing a loss in weight. The amount of water vapor found in the tube, initially filled with dry air and allowed to stand, corresponded closely with the loss in weight of the tube which took place during this period when the difference in density of air and water vapor was taken into consideration. This loss in weight in one case amounted to 0.75 mg. in two days, even when the tube was closed except for narrow grooves in the stoppers necessary for equalization of pressure within and without. How much of this was due to simple diffusion and how much to small fluctuations in temperature is difficult to determine. The effect was considerably more noticeable in the late spring and summer months when most of the experiments were carried out than in the early spring when the preliminary ones were performed.

The difficulty was largely overcome by providing the tube with a stopper grooved for only half its length. The groove could be connected with the outside at will by turning the stopper until the groove registered with a small opening in the socket. In this way the tube could be kept essentially sealed until shortly before the weighing, when connection with the outside could be established by turning the stopper.

Even with the new stopper moisture was found very slowly to enter the tube, to the extent of 0.20 mg. in twenty hours, on an average as determined in four concordant experiments. With uniform treatment the reaction tube whether empty or containing iodine pentoxide or iodine would always be affected to the same extent, so that the weight of oxygen would not be affected if it were not for the fact that this water was collected in the phosphorus pentoxide tube. It is obvious that the weight of water collected in each experiment must be corrected for the water diffusing into the reaction tube.

The moisture content of the iodine pentoxide was found by passing the oxygen which resulted from the decomposition through a counterpoised U-tube containing resublimed phosphorus pentoxide. Iodine pentoxide which has been formed by dehydration of iodic acid at the temperature used in our experiments has been found to contain from 0.0025 to 0.0062% of moisture according to the method of preparation and time of heating.[6] In order to avoid the uncertainty involved in applying an average correction, the water was collected in each experiment. Since experience has shown the practical impossibility of securing absolute blanks in a water determination, the rate of gain of the phosphorus pentoxide tube was found in the air stream utilized in our experiments. The following table gives the results of these experiments.

Duration, hours	H_2O found, mg.		H_2O found per hour, mg
a	0.09		0.03
3	.13		.04
2.75	.11		.04
2	.08		.04
1.5	.09		.06
		Average	.04

The air stream itself was cleansed and dried by passing through a train containing the following agents: hot copper oxide, aqueous silver nitrate, aqueous potassium hydroxide, fused potassium hydroxide, concentrated sulfuric acid, phosphorus pentoxide, sintered glass filter. The system was constructed wholly of glass with dry, ground-glass connections.

To prepare iodine pentoxide from iodic acid, crystals of the latter were powdered in an agate mortar, usually together with a small proportion of the first phase formed in the dehydration, $HIO_3 \cdot I_2O_5$, since the water is then given off at a comparatively low temperature (80–110°) by efflorescence without melting, and moisture retained by the final product somewhat reduced.[8] The powder contained in platinum boats was placed in a quartz tube connected with the train for purifying and drying air and surrounded by an aluminum block furnace? The temperature of the furnace was first maintained at 100–110° as long as water appeared to be given off and then was raised to 200–210° to expel the remaining water of composition. Finally the material was heated to 240°, the highest temperature found by Baxter and Tilley to be safe, for about three hours. In many cases the product remained perfectly white, in others, especially if the temperature exceeded 240° or the period of heating was longer, a slight brownish tint appeared. Even when the iodic acid was free from odor, the iodine pentoxide made from it always possessed the peculiar odor which has been noted before.

In the meantime the quartz reaction tube had been prepared for weighing by passing a current of dry air through it and, after the treatment described on page 972 and standing for fourteen hours, was weighed. By means of a platinum thistle tube extending into the decomposition chamber C the iodine pentoxide was introduced without contaminating the inlet tube. The platinum coil B was then replaced, Dry air was then passed through the tube, while usually at the same time the chamber C was warmed to about 100°. If C was warmed the air entered at L so that iodine formed by incipient decomposition of the pentoxide could not come into contact with the silver. After cooling with the air current running, the tube was treated and weighed after fourteen hours as in the first weighing. After some time, about six hours, the quartz tube was rapidly attached both to the air line and to the phosphorus pentoxide tube, which also had been weighed. A second phosphorus pentoxide tube was used to protect the weighed tube from back diffusion of moisture. The chambers F and E were surrounded with ice and water and the tube K containing silver was surrounded by an electrically heated sleeve. The platinum coils B and D were heated to redness by Méker burners and the ground connections were cooled with wet cotton wicks. Then an air current was started and the chamber C was cautiously heated with a flame until decomposition of the iodine pentoxide proceeded slowly and uniformly. Usually about two hours were required for complete decomposition. Care was necessary to avoid rapid decomposition since the pentoxide itself was likely to be blown about if the reaction proceeded too rapidly. The hot platinum coils served the purpose of decomposing powdered material which might have been expelled from the decomposition chamber. Clog-

[8] Baxter and Tilley, Ref. 6, p. 210.

[9] Baxter and Coffin, *Proc.* Am. *Acad.*, 44, 184 (1909).

ging of the system with condensed iodine was likely to occur and was remedied by judicious use of a flame.

When decomposition was complete the ice-water bath was transferred to the tube H and the iodine sublimed from E, where the greater part originally condensed, to F where it was eventually fused. Except for the silver the whole system was then allowed to come to room temperature. Next the phosphorus pentoxide tube was removed, the stopper inserted at L, and the silver in K allowed to cool while at the same time the dry air was maintained inside at atmospheric pressure so that no moist air was forced in during the cooling. Finally, after it had been disconnected and the stopper inserted at A, the system was prepared for weighing as usual and weighed fourteen hours later. The experiment was completed by the weighing of the phosphorus pentoxide tube.

Although a considerable quantity of silver iodide was formed on the inner end of the silver column, the outer end remained untarnished. Furthermore, tests for free iodine in the air which passed through the system during an analysis were negative. It therefore is unlikely that any iodine was lost in the air current.

After an experiment the decomposition tube was attached to the air train in the reverse fashion by the joint L and cleaned by subliming the iodine into a pyrex flask. A very slight residue was allowed to accumulate in C (see page 970).

Weights were calibrated by the Richards substitution method, just before and just after the analytical work was carried out. In only two cases was the correction of an individual weight found to vary by 0.02 mg. in this interval, although differences of 0.01 mg. were found in the case of more than half the weights. In computing vacuum corrections the following densities were assumed:

Air (0° and 760 mm.)	0.001293
Weights	8.3
I_2O_5	4.799[10]
I_2	4.94[11]

Results

The following table presents the data for all analyses which were completed except one. Of these, three are subject to known errors, Nos. 1, 2 and 6. In one experiment, not included in the table, the procedure was so changed that it was impossible to determine the weight of the pentoxide or that of the water with certainty.

The weights of iodine pentoxide given in the third column have been corrected by subtracting 0.001% for adsorbed air. Since the iodine was chiefly in the form of a fused mass, with a relatively small proportion of

crystals of considerable size, the surface exposed was small and adsorption of air must have been at a minimum.

Extreme deviation of Analyses 3, 4, 5, 7, 8, 9								.000007	0 00011

[a] Less a correction of 0.001% for adsorbed air.

[b] Less a correction of 0.20 mg. for moisture diffused into the system before weighing and of 0.04 mg. per hour of duration of the experiment. See pages 968 and 973.

In Analysis 1 iodine vapor was lost from the tube owing to plugging with condensed iodine. In Analysis 2 a crack developed in the tube and in addition, owing to overheating, silver iodide sublimed from the silver section. In Analysis 6 a stopcock in the system was accidentally left open so that owing to insufficient pressure iodine was lost by back diffusion. In Analysis 7 the quantity of material was made about half the size of that usually employed in the hope that a constant error might be uncovered.

One other correction remains to be discussed. The air in the decomposition tube must have been nearly saturated with iodine vapor at the time of weighing and therefore the weight of the tube was less than it should be by the weight of air displaced by the iodine. Since the vapor pressure of iodine at 25° is 0.3 mm.[12] and the interior volume of the tube about 200 ml., the air displaced is 0.08 ml. under average conditions and the weight of iodine too small by 0.10 mg. The effect of applying this correction is to raise the observed ratios of iodine to oxygen and iodine pentoxide by 0.001 and 0.0003%, respectively, to 3.17262 and 0.760342.

The values for these ratios to be expected from the atomic weight of iodine now considered most probable, 126.932, are 3.17330 and 0.760381, differences of 0.021 and 0.005%. The difference between the observed values and those to be expected corresponds to a difference in the atomic weight of iodine of —0.027. In other words the atomic weight of iodine calculated from our experimental results is 126.905. It is difficult to believe that this value is correct. On the basis of the more probable value 126.932 the computed deficiency in iodine obtained experimentally amounts

---

[12] Baxter, Hickey and Holmes, THIS JOURNAL, 29, 127 (1907).

to 0.0015 g. with a 40-g. sample of iodine pentoxide. This deficiency is far greater than the apparent experimental error.

The atomic weight of iodine calculated from the corrected experimental ratio of silver to iodine pentoxide, 0.646231, found by Baxter and Tilley, is 126.937, on the basis of the atomic weight 107.880 for silver, The coincidence is striking that the discrepancy in the composition of iodine pentoxide, though a little more than half as large, is in the same direction as that indicated by our experiments.

By combining the experimental ratios of silver and iodine to iodine pentoxide the ratio of iodine to silver is found to be 1.176579 and the atomic weight of iodine 126.929 on the basis of Ag = 107.880. This value for iodine differs very little from that found by direct comparison with silver, 126.932.

The percentage of iodine in iodine pentoxide is apparently too small, the percentage of oxygen too large. If the extra oxygen is wholly or in part in the form of a higher oxide, the oxidizing power of the iodine pentoxide should be too large. In a subsequent paper will be described a comparison of arsenic trichloride with iodine pentoxide in which it appears that this is the case. If the apparent excess of oxygen indicated by our work, 0.005%, is wholly in the form of the heptoxide, the proportion of the latter would be ten times as large.

We cannot avoid the conclusion, therefore, that iodine pentoxide of normal composition is difficult if not impossible to prepare and that conclusions based upon its actual composition are not sufficiently reliable for work of high precision.

SALT AND MEDIUM EFFECTS ON THE TEMPERATURE COEFFICIENT OF VELOCITY OF DECOMPOSITION OF DIACETONE ALCOHOL[1]

BY GEORGE M. MURPHY

RECEIVED JANUARY 13, 1931 PUBLISHED MARCH 6, 1931

The hydroxide-ion catalysis of diacetone alcohol has recently been investigated by Åkerlöf,[2] who determined the influences of different hydroxides at various concentrations and both weak and strong hydroxides in salt solutions upon the reaction rate. Further, results were obtained by him which showed the effects on this reaction rate of addition of some alcohols and other organic solvents to the aqueous hydroxide solutions. Results contained in this investigation demonstrate the influences of the

---

[1] The present study constitutes a part of a thesis presented to the Graduate School of Yale University as partial fulfilment of the requirements of the degree of Doctor of Philosophy, 1930.

[2] Åkerlöf, THIS JOURNAL, 48, 3046 (1926); 49, 2955 (1927); 50, 733 (1928).

addition of sodium chloride and methyl alcohol upon the temperature coefficient of reaction rate of the decomposition of diacetone alcohol catalyzed by suitable concentrations of sodium hydroxide. Measurements of the reaction rate at 20, 25, 30 and 35° in the presence of various strengths of sodium hydroxide between 0.01 and 0.1 molal have also been obtained.

Experimental Results

Since the measurements were made by means of a dilatometer and by a method similar to that described by Åkerlöf, little further need be added here. The temperature was controlled to within ±0.005° during a given measurement. Considerable care was exercised in the preparation of the solutions and the purification of the chemicals. The velocity constant was computed by the equation

$$K = \frac{1}{t} \log \frac{l_\infty}{l_\infty - l_t} = 0.434k \qquad (1)$$

where l_∞ is the length read on the dilatometer which corresponded to complete reaction, and l_t that which corresponded to the quantity changed in time, t. The over-all accuracy of this measurement is estimated to be approximately ±1%. Table I contains the results. The column headings are self-explanatory.

Discussion of Results

(1) Hydroxide Catalyst.—For the purpose of the present discussion, we shall supplement Bronsted's[3] theory of homogeneous reaction velocity by the inclusion of the term containing the energy of activation of the diacetone alcohol per mole, Q_{12}, and obtain

$$V = km_A m_{OH} \frac{\gamma_A \gamma_{OH}}{\gamma_i} e^{-Q_{12}/RT} \tag{2}$$

m_A and m_{OH} are the concentrations, γ_A and γ_{OH} the activity coefficients of the diacetone alcohol and hydroxide ion, respectively, and γ_i the activity coefficient of the intermediate. At constant temperature, this reduces to Brönsted's equation,

$$V = k'm_A m_{OH} \frac{\gamma_A \gamma_{OH}}{\gamma_i} \tag{3}$$

In dilute solutions the kinetic factor $\gamma_A\gamma_{OH}/\gamma_i$ approaches unity and Equation 3 becomes

$$V = k'm_A m_{OH} \tag{4}$$

That the velocity constant k' is proportional to the hydroxide concentration in the region of concentration from 0.01 to 0.1 molal has been shown by French,[4] and confirmed at all concentrations by the data in the first part of Table I. Since this is the case, the temperature coefficient is independent of the hydroxide concentration, as shown by the velocity constant ratios in the sixth and seventh columns of the table.

At hydroxide concentrations from 0.2 to 6 M, Åkerlöf found that the reaction velocity conformed with that predicted by the equation

$$v = km_A m_{OH} \sqrt{\gamma_M \gamma_{OH}} \tag{5}$$

Since the variation of the activity coefficient with the temperature is small, and probably uniform, we would also expect the temperature coefficient of the reaction velocity to be independent of the hydroxide concentration in the more concentrated solutions.

(2) Hydroxide–Chloride Catalysts.—From the ratios of the velocity

---

[3] Bronsted, *Chem. Rev.*, 5, 286 (1928).

constants at different temperatures contained in the last two columns of the second part of Table I, it is clear that the temperature coefficient of the velocity constant is independent of the concentration of the added salt. Further, the mean values of the temperature coefficients are the same as those in the case of the pure hydroxide solutions within the error of the present experimental method.

From these results the value of Q_{12} may be readily computed. Thus, from Equation 2, we find that

$$k = Ae^{-Q_{12}/RT} \tag{6}$$

whence, the equation of Arrhenius

$$\frac{\mathrm{d}\ln k}{\mathrm{d}T} = \frac{Q_{12}}{RT^2} \tag{7}$$

may be obtained by differentiation. Integrating between the limits k_{35} and T_1 and k_{25} and T_2, we obtain

$$\ln\frac{k_{35}}{k_{25}} = \frac{Q_{12}}{R}\,\frac{(T_1 - T_2)}{T_1T_2} \tag{8}$$

Substituting 308.1' for T_1 and 298.1' for T_2 and converting to common logarithms, we find that

$$Q_{12} = 42{,}011 \log\frac{k_{35}}{k_{25}} \tag{9}$$

If we substitute the average values, 2.67 and 2.70, from the last columns of parts (1) and (2) of Table I for k_{35}/k_{25} in this equation, we obtain Q_{12} = 17,918 cal. and Q_{12} = 18,122 cal., respectively. Thus the value of Q_{12} may be taken to be 18,000 cal.

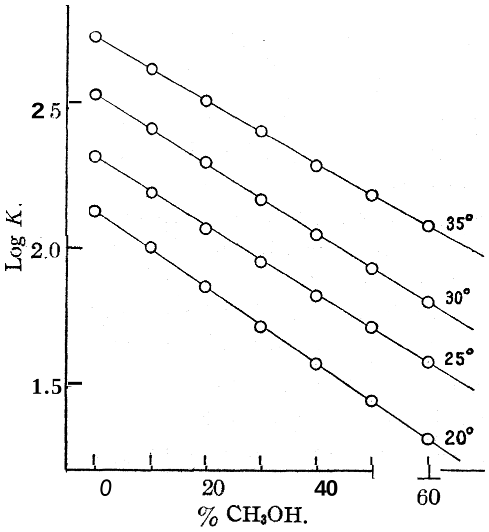

Fig. 1.

(3) Hydroxide Catalyst in Water–Methyl Alcohol **Mixtures.**—The addition of methyl alcohol to the aqueous solution of sodium hydroxide decreases the velocity of decomposition of diacetone alcohol. This was previously shown at 25° by Åkerlöf, who studied the effects of six organic solvent–water mixtures containing sodium hydroxide upon this reaction rate. In Fig. **1** the logarithm of the velocity constants at 20, 25, 30 and 35° contained in the third part of Table I are plotted against the weight percentages of methyl alcohol The plots appear as straight lines up to **a** concentration of 60% alcohol.

It is important to observe, however, that the temperature coefficient is not independent of the methyl alcohol concentration, but that the ratios of the velocity constants at 30 and 20°, and at 35 and 25°, increase with increasing methyl alcohol content, as shown by the sixth and seventh columns of the third part of Table I.

The writer takes this opportunity to thank Professor Herbert S. Harned for help and suggestions obtained from him during the course of this work.

Summary

1. The reaction velocity constant of decomposition of diacetone alcohol catalyzed by hydroxides has been measured at 20, 25, 30 and 35° in aqueous solutions of sodium hydroxide of different concentrations, in aqueous hydroxide–salt solutions, and in water–methyl alcohol mixtures containing sodium hydroxide.

2. The temperature coefficient of reaction velocity is independent of the strength of hydroxide. It is also independent of the sodium chloride concentration in the hydroxide–salt mixtures.

3. The temperature coefficient, however, is not independent of the concentration of methyl alcohol in the alcohol–water mixtures containing 0.1 M sodium hydroxide.

4. The energy of activation has been computed and is found to be 18,000 cal. The error in this observation is approximately ±0.7%.

A THEORY OF THE ARRANGEMENT OF PROTONS AND ELECTRONS IN THE ATOMIC NUCLEUS

BY WENDELL M. LATIMER

RECEIVED FEBRUARY 3, 1931 PUBLISHED MARCH 6, 1931

From a study of the number of protons and electrons in those atomic species whose atomic weights are approximately integral multiples of four, together with data on their abundance, I have been led to a geometrical representation of the atomic nuclei in which the protons and electrons are arranged in a definite space lattice. It appears certain that the nucleus must be held together by the coupling of the proton spins, and the model may be interpreted as the pattern determined by the directions of the spin vectors. In the proposed model the angle between any two proton vectors is that formed by lines from two corners of a tetrahedron to its center, and this in the new quantum mechanics is the angle at which two elementary spin vectors add to give a resultant of two units.

It seems reasonable to expect that existing relations would appear more clearly defined in the case of the atomic species with atomic weights multiples of four, since, at least in the lighter elements, these nuclei possess no resultant spin and have therefore a higher degree of symmetry. This nuclear type contains an even number of electrons and thus occurs only in elements of even atomic number with the exception of the two very unstable elements, Mesothorium II with a half life period of six hours, and Thorium c″ with a half period of 3.2 minutes. Every even atomic number from 2 to 90 appears to have at least one atomic species of this type, generally the most abundant form of the element; in fact, approximately 80% of the earth's crust is composed of such atoms.

In analogy to the known facts of radioactive disintegration, it has frequently been suggested[1] that these elements are composed of alpha particles, that is, united of four protons and two electrons, together with that number of extra or "cementing" electrons which, with the number of alpha particles, gives its atomic number. The numbers of these alpha particles and extra electrons are summarized in Table I; the figures in the table are the number of alpha particles for the element with the atomic number given at the left of the same row, and the number of extra electrons in the nucleus is given by the number at the top of the corresponding column.

[a] From chemical atomic weight and estimated packing fraction. Other values as determined by mass spectrograph.

It is to be observed that the lighter elements may be considered as composed of alpha particles alone, but the maximum number of alpha particles in nuclei of this type is 10, *i.* e., in Calcium, 40. We also find Argon, 40, which contains two extra electrons. Argon **36** and Argon 40 constitute the first example of an element having two isotopes differing in atomic weight by four.

The greatest number of alpha particles found in nuclei which contain two extra electrons is 16 and from this point on the number of extra electrons increases rapidly. Thus, thorium, **232.** the heaviest known member of the class, may be thought of as containing 58 alpha particles and 26 extra electrons. It may also be noted from Table I, that nuclear types containing 6, 12 and 24 extra electrons occur with a large range of atomic weights.

Data on the abundance of the various nuclear species may be expected to give some measure of the relative stabilities of various nuclear structures. In Fig. 1 the abundance, expressed as the logarithm of the percentage of the species in the earth's crust, has been plotted against the number of alpha particles in the various atoms listed in Table I. The data are those given by Harkins[1] for the abundance of the elements, corrected in case the element is a mixture of isotopes, to give the amounts of the element belonging to this nuclear type. Approximate values have been added also for neon and argon. The elements above atomic number 30 constitute but 0.15% of the earth's crust, and as the data regarding their abundance are not reliable the plot has not been extended beyond this point.

These, then, are the facts we wish to correlate with the model, first, that a given number of protons is associated with the number of electrons as given in Table I and, second, that certain groups of protons and electrons appear to be more stable than others as judged by their greater abundance.

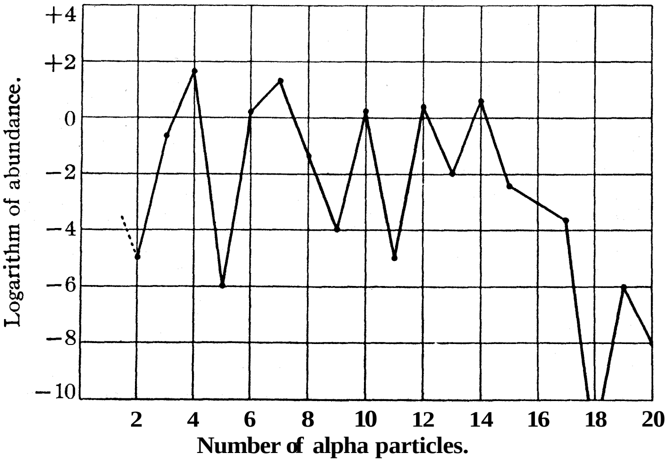

Fig. 1.—The abundance as the log of the percentage of the nuclear species in the earth's crust plotted against the number of alpha particles.

Maxima occur in the abundance curve at 4, 7, 10, 12 and 14 alpha particles. These numbers at once suggest that the alpha particles are combined in a tetrahedral pattern, with one alpha particle at each corner of the unit tetrahedron. Thus, one tetrahedron requires 4 alpha particles; two tetrahedra with one corner in common, seven, and three tetrahedra with a common corner, ten. Such a grouping occurs in face-centered cubic lattice types; the three tetrahedra have their bases in the same plane and share one corner together at the center of the hexagon formed by the outer edges of the base. If we continue this arrangement of tetrahedra, building toward spherical symmetry, we would place a layer of three tetrahedra above the first three as indicated in Fig. 2. With the completion of the first tetrahedron of this new layer we have 12 alpha particles, with the second 14 alpha particles, and with the third 16. Now it appears highly significant that in this arrangement of alpha particles the completion of each of the first five tetrahedra corresponds exactly to the first five maxima of the abundance curve. Moreover, the completion of the first group of three tetrahedra corresponds to the end of the first column of nuclei in Table I, that is, to the nuclei with no extra electrons, and the completion of the second layer of three tetrahedra to the second column of nuclei with two extra electrons. However, to give an explanation of this correspondence it is first necessary to discuss the coupling of the four alpha particles in the unit tetrahedron.

If we represent the alpha particle itself as a tetrahedral arrangement of four protons about an electron pair with zero resultant spin, and assume the four proton spin vectors are directed toward the center of the figure, then the whole alpha particle should have zero spin, in agreement with the experimental facts.[2] Now we wish to group four of these small tetrahedra (alpha particles) into a tetrahedron with such coupling of the spin vectors that a continuation of the pattern will give the arrangement of tetrahedra in Fig. 2. Such a coupling pattern is given in Fig. **3,** which then is to be taken as our model of the oxygen nucleus.

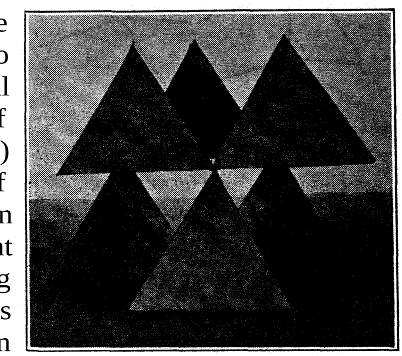

Fig. 2.—Representing the arrangement of 16 alpha particles at the corners of 6 unit tetrahedra.

As the pattern is continued to form the first group of three tetrahedra, we find with the addition of the tenth alpha particle that there is now a point (see A in Fig. 4) about which four spin vectors converge in the same manner as in the unit alpha particle, and it would seem that here too we should have an electron pair. This, then, appears to be an explanation of the entrance of the first pair of extra electrons at 10 alpha particles and provides a basis for the complete interpretation of the number of alpha particles and extra electrons which occur in the atomic nuclei as given in Table I.

[2] I have no doubt that the idea of the probable tetrahedral structure of the alpha particle has suggested itself to many men and it seems to me that this direction of spin vectors is a logical consequence of such a structure. Since preparing this manuscript Dr. O. K. Rice has written that he suggested the idea to me in a conversation a year ago. In the development of the theory I had not recalled his suggestions; however, I have never considered that this postulate regarding the alpha particle was at all original with me.

Several years ago Professor E. D. Eastman of this Laboratory observed that the abundance maxima occurred with a periodicity of 6 atomic numbers in the lighter elements. This observation may now be interpreted in the tetrahedral arrangement of the alpha particles.

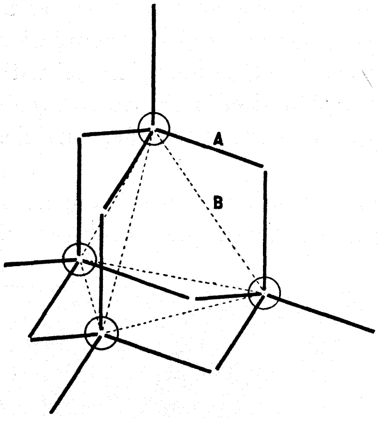

Fig. 3.—The coupling of 4 alpha particles in the unit tetrahedron. Electron pairs located at the positions of the circles and a proton located along each vector.

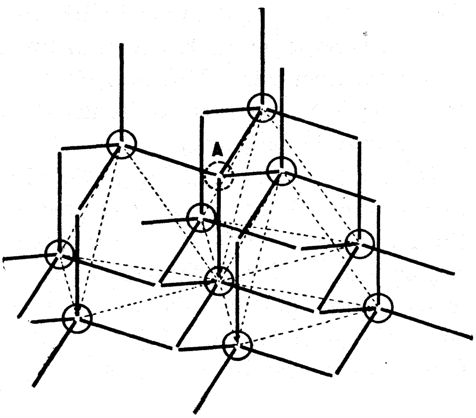

Fig. 4.—The group of 10 alpha particles constituting the first 3 unit tetrahedra. "A" indicates the position of the first pair of extra electrons.

As the pattern, by which the alpha particles are coupled, is continued, it is necessary to add a pair of extra electrons whenever four protons come together at a point and there only. Thus the extra electrons convert the face-centered cubic arrangement of alpha particles into a diamond type lattice of electron pairs, each pair surrounded by four protons which serve as bonds to four other electron pairs. In such a lattice the original alpha particles now appear to have lost their identity. (However, for the sake of clarity in exposition, in all diagrams these extra electron pairs have been represented by black balls, and the electron pairs of the original alpha particles by white balls.)

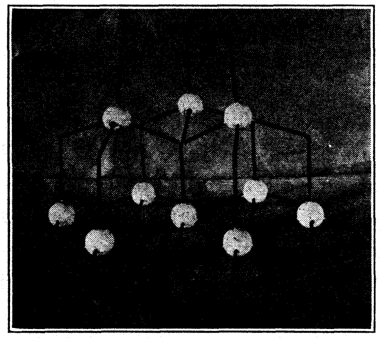

Fig. 5.—A model representing the same group of 10 alpha particles diagrammed in Fig. 4. Electron pairs represented by balls and protons by vectors, *i. e.*, the connecting bars. The model shows the 4 protons coming together at the center.

The method of combining alpha particles is such that it would lead to successive tetrahedra of 20, 35 and 56 alpha particles with 1, 4 and 10 extra electron pairs, respectively. However, the nuclei appear to tend toward spherical form due probably to coulombic forces and a new layer on one of the faces is always started before each of the above tetrahedra is completed, although in each case the figure reaches or approaches very closely the tetrahedra without the corners, that is figures of 16, 31 and 52 alpha particles with the 1, 4 and 10 extra electron pairs. (See Figs. 6, 7 and 8.)

When a new layer is started, one, and then very quickly another electron pair enter and thus we find the groups of electrons, 2 + 4 = 6, 8 + 4 = 12 and 20 + 4 = 24, corresponding, respectively, to the completion of the tetrahedra of 20, 35 and 56 alpha particles and the simultaneous starting of a new layer. This would seem to account for the long columns (see Table I) found with these numbers of extra electrons. Moreover, the evidence seems quite conclusive that when one electron pair goes into a new face, the additional pairs go into the same face of the figure.

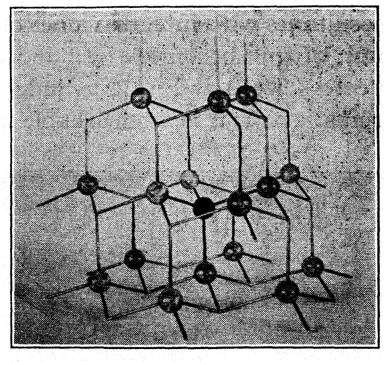

Fig. 6.—The group of 16 alpha particles, with one pair of extra electrons (black ball) at center of figure.

The radioactive thorium series corresponds to the last of these processes of starting a new layer. Thorium, 232, has three extra electron pairs and six alpha particles more than the 52 alpha particle structure of Fig. 8. However, it is not possible to say what should be the most probable location of these additional particles. The end product, lead 208, obviously has one additional pair of electrons in the surface of the 52 alpha particle structure, but again it is not possible to decide whether its alpha particle arrangement is just that of Fig. 8 or some slight variation from it.

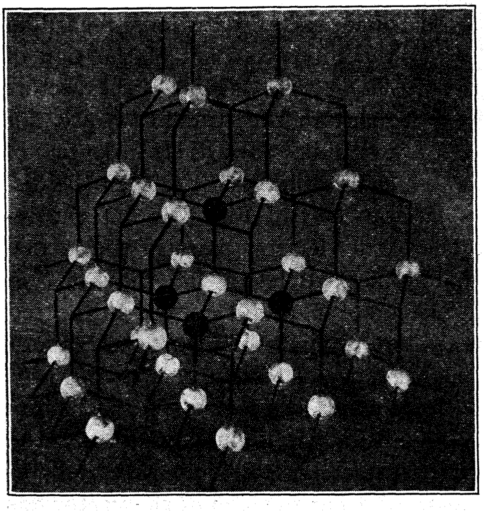

Fig. 7.—The group of 31 alpha particles and 4 pairs of extra electrons.

Although it is not planned to discuss in detail in this paper those elements whose atomic weights are not integral multiples of four, it may be pointed out that the heaviest known stable elements of odd atomic number, bismuth, 209, and thallium, 203, have 10 pairs of extra electrons, as does also lead 206. The latter may correspond to Fig. 8 with two protons removed.

If this proposed nuclear structure is correct in principle, the method of combining the spin vectors certainly should be in agreement with the quantum mechanic rule for vector combination.3 The radical change introduced by the new mechanics is the use of the quantity $\frac{1}{2}\sqrt{n(n+2)}$ as the magnitude of the vector representing n units of spin, and only resultants with integral values of n are permitted. Thus the vector for one unit of spin becomes $\frac{1}{2}\sqrt{3}$ and the only permitted resultants for two such vectors are 0 and $\sqrt{2}$, as judged by the known combinations of electron spins. Now it is a remarkable fact that if the length of the unit vector, **A**, of Fig. **3** is $\frac{1}{2}\sqrt{3}$, then the resultant distance, B, of two such vectors is $\sqrt{2}$. In other words, *the geometry of the tetrahedron is just that demanded by the quantum mechanics for the combination of two unit spin vectors.*

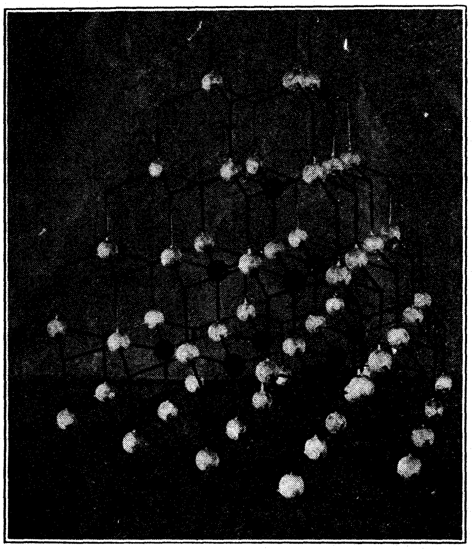

Fig. 8.—Fifty-two alpha particles and 10 pairs of extra electrons.

Unit vectors in two of the directions of the tetrahedron give a resultant of two; unit vectors in three directions, a resultant of one and unit vectors in each of the four directions, a resultant of zero. However, the model at once raises questions regarding the interpretation of the sign of the vectors. Thus if the vectors point in the ordinary sense, for example, toward the center of each alpha particle, then the distance B of Fig. **3** is not the resultant of two unit vectors. Also the extra electron pairs in the lattice would differ from those of the original alpha particles in that the direction of the four spin vectors would be out instead of in, and it might be expected that two kinds of alpha particles and helium atoms would exist corresponding to the two vector forms; yet the existence of the latter appears to be precluded by Lewis' application of the principle of identity to the helium spectrum.[4] However, since in the quantum mechanic vector rule the combination of two unit vectors in the same line can only give zero resultant, the question may be raised as to whether the sign of the vector has meaning in the ordinary sense.

The method of coupling alpha particles leads to a number of cases of

---

[3] I am indebted to Professor R. T. Birge for first calling my attention to this requirement.

[4] G. N. Lewis, *Phys. Rev.*, 36, 1144 (1930).

nuclear isomers even among the lighter elements. Thus in Fig. 9, there is given another possible form of calcium 40. This form is not directly obtainable by tearing down the model of Fig. 6, since in that figure the top tetrahedron is not complete; however, if calcium has been formed largely by building up processes rather than by the tearing down of heavier elements, it would seem that this should be an abundant form of the element. This model for calcium minus the four corners gives a very symmetrical form of magnesium, 24.

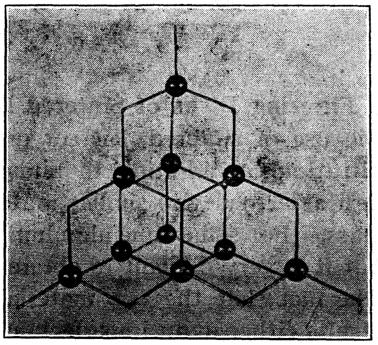

Fig. 9—An isomeric arrangement of 10 alpha particles. Compare Fig. 5.

Although there are numerous other phases of the theory which might be discussed, the author feels that a detailed development should not be undertaken without additional confirmation of the principles involved. It would seem that a study of those elements which have a resultant nuclear spin, may provide this confirmation. For example, if the other types of nuclei are in general derived from those nuclei with weights multiples of four by the removal of one, two or three protons, then the resultant spin should follow at once from the model, provided, of course, that the electrons are all coupled in such a way as to give a zero resultant. However, from the rather meager data we have at present there appears to be some question regarding the validity of this last assumption.

In conclusion the author wishes to express his indebtedness to Professor Gilbert N. Lewis for many valuable suggestions regarding the presentation of the theory.

Summary

An analysis has been made of the nuclear species whose atomic weights are approximately integral multiples of four with reference to the number of alpha particles and extra electrons present.

The abundance curve for the lighter elements of this series shows maxima for 4, **7,** 10, 12 and 14 alpha particles which suggests that the alpha particles are arranged in a tetrahedral pattern.

A pattern is proposed for the arrangement of 4 alpha particles in a tetrahedron with a certain coupling of proton spins. **A** continuation of the pattern to 10 alpha particles leads to a point in the lattice about which four protons converge in the same manner as in the alpha particle. The entrance of a pair of electrons at this point explains the first pair of extra electrons found in argon 40, and an extension of the principle appears

to give a complete explanation of the numbers of extra electrons required in the heavier elements.

With the addition of the extra electrons the proposed nuclear structure becomes a diamond type lattice of electron pairs joined by protons.

The method of coupling proton spins appears to be that demanded by the quantum mechanic rule for vector combination.

BERKELEY, CALIFORNIA

NOTE

Filtering Disks of Sintered Pyrex Glass.—The recent development of the use of sintered Jena or quartz glass disks and alundum plates for filtration, in addition to numerous other applications,[1] makes it very desirable to devise similar material which can readily be fused to pyrex glass. For some time alundum disks have been used in pyrex apparatus, but it is very difficult to obtain a dependable Alundum to pyrex contact. The fact that the two materials have different coefficients of expansion results either in an imperfect junction or in a dangerous strain even after the most careful cooling. The use of sintered pyrex disks would avoid these difficulties. Although these plates are not available from commercial sources, we are able to recommend a procedure whereby a person can, with a little care, prepare for himself satisfactory filtering disks of sintered pyrex.

Scrap pyrex glass crushed to a convenient size is ground to a fairly fine powder either in a pyrex or porcelain mortar or in a grinding machine. The powder is separated into several portions by sifting, *e. g.*: (a) the coarse material which will not pass through a sieve with sixty meshes to the inch, and which should be reground; (b) the part that passes a sixty-mesh sieve, but not an eighty-mesh sieve, and which can be used for making coarse-grained filters; (c) the particles which fall through an eighty-mesh sieve, but do not pass a one hundred-mesh net; (d) the fine powder which is not held by a one hundred-mesh sieve. When a metallic grinding machine is used, the third and especially the fourth portions are contaminated with finely divided metal which gives the disks a grayish cast unless it is removed by acid before sintering.

The apparatus for sintering includes a cylindrical mold, for which we used about one centimeter of nickel tubing with an internal diameter of one centimeter. As indicated in the figure, this cylinder rests on a nickel plate about two and a half centimeters square. The plate may be made large enough to accommodate molds of various sizes if this is desired. In suitable holes drilled at the corners of the plate are fastened nichrome wires arranged to serve both as a handle and as a guide and stay for the

---

[1] Prausnitz, *Arch. Pharm.*, 268, 170–184 (1939); *Chem.-Ztg.*, 53, 935–6 (1930).

cover. For this we used a second nickel plate, drilled like the first, sliding it up and down on the wires. A layer of glass powder one and a half to two millimeters thick is then placed in the cylinder and is leveled by gently tapping the container. The cover is put in place and the apparatus is set in a muffle furnace kept at a bright red heat, A little experimentation will give the temperature which gives a sintered disk in about two minutes. If the temperature is too high or the time of sintering too long, a non-porous lump of glass results; if the temperature is too low or the time too short, the disk is weak and friable. The metal of the mold comes to the temperature of the furnace in about a minute, and in the case of the coarse particles of portion (b), another minute is required for satisfactory sintering. The finest powder requires approximately one minute and forty-five seconds from the time the apparatus is put in the furnace. The apparatus is withdrawn from the furnace promptly and is set on a metal plate to cool. The cylinder containing the disk is then removed and inspection shows that, with the two smaller sizes in particular, a slight shrinkage away from the sides of the mold has occurred near the upper part of those disks which are satisfactorily sintered. The disk is quite rugged enough to be pushed out of the mold with a wooden rod. Any uneven places can readily be smoothed down by a file.

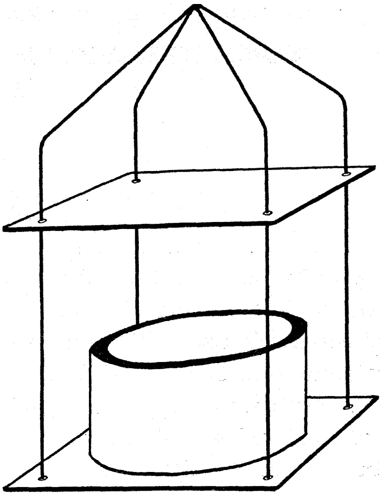

Fig. 1.

For sealing the disks to pyrex apparatus, a pyrex tube of slightly larger diameter than that of the disk is given a slight taper. The disk, inserted in the tube, is supported by the taper and, if necessary, is held straight by a glass rod with a flat end. By careful application of a small hot flame, the disk is attached to the tube at several points. Pushing the hot glass against the side of the disk by means of a nichrome wire may be used to hurry the process. The seal is completed either by rotating the tube in a small hot flame and drawing it down over the disk, or by blowing the glass around the plate in and out in the usual way of making a glass to **glass** seal. A flame of air and gas is preferable to one of oxygen and gas for this purpose.

Disks ten to fifteen millimeters in diameter made according to these directions have been in use for some time and have given entire satisfaction. Those made from particles of portion (b) hold by capillarity a column of mercury ten centimeters high. Filters made from the **fine** powder in portion (d) will hold mercury at half an atmosphere. The sole precaution which we have found necessary is to wrap the filter with asbestos paper if it is to be heated to a high temperature in a vacuum. This protection should also be used to provide slow cooling for a hot filter.

SOME NEW WATER-SOLUBLE ORGANO-MERCURY COMPOUNDS[1]

BY JOHN H. WALDO

RECEIVED JUNE 16, 1930 PUBLISHED MARCH 6, 1931

Introduction

The application of organo-metallic compounds in the therapeutic field too often has been limited by their insolubility in water. Organic mercury compounds having the mercury attached to a carbon atom have had considerable use in therapy, especially as germicidal agents, although the introduction of the —HgX group into an organic molecule tends to make the resulting compound insoluble in water. When mercury compounds are rendered soluble in water or dilute alkali solutions through the introduction of a sulfonic or carboxylic acid group, they generally become less toxic but undergo a marked reduction in their germicidal activity. However, if nitrogen-containing groups are introduced to give the desired solubility, the germicidal activity is retained, but they are many times more toxic than the group which contains an acid radical.

In 1922, Kharasch[2] developed a method whereby organo-metallic compounds can be made water soluble by condensing them with mercapto-carboxylic or sulfonic acids.

When mercurials of the type RHgX, where X is an inorganic radical, react with a mercapto acid, HSR', where R' is a group containing an alkyl or aryl carboxylic or sulfonic acid, a double decomposition occurs

$$\text{RHgX} + \text{HSR}' = \text{RHgSR}' + \text{HX}$$

The new compound RHgSR' is soluble in sodium bicarbonate solution and forms with the alkali metals soluble salts whose solutions are in general stable and do not give an immediate precipitate of mercuric sulfide with ammonium sulfide.

---

[1] A portion of this paper was presented before the division of Medicinal Products at the Detroit meeting of the American Chemical Society, September, 1927, by M. S. Kharasch, H. A. Shonle, and John H. Waldo.

[2] M. S. Kharasch, U. S. Patent 1,589,599, reissue 16,921,

Kharasch and Chalkley[3] showed that variations in the degree of electronegativity of the organic radical will produce a marked effect on the degree of ionization of mercury as evidenced by the readiness with which mercuric sulfide is formed when compounds are treated with hydrogen sulfide or ammonium sulfide. It should therefore be possible to prepare predetermined mercuri-carbon compounds possessing various degrees of lability of the mercury.

The stability of these new compounds depends upon two factors, first, the stability of the R—Hg linkage and second, the S—R' linkage. In regard to the former it could be predicted from the work of Kharasch and Marker,[4] that the higher homologs in the alkyl series would be more stable than the lower members and that aryl groups would be less stable than alkyl or alkaryl groups. Such a prediction proved to be true in this instance. The sulfur atom is quite strongly electronegative and it would therefore be predicted that an electronegative group, such as an aromatic nucleus, attached to it, would tend to produce a greater stability than less electronegative groups, such as those of the straight-chain aliphatic series. Experimental work confirmed this hypothesis.

Experimental Part

Preparation of Organo Mercury Halides.—The various alkyl and aryl mercury halides used in this investigation were prepared by the Grignard reaction. In carrying out these reactions, two reflux systems were used, designed to filter the Grignard reagent without contact with air. The flask containing mercuric chloride in ether was connected by a glass tube extending to the bottom of the Grignard reaction flask. At the completion of the original reaction the Grignard reagent was forced into the second flask by compressed air. The end of the connecting tube was covered with 200-mesh silk bolting cloth to act as a filter.

Preparation of Mercapto Acids.—All of the rnercapto acids used in this investigation have been described previously in the literature. Two general methods were used, the first according to Schacht and of Duvillier,[5] which consisted in treating the desired aliphatic halogen substituted acids with potassium hydrogen sulfide in alcohol solution; and the second as outlined by Leuchart,[6] which involves the formation of the xanthogen ester, by treating the desired diazonium salt with potassium ethyl xanthate. This hydrolyzed to the mercapto acid in about 60–70% yield. If, however, the initial precipitate of the crude acid is dissolved in excess alkali and reduced by boiling with zinc dust, the yield is frequently increased to 90%.

Preparation of the Salts of Organo Mercuri-mercapto Acids.—As

indicated above, the condensation of organo mercury salts with the mercapto acids proceeds very quickly and smoothly in a dilute alcoholic sodium hydroxide solution.

In carrying out the synthesis it was more convenient to use two moles of alkali instead of one, thus initially obtaining the water-soluble sodium salt. The water-insoluble acids are precipitated by acidification and purified by crystallization from alcohol or acetone.

Methyl Mercurithiosalicylic Acid, (o-$CH_3HgSC_6H_4COOH$).—Forty grams of methyl mercuric iodide (0.12 mole) is moistened with 20–30 cc. of 95% ethyl alcohol and to this is added 96 cc. of 10% sodium hydroxide solution (0.24 mole). This solution is then added to a 95% ethyl alcohol solution of 18 g. of thiosalicylic acid (0.12 mole). The solution is filtered, and methylmercurithiosalicylic acid precipitates by acidification with 10% sulfuric acid. Crystallization from 50 cc. of 95% ethyl alcohol gives an 80–85% yield. It is a white crystalline compound melting at 174°,[7] soluble in alcohol, ether and acetone, but insoluble in water and acid.

Anal. Subs., 0.2237: CO_2, 0.2135; H_2O, 0.0408. Calcd. for $C_8H_8O_2SHg$: C, 26.09; H, 2.17. Found: C, 26.01; H, 2.03. Subs., 0.2500: 13.2 cc. of N/10 KSCN. Calcd.: Hg, 54.34. Found: Hg, 52.95.

Ethyl Mercurithiosalicylic Acid, (o-$C_2H_5HgSC_6H_4COOH$).—Ethyl mercuric chloride and thiosalicylic acid are combined by an identical method, giving a white crystalline solid melting at 111°.

Anal. Subs., 0.2950: CO_2, 0.3077; H_2O, 0.0714. Calcd. for $C_9H_{10}O_2SHg$: C, 28.27; H, 2.63. Found: C, 28.40; H, 2.68. Subs., 0.2000: 10.45 cc. of N/10 KSCN. Calcd.: Hg, 52.41. Found: Hg, 52.40.

p-Ethyl Mercuri-mercaptobenzoic Acid, (p-$C_2H_5HgSC_6H_4COOH$).—Ethylmercuric chloride and p-mercaptobenzoic acid are combined by an identical method giving a white crystalline solid which does not melt up to 250°.

Anal. Subs., 0.2570: CO_2, 0.2718; H_2O, 0.0575. Calcd. for $C_9H_{10}O_2SHg$: C, 28.27; H, 2.63 Found: C, 28.84: H, 2.49. Subs., 0.3000: 15.6, 15.8 cc of N/10 KSCN. Calcd.: Hg, 52.41. Found: Hg, 52.14, 52.82.

Isoamyl Mercurithiosalicylic Acid, (o-iso-$C_5H_{11}HgSC_6H_4COOH$).—Isoamyl mercuric chloride and thiosalicylic acid are combined by an identical method giving a white crystalline solid melting at 78°.

Anal. Subs, 0.2720: CO_2, 0.3321; H_2O, 0.0883. Calcd. for $C_{12}H_{16}O_2SHg$: C, 33.95; H, 3.77. Found C, 33.30; H, 3.60. Subs., 0.3000: 14.25 cc. of N/10 KSCN. Calcd.: Hg, 47.19. Found: Hg, 47.63.

Several additional products were made, but due to small amounts of reagents low yields were obtained. It seemed more desirable to ascertain their germicidal value and sacrifice a complete chemical analysis. There-

---

[7] All melting points taken with a standardized thermometer and corrected for stem exposure

fore, only mercury assays were made. In view of the fact, however, that identical methods were used and that they were purified by crystallization to constant melting points, it is reasonable to assume the structure of all is the same.

TABLE I

COMPOUNDS, CONSTANTS AND ANALYTICAL DATA

Acid, ( ) = mercuri	M. p., °C.	Formula	Metcury analyses, % Calcd.	Found	
Phenyl ()-thiosalicylic	228.5 (dec.)	$C_{13}H_{10}O_2SHg$	46.57	46.63	46.79

All compounds are white crystalline solids. Mercury analyses by the potassium thiocyanate method.

p-Ethyl Mercuri-mercaptobenzenesulfonic Acid, (*p*-$C_2H_5HgSC_6H_4$-SO_3H.—Five grams of ethyl mercuric chloride dissolved in 20–30 cc. of warm 95% ethyl alcohol is added to 3.6 g. of *p*-mercaptobenzenesulfonic acid in an equal volume of alcohol. A precipitate starts forming in a few minutes. After standing for two to three hours at room temperature, the precipitate is recovered and dried.

Discussion

It is not the purpose of this paper to outline any bacteriological test. However, some indication of the change in toxicity and germicidal effect may be obtained from an examination of the values for the sodium salts of the above compounds. Disregarding other factors, the best germicide in any series should combine the lowest toxicity with the highest bactericidal value. A therapeutic index may be obtained by the product of these values, and if sodium ethyl mercurithiosalicylate be given the value one, a representative ratio of indices is given. The germicidal values were obtained by a slight modification of the technique outlined by Reddish,[8] by using undiluted horse serum for the diluent. The data and therapeutic index are given in Table II.

The table indicates that the alkaryl mercuri derivatives are less toxic than the aryl, that salts of carboxylic acids are less toxic than sulfonic acids, that some decrease in the index is produced by a change from the ortho to the para position on the benzene ring,[9] and by alkyl instead of alkaryl derivatives. Further, it has been observed that alkyl compounds are decidedly less stable, either in solution or dry than alkaryl products.

The benzyl mercurithiosalicylic acid described above was not obtained in sufficient quantity to obtain authentic figures on toxicity, but its germi-

cidal values were sufficiently low to indicate the influence of the aryl group on toxicity and its probable low index.

The writer is indebted to Dr. G. H. A. Clowes and H. A. Shonle for many suggestions connected with the preparation of these compounds and to R. M. Lingle for the mercury assays.

Summary

1. Nine new organo-mercury compounds have been prepared.
2. In water solution their sodium salts are desirable germicides.
3. A therapeutic index indicates that an alkaryl combination is the most stable and germicidal type.

ACYL DERIVATIVES OF ORTHO-AMINOPHENOL. VI

BY C. B. POLLARD AND R. E. NELSON

RECEIVED AUGUST 1, 1930 PUBLISHED MARCH 6, 1931

When diacyl derivatives of o-aminophenol were prepared in the past by the usual methods, it was found in most cases that the order of introduction of the two different acyl groups has no influence upon the formation of the diacyl, identical products being isolated from the two acylations. The position of the acyl groups of the molecule can be determined by removing the group attached to the oxygen by saponification with dilute alkali, and determining from the physical constants of the remaining monoacylated product the group attached to the nitrogen. The identical diacyls mentioned above were found to saponify to yield identical products, as would be expected.

The formation of identical rather than isomeric products on reversing the order of acylation indicates that during acylation a rearrangement must have occurred in one of the two cases. It has been found that certain acyl groups have more power than others to bring about this migration, weight and acidity of the group being considered to have the predominating influence in their obtaining a position in the more basic amino group in preference to the phenol group.

Previous work on this subject by Ransom,[1] Ransom and Nelson,[2] Nelson and others,[3] and Raiford and others[4] is discussed in the literature.

In view of the experimental evidence that relative acidity and weight of the acyl groups play some role in these rearrangements, this investigation was an attempt to determine the effects of these factors when one of the acyl groups was a constant throughout the experiments. Phenylacetyl chloride was used as one of the acylating agents in the preparation of all diacyl derivatives of o-aminophenol in these experiments. The selection of the phenylacetyl group afforded the use of lighter and heavier acyl groups and acyl groups derived from weaker and stronger acids.

When o-phenylacetylaminophenol was acylated with acetyl chloride, a diacyl melting at 101–102° was produced, while the acylation of o-acetylaminophenol with phenylacetyl chloride gave a diacyl melting at 99–100°. A mixture of these two diacyls melted at 76–79°, showing the two to be different. Saponification of each of these diacyls produced only *o*-phenylacetylaminophenol, indicating that in the latter case migration of the phenylacetyl group from the oxygen to the nitrogen must have occurred. Similar results were obtained with diacyls containing the propionyl and chloroacetyl groups. The saponification of these isomers involved rearrangements in which the phenylacetyl group replaced the lighter and less acidic acetyl and propionyl groups and the lighter and more acidic chloroacetyl group.

o-Phenylacetylaminophenol acylated with n-butyryl chloride gave *o*-phenylacetylaminophenyl *n*-butyrate, which yielded *o*-phenylacetylaminophenol on saponification. Acylation of o-n-butyrylaminophenol with phenylacetyl chloride produced o-n-butyrylaminophenyl phenylacetate. Saponification of this diacyl gave o-n-butyrylaminophenol. A rearrangement did not occur in either case. In the first case the phenylacetyl group, which is the heavier and more acidic group, is attached while in the second case the lighter and less acidic n-butyryl group is attached to the nitrogen. Similar results were obtained with diacyls containing the benzoyl group, which is lighter and more acidic than the phenylacetyl group.

Acylation of o-phenylacetylaminophenol with *n*-valeric anhydride gave

[4] (a) Raiford and others, *ibid.*, 41, 2068 (1919); (b) 44, 1792 (1922); (c) 45, 469 (1923); (d) 45, 1728 (1923); (e) 44 430 (1924); (f) 46, 2051 (1924); (g) 46, 2246 (1924); (h) 46, 2305 (1924); (i) 47, 1111 (1925); (j) 47, 1454 (1925); (k) 48, 483 (1926).

o-phenylacetylaminophenyl n-valerate. Saponification of this diacyl produced crystals melting from 94–99° which when mixed with *o*-phenylacetylaminophenol (m. p. 149–150°) melted from 102–120°. When mixed with o-n-valerylaminophenol (m. p. 78.5–79.5°), the mixture melted from 72–75°. Mixtures of the two possible pure monoacyls were made; such a mixture of approximately 65% o-phenylacetylaminophenol and 35% o-n-valerylaminophenol melted from 93–98°. Some of the saponification product was added to this mixture of the pure monoacyls and the resulting mixture melted through practically the same range. Evidently the saponification product was about 65% *o*-phenylacetylaminophenol and 35% o-n-valerylaminophenol, showing that a partial rearrangement occurred. When o-n-valerylaminophenol was acylated with phenylacetyl chloride, o-n-valerylaminophenyl phenylacetate was produced. Saponification of this diacyl gave only *o*-*n*-valerylaminophenol, a rearrangement did not occur and the lighter and less acidic valeryl group was attached to the nitrogen atom.

When o-phenylacetylaminophenol was acylated with isovaleryl chloride, o-phenylacetylaminophenyl isovalerate was formed, while the introduction of the acyl groups in reverse order gave the isomeric diacyl *o*-isovalerylaminophenyl phenylacetate. Saponification of each of these diacyls produced o-isovalerylaminophenol. In the first case the isovaleryl radical, which is the lighter and less acidic radical, migrated from the oxygen to the nitrogen.

Acylation of o-phenylacetylaminophenol with m-chlorobenzoyl chloride gave o-phenylacetylaminophenyl m-chlorobenzoate. Introduction of the acyl group in reverse order gave *o*-(*m*-chlorobenzoylamino)-phenyl phenylacetate. Each of these diacyls gave m-chlorobenzoylaminophenol on saponification. A migration of the m-chlorobenzoyl group, which is the heavier and more acidic radical, from the oxygen to the nitrogen occurred during saponification of the first diacyl.

The acylation of *o*-(*m*-bromobenzoylamino)-phenol with phenylacetyl chloride produced *o*-(*m*-bromobenzoylamino)-phenyl phenylacetate. On saponification this diacyl gave *o*-(*m*-bromobenzoylamino)-phenol. Attempts to prepare this diacyl or its isomer by introducing the acyls in reverse order were unsuccessful.

When o-phenylacetylaminophenol was acylated with methyl chlorocarbonate, the same diacyl was produced as when methyl *o*-hydroxycarbanilate was acylated with phenylacetyl chloride. Saponification of this diacyl yielded a mixture of approximately 50% of each of the two possible monoacyls. A partial rearrangement occurred during saponification or the diacyl was an equilibrium mixture of the two possible diacyls. The latter does not seem probable, as the diacyl melted at 105–106°.

When o-phenylacetylaminophenol was acylated with ethyl chlorocarbonate, the same diacyl was obtained as when ethyl o-hydroxycarbanilate was acylated with phenylacetyl chloride, Saponification gave ethyl *o*-hydroxycarbanilate, showing the carboethoxy group to be attached to the nitrogen.

Acylation of *o*-phenylacetylaminophenol with isobutyl chlorocarbonate gave the same diacyl as when isobutyl o-hydroxycarbanilate was acylated with phenylacetyl chloride. Saponification showed the isocarbobutoxy group attached to the nitrogen.

Experimental

All monoacyls were prepared by the method of Groenvik[6] using *o*-aminophenol and the acid chloride. Their properties are summarized in Table I.

TABLE I

PROPERTIES OF MONOACYLS

Phenol	Formula	M. p., °C.	Yield, %	Analyses, N, % Calcd.	Found
o-Phenylacetylamino-	$HOC_6H_4NHCOCH_2C_6H_5$	149–150	60	6.16	6.21
o-*n*-Butyrylamino-	$HOC_6H_4NHCOC_3H_7$	80–81	58	7.81	7.62
o-(*m*-Bromobenzoylamino)-	$HOC_6H_4NHCOC_6H_4Br$	180	60	4.79	4.86
o-(*m*-Chlorobenzoylamino)-	$HOC_6H_4NHCOC_6H_4Cl$	156–158	52	5.64	5.51

The other monoacyls used, which have been described previously, were made by the same method.

o-Phenylacetylaminophenyl Acetate ($C_6H_5CH_2CONHC_6H_4OCOCH_3$).—To 3 g. of o-phenylacetylaminophenol a slight excess (1.4 g.) of acetyl chloride was added. After the addition of a drop of sulfuric acid, the mixture was stirred and heated on the water-bath for thirty minutes. A purplish-black oil formed which solidified when cold water was added. The solid was finely ground and washed with warm water. It was then dissolved in hot dilute alcohol, filtered and crystallized as flesh-colored, light flaky crystals. Repeated crystallizations gave crystals melting at 101–102°.

About 1 g. of this compound was saponified in the equivalent quantity of 10% potassium hydroxide. After complete solution resulted, the solution was acidified with dilute hydrochloric acid. A yellowish-brown precipitate formed which was washed with warm water and crystallized from dilute alcohol. These crystals melted at 147.5–148.5° and when mixed with o-phenylacetylaminophenol (m. p. 148–149°) melted at 148–149°, showing them to be identical.

o-Acetylaminophenyl Phenylacetate ($CH_3CONHC_6H_4OCOCH_2C_6H_5$).—A slight excess (3.2 g.) of phenylacetyl chloride was added to 3 g. of o-acetylaminophenol. A drop of sulfuric acid was added, the mixture stirred and heated on the water-bath for thirty minutes. A dark blue oil formed which solidified on addition of cold water. The solid was ground fine, washed with warm water and dissolved in hot dilute alcohol. On cooling it crystallized as pinkish-brown flakes. After four crystallizations the melting point was constant at 99–100°. Some of these crystals were mixed with the diacyl made in the reverse order and the mixture melted from 76–79", showing the two to be different.

This diacyl was saponified in the same manner as the preceding one and yielded *o*-phenylacetylaminophenol. A rearrangement must have occurred during saponification.

All diacyl derivatives of o-aminophenol except the phenylacetates of methyl, ethyl and isobutyl o-hydroxycarbanilate were made by the method described above using the monoacyl, the acid chloride and a drop of sulfuric acid, which is a modification of the method of Jacobs, Heidelberger and Rolf or by the method of Jacobs, Heidelberger and Rolf[6] using the monoacyl, the acid anhydride and a drop of sulfuric acid. The *o*-hydroxycarbanilates were made by the Schotten–Baumann reaction. The properties of all of these diacyls are summarized in Table II.

The melting points in the cases of three pairs of isomers listed above as 1, 2, 13, 14, 15 and 16 might indicate the possibility that in each case they were identical substances in an impure state, but the facts that each substance appeared to be homogeneous and the melting points of the mixtures were decidedly lower lead to the conclusion that they were isomers.

Mixed melting point of 1 and 2	76–79"
Mixed melting point of 13 and 14	80–90°
Mixed melting point of 15 and 16	128–135°

Summary

A study of the diacyl derivatives of o-aminophenol, when one of the acyl groups was always the phenylacetyl radical, has been made. The phenylacetyl group was checked against the acetyl, propionyl, butyryl, valeryl, isovaleryl, monochloroacetyl, benzoyl, m-chlorobenzoyl, *m*-bromobenzoyl, carbomethoxy, carboethoxy and isocarbobutoxy groups.

When both acylating agents were of the type (ClCOR), isomeric diacyls were obtained depending on the order of introduction of the acyl groups. In five cases out of eight complete rearrangement occurred during saponification, one case showed partial rearrangement and in two rases rearrangement did not occur.

Apparently relative acidity and weight are not the controlling factors in this type of rearrangement. Where complete rearrangement did occur the nitrogen atom was shown to be attached to the heavier and more acidic group in three cases, to the heavier and less acidic in one case and to the lighter and less acidic in another. Although there were differences in weight and acidity of the acyl groups, one case showed only partial rearrangement and two cases showed no migration of the acyl groups even during saponification.

Where one of the acylating agents was an alkyl chlorocarbonate (ClCOOR), the same diacyl derivative was obtained regardless of the order of introduction of the groups. Saponification of these diacyls gave a mixture of the two possible monoacyls in one case and showed no migration of the groups in the other two cases. In the last two cases the phenylacetyl group was removed by saponification, showing it to be attached to the oxygen in the diacyls.

New mono and diacyl derivatives of o-aminophenol have been made and studied.

THE NITROGEN COMPOUNDS IN PETROLEUM DISTILLATES. III. THE STRUCTURE OF A HYDROAROMATIC BASE OF THE FORMULA $C_{16}H_{25}N$[1]

BY W. C. THOMPSON[2] AND J. R. BAILEY[3]

RECEIVED AUGUST 8, 1930 PUBLISHED MARCH 6, 1931

Introduction

Recently there was published from the Texas Laboratory a paper entitled "An Investigation of the Bases in the Kerosene Distillate of California Petroleum."[4]

This work has been continued in an attempt to establish the structural formula of a *hydroaromatic* base of the formula, $C_{16}H_{25}N$, and the reader is referred to the paper cited for detailed information on the procedure followed in its isolation.[5] It is obvious that the structural problems involved here are comparable to those in alkaloidal chemistry; as a matter of fact, were it of plant occurrence, the $C_{16}H_{25}N$ compound would undoubtedly be termed an alkaloid. Since hydroaromatic bases, in contrast to those of aromatic types, predominate in petroleum distillates,[6] it might seem appropriate to give the hydroaromatic types the class name, "*Petroleum Alkaloids*."[7] While it is true that the so-called petroleum bases,

---

[1] This paper contains results obtained at the Chemical Laboratory, University of Texas, in an investigation on "The Nitrogen Compounds in Petroleum," listed as Project **20** of American Petroleum Institute Research. Financial assistance in this work has been received from a research fund of the American Petroleum Institute donated by John D. Rockefeller. This fund is being administered by the Institute with the coöperation of the Central Petroleum Committee of the National Research Council.

[5] Our supply of crude kerosene bases was extracted from **150** barrels of the residue obtained at the Oleum Plant of the Union Oil Company of California in refining their crude kerosene stock with liquid sulfur dioxide. In the paper cited, p. **1242,** this material is referred to as "probably the largest amount of so-called petroleum bases ever assembled for investigation."

Mr. H. K. Ihrig of Pittsburgh, Penna., recently informed one of the authors that during **1926–1927,** in an investigation financed by the Associated Oil Company, he isolated **1100** gallons of base from **10,000** barrels of Edeleanu extract. U. S. patents, **1,671,721** (5/29/28), and **1,686,136** (10/2/28), assigned "one-half to S. E. Campbell of Associated, California, and one-half to Associated Oil Company, of San Francisco," were an outgrowth of this work.

[6] On the suspected presence of hydroaromatic bases in coal-tar distillates, *cf.* J. von Braun, **Ann,** 478, **182 (1930);** Decker and **Dunant, Ber.,** 42, **1178 (1903).**

[7] Prof. Austin M. Patterson, to whom the authors are indebted for valuable suggestions in connection with problems of nomenclature presented in this paper, writes:

unlike the most important plant alkaloids, are oxygen-free, there are also oxygen-free plant alkaloids, such as coniine and nicotine. Furthermore, it may be expected that further study of the bases in petroleum distillates will reveal hydroaromatic types containing the *pyrrole* nucleus and a closer analogy be thus established. Whether any of the basic substances formed in the distillation of petroleum will ever attain a pharmacological importance at all comparable to that of plant alkaloids presents a question that cannot be answered at this time.[8]

Developments in connection with A. P. I. Project 20, as well as investigations elsewhere, indicate conclusively that hydroaromatic bases in great numbers and of various types, along with aromatic bases,[9] exist in all unrefined, California, petroleum distillates. The procedure being employed in the Texas Laboratory for the isolation of so-called petroleum bases, and for the perfection of which Research Fellow, E. J. Poth, deserves a large share of credit, involves the successive employment of: (1) dilute sulfuric acid extraction; (2) exhaustive fractional distillation; **(3)** resolution with buffered acid solutions; and (4) recrystallization of appropriate salts. In this way both types of bases, in contrast to the non-reactive, associated hydrocarbons, can be isolated free of admixtures.

The $C_{16}H_{25}N$ base shows an unusual stability toward permanganate in both neutral and alkaline solution but is quite readily attacked in acid solution. However, it is very resistant to oxidation with chromic acid in sulfuric acid solution. Heated with fuming sulfuric acid, it is oxidized with a violent evolution of sulfur dioxide just above 200°, but the reactions involved have not been studied. After numerous preliminary experiments

---

"These hydroaromatic bases are like plant alkaloids in structure and the term, alkaloid, has been used for organic bases of non-vegetable origin; still, the tendency in recent times has been to restrict it to plant bases." On prior use of phrase "petroleum alkaloids," cf. **A.** Weller, *Ber.*, 20, 2098 (1887); F. X. Bandrowski, *Monatsh.*, 8,224 (1887).

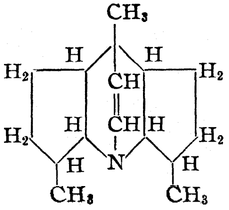
[8] A report on physiological tests, carried out on dogs and guinea pigs with the hydrochloride of the $C_{16}H_{25}N$ base, by Dr. E. J. Poth of Johns Hopkins University is submitted: "It is of low toxicity. Upon intravenous administration to anesthetized animals, the blood pressure and heart-rate are not altered and there is no action on bronchial musculature. However, there is a low-grade irritant action, from which recovery is slow, on isolated strips of virgin guinea pig's uterus. The substance was not further investigated."

As an indication of the importance petroleum bases may assume, the following communication from Dr. Erich Hesse, Professor of Pharmacology and Experimental Therapy in the University of Breslau, Breslau, Germany, is of interest: "I am anxious to examine the different fractions of your crude bases in their action on tubercular bacilli. Strong evidence warrants the forecast of anti-bacterial, active constituents among the kerosene bases."

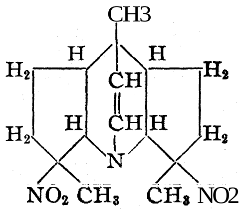
[9] King and Bailey obtained 2,3,8-trimethylquinoline from the distillation fraction where the $C_{16}H_{25}N$ base occurs and proved its structure by synthesis (Ref. 4, p. 1245). Proof is furnished in the same article, p. 1240, for the assumption of a great complexity of kerosene bases.

nitric acid of sp. gr. 1.260, at a temperature of 170°, was found to give the most promising results, although the yields of reaction products are very poor.

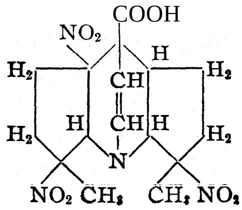
In order to discuss more clearly the important conclusions arrived at from the data obtained in the nitric acid reactions, there are subjoined structural formulas tentatively assigned to four nitric acid reaction products and preceding these the structural formula proposed for the $C_{16}H_{25}N$ base



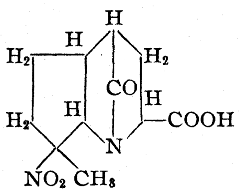
I



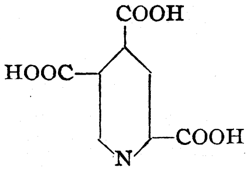
II



III

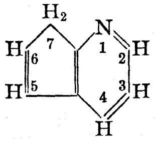


IV

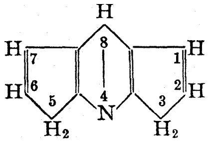


V

The following formulas, VI, C_8H_7N, and VII, $C_{11}H_9N$, for which the names, *pyrindine*[10] and *pyrindacine*,[11] respectively, are proposed, contribute to a simplification of the nomenclature of the products discussed



VI



VIII

There are derived from these parent compounds the names: (I) decahydro-3,5,8-trimethyl-4,8-ethenopyrindacine, (II) decahydro-3,5,8-trimethyl-3,5-dinitro-4,8-ethenopyrindacine, (III) decahydro-3,5-dimethyl-

---

[10] Dr. Patterson favors the spelling **pyrindine** rather than pyrindene [*cf.* Zincke, Ann., 290, **321** (1896)] because the compound is a base. Several isomeric pyrindines are possible due to the relative positions of the CH_2 and N [*cf.* Meyer and Jacobson, II, (3) 1050], of which VI is "**1,7-pyrindine.**"

[11] The corresponding hydrocarbon, *indacene*, is shown in the form of derivatives [see M. V. Jonescu, Bull. *soc. chim.*, 37, **916 (1925)**; **41, 1096** (1927)], and bears the same relation to *pyrindacine* as anthracene to *acridine*. As in the case of **pyrindines** a number of isomeric pyrindacines are possible.

3,5,7 a-trinitro-4,8-ethenopyrindacine-8-carboxylic acid, (IV) octahydro-7-methyl-7-nitro-1,4-carbonylpyrindine-3-carboxylic acid.

Formula I, which may be considered elucidated in its most important features, *reflects an important structural relationship between this hydroaromatic base and the petroleum naphthenes.* In view of the wealth of bases in petroleum distillates it is highly probable that the $C_{16}H_{25}N$ product is the forerunner of a family of compounds of a type that may be termed appropriately "Naphthenic Bases," a study of which may contribute to a solution of the difficult structural problems presented by the naphthenic acids.[12]

It soon became evident in this investigation that the $C_{16}H_{25}N$ base represents an unusual type of compound. The failure of all hydrogenation and dehydrogenation experiments to effect a chemical change in the substance makes improbable such products as a heptamethyltetrahydroquinoline or a trimethyldecahydroacridine. Further evidence of the improbability of such structural types is also furnished by the great stability of the base toward alkaline permanganate.

Since in numerous instances it has been established conclusively that the so-called naphthenes are alkylated cyclopentanes, and since the chemical behavior of the $C_{16}H_{25}N$ compound, where its basic properties are not involved, strongly parallels that of methylcyclopentane,[13] a structural interpretation is presented in I that assumes a condensation of two cyclopentane nuclei with a piperidine nucleus. In each of the five-membered rings a tertiary carbon appears in explanation of the fact that, analogous to corresponding napthenes containing one tertiary carbon and forming *mononitro* derivatives,[14] our product yields a colorless, alkali-insoluble, *dinitro* derivative, II. The assumption of a piperidine complex in the molecule is warranted by the formation of product V, $C_8H_5O_6N$, in the nitric acid oxidation. The only structure admissible for this substance is that of a pyridine tricarboxylic acid. All six isomers are known and the properties of our product prove it to be pyridine-2,4,5-tricarboxylic acid, *i. e.*, berberonic acid.[15,16] This substance is of very little importance in proof of structure other than to indicate that the nitrogen in the $C_{16}H_{25}N$

---

[12] On the cyclopentane structure of naphthenic acids see Zelinsky, *Ber.*, 57, 51, 57 (1924); Bushong and Humphry, "Eighth International Congress of Applied Chemistry," Vol. VI, p. 58; von Braun, *Z. angew. Chem.*, 43, 1051 (1930).

[13] Wischin, "Die Naphthene," 1901, p. 20, states: "permanganate in neutral as well as in alkaline solution reacts very slightly on naphthenes; only after prolonged action at 40° can a weak oxidizing effect be observed." The extraordinary stability of methylcyclopentane against dehydrogenation was established by Zelinsky, *Ber.*, 45, 678 (1912).

[14] Markownikoff and Konovalow, *ibid.*, 28, 1234 (1895); Kijner, *J. prakt. Chem.*, 56,364 (1897); Markownikoff, *Ann.*, 307,335 (1899).

[15] H. Weidel, *Ber.*, 12, 410 (1879).

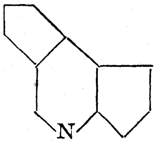
[16] Mumm and Hüneke, *ibid.*, 51, 162 (1918).

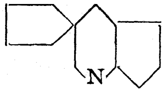
base is in a six-membered ring. It cannot be employed in proof of how the methyl cyclopentane rings are condensed with the six-membered ring, because the higher pyridine-polycarboxylic acids readily split out carbon dioxide at temperatures lower than that at which this pyridine acid was formed. The location of a methyl at the y-position in the piperidine ring harmonizes with our failure to isolate a *trimethyl-trinitro* derivative among the nitric acid reaction products corresponding to the *dinitro* compound, II.

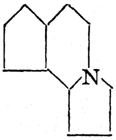
The only unsaturated group assumed in the structurally symmetrical formula assigned the naphthenic base is the etheno bridging between the nitrogen and the y-carbon in the piperidine ring. The fact that this part of the molecule is attacked readily by neither oxidizing nor reducing agents may be plausibly accounted for by steric hindrance. Not until one of the cyclopentane nuclei is disrupted, does the —CH═CH— grouping disappear, as in the $C_{11}H_{14}O_5N_2$ oxidation product, IV, where there is assumed a carbonyl bridging, due to an inner amide formation between a y-carboxyl and the imino group of the piperidine complex. Failure to obtain a nitroso derivative eliminates the isomeric anhydride that would result from dehydration between two carboxyl groups.

Intermediary between products II and IV is the trinitrocarboxylic acid, III, where the presence of three *tertiary* nitro groups was confirmed by titration; this revealed a monobasic acid, whereas, if there were present in addition to the carboxyl a *secondary* nitro group, the substance would be a dibasic acid.

Despite the satisfactory interpretation of the reactions of the $C_{16}H_{25}N$ base furnished by the structure assigned, there are a number of trinuclear cyclic arrangements other than that proposed in I which remain to be eliminated. As examples of other possible condensations of one six- and two five-membered rings there may be considered





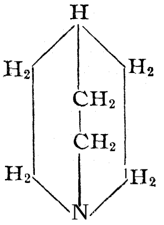


It is obvious that, in the absence of a synthesis of the naphthenic base, absolute proof of structure here presents a very difficult problem in orientation.

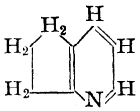
Even granted that the position of contact of the two methylcyclopentane rings with the piperidine ring is as shown in Formula I, the location of methyls at positions 3 and 5, respectively, involves an arbitrary assumption.

From the above discussion it is obvious, and likewise not surprising, that the experimental evidence so far obtained does not offer conclusive proof of the structure of the naphthenic base; still the formulas, tentatively assigned to the different products concerned, should contribute to a clearer conception of their interrelationship.

It is interesting to note that the structure assigned the $C_{16}H_{25}N$ base is related to quinuclidine, i. *e.*, 1,4-ethanopiperidine, A, assumed by Koenigs[17] as one of the parent cyclic nuclei in quinine. Quinuclidine,[18] as well as its alkyl derivatives, is readily synthesized and, like our $C_{16}H_{25}N$ base, piperidine derivatives of this type possess an unusual stability.



Quite recently there has been isolated from Fushun shale oil a base of the formula, C_8H_9N,[19] that is undoubtedly 5,6-dihydropyrindine, B.[19a] This formula not only harmonizes with the pyrindacine structure assigned the $C_{16}H_{25}N$ base but makes it highly probable, even if 5,6-dihydropyrindine itself is not present among the numerous kerosene bases, that compounds of the pyrindine type occur here.



Experimental Part

The Naphthenic Ease, **$C_{16}H_{25}N$**.—After several crystallizations of the picrate from 95% alcohol, the salt is decomposed with ammonium hydroxide, ammonium picrate washed out of the supernatant oil with water and the base dried at 100° in a current of air. In final purification it can be distilled undecomposed at 10–15 mm. pressure.

The following physical constants were determined: b. p. at 746 mm. 278.2"; d_4^{20} 0.9391; n_D^{20} 1.5129. It is a colorless, odorless, optically inactive oil, only slightly soluble in water and readily soluble in the common organic solvents. With the common alkaloidal reagents it forms difficultly soluble salts.

Anal. Calcd. for $C_{16}H_{25}N$: C, 83.12; H, 10.82; N, 6.06. Found: C, 83.25, 83.30; H, 10.78, 10.81; N, 5.95, 6.12. *Mol. wt.* Subs., 0.1694 g.; benzene, 21.915 g.; *At*, 0.183°. Calcd. for $C_{16}H_{25}N$: mol. wt., 231. Found: mol. wt., 211.

Salts of the Naphthenic Base

Picrate.—This salt separates from a hot, alcoholic solution of the base and picric acid in slender, yellow prisms melting at 151°. It is readily soluble in hot alcohol, glacial acetic acid, benzene, acetone and ethyl acetate and only slightly soluble in water, ether and petroleum ether.

---

[19] Eguchi, *Bull. Chem. Soc. Japan*, 3, 239 (1928); *Chem. Zentr.*, **100**, 331 (1929).

[19a] Since this paper was submitted to the Journal, one of the authors, W. C. Thompson, has confirmed the structure of the Eguchi base by its synthesis through condensation of hydroxymethylene-cyclopentanone [Wallach, *Ann.*, 329, 114 (1903)] with cyanoacetamide to 2-hydroxy-3-cyano-5,6-dihydropyrindine [*cf.* Sen-Gupta, *J. Chem. Soc.*, **107**, 1347 (1915)], followed by the series of reactions developed by J. von Braun [*Ann.*, 478, 191 (1930), in the conversion of 2-hydroxy-3-cyano-5,6,7,8-tetrahydroquinoline to 5,6,7,8-tetrahydroquinuline. The results of this investigation will be published in the near future.

Anal. Calcd. for $C_{22}H_{28}O_7N_4$: C, 57.39; H, 6.11; N, 12.17. Found: C, 57.00; H, 6.36; N, 12.46.

Acid Sulfate.—The calculated amount of concentrated sulfuric acid is added to the base in glacial acetic acid and the salt precipitated with ether. It crystallizes from acetone in square, colorless plates melting at 196' and is readily soluble in water and alcohol.

Anal. Calcd. for $C_{16}H_{25}N \cdot H_2SO_4$: S, 9.72. Found: S, 9.69.

Hydrochloride.—A hydrochloric acid solution of the base is evaporated to dryness, the residue dissolved in hot acetone and the salt precipitated with ether. It is readily soluble in water and alcohol and crystallizes from acetone in prisms melting at 251°.

Anal. Calcd. for $C_{16}H_{25}N \cdot HCl$: N, 5.23. Found: N, 5.14, 5.38.

Nitrate.—Very characteristic of the base is its behavior toward nitric acid. When it is introduced into an excess of not too dilute nitric acid, two layers are formed. On cooling and vigorous stirring of the upper layer, the nitrate separates with one molecule of water in crystals of octahedral appearance. A convenient method of preparation is to suspend the base in twice its weight of water, add the calculated amount of nitric acid of sp. gr. 1.30. heat until all the oil has disappeared and chill with stirring. It melts at 79°, at 110° is dehydrated and then has a melting point of 141°. Its solubility in water is 1:20 at 30°. The nitrate is readily soluble in alcohol, glacial acetic acid and acetone. Samples with and without water of crystallization were analyzed.

Anal. Calcd. for $C_{16}H_{25}N \cdot HNO_3 \cdot H_2O$: N, 8.97. Found: N, 8.82. Calcd. for $C_{16}H_{25}N \cdot HNO_3$: N, 9.52. Found: N, 9.57.

The chloroplatinate, prepared in dilute hydrochloric acid and then recrystallized from the same medium, is obtained in slender rods decomposing at 240°.

Anal. Calcd. for $(C_{16}H_{25}N)_2 \cdot H_2PtCl_6$: Pt, 22.35. Found: Pt, 22.29.

The zinc chloride salt, prepared by the addition of a solution of zinc chloride to the base in hydrochloric acid, crystallizes from water in rosets of short, pointed prisms melting at 171'. It is readily soluble in alcohol, hot water and hot glacial acetic acid.

Anal. Calcd. for $C_{16}H_{25}N \cdot ZnCl_2$: N, 3.81. Found: N, 4.12.

The mercuric chloride salt, prepared similarly to the zinc chloride salt, is obtained as an oil which on stirring solidifies. It crystallizes from alcohol in clusters of slender rods melting at 157.5'. It is very difficultly soluble in water and quite soluble in hot alcohol and hot glacial acetic acid.

Anal. Calcd. for $C_{16}H_{25}N \cdot HgCl_2$: N, 2.78. Found: N, 2.86.

The methiodide, prepared in quantitative yield by heating the base with an excess of methyl iodide at 100° in a sealed tube for twenty-four hours, is obtained in the form of slender, colorless prisms by crystallization from alcohol, then from water. It begins to soften around 250" and finally decomposes without melting.

Anal. Calcd. for $C_{17}H_{28}NI$: N, 3.75. Found: N, 3.99.

Proof of the Absence of an N-Alkyl Group in the Naphthenic Base.—In accordance with the procedure of Herzig and Meyer,[20] 1 g. of base, 5 g. of ammonium iodide and 12 cc. of hydriodic acid, sp. gr. 1.70, were heated slowly in a current of carbon dioxide up to 300° and this temperature was maintained for two hours longer. No alkyl iodide was formed and the unchanged base after recovery in the usual way was identified by conversion to the picrate. The hydrochloride of the base heated in a current of hydrogen chloride, in accordance with the method of Ladenburg,[21] also gave a negative result

---

[20] Herzig and Meyer, *Monatsh.*, 15, 613 (1894).

[21] See Cohen, "Organic Chemistry for Advanced Students," Vol. III, p. 353.

Finally the base was heated with benzoic acid at 250–280° for twelve hours,[22] in the hope of obtaining the benzoyl derivative of a secondary amine and the alcohol corresponding to the alkyl that might be joined to nitrogen. Here again only unchanged base was recovered.

Dehydrogenation Experiments.—One-half gram of base, 2.5 g. of mercuric acetate and 2.5 cc. of 50% acetic acid were heated in a sealed tube at 150° for twelve hours.[23]

There was no separation of mercury and the original base was recovered in the usual way. The method of Kann and Tafel,[24] where distillation with admixed silver sulfate and kieselguhr is employed, gave back the base unchanged. The dehydrogenation method of Borsche,[25] employing pumice stone impregnated with lead dioxide, also failed to alter the base. Finally it was found that the base mixed with zinc dust could be distilled out unchanged.[26]

Action of Bromine on the $C_{16}H_{25}N$ Base.—With an excess of bromine in chloroform solution 1,2,3,4-tetrahydroquinoline is readily converted to tribromoquinoline.[27] When to the naphthenic base in chloroform an excess of bromine is added, there remains after evaporation of the solvent a red, oily residue. This represents a loose bromine addition product, since from its alcoholic solution the characteristic picrate of the original base separates on addition of picric acid. On treatment of the base with bromine water the color of the solution disappears and there is formed a viscous, red-brown gum, insoluble in water and dilute acids and soluble in glacial acetic acid. Caustic soda reconverts this product to the original base.

Since the aromatic base, 2,3,8-trimethylquinoline, accompanies the hydroaromatic base in the 276° fraction of the kerosene bases, their difference in behavior toward bromine is of especial interest. The addition of bromine to a chloroform solution of the aromatic base is followed by an immediate separation of a reaction product crystallizing in light yellow needles. This, however, is a loose bromine addition product since caustic soda solution removes the bromine and restores the original base.

Oxidation with Permanganate.—The naphthenic base in permanganate solution was boiled over a period of one hundred and fifty hours, when the greater part of the base was ethered out unchanged. The remaining solution was then decolorized with sulfur dioxide, filtered, acidified with nitric acid, and, in order to remove free nitric acid, evaporated to dryness. The residue dissolved in water gave with a silver nitrate solution a precipitate that proved to be silver oxalate.

Hydrogenation Experiments.—With sodium and absolute alcohol pyridine is reduced to piperidine,[28] and 5,6,7,8-tetrahydroquinolines to decahydroquinolines.[29] This procedure proved ineffective with the naphthenic base, as did the employment of sodium and amyl alcohol. Without avail reduction with tin and hydrochloric acid was attempted in accordance with the method employed in the conversion of 5,6,8-trimethylquinoline to the corresponding Py-tetrahydroquinoline.[30] Although 1,2,3,4-tetrahydroquinoline is reduced to decahydroquinoline with hydriodic acid and red phosphorus,[31] this form of reduction gave with the naphthenic base likewise a negative result.

Action of Nitric Acid on the Naphthenic Base.—One gram of base is heated in a sealed tube with 10 cc. of nitric acid, sp. gr. 1.260, slowly over a two hour period up to 170° and this temperature then maintained for three hours. The pressure generated makes it inadvisable to employ larger amounts of material. Although the yields were unfavorable, four reaction products in apparently pure form were isolated. These substances of the composition, $C_{16}H_{23}O_4N_3$, $C_{16}H_{20}O_8N_4$, $C_{11}H_{14}O_5N_2$ and $C_8H_5O_6N$, are referred to in the introduction as products, II, III, IV and V, respectively.

For isolation of the nitric acid reaction products, the material from 24 g. of base is combined and concentrated by vacuum distillation to a gummy consistency. In order to remove traces of nitric acid, the residue is taken up in water and the distillation repeated. On addition of 150 cc. of water, product III in poor yield remains undissolved as a smear. The decanted solution is made alkaline to methyl orange with *N*/3 barium hydroxide and filtered from the barium salt of product V. On further addition of barium hydroxide to the phenolphthalein end-point, product II separates and is ethered out. With all basic material removed the barium in the form of hydroxide and nitrate is exactly precipitated as sulfate, the barium sulfate filtered off and the solution evaporated to dryness. The residue is next taken up in a little alcohol and ether added as long as it causes precipitation. From the gummy material obtained in this way, and dissolved in a small volume of hot acetone, there separates after several days' standing in the icebox product IV in crystalline form. Methods of isolating the residual products in the acetone solution have not been worked out, and no attempt was made to identify among the oxidation products volatile, fatty acids.

Product II for purification is converted to its picrate and the latter recrystallized from alcohol in diamond-shaped plates melting at 231°. The picrate is then treated with ammonium hydroxide and the liberated base recrystallized from alcohol in the form of colorless, slender rods melting at 116.5° and distilling even at low pressures with partial decomposition. It is readily soluble in organic solvents and insoluble in water.

Anal. Calcd. for $C_{16}H_{23}O_4N_3$: C, 59.81; H, 7.16; N, 13.09. Found: C, 59.89 H, 7.43; N, 12.80. *Mol. wt.* Subs., 10.8 mg.; camphor, 89.7 mg.; *At*, 15. Calcd. for $C_{16}H_{23}O_4N_3$: mol. wt., 321. Found: mol. wt., 320.

Product III on crystallization from alcohol is obtained in the form of yellow, rhombic plates melting with decomposition at 347°. Although insoluble in water it, unlike product I, is alkali soluble.

And. Calcd. for $C_{16}H_{20}O_8N_4$: C, 48.48; H, 5.05; N, 14.14. Found: C, 47.90; H, 4.92; N, 14.47. *Mol. wt.* Subs., 8.8215 mg.; camphor, 92.7 mg.; At, 11. Calcd. for $C_{16}H_{20}O_8N_4$: mol. wt., 396. Found: mol. wt., 348. *Titration.* Subs., 8.882 mg.: 0.89 cc. of 0.0258 *N* NaOH. Calcd. for $C_{16}H_{20}O_8N_4$ as monobasic acid: 0.87 cc.

Product IV on crystallization from alcohol separates in the form of colorless prisms melting with decomposition at 189–190°. It is readily soluble in water or hot alcohol and only slightly soluble in ether. In contrast to the parent naphthenic base, it is readily oxidized with alkaline permanganate. It does not give colorations with either ferrous sulfate or ferric chloride. Attempts to prepare a nitroso derivative were unsuccessful.

Anal. Calcd. for $C_{11}H_{14}O_6N_2$: C, 51.97; H, 5.51; N, 11.02. Found: C, 52.48; H, 5.43; N, 11.03. *Mol. wt.* Subs., 7.618 mg.; camphor, 92.5 mg.; *At*, 14. Calcd. for $C_{11}H_{14}O_5N_2$: mol. wt., 254. Found: mol. wt., 235. *Titration.* Subs., 0.539 mg.: 3.00 cc. of 0.0257 N NaOH. Calcd. for $C_{11}H_{14}O_5N_2$ as dibasic acid: **2.93** cc.

Berberonic Acid, Product V, crystallizes from water with two molecules of water of crystallization in a network of hair-like needles melting with decomposition at 240–241°. It is readily soluble in cold alcohol and possesses a wide difference in solubility in hot and cold water. With ferrous sulfate it gives even at a dilution of 1 part in 2500 parts of water a blood-red coloration. A characteristic property of this acid is the formation of a calcium salt on boiling its aqueous solution with animal charcoal. This salt crystallizes from water in plates with well-defined, diamond-shaped end faces.

Found: mol. wt., 216. *Titration.* Subs., 16.848 mg.: 9.20 cc. of 0.0257 *N* NaOH. Calcd. for $C_8H_5O_6N$ as tribasic acid: 9.33 cc.

Summary

1. A hydroaromatic base, $C_{16}H_{25}N$, isolated from the crude kerosene distillate as produced at the Oleum Plant of the Union Oil Company of California, is described along with a number of characteristic salts.

2. This base is regarded as 4-methyl-1,4-ethenopiperidine, condensed at 2,3 as well as at 5,6, with methylcyclopentane. In addition to the two cyclopentane nuclei, this structure presents two tetrahydropyridine complexes within the piperidine periphery, so that in all five rings are involved.

3. Corresponding to the structural formula proposed, the $C_{16}H_{25}N$ compound, apart from possessing the properties of a tertiary amine, behaves similarly to methyl cyclopentane.

4. The term "Naphthenic Bases" is proposed for bases like the $C_{16}H_{25}N$ compound of the cyclopentane type, in order to emphasize their relationship to the so-called naphthenes.

5. The claim previously advanced that *"petroleum offers the greatest wealth of nitrogen compounds of any natural source"* is strengthened by the results reported in this paper and the isolation, proof of structure and even synthesis of a host of so-called petroleum bases only await a realization of the attractive field of research presented.

FLUOSILICATES OF ORGANIC BASES. II

BY C. A. JACOBSON[1]

RECEIVED SEPTEMBER 24, 1930 PUBLISHED MARCH 6, 1931

Continuing the work of Jacobson and Pray,[2] eleven new fluosilicates have been prepared and analyzed.

In general, the preparation of these compounds was similar to that recorded in the first paper. The purest Eastman Kodak Co. bases were

[1] The Author wishes to acknowledge the assistance of the following persons in the completion of the present work: H. McMillen and C. W. Weaver on o-tolidine fluosilicate; E. Stutzman on di-α-, and di-β-naphthylamine fluosilicate; Christine Arnold on di-diphenylamine and m-phenylenediamine fluosilicates; C. G. Rollins on the fluosilicates of ethylaniline, *p*-nitrosodiphenylamine, *p*-aminoazobenzene and *p*-aminobenzoic acid.

[2] Jacobson and Pray, THIS JOURNAL, 50,3055 (1928).

used and always recrystallized if the microscopic examination showed impurities present.

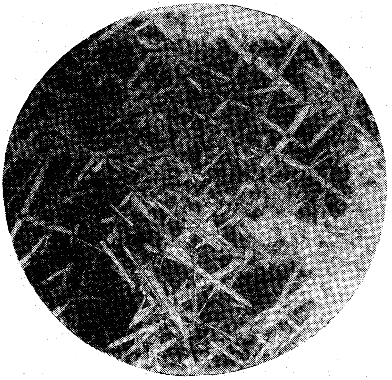

Fig. 1.—*o*-Tolidine fluosilicate.

All the fluosilicates prepared are recorded in the table, giving name, formula, properties and analytical values. They were all recrystallized from 95% ethyl alcohol except Nos. 1 and 9. o-Tolidine fluosilicate was recrystallized from 75% ethyl alcohol and di-nitrosodiphenylamine fluosilicate from a mixture of 95% ethyl alcohol and acetone. The analyses of these compounds indicate that they are all composed of two molecules of the base with one of the acid except Nos. 1, 6 and 7, which have a one to one ratio. This fact is indicated by applying the prefix di- to the name of the compound.

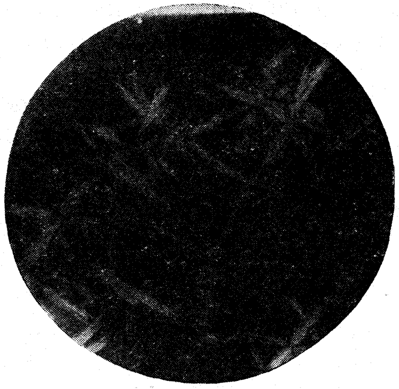

Fig. 2.—Di-a-naphthylamine fluosilicate.

Fig. 3—Di-*β*-naphthylamine fluosilicate.

Table I

Compounds and Data

No.	Fluosilicate of	Formula	Crystal form	M. p., °C.
1	o-Tolidine	$(CH_3NH_2C_6H_3)_2H_2SiF_6$	Tiny microscopic prisms	268–269
2	Di-*α*-naphthylamine	$(C_{10}H_7NH_2)_2H_2SiF_6$	Rosets of needles	218 (dec.)
3	Di-*β*-naphthylamine	$(C_{10}H_7NH_2)_2H_2SiF_6$	Hexagonal plates	236.3
4	Di-m-nitraniline	$(C_6H_4NO_2NH_2)_2H_2SiF_6$	Rhomboidal plates	200
5	Di-diphenylamine	$[(C_6H_5)_2NH]_2H_2SiF_6$	Rods forming rosets	169
6	m-Phenylenediamine	$C_6H_4(NH_2)_2H_2SiF_6$	Long needle-like prisms	243–244
7	*p*-Phenylenediamine	$C_6H_4(NH_2)_2H_2SiF_6$	Six-sided irregular plates	Dec.
8	Di-ethylaniline	$(C_6H_5NHC_2H_5)_2H_2SiF_6$	Pointed prisms	165.3
9	Di-nitrosodiphenylamine	$[(C_6H_5)_2N{=}NO]_2H_2SiF_6$	Butterfly-shaped	124.5 (dec.)
10	Di-*p*-aminoazobenzene	$(NH_2C_6H_4N_2C_6H_5)_2H_2SiF_6$	Long needles	220 (dec.)
11	Di-*p*-aminobenzoic acid	$(NH_2C_6H_4COOH)_2H_2SiF_6$	Long narrow prisms	240–245

In the analyses nitrogen was determined by the **Kjeldahl** method, and the fluosilicic acid radical by the author's own method recorded.[3]

TABLE II

SOLUBILITIES AND ANALYSES

No.	Solubilities in 100 cc. of 95% EtOH at 25°		Nitrogen, % Calcd.	Found			H_2SiF_6, % Calcd.	Found	
1	0.013	0.041 at 35°	9.85	9.17	9.06		40.44	40.52	
2	.1504		6.50	6.36	6.54	6.58	33.48	33.46	33.50

11	91		6.94	6.71	6.89		34.45	34.59	34.67

All the above compounds are white in color except No. 6, which is chocolate-brown, No. 7 pinkish, No. 9 indigo and No. 10 cinnamon-brown. They are all stable in the air except No. 4, which turns yellow on long standing, and No. 5, whose surface becomes blue after some weeks exposure to the air.

All are stable in water solution except Nos. 2, 6 and 9. Nos. 3, 4 and 10 also decompose in the presence of water although more slowly. The remaining fluosilicates are all insoluble in water except Nos. 7, 8 and 11, which are readily soluble. No. 3 exhibits a high surface tension and at first floats on the water like lycopodium.

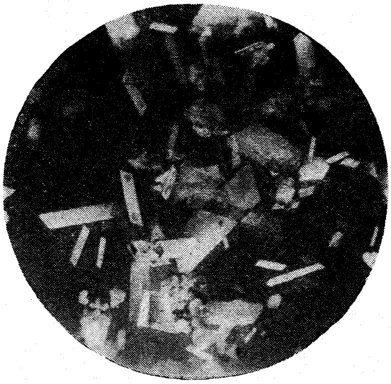

Fig. 4.—Di-m-nitroaniline fluosilicate.

Fig, 5.—Di-diphenylamine fluosilicate.

The fluosilicates are all crystalline compounds possessing definite and characteristic crystal forms, as shown in the accompanying micro photographs. In the case of No. 9, very fine hair-like crystals were obtained from 95% ethyl alcohol, while differently shaped crystals, as shown in

LOCAL ANESTHETICS IN THE PYRROLE SERIES. II[1]

BY F. F. BLICKE AND E. S. BLAKE

RECEIVED OCTOBER 2, 1930 PUBLISHED MARCH 6, 1931

The structure of novocaine has been modified by a number of investigators in the hope that a better medicament might be obtained and also in order that more information might be acquired regarding the relationship between structure and local anesthetic action.[2] This has been accomplished by a variation in one or more of the three units A, B and C in the novocaine molecule (I).

$$(4)\ \underbrace{H_2N—C_6H_4—}_{A}CO—O—\underbrace{CH_2—CH_2—N(C_2H_5)_2}_{B\qquad\qquad C}$$

I

The primary object of our investigation was to determine, with regard to local anesthetic activity, the effect of a replacement of 4-aminobenzoyl by 2-pyrroyl and the result of a substitution of 1-pyrryl and 1-pyrrolidyl for the diethylamino group.[3] Thus in the analogs of novocaine which we obtained unit A is represented by benzoyl, 4-aminobenzoyl and 2-pyrroyl,

---

[1] This paper represents the second part of a dissertation submitted to the Graduate School by E. S. Blake in partial fulfilment of the requirements for the degree of Doctor of Philosophy in the University of Michigan. The first part of the dissertation was published in THIS JOURNAL, 52, 235 (1930).

This investigation was made possible by the grant of a fellowship by Frederick Stearns and Company and we wish to express our appreciation for the aid which has been given us.

Braun and co-workers, *Ber.*, 52, 2011 (1919); *ibid.*, 55, 1666 (1922); McElvain and co-workers, THIS JOURNAL, 48, 2179, 2239 (1926); *ibid.*, 49, 2835 (1927); 51, 887, 922 (1929); Barnes and Adams, *ibid.*, 49, 1307 (1927); Marvel and co-workers, *ibid.*, 50, 563 (1928); 51, 915 (1929); Tréfuel, Tréfuel and Barbelet, *Bull. sci. pharmacol.*, 37, 184, 240 (1930); *Chem. Abstracts*, 24, 3502 (1930).

[3] Luft [*Ber.*, 38, 4044 (1905)] has described the preparation of 4-(N-piperidyl)-antipyrine, while v. Braun and Lemke [*ibid.*, 55, 3540, 3557 (1922)] prepared 4-(N-pyrrolidyl)- and 4-(N,Δ^3-pyrrolyl)-antipyrine. According to the latter investigators the pyrrolidyl is a stronger antipyretic than the piperidyl or the pyrrolyl derivative.

unit C by 1-pyrryl and 1-pyrrolidyl, respectively, and in some instances the trimethylene group has been substituted for B.

I	$C_6H_5COOCH_2CH_2NC_4H_4$	V	$C_6H_5COOCH_2CH_2CH_2NC_4H_4$
II	$H_2NC_6H_4COOCH_2CH_2NC_4H_4$	VI	$H_2NC_6H_4COOCH_2CH_2CH_2NC_4H_4$
III	$C_4H_4NCOOCH_2CH_2NC_4H_4$	VII	$C_4H_4NCOOCH_2CH_2CH_2NC_4H_4$
IV	$H_2NC_6H_4COOCH_2CH_2NC_4H_8$	VIII	$H_2NC_6H_4COOCH_2CH_2CH_2NC_4H_8$

The benzoyl (I), 4-aminobenzoyl (II) and the 2-pyrroyl (III) derivatives of β-(1-pyrryl)-ethyl alcohol, $C_4H_4NCH_2CH_2OH$, were prepared in the following manner. Potassium pyrrole was condensed with β-chloroethyl acetate with the formation of the acetyl derivative of β-(1-pyrryl)-ethyl alcohol. The latter was hydrolyzed, the alcohol converted into its potassium derivative and then allowed to react with benzoyl chloride. The 4-nitrobenzoyl and the 2-pyrroyl compounds were obtained by a similar series of reactions. Upon catalytic reduction of the 4-nitrobenzoic acid ester, $NO_2C_6H_4COOCH_2CH_2NC_4H_4$, the corresponding 4-amino derivative was formed.

4-Aminobenzoic acid was condensed with ethylene chlorohydrin with the formation of β-chloroethyl 4-aminobenzoate, $H_2NC_6H_4COOCH_2CH_2Cl$. The latter, when heated with pyrrolidine, yielded the 4-aminobenzoyl derivative of β-(1-pyrrolidyl)-ethyl alcohol (IV).

γ-(1-Pyrryl)-propyl alcohol was prepared in a manner similar to that described in the case of pyrrylethyl alcohol and the benzoyl (V), 4-aminobenzoyl (VI) and 2-pyrroyl (VII) derivatives were obtained by methods analogous to those outlined above.

γ-Chloropropyl 4-aminobenzoate, synthesized from 4-aminobenzoic acid and trimethylene chlorohydrin, was condensed with pyrrolidine to form the 4-aminobenzoyl derivative of γ-(1-pyrrolidyl)-propyl alcohol (VIII).

Stovaine (IX) is obtained by benzoylation of methylethyldimethylaminomethylcarbinol. Pyrroylation of this carbinol yielded compound XI. In order to determine the effect of the substitution of a saturated

IX	$(CH_3)(C_2H_5)[(CH_3)_2NCH_2]COCOC_6H_5$	XII	$(CH_3)(CH_3)(C_4H_4NCH_2)COH$
X	$(CH_3)(C_2H_5)(C_4H_8NCH_2)COCOC_6H_5$	XIII	$(C_2H_5)(C_2H_5)(C_4H_4NCH_2)COH$
XI	$(CH_3)(C_2H_5)[(CH_3)_2NCH_2]COCOC_4H_4N$	XIV	$(C_2H_5)(C_2H_5)(C_4H_4NCH_2CH_2)COH$

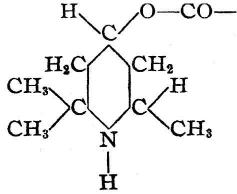
cyclic amine for the dimethylamino group, compound X was prepared by the interaction of methylethylchloromethylcarbinol with pyrrolidine and subsequent benzoylation of the reaction product.

We also synthesized the three tertiary carbinols dimethyl-1-pyrrylmethylcarbinol (XII), diethyl-1-pyrrylmethylcarbinol (XIII) and diethyl β-(1-pyrryl)-ethylcarbinol (XIV). It was hoped that these compounds might be benzoylated and pyrroylated through reaction of the potassium derivatives of the carbinols with benzoyl and pyrroyl chloride, respectively, especially since it was found that stovaine can be obtained from the potassium derivative of methylethyldimethylaminomethylcarbinol and benzoyl chloride. Direct interaction of the carbinols with the acid chlorides yielded only gums or resins since the hydrogen chloride formed during the reaction attacked the pyrrole nucleus. However, the products obtained from the potassium derivatives of the carbinols were oils which we were unable to purify. Although it was realized that the material may have contained a small quantity of unchanged benzoyl chloride, the benzoylation product of carbinol XIII was hydrolyzed and the benzoic acid produced was weighed. The calculated amount of acid was 1.22 g.; the quantity found was 1.18 g. In the event that the compound hydrolyzed was the benzoyl derivative of the carbinol, it seems strange that the material should have been found to be devoid of anesthetic action.

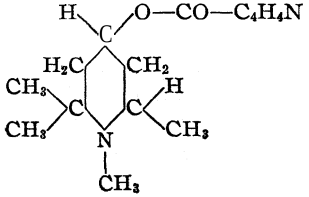
Carbinol XII was obtained by the action of potassium pyrrole on ethyl chloroacetate and subsequent treatment of the ethyl 1-pyrrylacetate with methylmagnesium iodide. When ethylmagnesium bromide was used diethyl-(1-pyrryl)-methylcarbinol (XIII) was formed.

By a similar series of reactions—interaction of potassium pyrrole with ethyl β-bromopropionate and treatment of the ethyl β-(1-pyrryl)-propionate formed with ethylmagnesium bromide—diethyl-(1-pyrryl)-ethylcarbinol (XIV) was synthesized.

In the case of β-eucaine (XV), the benzoyl derivative of the stable form of 2,2,6-trimethyl-4-hydroxypiperidine (vinyldiacetone alkamine), the molecule was modified by the substitution of a 2-pyrroyl for the benzoyl group and the replacement of the 1-hydrogen of the piperidine nucleus by a methyl group (XVI). The latter group was introduced merely in order to facilitate one stage of the synthesis.



XV



XVI

We prepared, in addition, the 4-(2-pyrroyl)-1-methyl derivative of the labile form of 2,2,6-trimethyl-4-hydroxypiperidine. The stable and labile forms of the secondary carbinol were obtained as follows. Diacetone alcohol was converted into mesityl oxide and from the latter diacetoneamine hydrogen oxalate was prepared. Reduction of the oxalate yielded a mixture of the two stereoisomeric forms of vinyldiacetone alkamine. The isomers were separated and methylated. Upon interaction of the potassium derivatives of the alcohols with 2-pyrroyl chloride the desired esters were formed.

In the novocaine series compounds I and V seemed to be inert while the other derivatives produced a distinct local anesthetic effect. The compounds were tested by the application of a concentrated alcoholic solution to the tongue and the inner side of the lips. Because of the burning and drying effect of alcohol on the mucous membrane, it is obvious that the use of this solvent is objectionable. However, in spite of these features of the alcohol the local anesthetic action produced by the compounds tested was unmistakable. The undesirable action of the alcohol is mitigated to a considerable degree by the addition of water but, unfortunately, the products tested although very soluble in alcohol are precipitated upon the addition of any appreciable quantity of water to the alcoholic solution.

Aqueous solutions of the hydrochlorides of compounds IV and VIII produced no anesthetic effect, a behavior which would be expected since novocaine (hydrochloride) is without action on the tongue but novocaine base, in alcohol, exhibits a very decided anesthesia.

-Compounds X and XI, stovaine analogs, were active both as base and hydrochloride, a behavior which is consistent with that of stovaine (hydrochloride) since the latter anesthetizes the tongue.

The base of the 4-(2-pyrroyl)-1-methyl derivative of the stable form of 2,2,6-trimethyl-4-hydroxypiperidine was found to be active; the corresponding derivative of the labile form inactive.

Our investigation has shown that, in certain types of compounds at least, the following substitutions may be made in local anesthetics without loss, in a qualitative sense, of anesthetic activity—the substitution of 2-pyrroyl for benzoyl and 4-aminobenzoyl and the replacement of the dimethyl- and diethylamino by the 1-pyrryl or the 1-pyrrolidyl nucleus.

Experimental Part

β-Chloroethyl Acetate and **γ-Chloropropyl** Acetate.—Four hundred grams of ethylene chlorohydrin was placed in a flask fitted with a reflux condenser and a dropping funnel. The latter contained 450 g. of technical acetyl chloride which was allowed to drop into the chlorohydrin at a very slow rate. During this operation the flask was cooled with ice water and was shaken occasionally. The mixture was then heated for two hours on a steam-bath, cooled and poured into a small quantity of ice water. After the excess acetyl chloride had hydrolyzed, the oil was separated and washed with a concd. solution of sodium bicarbonate until free from hydrochloric acid. The oil was then dried with fused sodium sulfate and distilled through a fractionation column. There was obtained 500 g. of the ester which boiled at 142–145°. The yield was 82% of the calculated amount.

γ-Chloropropyl acetate was prepared from trimethylene chlorohydrin[4] and acetyl chloride in the manner described above. The ester boiled at 168–173°.[5]

---

[4] "Organic Syntheses," John Wiley and Sons, Inc., New York, 1928, Vol. VIII, p. 112.

[5] Derick and Bissel [This Journal, 38, 2483 (1916)] reported the boiling point to be 160–166°.

β-(1-Pyrryl)-ethyl Alcohol.—Potassium pyrrole was prepared by the addition of 80 g. of potassium to 330 cc. of warm pyrrole in a flask fitted with a reflux condenser. After the potassium had reacted completely, absolute ether was added to the clear solution in order to precipitate the potassium compound in the form of fine crystals, Unless ether is added the potassium pyrrole separates from the cold mixture in the form of a hard cake. The potassium derivative was filtered and washed with absolute ether. The excess pyrrole can be recovered readily from the filtrate by fractionation.

One hundred and fiiteen grams of potassium pyrrole was placed in a flask fitted with a reflux condenser and 100 g. of β-chloroethyl acetate was added in small portions. The mixture was cooled thoroughly during this process. The pasty reaction mixture was heated in an oil-bath to 70° for several hours, then cooled and, after the addition of absolute ether, filtered. Tbe ether was removed from the filtrate on a steam-bath and the residue distilled under diminished pressure. After the material had been fractionated twice there was obtained 28 g. of the acetyl derivative of β-(1-pyrryl)-ethyl alcohol which boiled at 222–225° under 740 mm. pressure. This substance seemed to possess a very slight local anesthetic action. In order to hydrolyze the ester 55 g. of the latter was heated on a steam-bath for several hours with a mixture which consisted of 40 g. of potassium hydroxide, 30 cc. of water and 50 cc. of alcohol. The alcohol and water were removed under diminished pressure and the semi-solid residue was treated with a small quantity of water. The oil which separated was extracted with ether and the ether solution dried with fused sodium sulfate. Upon fractionation 42 g. of B-(1-pyrryl)-ethyl alcohol was obtained which boiled at 110–113° under 12 mm. pressure,

Benzoyl Derivative (I).—Thirteen and two-tenths grams of β-(1-pyrryl)-ethyl alcohol, dissolved in 150 cc. of dry benzene, was heated with 4.8 g. of potassium until all of the metal had disappeared. Sixteen and eight-tenths grams of benzoyl chloride, dissolved in 100 cc. of absolute ether, was then added. A precipitate of potassium chloride formed immediately. After the mixture had been heated at 70° for several hours it was filtered from potassium chloride and the ether and benzene removed under diminished pressure. The residue, after it had been cooled, consisted of crystals contaminated by a small amount of oil. The mixture was placed on a porous plate and after some time the crystalline material was recrystallized from petroleum ether (90–120°). The yield of pure material was 20 g. or 78% of the calculated amount; m. p. 53–55°.

Anal. Calcd. for $C_{13}H_{13}O_2N$: C, 72.52; H, 6.09; N, 6.51. Found: C, 72.36; H, 6.19; N, 6.56.

4-Aminobenzoyl Derivative (II).—We prepared, first, the β-(-pyrryl)-ethyl ester of 4-nitrobenzoic acid in the following manner. Three and three-tenths grams of P-(1-pyrryl)-ethyl alcohol, dissolved in 50 cc. of dry benzene, was heated with 1.2 g. of potassium. After the metal had reacted the mixture was cooled with ice and 5.5 g. of pure 4-nitrobenzoyl chloride,[6] dissolved in 50 cc. of absolute ether, was added in small portions. The reaction mixture became intensely red but the color disappeared after all of the nitrobenzoyl chloride had been added. The mixture was heated to 60° in a bath for one hour and then filtered. The residue was washed with absolute ether and the ether added to the filtrate. After the solvents had been removed under diminished pressure, a dark brown oil was obtained which became solid when it was cooled. The material was pulverized, dissolved in ether and dark colored impurities precipitated by the addition of petroleum ether (20–40°). The solvents were then allowed to evaporate. After recrystallization from alcohol, 5 g. of slightly yellow, crystalline material was obtained which melted at 92–94'.

---

[6] "Organic Syntheses," John Wiley and Sons, Inc., New York, 1923, Vol. III, p. 75.

In order to obtain the amino compound, 5.2 g. of the nitro derivative, dissolved in 190 cc. of absolute alcohol, was reduced with hydrogen in the presence of 0.3 g. of platinum oxide catalyst[7] under an initial pressure of four atmospheres. The calculated amount of hydrogen was absorbed in twenty-five minutes. After filtration the solvent was removed under diminished pressure and the solid residue recrystallized from a mixture of petroleum ether (90–120") and benzene; m. p. 87–88'.

Anal. Calcd. for $C_{13}H_{14}O_2N_2$: C, 67.78; H, 6.13; N, 12.17. Found: C, 67.71; H, 6.02; N, 12.25.

2-Pyrroyl Derivative (III).—In order to prepare the potassium derivative of **β-(1-pyrryl)-ethyl** alcohol, 6.6 *g.* of the alcohol, 2.4 *g.* of potassium and 100 cc. of dry benzene were heated to 90° in an oil-bath. Seven and seven-tenths grams of **2-pyrroyl** chloride, dissolved in 100 cc. of absolute ether, was added and the mixture heated for several hours. The potassium chloride was removed by filtration and the filtrate heated under diminished pressure in order to remove the solvents. The residue was dissolved in absolute ether and low-boiling petroleum ether added to precipitate dark colored impurities. After evaporation of the solvents the colorless, crystalline material was recrystallized from a mixture of benzene and petroleum ether; m. p. 73–74°.

Anal. Calcd. for $C_{11}H_{12}O_2N_2$: C, 64.67; H, 5.87; N, 13.72. Found: C, 64.72; H, 5.93; N, 13.67.

β-(1-Pyrrolidyl)-ethyl 4-Aminobenzoate (IV).[8]—Five grams of pure **β-chloroethyl** 4-aminobenzoate, which had been prepared from 4-aminobenzoic acid, ethylene **chlorohydrin** and sulfuric acid[9] was heated in a sealed tube with 6 cc. of pyrrolidine for eight hours in a bath at 115–120°. The reaction mixture was treated with water to remove pyrrolidine hydrochloride and excess pyrrolidine and the solid material was dried and recrystallized from a mixture of benzene and petroleum ether; m. p. 98–100°.

Anal. Calcd. for $C_{13}H_{18}O_2N_2$: C, 66.62; H, 7.74; N, 11.98. Found: C, 66.67; H, 7.84; N, 12.09.

γ-(1-Pyrryl)-propyl Alcohol.—This compound was prepared in a manner similar to that described in the case of the ethyl **homolog.** From potassium pyrrole and **γ-chloro**propyl acetate the acetyl derivative of **γ-(1-pyrryl)-propyl** alcohol was obtained. The latter boiled at 127–135° under 13 mm. pressure and 93 g. of the material was obtained from two moles of potassium pyrrole. From 258 g. of the acetate we obtained, by hydrolysis, 150 g. of the pure alcohol. The latter boiled at 229–231° under 743 mm. pressure.

Benzoyl Derivative @).—The material obtained from the interaction of the potassium derivative of the above alcohol and benzoyl chloride boiled at 120–170° under 5 mm. pressure and was evidently a mixture of compounds. One and eighteen-hundredths grams of the oil which boiled at 165–170° under 5 mm. pressure was hydrolyzed with alcoholic potassium hydroxide. There was obtained 0.64 g. of benzoic acid; the calculated amount of acid based on formula V is 0.61 g.

4-Aminobenzoyl Derivative @I).—We prepared first the 4-nitrobenzoyl derivative from 7.5 g. of **γ-(1-pyrryl)-propyl** alcohol, 2.4 g. of potassium and 11.1 g. of 4-nitrobenzoyl chloride. The crude, solid reaction product was dissolved in alcohol and aque-

[8] **β-(1-Piperidyl)-ethyl** 4-aminobenzoate has been described by Einhorn and Uhlfelder, *Ann.*, 371, 140 (1909), and **β-(1-piperidyl)-ethyl** benzoate by Laun, *Ber.*, 17, 680 (1884). **β-(1-Pyrrolidyl)-ethyl** benzoate has been obtained by v. Braun, **Braunsdorf** and Rath, *ibid.*, 55,1673 (1922).

[9] German patent 194,748.

ous sodium carbonate was added. The precipitate was removed by filtration, dried and recrystallized from alcohol; m. p. 68–70°. The yield of pure material was 5 g.

Twenty-one and five-tenths grams of the nitro compound, 250 cc. of absolute alcohol and 0.3 g. of platinum oxide catalyst were treated with hydrogen under an initial pressure of four and one-half atmospheres. The reduction required twenty minutes. The catalyst was removed and the amino compound was precipitated in crystalline form by the addition of water. After recrystallization from a mixture of benzene and petroleum ether, the compound melted at 114–116°. The yield was 17 g.; the calculated yield is 19 g.

Anal. Calcd. for $C_{14}H_{16}O_2N_2$: C, 68.81; H, 6.65; N, 11.47. Found: C, 68.74; H, 6.65; N. 11.71.

2-Pyrroyl Derivative (VII).—The potassium derivative of γ-(1-pyrryl)-propyl alcohol, obtained from 6.2 g. of the alcohol, 2 g. of potassium and 75 cc. of dry benzene, was heated for three hours with 6.4 g. of 2-pyrroyl chloride,[10] dissolved in 100 cc. of absolute ether. The potassium chloride was removed by filtration and the solvents distilled under reduced pressure. The residue was dissolved in alcohol and the pyrrole derivative precipitated by the addition of aqueous sodium carbonate. After recrystallization from a mixture of benzene and petroleum ether the product melted at 69–70". The yield was 5 g.

Anal. Calcd. for $C_{12}H_{14}O_2N_2$: C, 66.01; H, 6.46; N, 12.84. Found: C, 66.00; H, 6.48; N, 12.77.

γ-(1-Pyrrolidyl)-propyl 4-Aminobenzoate (VIII).[11]—γ-Chloropropyl 4-aminobenzoate was prepared as follows. Seventy grams of trimethylene chlorohydrin, 103 g. of 4-aminobenzoic acid and 400 g. of sulfuric acid were heated for twelve hours on a steam-bath. The mixture was treated with ice and then with sodium carbonate solution. The crude product was recrystallized from alcohol a number of times and finally from a mixture of benzene and petroleum ether; m. p. 86–87°.

γ-(1-Pyrrolidyl)-propyl 4-aminobenzoate was obtained from γ-chloropropyl 4-aminobenzoate and pyrrolidine in the same manner as compound IV. The compound melted at 84–85° after recrystallization from a mixture of benzene and petroleum ether.

Anal. Calcd. for $C_{14}H_{20}O_2N_2$: C, 67.69; H, 8.12; N, 11.29. Found: C, 67.54; H, 8.20; N, 11.80.

Benzoyl Derivative of Methylethyldimethylaminomethylcarbinol (Stovaine, IX).—Although stovaine is prepared usually by the interaction of the tertiary carbinol and benzoyl chloride[12] we found that it can be obtained in the following manner, a procedure which we used in the case of certain pyrrole derivatives in order to avoid the formation of hydrogen chloride. Three and nine-tenths grams of methylethyldimethylaminomethylcarbinol, dissolved in 50 cc. of dry benzene, was refluxed with 1.2 g. of potassium until the metal had reacted completely. Four and two-tenths grams of benzoyl chloride was then added and the mixture heated to 60–70° for one hour. The potassium chloride was removed by filtration and the filtrate treated with hydrogen chloride. The stovaine hydrochloride, after recrystallization from absolute alcohol, melted at 172–174°. The yield was 5 g.; calcd. yield, 8 g.

[11] Andrews and McElvain [This Journal, 51, 890 (1929)] synthesized γ-(1-pyrrolidyl)-propyl benzoate and γ-(1-piperidyl)-propyl benzoate has been prepared by Dunlop [*J. Chem. Soc.*, 101, 2002 (1912)].

[12] Fourneau, "Organic Medicaments," P. Blakiston's Son and Co., Philadelphia. 1925, p. 218.

Benzoyl Derivative of Methylethyl-(1-pyrrolidyl)-methylcarbinol (X).—Twelve grams of methylethylchloromethylcarbinol[13] and 20 cc. of pyrrolidine were heated in a sealed tube to 115–120° for eight hours. Upon the addition of water to the reaction mixture an oil separated. Since the latter would not solidify when cooled the mixture was made slightly acidic with hydrochloric acid, extracted with ether to remove acid-insoluble material and the aqueous, acid layer was made alkaline with sodium hydroxide. It was then subjected to steam distillation until most of the pprolidine had been removed.[14] The contents of the steam distillation flask were shaken with ether a number of times, the ether layer separated and dried with fused sodium sulfate. After removal of the solvent the tertiary carbinol remained in the form of an oil. The latter was benzoylated in the following manner. Five and seven-tenths grams of the carbinol, 7.1 g. of benzoyl chloride and 25 cc. of dry benzene were heated for three hours on a steam-bath. The mixture was cooled with ice, whereupon the solid, crystalline hydrochloride of the benzoylated carbinol separated. The hydrochloride was found to be very soluble in ethyl acetate and absolute alcohol. The material was recrystallized from the latter solvent but because of the hygroscopic nature of the compound it was converted into the oily base for analysis. The latter was dried for four hours at 65° under 20 mm. pressure.

Anal. Calcd. for $C_{16}H_{23}O_2N$: N, 5.36. Found: N, 5.61.

2-Pyrroyl Derivative of Methylethyldimethylaminomethylcarbinol (XI).—Five and two-tenths grams of methylethyldimethylaminomethylcarbinol[15] was dissolved in 75 cc. of absolute ether. The solution was then added, dropwise, to 5.2 g. of 2-pyrroyl chloride, dissolved in 75 cc. of absolute ether. A black, gummy precipitate formed immediately upon the addition of a small quantity of the carbinol. The solution was decanted from this material and upon the addition of more carbinol a colorless, gummy compound precipitated which after some time became partly crystalline. The material was dissolved in a small amount of hot, absolute alcohol and the solution cooled. The hydrochloride separated in crystalline form upon the addition of absolute ether. After recrystallization from absolute alcohol it melted at 194–195°.

Anal. Calcd. for $C_{12}H_{21}O_2N_2Cl$: N, 10.75; Cl, 13.60. Found: N, 10.83; Cl, 13.55.

Dimethyl-1-pyrrylmethylcarbinol (XI).—Ethyl chloroacetate was prepared from chloroacetyl chloride and absolute alcohol. One mole of potassium pyrrole was covered with absolute ether and heated with 100 g. of ethyl chloroacetate for one hour on a steam-bath. The potassium chloride was removed and the crude ethyl 1-pyrrylacetate, $C_4H_4NCH_2COOC_2H_5$, distilled. It boiled at 110–115° under 16 mm. pressure. The yield was 26 g.

A portion of the ester was warmed for several hours with aqueous sodium hydroxide. The clear, alkaline solution was boiled with charcoal, filtered, the filtrate acidified and then extracted with ether. After evaporation of the solvent the crystalline 1-pyrrylacetic acid was recrystallized from a mixture of benzene and low boiling petroleum ether; m. p. 94–95°.

Methylmagnesium iodide was prepared from 56.4 g. of methyl iodide, 9.6 g. of magnesium and 100 cc. of ether. Twenty-three grams of the above ester was added, drop by drop, to the Grignard reagent and the mixture heated for one hour on a steam-bath. The reaction mixture was decomposed with ice and ammonium chloride and the tertiary carbinol purified by distillation; b. p. 86–88" under 2–3 mm. pressure. The yield was 18 g.

---

[13] Ref. 12, p. 214.

[14] After most of the pyrrolidine had distilled a colorless oil began to collect in the receiver. We did not determine whether this oil was the tertiary carbinol or some by-product of the reaction.

[15] Ref. 12. p. 215.

The carbinol was converted into its potassium derivative in the presence of benzene and then treated with the calculated amount of benzoyl chloride and 2-pyrroyl chloride, respectively. The products in both instances were oils.

Diethyl-1-pyrrylmethylcarbinol (XIII).—Forty-five grams of ethyl 1-pyrrylacetate was added to the Grignard reagent obtained from one mole of magnesium and one mole of ethyl bromide. After the mixture had been heated for several hours on a steam-bath, it was decomposed in the usual manner. The tertiary carbinol was purified by distillation; b. p. 108–110° under approximately 1 mm. pressure (bath temperature 125–130°). The yield was 38 g.

Anal. Calcd. for $C_{10}H_{17}ON$: N, 8.37. Found: N, 8 28.

In the case of this carbinol, as well as the following one, the material obtained from the interaction of the potassium derivative and benzoyl chloride was a liquid.

Diethyl-1-pyrrylethylcarbinol (XIV).—One hundred and eighty-one grams of ethyl β-bromopropionate[16] was added, drop by drop, to 126 g. of potassium pyrrole which was cooled with ice. After all of the ester had been added the mixture was heated to 140° for one hour. The potassium chloride was removed and the ethyl β-(1-pyrryl)-propionate distilled; b. p. 119–122" under 14 mm. pressure. The yield was 31 g.

A portion of the ester was hydrolyzed with aqueous sodium hydroxide. The alkaline solution was then boiled with charcoal, filtered and the filtrate concentrated. When the alkaline solution was acidified and cooled the β-(1-pyrryl)-propionic acid precipitated in the form of colorless crystals. The compound is very soluble in hot water. After recrystallization from a mixture of benzene and low-boiling petroleum ether the acid melted at 62–64'. The compound possesses a repulsive odor somewhat similar to that of butyric acid.

The tertiary carbinol was prepared from ethyl β-(1-pyrryl)-propionate and ethylmagnesium bromide. It boiled at 125–128° under 4–5 mm. pressure (bath temperature 135–140°).

Anal. Calcd. for $C_{11}H_{19}ON$: N, 7.73. Found: N, 7.88.

4-(2-Pyrroyl)1-Methyl Derivative of the Stable and Labile Form of 2,2,6-Trimethyl-4-hydroxypiperidine (XVI).—In order to obtain these compounds it was necessary to prepare first vinyldiacetone alkamine. The latter was separated into the stable and labile modifications and these were then pyrroylated in the form of their 1-methyl derivatives.

Diacetone alcohol[17] was converted into mesityl oxide[18] and from the latter diacetoneamine hydrogen oxalate[19] was prepared. We found it unnecessary to convert the oxalate into the free amine[20] in order to reduce it to vinyldiacetone alkamine,[21] since the salt reduces in a satisfactory manner. From 50 g. of the hydrogen oxalate there was obtained 30 g. of the alkamine after the latter had been recrystallized from benzene. The separation of the alkamine into its two isomeric forms was effected by the method of Harries[22] and the latter were then methylated according to the directions given by this investigator.[23]

[18] Ref. 17, p. 53.

[19] "Organic Syntheses," Vol. VI, p. 28.

[20] E. Fischer, Ber., 17, 1793 (1884).

[21] E. Fischer, *ibid.*, 17, 1794 (1884).

[22] Harries, *Ann.*, 294, 372 (1897).

[23] Harries, *ibid.*, 417, 178 (1918). Conversion of the mixture of the two stereoisomers into the labile form of the alkamine by means of sodium amylate in amyl alcohol is described on p. 274 of this reference. However, the amount of amyl alcohol (40 cc) employed by Harries seems too small and we were obliged to use 100 cc. of the solvent.

The potassium derivative of the stable form of 1-methylvinyldiacetone alkamine was prepared in the following manner. Seven and eighty-five hundredths grams of the stable 1-methyl alkamine, dissolved in 50 cc. of dry xylene, was treated with 1.95 g. of potassium and the mixture refluxed for five hours. The mass should be stirred during this time to prevent the formation of a hard cake. Seven and seventy-four hundredths grams of 2-pyrroyl chloride, dissolved in 125 cc. of absolute ether, was added dropwise to the hot suspension of the potassium derivative. During this process the mixture was shaken constantly. The material was heated for ten minutes, cooled, filtered, the filtrate cooled with ice and treated with hydrogen chloride. The precipitated hydrochloride was found to be very hygroscopic, at least in the crude state. It was separated, dissolved in water and the compound precipitated as the base by the addition of ammonium hydroxide. The oily base was extracted with ether, the ether solution dried with fused sodium sulfate and the solvent removed. When the oily residue was cooled with ice and rubbed under low-boiling petroleum ether it became solid. The yield of crude product was 9 g. After recrystallization from petroleum ether the compound melted at 106–107°.

Anal. Calcd. for $C_{14}H_{22}O_2N_2$: C, 67.14; H, 8.86. Pound: C, 67.14; H, 8.87.

When the base was dissolved in absolute ether and a saturated ether solution of picric acid added a yellow picrate precipitated. After recrystallization from dilute alcohol the latter melted at 192–193°.

Seven and eighty-five hundredths grams of the labile form of 1-methylvinyldiacetone alkamine was converted into the potassium derivative and pyrroylated in the manner described above. There was obtained 7 g. of the crude pyrroyl derivative. After recrystallization from petroleum ether it melted at 106–107°. Since this melting point was identical with that found in the case of the pyrroyl derivative of the stable form of 1-methylvinyldiacetone alkamine, a mixed melting point of the two compounds was determined; this was found to be 80–83°.

Anal. Calcd. for $C_{14}H_{22}O_2N_2$: C, 67.14; H, 8.86. Found: C, 67.19; H, 8.89.

Notes on the Preparation of Pyrrolidine.—This compound was prepared from adipic acid[24] according to a series of reactions described by Miiller and Sauerwald[25] and by v. Braun and Lemke.[24] The methods described below were found by us to be satisfactory for the preparation of certain intermediates. Adipamide can be obtained conveniently by the following procedure. Adipic acid was treated with the amount of sodium carbonate solution required for the formation of the disodium salt and the solution evaporated to dryness. Thirty-seven grams of the oven-dried salt was placed in a round-bottomed flask, fitted with a reflux condenser, mixed thoroughly with 28 g. of pure phosphorus oxychloride and heated for five hours in an oil-bath to 50–55°. Because of the tendency of the mixture to form a hard cake, the yield of acid chloride would, undouhtedly, have been increased if the mixture had been stirred. The acid chloride was not isolated but was converted into the acid amide by the addition of the reaction mixture, in small amounts, to ten times the calculated quantity of a technical grade of ammonia water. The yield of the crude amide, based on adipic acid, was 70% of the calculated amount.

The following method for the preparation of 4-toluenesulfonamide is devoid of danger and more convenient than that described in the literature[26] since the use of a pressure bottle is avoided. Six to ten times the calculated amount of technical ammonium

---

hydroxide was poured into a large beaker, heated almost to the boiling point and stirred vigorously with a mechanical stirrer. 4-Toluenesulfonechloride was then added in small portions. A vigorous reaction ensued with each addition of the chloride. After all of the material had been added the clear solution was cooled, whereupon the amide precipitated. The latter was separated, dissolved in boiling water and treated with charcoal. After filtration the sulfonamide separated from the cold, concentrated solution in the form of colorless crystals.

Summary

Eight analogs of novocaine and several compounds analogous to stovaine and β-eucaine have been prepared and tested for local anesthetic action by application to the tip of the tongue. It was found, at least as far as the compounds discussed in this paper are concerned, that the local anesthetic action of a compound can be retained by the substitution of 2-pyrroyl for the benzoyl and the 4-aminobenzoyl group and by the replacement of dimethyl- and diethylamino by the 1-pyrryl and I-pyrrolidyl nuclei.

DISTIBYLS. I. TETRAPHENYLDISTIBYL. ATTEMPTS TO OBTAIN TETRAPHENYLDIBISMUTHYL[1]

BY F. F. BLICKE, U. O. OAKDALE AND F. D. SMITH

RECEIVED OCTOBER 2, 1930 PUBLISHED MARCH 6, 1931

We began our present study in the hope that we might obtain tetraphenyldistibyl, $(C_6H_5)_2Sb-Sb(C_6H_5)_2$, and tetraphenyldibismuthyl, $(C_6H_5)_2Bi-Bi(C_6H_5)_2$, compounds analogous to the diarsyls[2] which have been investigated recently in this Laboratory. It was found that the first mentioned compound could be prepared from the interaction of diphenylstibyl iodide and sodium hypophosphite.[3]

Tetraphenyldistibyl, in solution, proved to be extremely reactive toward oxygen and the gas was absorbed with the same rapidity which is so characteristic of a solution of *a* tetra-aryldiarsyl or a triarylmethyl; hence the preparation of the distibyl was carried out in a free radical apparatus and the product isolated in an atmosphere of nitrogen or carbon dioxide.

---

[1] This paper represents the first part of a dissertation to be submitted to the Graduate School by U. O. Oakdale in partial fulfilment of the requirements for the degree of Doctor of Philosophy in the University of Michigan.

This investigation was made possible by the aid of the Parke, Davis and Company Fellowship and by a grant from the Faculty Research Fund of the University of Michigan.

[2] Blicke and Smith, THIS JOURNAL, 51, 2272 (1929); Blicke, Weinkauff and Hargreaves, *ibid.*, 52, 780 (1930); Blicke and Smith, *ibid.*, 52, 2937 (1930).

[3] Schmidt [*Ann.*, 421, 235 (1920)] stated that tetraphenylstibyl oxide, $(C_6H_5)_2Sb-O-Sb(C_6H_5)_2$, when treated with hypophosphorous acid, yields a yellow compound which he thought might be tetraphenyldistibyl. However, no analysis or further description of the material was recorded.

The amount of oxygen absorbed corresponded to that required for the formation of tetraphenylstibyl peroxide, $(C_6H_5)_2Sb-O-O-Sb(C_6H_5)_2$. The colorless, crystalline distibyl possessed a sharp melting point and dissolved in organic solvents with the formation of colorless solutions.

Diphenylbismuthyl iodide, dissolved in bromobenzene, was shaken with molecular silver, mercury, zinc powder and copper bronze, respectively. In the case of the first two metals black precipitates were formed. However, none of the solutions obtained absorbed oxygen. Sodium hypophosphite, at ordinary temperature, did not seem to react with an alcoholic solution of diphenylbismuthyl iodide. When the mixture was warmed a black product was produced. A mixture of diphenylbismuthyl iodide, bromobenzene and copper was placed in an absorption flask, connected with an oxygen reservoir, and shaken vigorously for eight hours. The absorption of oxygen, based on peroxide formation, was approximately 50% of the calculated amount. Similar results were obtained with molecular silver.

Experimental Part

Diphenylstibyl Iodide.—Two hundred grams of crude, dry phenylstibinic acid[4] was dissolved in 500 cc. of hydrochloric acid and 250 cc. of water added to precipitate colored impurities. After filtration the solution of phenylstibinic acid was cooled with ice and treated with sulfur dioxide for three hours. The mixture was then allowed to remain in an ice-bath for six hours. The phenyldichlorostibine,[5] which had separated in crystalline form, was filtered with suction. To prepare phenylstibine oxide a cold acetone solution of phenyldichlorostibine was added, dropwise, to cold dilute ammonia water. The mixture was stirred vigorously during this process and kept cold by the addition of icr The precipitated phenylstibine oxide was filtered with suction, washed with acetone and dried.

Twenty-gram portions of finely powdered, crude phenylstibine oxide were placed in 250-cc. Erlenmeyer flasks fitted with two-holed stoppers through which inlet and outlet tubes were inserted. A stream of dry nitrogen was passed through the flasks and the latter were heated at 90° in an oil-bath for two hours. The viscous reaction products, which contained tetraphenylstibyl oxide, were extracted several times with hot alcohol, the alcoholic extracts filtered and the alcohol removed.[6] The oily residue obtained from each twenty-gram portion of phenylstibine oxide was treated with 10 cc. of acetic acid and stirred, whereupon the material crystallized almost immediately. This substance, diphenylstibyl acetate, was filtered with suction and recrystallized from acetic acid; 1 cc. of acetic acid was used for each gram of the acetate; m. p. 133–135°.[7]

In order to convert the acetate into the corresponding chloride or bromide, or the chloride into the iodide, it is essential that all products should be in a very pure state before the conversion is attempted.

For the preparation of diphenylstibyl chloride 20 g. of pure diphenylstibyl acetate was dissolved in 60 cc. of hot acetic acid. The solution was cooled quickly to room

---

[4] Schmidt, *Ann.*, 421, 189 (1920).

[5] Solutions of this material are powerful skin irritants.

[6] This process represents a slight modification of that used by Schmidt [*Ann.*, 421, 234 (1920)] for the conversion of phenylstibine oxide into tetraphenylstibyl oxide.

[7] Schmidt [*Ann.*, 429, 140 (1922)] recorded the melting point as 132°.

temperature and 80 cc. of hydrochloric acid was added immediately in small portions. The mixture was cooled during the addition of the hydrochloric acid. The chloride precipitated at once in crystalline form and was recrystallized from an equal weight of acetic acid; m. p. 68°.[8]

When diphenylstibyl acetate was dissolved in hot acetic acid, the solution cooled to room temperature and an excess of 48% hydrobromic acid added an oil precipitated. When cooled the latter became solid. After three recrystallizations from acetic acid the compound, undoubtedly diphenylstibyl bromide, melted at 86°.

Diphenylstibyl iodide was prepared as follows. Twenty grams of the chloride, dissolved in 25 cc. of pure acetone, was added to three times the calculated amount of sodium iodide dissolved in the same solvent. After twelve hours the sodium chloride was removed and the acetone allowed to evaporate spontaneously. The crystalline iodide, obtained after the addition of water to the residue, was recrystallized twice from acetic acid and twice from absolute alcohol; m. p. 68–70". The iodide is not affected by cold water and is hydrolyzed only very slowly by boiling water.

Anal.[9] Calcd. for $C_{12}H_{10}SbI$: Sb, 30.23; I, 31.51. Found: Sb, 30.20; I, 31.42.

Neither diphenylstibyl iodide nor triphenylmethyl bromide, dissolved in bromobenzene, absorbs oxygen. When diphenylstibyl iodide (0.003 mole) and triphenylmethyl bromide (0.003 mole) were put into a test-tube, the latter constricted and then filled quickly with bromobenzene which had been saturated with nitrogen a deep red solution was formed immediately. When the tube was broken in an oxygen absorption apparatus[10] 51 cc. of oxygen was absorbed very rapidly. This quantity of oxygen is more than that required for the formation of triphenylmethyl peroxide (34.2 cc.) and is less than that necessary for the formation of both triphenylmethyl peroxide and tetraphenylstibyl peroxide. A phenomenon entirely analogous to that described above is observed when diphenylarsyl iodide and triphenylmethyl bromide are mixed.[11]

Action of Metals on Diphenylstibyl Iodide.—Two tubes were prepared each of which contained diphenylstibyl iodide, bromobenzene[12] and copper bronze.[13] After the tubes had been shaken for a definite period of time the one tube was broken in an oxygen absorption apparatus while the contents of the other tube were analyzed for copper halide. Several series of such tubes were shaken for different periods of time. The data obtained showed that the percentage of iodine removed, which should serve as a measure of the amount of tetraphenyldistibyl formed, did not correspond to the percentage of oxygen absorbed. The latter was calculated based on the assumption that tetraphenylstibyl peroxide, $(C_6H_5)_2Sb–O–O–Sb(C_6H_5)_2$, is the primary product of the oxidation. These results indicate that the distibyl undergoes decomposition or that it is rendered inactive toward oxygen by combination with unchanged diphenylstibyl iodide or the copper halide. However, we have shown that the isolated distibyl, dissolved in bromobenzene, retains its activity toward oxygen for a period of several days at least.

In one instance the distibyl was allowed to absorb oxygen as fast as it was formed. One and six-tenths grams of diphenylstibyl iodide, 15 cc. of bromobenzene and 2 g. of copper were placed in an absorption flask attached to a reservoir filled with oxygen and

[9] Method of Thompson and Oakdale, THIS JOURNAL, **52,** 1195 (1930).

[10] Gomberg and Schoepfle, *ibid.*, **39,** 1661 (1917).

[11] Blicke and Smith, *ibid.*, **51,** 2275 (1929).

[12] This solvent was used because of its comparatively low vapor pressure. Gomberg and Schoepfle, *ibid.*, **39,** 1661 (1917).

[13] Magnesium powder, molecular silver, mercury and zinc dust were tried but only copper and zinc seemed to remove the halogen rapidly.

the absorption flask was shaken vigorously and continuously. After five minutes 20 cc., after one hour 32 cc. and after nine hours 44.8 cc., the amount of the gas calculated for peroxide formation, had been absorbed. An analysis of the copper halide formed showed that practically all of the iodine had been removed from the diphenylstibyl iodide at the end of nine hours.

Tetraphenyldistibyl.—Three and two-tenths grams of diphenylstibyl iodide, dissolved in 25 cc. of absolute alcohol, was poured into a free radical apparatus[14] of 125-cc. capacity. One and three-tenths grams of sodium hypophosphite was dissolved in 5 cc. of water and 20 cc. of alcohol added. This solution was then poured into the radical apparatus. The reaction mixture was protected from light and allowed to remain at ordinary temperature for twelve hours. The distibyl separated from the mixture in the form of pale yellow-green needles. The liquid was decanted through the stopcock with the aid of suction and the product was washed several times with small amounts of alcohol, whereupon it became practically colorless. The compound was dried by allowing the apparatus to remain attached to the suction pump for six hours. The material was then removed from the radical apparatus in the manner described previously in the case of diarsyls.[15] The amount of distibyl isolated was usually somewhat in excess of one gram.

The product when pure was practically colorless and the copper wire test proved it to be halogen free. In a sealed tube filled with nitrogen it melted at 121–122°. In order to prevent oxidation during the weighing of the material it was found advantageous to compress the distibyl in the form of tablets in a tablet machine. Each tablet was then weighed in a closed tube, filled with nitrogen, just large enough to contain it.

Anal.[9] Calcd. for $C_{24}H_{20}Sb_2$: Sb, 43.93. Found: Sb, 44.13.

The diarsyl reacts instantly with iodine. In an apparatus filled with nitrogen there was placed 0.4320 g. of the distibyl. The latter was then dissolved in 15 cc. of benzene and a $N/10$ solution of iodine in carbon tetrachloride was added. The iodine color disappeared instantly but after 15.8 cc. of the solution had been added a permanent color was produced. The calculated amount of iodine solution necessary for the formation of diphenylstibyl iodide is 15.7 cc. The solution was poured into a dish and the carbon tetrachloride evaporated. The yellow, crystalline residue was washed with a very small amount of acetic acid; m. p. 64–65". Mixed with diphenylstibyl iodide it melted at the same temperature.

Potassium permanganate, dissolved in acetone, is decolorized instantly by the distibyl.

A portion of the isolated tetraphenyldistibyl, which weighed 0.7609 g., was dissolved in bromobenzene and the solution preserved in a sealed tube, protected from light for four days. The tube was then broken in an oxygen absorption apparatus. Twenty-nine cc. of oxygen was absorbed almost instantly; the calculated amount is 29.4 cc.

Triphenylbismuthine.—Phenylmagnesium bromide was prepared from 80 g. of bromobenzene (0.5 mole), 12 g. of magnesium and 300 cc. of ether. After the addition of 200 cc. of dry benzene the solution was stirred vigorously and 41 g. of finely-divided, freshly distilled bismuth trichloride (0.13 mole)[16] was added in five portions during the

[15] Blicke, Weinkauff and Hargreaves, ibid., 52, 782 (1930).

[16] The best quality of bismuth trichloride which we could obtain contained considerable liquid. The material was drained thoroughly, placed on a porous plate and the latter put into a desiccator. After several days the chloride was distilled from a retort with a very short side arm.

course of one-half hour. The mixture was then heated on a steam-bath and stirred for four hours. The mixture was decomposed with ice and ammonium chloride, the ether layer separated and dried with fused sodium sulfate. After removal of the solvent the oily residue soon solidified. The material war washed with petroleum ether (30–60°); m. p. 76–77°; yield, 48 g., or 84% of the calculated amount.[17]

Diphenylbismuthyl Iodide.—Twenty three grams of diphenylbismuthyl chloride[18] was dissolved in 200 cc. of absolute alcohol, 9 g. of solid sodium iodide added and the mixture shaken for twelve hours. It was then poured into 600 cc. of boiling water. Diphenylbismuthyl iodide separated in the form of yellow flakes. The latter were filtered, washed with water and dried in a vacuum desiccator. The product was treated with hot ethyl acetate in order to dissolve the diphenylbismuthyl iodide, the mixture cooled to room temperature and filtered to remove the red by-product. The solvent was distilled from the filtrate under diminished pressure in a stream of nitrogen. The iodide was powdered, triturated with 20 cc. of petroleum ether (30–60°) in order to remove triphenylbismuthine, the petroleum ether decanted and the process repeated several times; m. p. 132–134°.[19]

Diphenylbismuthyl iodide, dissolved in acetone, instantly decolorizes potassium permanganate dissolved in the same solvent. If a carbon tetrachloride solution of iodine is added to the bismuthyl iodide, dissolved in benzene, the first portion of the iodine solution is decolorized immediately. Upon further addition of iodine a brick-red and then a brown precipitate is formed.

Summary

Tetraphenyldistibyl, $(C_6H_5)_2Sb–Sb(C_6H_5)_2$, has been prepared from diphenylstibyl iodide and sodium hypophosphite. The distibyl, in solution, is just as reactive toward oxygen as solutions of tetra-aryldiarsyls or triarylmethyls.

We have not been able to obtain tetraphenyldibisrnuthyl by the methods used for the preparation of the analogous arsenic and antimony compounds.

OPTICALLY ACTIVE ALPHA-PINENES[1]

BY F. H. THURBER AND R. C. THIELKE

RECEIVED OCTOBER 3, 1930 PUBLISHED MARCH 6, 1931

Since there is some doubt regarding the purity of a-pinenes obtained from natural sources, and likewise regarding the purity of derivatives prepared from them, we have obtained pure products by the method devised by Lynn,[2] that is, by the preparation of the nitroso chlorides of the active pinenes, recrystallization of these compounds to insure their purity and finally decomposition of the nitroso chlorides with dimethylaniline to set free the pinenes. In this preparation we have found that the presence of small amounts of water aided in the formation of the nitroso chloride. In fact, we were able to obtain only traces of the desired product previous to this discovery. Lynn in a private communication informed us that in some runs the nitroso chloride precipitated and in others it did not precipitate. Apparently water catalyzes the reaction. The hydrochlorides of pure dextro, levo and inactive pinenes were prepared and their optical rotations observed. The rotations of the active pinenes were equal and opposite in sign. Methods used in the preparations and results observed are given below in the experimental part.

Preparation of Dextro and Levo α-Pinenes.—Dextro a-pinene was obtained from Port Orford cedar oil by the method previously outlined,[3] that is, by fractionation of the oil and distillation over sodium. Levo or-pinene was obtained from Douglas Fir balsam. The method of purification was identical with that used for the dextro compound. The constants observed for the levo compound were b. p. 155–156°, $[\alpha]_D^{20}$ −42.6". n_D^{20} 0.4676; d_{20} 0.8598. It is of interest to note that there is an almost unlimited supply of Douglas Fir balsam available.

a-Pinene with a low specific rotation was obtained from American turpentine oil. It was used for the preparation of the inactive nitroso chloride by the method outlined by Wallach.[4]

Active Nitroso Chlorides.—These compounds were prepared by the method outlined below. The method is given in some detail since the exact conditions for the preparation of such compounds have not been published up to this time.

To 40 cc. of I-or-pinene, 40 cc. of methyl alcohol (10% water by volume) and 40 cc. of ethyl nitrite were added. The mixture was placed in a wide-mouthed bottle closed with a stopper bearing a thermometer and mechanical stirrer, and was kept at a temperature of −20" during the addition of the theoretical amount of hydrochloric acid. The hydrochloric acid solution was prepared by passing hydrogen chloride gas into 90% methyl alcohol until an approximately 5 *N* solution was obtained. It was found to be advisable to introduce the alcohol–acid solution below the surface of the liquid and to cool the addition tube through which the acid flowed in order to prevent local super-

[4] Wallach, *Ann.*, 253, 251 (1889).

heating. A period of approximately two and one-half hours was required for the addition. After all of the acid had been added the reaction mixture was allowed to stand for a short time and was then filtered to remove the inactive derivative which had precipitated.

The filtrate was immediately cooled to −20° and another 200 cc. of cold 90% methyl alcohol added to it. The mixture was then allowed to stand for twenty-four hours, the temperature being maintained at −20° to insure complete precipitation of the active nitroso chloride. Some crystals usually appeared almost immediately after the addition of the cold 90% alcohol. The crystals were removed by filtration and were purified by recrystallization from a 1:2 mixture of chloroform and methyl alcohol.

Dextro pinene nitroso chloride was prepared from d-pinene in a similar manner. However, pinene from Port Orford cedar oil does not yield an inactive nitroso chloride, so that the removal of this product is dispensed with. The yield varied with the type of pinene used but was always very low, usually about 2 g. per run.

Properties of Pinene **Nitroso** Chlorides.—The active nitroso chloride decomposes at room temperature to a brown oily mass in a period of about three weeks. At −20° the compound is stable for a much longer period of time. Some attempts were made to determine the molecular weights, by the freezing point method, of both the active and inactive nitroso chlorides. Definite results could not be obtained but rather high molecular weights were indicated. The active nitroso chlorides are considerably more soluble than the inactive in such solvents as benzene. We expect to make a study of the molecular weights of these compounds at some later time. After recrystallization the following constants were observed.

Nitroso chloride....	dl-	d-	*l*-
M. p., °C..........	115	89.5	90.0
$[\alpha]^{20}_{D}$ (in benzene)..	0.0	+396.2	−366.8

These compounds are somewhat unstable near their melting points and different observers may obtain widely varying melting points, depending upon the rate of rise of temperature of the melting point bath.

Optically Active **Pinene** from **the Nitroso** Chloride Derivative.—The method described by Tilden was used.[5] Twenty grams of a-pinene nitroso chloride was warmed with a mixture of 24 g. of dimethylaniline and 60 cc. of 95% ethyl alcohol. The liberated pinene was recovered by steam distillation and was then washed and purified by refluxing over metallic sodium; yield, 8 *g*. While this is not a large amount of material to work with we were able, by using small-sized apparatus, to determine the physical properties of the pinenes and to prepare their hydrochlorides and determine their properties. The physical properties of the pinenes synthesized are tabulated below.

		B. p., °C. (760 mm.)	$[\alpha]^{20}_{D}$	$[\alpha]^{20}_{D}$ (in alc. soln.)	d_{20}	n^{20}_{D}
Regenerated	dl-a-pinene	155–156	0.00	0.00	0.8592	1.4664
Regenerated	d-a-pinene	155–156	+51.14	$53.91	.8591	1.4663
Regenerated	I-a-pinene	155–156	−51.28	−54.04	.8590	1.4662

A tube 2.95 cm. long and holding 1 cc. of liquid was used for the direct determination of the specific rotation, while a 10-cm. tube was used for the determinations in 4% alcohol solution. Apparently the solvent increased the rotation numerically to a slight degree. The main point, however, is that the rotations are equal and opposite in sign within the limits of experimental error. The samples were considered to be pure and were used for the preparation of the hydrochlorides.

---

[5] Tilden, *J. Chem. Soc.*, 85, 759 (1904).

α-Pinene Hydrochloride.—The hydrochloride was prepared by saturating 3-cc. samples of pinene with dry hydrochloric acid gas, at a temperature of from 10–15°. Thereafter the mixture was kept at −5° for one hour. The product was then filtered with suction and recrystallized from five times its weight of absolute methyl alcohol. The alcohol was removed by suction filtration and the melting points and specific rotation were determined immediately. These properties are tabulated below.

	M. p. (corr.), °C.	$[\alpha]_D^{20}$ (1 % alcohol solution)
dl-a-Pinene hydrochloride	132	0.00
d-α-Pinene hydrochloride	132	4–33.52
l-α-Pinene hydrochloride	132	−33.24

The chief point of interest here is that the optical rotations are again equal and opposite in sign within the limits of experimental error. When samples were allowed to stand in the air for even very short periods of time the melting points were somewhat lower. Undoubtedly this accounts for the wide range of melting points (118–133°) reported in the literature.

Summary

1. Samples of pure d-a-pinene, 1-a-pinene and dl-a-pinene were prepared and their physical properties determined. 2. The conditions necessary for the formation of active a-pinene nitroso chloride were worked out. 3. It was found that when methyl alcohol is used as a solvent a small amount of water must be present to bring about the formation of the active nitroso chloride. 4. The hydrochlorides of dextro, dl and levo α-pinene were prepared and their properites studied. 5. Contrary to reports in many texts and journal articles these compounds exhibit a normal behavior, that is, *dl*-α-pinene yields an inactive hydrochloride and the active pinenes yield active hydrochlorides whose rotations are equal and opposite in sign. 6. A study of the molecular weights of the nitroso chlorides will be made later.

SEVERAL NEW 4'-SULFO-ORTHO-BENZOYLBENZOIC ACID DERIVATIVES AND THE CORRESPONDING ANTHRAQUINONE COMPOUNDS[1]

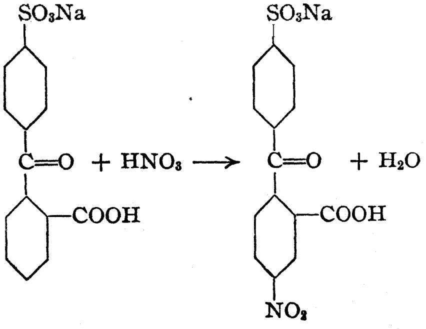
BY IVAN GUBELMANN, H. J. WEILAND AND O. STALLMANN

RECEIVED OCTOBER 30, 1930 PUBLISHED MARCH 0,1931

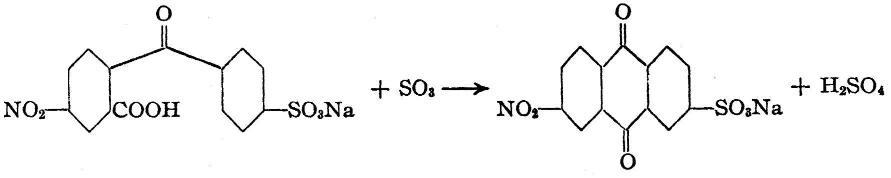
Several new 4'-sulfo-o benzoylbenzoic acid derivatives and the corresponding anthraquinone compounds are described. They are, 4'-sulfo-2-benzoyl-5-nitrobenzoic acid, 2-nitroanthraquinone-7-sulfonic acid, 2-nitro-7-chloroanthraquinone, 2-amino-7-chloroanthraquinone, 4'-sulfo-2-benzoyl-5-aminobenzoic acid, 2-aminoanthraquinone-7-sulfonic acid, 2,7-diaminoanthraquinone.

In the synthesis of anthraquinone derivatives from 4'-sulfo-o-benzoylbenzoic acid, a very interesting series of new compounds has been studied.

When 4'-sulfo-o-benzoylbenzoic acid is nitrated the nitro group enters the benzoic acid ring, not the sulfo benzene ring, as expected. The main product formed is 4'-sulfo-2-benzoyl-5-nitrobenzoic acid.



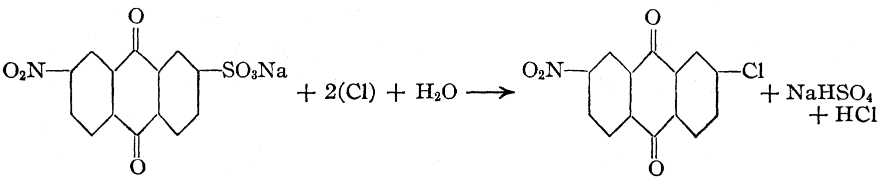
4'-Sulfo-2-benzoyl-5-nitrobenzoic acid is soluble in concentrated sulfuric acid and on heating the solution the ring closes to form 2-nitroanthraquinone-7-sulfonic acid.



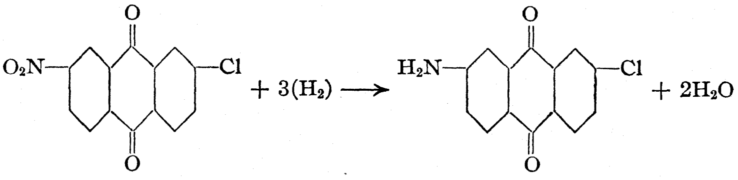
By treating 2-nitroanthraquinone-7-sulfonic acid with sodium chlorate in dilute acid solution, the sulfonic acid group is replaced by chlorine and 2-nitro-7-chloroanthraquinone is produced quantitatively.

---

[1] Presented before the Division of Dye Chemistry at the 80th Meeting of the American Chemical Society, Cincinnati, Ohio, September 8–12, 1930, by J. M. **Tinker.**

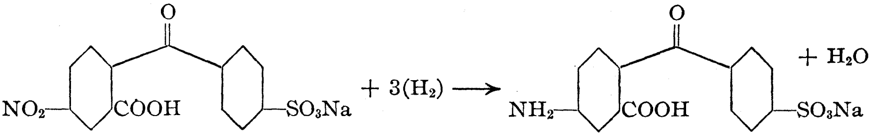


This nitrochloro compound crystallizes from chlorobenzene in light yellow crystals melting at 251 to 252° and has not been described. By reducing the 2-nitro-7-chloroanthraquinone with sodium sulfide, the 2-amino-7-chloroanthraquinone is formed.

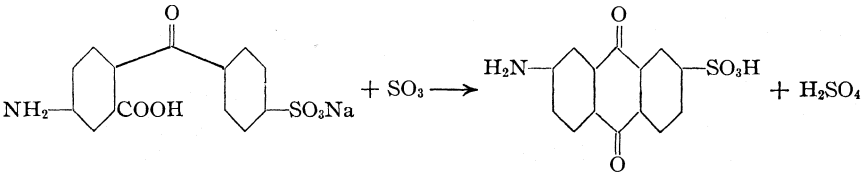


When pure it crystallizes in light orange needles melting at 302 to 303°.

Instead of ring closing 4'-sulfo-5-nitro-2-benzoylbenzoic acid, the nitro group may be first reduced to the 4'-sulfo-2-benzoyl-5-aminobenzoic acid.



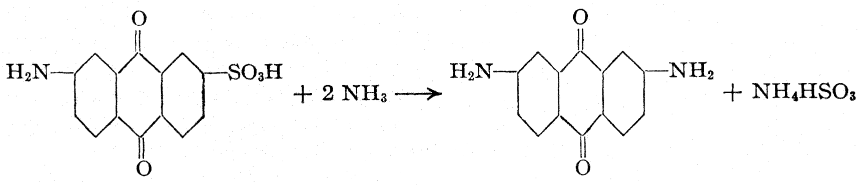
This amino compound analyzes 99.8% by nitrite titration based on a molecular weight corresponding to the formula above and on ring closing this amino compound with sulfuric acid, the 2-amino-anthraquinone-7-sulfonic acid is formed.



This product corresponds to the 2-aminoanthraquinone-7-sulfonic acid described by F. Kaufler,[2] obtained from the 2,7-anthraquinone-disulfo acid by amination.

By treating this aminoanthraquinone-sulfo acid with ammonia and arsenic acid, the well-known 2,7-diaminoanthraquinone is produced.

[2] F. Kaufler, *Ann.*, *351*, 158 (1907).



This diaminoanthraquinone is easily recrystallized from nitrobenzene, giving dark violet crystals melting at **330** to 332°. On conversion to the dioxy derivative by the Sandmeyer method, a dioxy body is formed melting above 340°. On acetylation a diacetyldioxyanthraquinone is formed which melts at 190 to 191°.

E. Noelting and W. Wortmann[3] describe a diaminoanthraquinone obtained from 2,7-dinitroanthraquinone, which is the same in properties as the one obtained by this synthesis.

Compound	M. p., °C.	Compound M. p., °C.
2,7-Dioxy-anthraquinone	Over 330	Diacetyl 190 to 191
2,6-Dioxy-anthraquinone	Over 330	Diacetyl 228 to 229
2,3-Dioxy-anthraquinone	Over 260	Diacetyl 203 to 205
1,7-Dioxy-anthraquinone	Over 292 to 293	Diacetyl 198 to 199
1,8-Dioxy-anthraquinone	Over 191	Diacetyl 227 to 232
1,6-Dioxy-anthraquinone	Over 276	Diacetyl 204 to 205
1.5-Dioxy-anthraquinone	Over 280	Diacetyl 244 to 245
1,4-Dioxy-anthraquinone	Over 194 to 195	Diacetyl 200
1,3-Dioxy-anthraquinone	Over 270	Diacetyl 183 to 184
1,2-Dioxy-anthraquinone	Over 289 to 290	Diacetyl 184
Unknown dioxy-anthraquinone	Over 330	Diacetyl 190 to 191

Experimental Part

(1) Preparation of **4′-Sulfo-2-benzoyl-5′-nitrobenzoic** acid, Monosodium **Salt.**—Dissolve 328 g. of 4'-sulfo-o-benzoylbenzoic acid monosodium salt in 650 parts of 100% sulfuric acid at 15 to 20". While agitating, add over a period of six to eight hours, 580 g. of mixed acid (made by mixing 100 g. of mixed acid containing 70% nitric acid, 22% sulfuric acid and 8% water with 480 parts of 25% oleum). Hold the temperature at 15 to 20° during the addition, then raise to 35° and hold for three hours.

Dilute the finished nitration by pouring onto 2500 g. of ice and 1500 g. of water, then salt out the 4'-sulfo-2-benzoyl-5-nitrobenzoic acid monosodium salt with 1000 g. of salt. Filter after a few hours, wash with cold water and dry (weight 350 g.). It is a white crystalline powder easily soluble in water to a pale yellow solution. With alkalies it forms the diacid salts, which are very soluble in water. It is difficultly soluble in cold alcohol and is best purified by crystallizing from a hot dilute sulfuric acid solution.

Anal. Calcd.: S, 8.58; N, 3.75. Found: S, 8.49; N, 3.70.

(2) Preparation of 2-Nitroanthraquinone-7-sulfonic Acid.—Dissolve 100 g. of 4'-sulfo-2-benzoyl-5-nitrobenzoic acid in 400 g. of 25% oleum and heat to 150°. Cool quickly and pour onto 2500 g. of ice. Filter the precipitated 2-nitroanthraquinone-7-sulfonic acid and wash well with cold water. This yield is 80 g.

---

[3] Noelting and Wortmann, *Ber.*, 39, 641 (1906).

(3) Preparation of **2-Nitro-7-chloroanthraquinone.**—Suspend 35.5 g. of 2-nitroanthraquinone-7-sulfo acid (sodium salt) in 1750 cc. of water and 90 g. 20° Bé. hydrochloric acid in a five-liter flask with a glass agitator. Heat to boiling and add a solution of 35.5 g. of sodium chlorate dissolved in 500 cc. of water over a period of twenty to twenty-four hours. The volume is kept constant at 2 liters. When finished, filter, wash well with hot water and dry at 100° in vacuum. The yield is quantitative.

The 2-nitro-7-chloroanthraquinone is easily purified by crystallizing from chlorobenzene or glacial acetic acid as light yellow crystals melting at 251 to 252°.

(4) Preparation of **2-Amino-7-chloroanthraquinone.**—287 g. of 2-nitro-7-chloroanthraquinone is suspended in 5 liters of water containing 40 g. of sodium hydroxide and 625 g. of sodium sulfide crystals. Heat to boiling in two to three hours and hold at the boiling point for two hours. The 2-amino-7-chloroanthraquinone is then filtered off and washed well with hot water. The yield is almost quantitative. This body crystallizes easily from chlorobenzene in light orange needles melting at 302 to 303°.

Anal. Calcd. for $C_{14}H_8SO_2NCl$: N, 5.44; Cl, 13.8. Found: N, 5.34; Cl, 14.3.

(5) Preparation of **4′-Sulfo-2-benzoyl-5-aminobenzoic Acid.**—373 g. of 4′-sulfo-2-benzoyl-5-nitrobenzoic acid monosodium salt is suspended in about 300 g. of hot water. Add this mixture in about three to four hours to an agitated mixture of water, 750 g. of powdered iron and 75 g. of glacial acetic acid held at 93 to 97°. Hold for another hour at 95 to 97°, then neutralize with about 175 g. of sodium carbonate. Filter off the iron sludge and wash well with about 1 liter of boiling water. Acidify the mother liquor and wash water with hydrochloric acid, when the 4'-sulfo-2-benzoyl-5-aminobenzoic acid monosodium salt will precipitate and is filtered and washed with cold water. The yield is 300 g. This is a white crystalline product, easily purified by crystallizing from hot water. It is easily soluble in alkalies but sparingly soluble in cold water and dilute mineral acid, 95% alcohol, glacial acetic acid or other organic solvents.

(6) Preparation of **2-Amino-anthraquinone-7-sulfo Acid.**—Dissolve 40 g. of 4′-sulfo-2-benzoyl-5-aminobenzoic acid monosodium salt in 240 g. of a mixture of 87 g. of 66" Bé. acid and 113 g. of 25% oleum, heat to 180° and hold at this temperature for one hour. Pour onto ice, then filter, wash and dry.

(7) Preparation of **2,7-Diaminoanthraquinone.**—Charge a high-pressure steel autoclave with 318 g. of ammonium salt of 2-aminoanthraquinone-7-sulfo acid, 156 g. of arsenic acid and 1860 g. of 27% ammonia and heat for twenty-four hours at 180°.

After cooling, the reaction mass is filtered and washed well. The dried product is red needles melting at 330 to 332°. Further crystallization from nitrobenzene does not change this melting point.

Conclusion

When 4'-sulfo-2-benzoylbenzoic acid is nitrated, the nitro group enters the benzoic acid ring. Proof of structure is based on the melting point of the 2,7-diaminoanthraquinone, as well as the melting point of the 2,7-dioxyanthraquinone and 2,7-diacetyl-dioxyanthraquinone, which are prepared from the sulfo-benzoyl-*o*-benzoic acid. The several intermediate products are described.

NOTE ON THE TER MEULEN–HESLINGA METHODS FOR THE ESTIMATION OF NITROGEN, CARBON AND HYDROGEN IN ORGANIC MATERIAL[1]

BY E. P. GRIFFING AND C. L. ALSBERG

RECEIVED DECEMBER 8, 1930 PUBLISHED MARCH 6, 1931

The purpose of this note is to make the excellent methods of Ter Meulen and Heslinga for the estimation of carbon, hydrogen and nitrogen more generally known in America, and to suggest some slight modifications based on two years' experience in their use. Both methods employ much less material than the customary macro methods without requiring the special equipment or unusual technique of the micro methods in general use.

The Carbon–Hydrogen Method.—This depends upon catalytic oxidation with manganese dioxide. A micro-balance is not necessary, though one with a sensitivity of 0.05 mg. is desirable. If such a balance is not available, the sample to be taken must be larger. With an ordinary analytical balance sensitive to 0.1 mg., the carbon–hydrogen estimation requires fifty to one hundred milligrams and takes one hour.

Several changes in the apparatus set-up recommended by Ter Meulen and Heslinga are suggested. We used compressed commercial oxygen, regulating the velocity of the gas flow by a double-head reduction valve, and introduced a manometer in the line next to the oxygen cylinder to register any resistance to the passage of the products of combustion or to the flow of oxygen that might arise. The oxygen was passed through a purifying train consisting first of sulfuric acid, then of ascarite to absorb carbon dioxide and lastly of dessicite to absorb moisture.

We used a much larger quartz combustion tube than that specified by Ter Meulen and Heslinga, namely 35 cm. long and 10 mm. bore. The additional length permits the use of a copper wire coil between the combustion boat and the end of the tube through which the boat is introduced. Heating this coil to a high temperature by a separate micro-burner during combustion helps to prevent back flow of gases, should there be a sudden increase in pressure. The larger diameter permits the use of more catalyst per unit length, so that it need not be renewed so frequently. A copper wire coil extending the length of the catalyst was found advantageous to prevent the catalyst from becoming too densely packed due to sudden increase in pressure, if combustion was too fast.

Much difficulty was encountered at first in preparing active catalyst.

---

[1] H. Ter Meulen and H. Heslinga, Leipzig, 1927; H. Ter Meulen. *Rec. trav. chim.*, 43, 643 (1924); H. Ter Meulen, *ibid.*, 44, 271 (1925).

We adopted the method of Rogers, Piggot, Bahlke and Jennings[2] for preparing manganese dioxide from calcium permanganate. We have found it advantageous in order to increase its density to subject the wet precipitate of manganese dioxide to great pressure in a hand-press before drying on a sand-bath. Catalyst thus prepared is very active and has a very long life. As it becomes exhausted, it changes in color from intense black to rusty black.

In analyzing nitrogenous substances Ter Meulen and Heslinga employ a layer of lead peroxide behind the manganese dioxide to hold back the nitrous oxide. Since the lead peroxide in the powdered form has a tendency to pack in the tube, we used it in granulated form of a 12–20 mesh size.

For absorption of the combustion products very light weight U-tubes were used, so that their loaded weight did not exceed 25 g. Water was absorbed by dessicite, carbon dioxide by ascarite. Behind the ascarite in the carbon dioxide absorption tube a short length of dessicite was used to prevent loss of moisture from this tube. Following the absorption train we found it most advantageous to use a Marriotte flask (aspirator bottle) in order to maintain a uniform, slightly reduced pressure in the absorption train. This can be attained by having the opening of the inlet tube dipping into the water in the bottle 20 mm. above the orifice of the outlet tube.

The method itself is very accurate; the limiting factor is the accuracy of weighing. Therefore, results obtained with an ordinary analytical balance and small samples will prove of interest. Thirteen analyses of sucrose, the average weight of sample being 40 mg., gave an average carbon content of 42.31% as against 42.1% theoretical. The sensitivity of the balance used was such that the variability due to lack of sensitivity of the balance might amount to 0.21% carbon for a 40-mg. sample. Six determinations of the carbon content of oxalic acid, the average weight of sample being 28 mg., gave 19.21% as against 19.05% theoretical. The experimental error that might be due to the weighing was 0.25% carbon. It is obvious, therefore, that if only an ordinary analytical balance is available, somewhat larger samples should be used.

The Nitrogen Method.—This depends upon hydrogenation with a nickel catalyst and titration of the resulting ammonia. Using an ordinary analytical balance we have obtained satisfactory results with as little as 20 mg. of sample. The time required is only thirty minutes.

The following modifications in set-up of apparatus are suggested: instead of heating the catalyst by a gas-burner under an asbestos box, we used an electric furnace for that portion of the quartz tube containing the

---

[2] T. H. Rogers, C. S. Piggot, W. H. Bahlke, and J. M. Jennings, THIS JOURNAL, 43, 1973 (1921), Method 5.

catalyst. It is not then necessary to cool down during the day, even when changing the boats; a constant temperature may be maintained. Instead of collecting the ammonia in a solution kept just on the acid side of neutrality by addition from time to time of standard acid from a buret supported over the flask, we found it advantageous to collect it in an excess of acid and to titrate the excess at the end of the combustion, after having boiled the contents to remove carbon dioxide. We also found a 1% solution of alizarin sulfonate to be superior to methyl orange for the titration of the seventieth normal acid which we used. Micro-burets of 5 cc. capacity, with scale divisions of 0.02 cc. which could be estimated to 0.002 cc., were used for the titration.

By this technique we were able to determine total nitrogen in such plant materials as wheat leaves and straw in about 250 samples with an accuracy such that duplicate analyses varied by less than 0.1% of nitrogen and very often by only one or two hundredths per cent. When one considers that it is extremely difficult to secure homogeneity in such small samples of this type of material, the method may well be regarded as extremely satisfactory. The results are more accurate than those we could obtain upon the same material with the customary macro Kjeldahl method.

We regard the method as preferable to the Kjeldahl method wherever only a few determinations a day are to be made, for it is not much more time consuming. It is more accurate and does not require a separate digestion room with special hood to remove the gases of boiling sulfuric acid. If, as is the case in fertilizer and feeding stuffs control laboratories, hundreds of analyses have to be made daily, the Kjeldahl method is more expeditious. Moreover, since the Kjeldahl method employs a very much larger sample, it is to be preferred for inhomogeneous materials like fertilizers and feeding stuffs that are difficult to sample.

SOME ORGANIC ACIDS OF WHEAT PLANTS[1]

BY E. K. NELSON[2] AND HEINRICH HASSELBRING[3]

RECEIVED DECEMBER 13, 1930 PUBLISHED MARCH 6, 1931

Many of the constituents of wheat plants have been repeatedly and thoroughly investigated. In Wehmer's book, "Die Pflanzenstoffe," second edition, 1929, mention is found of a considerable number of organic and inorganic constituents. However, the non-volatile organic acids are not mentioned.

In the course of a study on the buffer system of the wheat plant,[4] Hurd-Karrer found that the form of the titration curve between P_H 2.0 and 6.0 suggested the presence of malic acid in the juice, which observation directed attention to the fact that the nature of the organic acids of wheat had not been reported. The present work was accordingly undertaken, in cooperation with the office of Cereal Investigations of the United States Department of Agriculture, to determine the identity and relative amounts of the acids in the tissues of the wheat plant.

The material used for this study was winter wheat grown on the Arlington Experimental Farm at Rosslyn, Virginia, during the season of 1927–1928. Samples were collected from May 15 until May 28, 1928. The plants at this time were in a vigorous state, free from rust and other diseases. When cutting was begun, no heads had appeared, but toward the end of the cutting, heads had begun to show. The plants were cut about four inches or more above the ground so that none of the basal, yellowing leaves were included in the samples.

The material was immediately taken into the laboratory, cut into short pieces in a meat slicer, weighed and thoroughly extracted with boiling water. The total weight of the green plants was 76,054 g., 14,527 g. of which was dry matter.

The liquid was strained through a closely woven bag to which the solid residue was finally transferred. The remaining liquor in the residue was pressed out in a tincture press, and was added to the strained portion.

The liquid portion was treated with successive portions of a saturated solution of basic lead acetate until no precipitate was formed by further addition of lead acetate. The precipitates were collected on Büchner funnels and dried at room temperature. Combined, they amounted to 1715 g.

[4] Hurd-Karrer, "Titration Curves of Etiolated and of Green Wheat Seedlings Reproduced with Buffer Mixtures," Plant Physiol., 3, 307–328 (1930).

For the separation of the non-volatile acids by the ester distillation method, 685 g. of the lead precipitate was decomposed by sulfuric acid, and filtered from lead sulfate. The excess of sulfuric acid in the filtrate was removed by its exact equivalent of barium hydroxide. The barium sulfate was removed by filtration, and the solution of organic acids was concentrated to small volume, treated with a liberal quantity of absolute alcohol, and filtered from precipitated proteids and extraneous materials

The alcoholic solution was evaporated to dryness and esterified with alcoholic hydrochloric acid (one liter of absolute alcohol containing 25 g. of dry hydrochloric acid). The excess alcohol was evaporated and the esterification repeated. The alcohol was again evaporated and the residue dissolved in ether. Considerable insoluble material was left. The ethereal solution was filtered, shaken with a solution of sodium hydroxide to remove free acids and evaporated. Fifty-two grams of the crude mixed esters were obtained.

The esters were submitted to fractional distillation at **10** mm., and the distillates were re-fractionated at the same pressure.

The results of the fractionation are as follows

		G.
1	90–100° (redistilled at 85–90°)	2.2
2	100–120°	0.1
3	120–125°	.1
4	125–135° (α_D −10.7")	21.0
5	135–145"	1.8
6	145–155°	1.5
7	155–165°	0.6
8	165–170°	13.2
	Residue (oily)	6.8
		47.3

The hydrazides were prepared from these fractions.

Fraction **1** yielded a hydrazide which came down at once in needles. These were in very small quantity and when recrystallized melted at 235°. They agreed in optical properties[5] with oxalic hydrazide.

The filtrate from this hydrazide, on longer standing, yielded another hydrazide, crystallizing in plates, melting after recrystallization at 149–151'. Optical examination confirmed its identity with malonic hydrazide.

The filtrate from malonic hydrazide, on evaporation, yielded a small quantity of an alcohol-soluble hydrazide, melting at 68–75°, which indicated levulinic hydrazide. As levulinic acid may have been formed by the action of alcoholic hydrochloric acid on carbohydrates, it is not considered as originally present in the plant.

Fractions 2 and **3,** being small in quantity, were disregarded.

---

[5] Optical crystallographic examinations were made by G. L. Keenan of the Food, Drug and Insecticide Administration.

Fraction 4 yielded a copious precipitate of a hydrazide having the appearance of malic hydrazide. It melted at 178–179°. Admixture with *l*-malic hydrazide caused no depression in the melting point. The optical rotation of this fraction also indicates that it is the ester of *l*-malic acid.

Fractions 5 and 6 also yielded impure malic hydrazide. These fractions were saponified and tested for tartaric acid by the tentative method of the A. O. A. C., with negative results.

Fraction 7 yielded an impure hydrazide which appeared to contain malic and citric hydrazide.

Fraction 8 also yielded a pasty hydrazide which was partly crystalline. As its behavior indicated that it was aconitic acid, a small quantity of the fraction was saponified, acidified and extracted with ether. Aconitic acid was identified in the residue from the ether. Therefore fraction 8 was refractionated. Six grams boiling at 170° at 10 mm. was obtained which afforded a hydrazide melting at 104–105° and agreeing with citric hydrazide in optical properties.

For the separation of aconitic acid, the mixed acids, liberated from 500 g. of the lead precipitate, were dissolved in water and extracted with ether in an apparatus designed for the continuous extraction of liquids with ether until negligible quantities of ether-soluble acids were left in the aqueous liquid. The extracted acids were partly crystalline. They were dissolved in ether, and the ether solution was shaken out with five 5-cc. portions of water. The water solution was diluted and shaken out four times with an equal volume of ether, which was then united with the main ether solution.

The ether was evaporated in a tared beaker, and the residue was dried on a steam-bath at reduced pressure until free from water and volatile acids. It was a solid, crystalline acid, weighing 9.0 g. On recrystallizing from water the acid melted at 183–185°. It decolorized permanganate solutions, gave the acetic anhydride test for aconitic acid, and agreed with that acid in its optical crystallographic properties.

The citric and malic acids were further determined in a portion of the lead precipitate by the tentative methods given in "Methods of Analysis," A. O. A. C., second edition.[6] Citric acid was determined as pentabromoacetone and malic acid by the polariscope method. The figures were somewhat higher than those obtained by the ester distillation method.

Oxalic acid, left in the extracted plants as an insoluble salt, was determined by the Arbenz[7] method.

The percentages of non-volatile acids, calculated on the basis of green wheat plants, were found to be as follows

Malonic acid (by fractionation of esters)	0 005%
Aconitic acid (by ether extraction of acids)	.040%

---

[6] These analyses were made by H. H. Mottern of the Food Research Division.

[7] Arbenz, *Mitt. Lebensm. Hyg.*, 8, 98 (1917).

Malic acid (by fractionation of esters)	0.056%
Malic acid (by polarization)	.064%
Citric acid (by fractionation of esters)	.016%
Citric acid (by pentabromoacetone)	.019%
Oxalic acid	Trace
Oxalic acid in residue, dry basis	0.11%
Oxalic acid in residue, fresh basis	.02%

Aconitic acid has been identified previously in two species of the *Gramineae* (sugar cane and sorghum).

Malonic acid has not been found in any of the investigations on the organic acids of fruits, but was reported present in alfalfa by Turner and Hartman.[8]

Summary

In this investigation of the organic acids in growing wheat plants the water extract was found to contain aconitic, citric, malic and malonic acids with a trace of oxalic acid. The residue after water extraction was found to contain oxalic acid.

WASHINGTON, D. C.

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

THE RELATION OF THE STRUCTURE OF KETONES TO THEIR REACTIVITY AND AFFINITY IN ACETAL FORMATION. II

BY GEORGE J. PFEIFFER AND HOMER ADKINS

RECEIVED DECEMBER 20, 1930 PUBLISHED MARCH 6, 1931

The reaction of orthoformic ester and ketones to form acetals and ethyl formate (Equation I) is a reversible reaction suited to the study of the relationship of the structure of compounds to the strength of oxygen to carbon linkages.

$$R_2CO + HC(OC_2H_5)_3 \longleftrightarrow R_2C(OC_2H_5)_2 + HCO_2C_2H_5 \qquad (I)$$

Recently the extent of acetal formation for eight ketones was reported.[1] In extending the study of this reaction it became apparent that the previous evaluation of the analytical data was in error in the case of one ketone, so the method of analysis was subjected to a more thorough study.

The analytical method used by Carswell for the determination of the extent of the acetal reaction was based upon the observation of Geuther that ethyl formate in the presence of sodium ethoxide decomposed into carbon monoxide and alcohol. Geuther formulated the reaction as in Equation II.

$$HCO_2C_2H_5 = CO + C_2H_5OH \qquad (II)$$

---

[8] Turner and Hartman, THIS JOURNAL, 47, 2044 (1925).

[1] Carswell and Adkins, *ibid.*, 50, 235 (1928).

Geuther did not obtain the theoretical yield of carbon monoxide but accounted for the discrepancy by the assumption that the reaction is reversible. This assumption was based upon the finding that ethanol inhibited the decomposition of the ester. In order to avoid this effect of ethanol upon the decomposition, Carswell carried out the decomposition in the presence of metallic sodium, thus perhaps changing the course of the reaction. Under these conditions he found that the amount of carbon monoxide was 64.4 ± 1.5% of that required by Geuther's equation. More recently in a series of eight consecutive decompositions of ethyl formate the amount of carbon monoxide was found to be 66.1, 66.4, 65.7, 69.4, 63.6, 66.1, 66.6, 62.7, or an average of 65.8% of the amount required by Geuther's equation. That is to say, three moles of ethyl formate gave two moles of carbon monoxide. Moreover, methanol was shown by Trillat's test to be in the residue from the decomposition.[2] Mr. Ralph Dunbar in this Laboratory has recently obtained a mixture of alcohols consisting of 9.5% methanol and 90.5% ethanol as a result of the hydrolysis of the residue from the decomposition of ethyl formate with sodium and an excess of sodium ethoxide. The decomposition of ethyl formate under these conditions may then be formulated as in Equation III. The mechanism will be discussed in a later paper.

$$3HCO_2C_2H_5 + 4Na = 2CO + CH_3ONa + 3C_2H_5ONa \qquad \text{(III)}$$

The ratio of carbon monoxide to ethyl formate was found to be independent of the amount of orthoformic ester or of ketone acetal which may be present in the mixture subjected to analysis. However, the ratio of carbon monoxide to ethyl formate was dependent upon the amount of ethanol and the amount and kind of ketone present in the mixture subjected to analysis. Since the ethanol present before the decomposition of the ethyl formate and formed during the decomposition would be in the form of sodium ethoxide, it may perhaps be better to state that the amount of ethyl formate converted to carbon monoxide was a function of the amount of sodium ethoxide and of the amount and kind of ketone in the reaction mixture. Sodium ethoxide no doubt decreased the amount of ethyl formate converted to carbon monoxide because it facilitated the reaction of ethyl formate with the ketone. These reactions are of at least two types as indicated in Equations **IV** and V. Reaction **IV** is the Claisen reaction, while reaction V is, so far as the authors are aware, a hitherto unknown reaction which will be described in detail in a later publication.

$$HCO_2C_2H_5 + CH_3C(O)CH_3 = C_2H_5OH + CH_3C(O)CH{=}CHOH \qquad \text{(IV)}$$
$$HCO_2C_2H_5 + (C_6H_5)_2CO = (C_6H_5)_2C(OH)CO_2C_2H_5 \qquad \text{(V)}$$

The amount of ethyl formate equivalent to a given volume of carbon monoxide under the conditions of analysis was determined by experi-

---

[2] Trillat, *Analyst,* 24, 13, 211 (1899).

ment. Various mixtures containing known amounts of ethyl formate and ethanol, and various kinds and amounts of ketones were therefore subjected to the action of sodium and sodium ethoxide and the amount of carbon monoxide so formed was measured. The sum of the amounts of ester and of ketone in a mixture submitted to analysis was always 0.1 of a mole since that ratio would exist in the reaction mixtures which were to be analyzed. These prepared mixtures were made up to a volume of 50 ml. with dry toluene. A 5-ml. aliquot was taken from each and treated with 0.5 g. of sodium ethoxide and an excess of sodium, and subjected to decomposition at 110 to 115°. There are given in Table I the data obtained in a group of such analyses.

TABLE I

Carbon Monoxide (in Moles × 10^3) from Ethyl Formate in the Presence of Various Amounts of Ethanol and Ketones

Ketones		Ester, moles	Ethanol, ml

The reaction of the various ketones with orthoformic ester was carried out by mixing 0.1 mole of the ketone and 0.1 mole of orthoformic ester in enough dry ethanol to give a total volume of 49 ml., and then after the mixture was at 25°, adding 1 ml. of an ethanol solution containing 0.0136 g. of hydrogen chloride. After fifty to sixty hours 5-ml. aliquots were removed and decomposed with sodium and sodium ethoxide as previously described. The evolved gas was collected and analyzed and the amount of carbon monoxide calculated. The amounts of carbon monoxide formed from the various reaction mixtures are recorded in Column 3 of Table II. Duplicate syntheses of acetal and duplicate analyses of the reaction mixture were made and the variation in the amount of carbon monoxide found is indicated in the table. The amount of ethyl formate required to produce the amount of carbon monoxide actually obtained in the decomposition of an aliquot from an acetal reaction mixture, in the concentration of ethanol given in Column 2 of Table II, may then be determined from the data given in Table I. In order to facilitate this determination the relationship of ethanol and ethyl formate to the amount of carbon monoxide produced in the presence of the various concentrations of each ketone was plotted and the amount of ethyl formate equivalent to a given amount of carbon monoxide read off directly, usually without extensive interpolation from the experimental values. The amount of ethyl formate so calculated is given in Column 4 of Table II. From this value the percentage conversion of the ketone to the acetal and the equilibrium constant are readily calculated.

TABLE II

EXTENT OF ACETAL FORMATION IN REACTION OF 0.1 MOLE OF ORTHORORMIC ESTER WITH 0.1 MOLE OF VARIOUS KETONES IN A SOLUTION MADE UP TO 50 ML. WITH ETHANOL

Ketone	Ethanol, ml.	CO, mole	HCOOEt, mole	% Acetal, calcd.	$K_E \times 10^2$
Dimethyl	24.5	0.0426 ± 4	0.0948	94.8	3.34
Methyl ethyl	25.3	.0375 ± 5	.0901	90.1	0 83
Methyl β-phenylethyl	19.2	.0377 ± 10	.0891	89.1 (88 9)	.66
Methyl phenyl	22.0	.0302 ± 5	.0862	86.2 (85.1)	.39
Methyl neopentyl	18.0	.0257 ± 7	.0840	84.0	.28
Di-isopropyl	19.5	.0173 ± 3	.0654	65.4	.034
Methyl *tert.*-butyl	17.5	.0081 ± 2	.0501	50.1 (52.9)	.0101
Ethyl *tert.*-butyl	20.8	.0106 ± 2	.0362	36.2	.0033
Diphenyl	19 0	.0052 ± 1	.0337	33.7	.0026
Tert.-butyl isopropyl	18.2	.0067 ± 2	.0258	25.8	.0012
Di-*tert.*-butyl	17.0	.0036 ± 2	.0172	17.2	.0004

The equilibrium point in the acetal reaction was also arrived at from the reaction of ethyl formate with an acetal of three of the ketones. One tenth mole each of the acetal and of the ethyl formate was made up to a volume of 49 ml. with dry ethanol and 1 ml. of ethanol containing 0.0136 g.

of hydrogen chloride was added. After the reaction had proceeded for several days, the ethyl formate in an aliquot was decomposed and the amount of carbon monoxide, ethyl formate and percentage conversion to the acetal calculated as in the synthesis of the acetal. The results are given in parentheses in Table II, for the three ketones involved.

An inspection of the values given in Table II for the percentage conversion of various ketones to their acetals makes it clear that any substitution in the methyl groups in acetone results in a lowering of the extent of the reaction. The extent of conversion is decreased only slightly by the substitution of a benzyl group for one of the hydrogens of acetone. The effect of the replacement of a methyl group in acetone by a phenyl group is marked but much less so than might be expected from the differences between methyl and phenyl in most reactions. In contrast with this observation is the fact that two phenyl groups reduce the percentage conversion to acetal to about one-third of the value for acetone. The replacement of a methyl group in acetone by the tertiary butyl group results in a decrease in conversion to the acetal from 94.8 to 50.1%. If the tertiary butyl group is separated from the carbonyl group by one carbon atom it is much less effective in decreasing the extent of the acetal reaction.

The replacement of both methyl groups in acetone by isopropyl groups is also very effective in reducing the percentage conversion to an acetal although not so effective as is one tertiary butyl group. This is further evident from a comparison of the symmetrical and unsymmetrical tetramethyl acetone as the former shows 65.4% conversion to the acetal while the latter is but 36.2%. A further substitution of methyl groups in acetone results in marked lowerings of the percentage conversion to the acetal. The percentage conversion of the ketone to the acetal decreased by about 30% of the former value each time one of the hydrogens in methyl tertiary butyl ketone was replaced by a methyl group. It should be noted that in the case of acetophenone and pinacolone the extent of conversion to the acetal is considerably higher than that previously reported.

Preparation and Purity of Reagents.—Benzyl acetone was prepared in 96% yield by the hydrogenation of benzal acetone at 65° under a pressure of 135 atmospheres of hydrogen over a nickel catalyst. Di-isopropyl ketone was obtained in 10 to 11% yield by the decomposition of calcium isobutyrate at 500°. Some of it was also purchased from Poulenc-Frères (Paris). Methyl neopentyl ketone was prepared as previously described.[3] The two tetramethyl, the pentamethyl and the hexamethyl acetones were prepared by the Haller and Bauer[4] method involving the use of sodamide, methyl iodide and the appropriate ketone. Their directions were followed except that in the prepara-

tion of hexamethyl acetone it was found necessary to carry out the methylation at 115° in a sealed tube rather than under a reflux. The acetal of acetophenone was prepared by allowing 60 g. of acetophenone to react for twenty-four hours at 25° with 100 g. of orthoformic ester in the presence of 50 g. of ethanol and 0.0136 g. of hydrogen chloride. The mixture was then made alkaline by the addition of a few drops of an anhydrous ethanol solution of sodium ethoxide and fractionated. The yield was 73% of the theoretical. The other acetals were prepared in a similar manner. The other reagents used were prepared or purified by the standard methods. The reagents had the physical constants noted in Table III.

TABLE III

PHYSICAL CONSTANTS OF REAGENTS

Name of compound	Boiling point, °C.	d^{25}_{25}
Acetone	56.2–56.7	0.7973
Acetophenone	200–202 (m. p. 20°)	1.029

Ethyl formate	54–54.5	.9250

Summary

The extent of conversion of eleven ketones to their acetals through their reaction with orthoformic ester has been determined. This has necessitated a rather extensive experimental investigation of the extent of reaction of various amounts of ten ketones with ethyl formate in the presence of various amounts of sodium ethoxide.

A STUDY OF THE CONDENSATION BETWEEN ALIPHATIC ESTERS AND KETONES[1]

BY S. G. POWELL AND KEITH M. SEYMOUR

RECEIVED DECEMBER 22, 1930 PUBLISHED MARCH 6, 1931

The condensation between ketones and esters has long served as a method for obtaining 1,3-diketones. In the case of unsymmetrical ketones the reaction can take place in either of two ways, and it has been found[2] that ketones of the type CH_3COCH_2R react through the methyl rather than the methylene group. This is not what might be expected from the fact that the reaction between 2-butanone and aldehydes[3] indicates the methylene as the more reactive group. That a methylene group is capable of reacting with esters was shown by Morgan, Drew and Porter,' who obtained diketones from 3-pentanone and from 4-heptanone. The same authors found that in the case of ethyl acetate and 3-pentanone the product was the expected 3-methyl-2,4-hexanedione when the reaction mixture was not heated, but was 2,4-hexanedione if the standard procedure was followed.

The 2,4-hexanedione apparently results from a reaction between the ethyl acetate and 2-butanone formed by alcoholysis of the 3-methyl-2,4-hexanedione.

In view of the above it seemed possible that under certain conditions ketones of the type CH_3COCH_2R might react through the methylene group and that, if alcoholysis could be prevented, the resulting diketones might be isolated. In none of the cases studied in this investigation was any evidence found that such a reaction occurred.

TABLE I

EXPERIMENTAL RESULTS

No.	Ester	Ketone	Diketone	Yield, %
1	Ethyl acetate	2-Butanone	2,4-Hexanedione	11
2	Ethyl propionate	Acetone	2,4-Hexanedione	15
3	Ethyl propionate	2-Pentanone	3,5-Octanedione	9
4	Ethyl butyrate	2-Butanone	3,5-Octanedione	..
5	Ethyl acetate	3-Methyl-2-butanone	2-Methyl3.5-hexanedione	14
6	Ethyl isobutyrate	Acetone	2-Methyl-3,5-hexanedione	6

---

[4] Morgan, Drew and Porter, Ber., 58,338 (1925).

The course of the reaction when the standard procedure was followed was determined by preparing a diketone by two different ester–ketone combinations such that the identical product would be obtained if the reaction took place through the methyl group. The results are shown in Table I.

Of the three diketones obtained, 2,4-hexanedione and 3,5-octanedione have been previously prepared by reactions 1 and 4, respectively, whereas 2-methyl-3,5-hexanedione has not heretofore been prepared by the Claisen reaction, although obtained by other methods.[5]

The reaction was carried out as described by Claisen and Ehrhardt,[6] and by modifications of this method. Wherever the work was a repetition of that of others, our results were identical with theirs and are not described. According to the standard procedure as described by Claisen and Ehrhardt, the reaction mixture is allowed to stand for twelve hours and then refluxed for one hour. Since it has been shown that heating brings about alcoholysis in the case of the reaction between ethyl acetate and 3-pentanone, reactions 3, 4 and 5 (Table I) were repeated omitting the refluxing. In no case was there any evidence of the presence of any other diketone than the one resulting from the reaction between the ester and the methyl group of the ketone. Nor did omitting the refluxing in the reaction between ethyl acetate and 2-pentanone and between ethyl propionate and 2-butanone lead to any different results than those obtained by other investigators who used the standard procedure.

Reaction 1 (Table I) was repeated, changing the time of standing before refluxing from twelve hours to three hours in one case and to forty-eight hours in another. The sole effect seemed to be a diminution of the yield.

As reactions 2, 3, 5 and 6 have not been described heretofore, the results obtained in these cases are given. Unless otherwise stated all reactions were carried out using 0.5 atom of sodium, 0.5 mole of ketone and 1.0 mole of ester,[7] and following the standard procedure.

Ethyl Propionate + Acetone.—Diketone, b. p. 150–158°; $n_D^{24.5}$ 1.4505. Copper salt, m. p. 197°. 2,4-Hexanedione boils at 158° and its copper salt melts at 197–198°.[8] A second trial using 1 mole of acetone also gave 2,4-hexanedione in much smaller yield.

Ethyl Propionate + 2-Pentanone.—Refluxing omitted; diketone, b. p. 187–190°; $n_D^{24.5}$ 1.457. Copper salt, m. p. 157–158". 3,5-Octanedione boils at 189–190° and its copper salt melts at 157°.[9]

Ethyl Acetate + 3-Methyl-2-butanone.—Twenty-five grams (0.3 mole) of the ketone, 7 g. (0.3 atom) of sodium and 26 g. (0.3 mole) of ester were used. No reaction

[7] Adkms, Kutz and Coffman, THIS JOURNAL, 52, 3218 (1930), have shown that the maximum yields are obtained by using sodium, ketone and ester in the molecular ratio 2:1:3.

[8] Morgan and Reeves, *J. Chem. Soc.*, 123,444 (1923).

[9] Morgan and Drew, *ibid.*, 125, 731 (1924).

took place at 0" and it was slow at room temperature. Refluxing was omitted. Diketone, b. p. 164–166°; copper salt, **m.** p. 172°. 2-Methyl-3,5-hexanedione boils at 160–170" and its copper salt melts at **171**°.[10]

Ethyl Isobutyrate + Acetone.—One-half mole of ester, ketone and sodium were used. The reaction was vigorous but only a small quantity of the copper salt melting at **171**° was obtained. **A** mixture of this with that obtained in the preceding reaction also melted at 171°.

Summary

1. The Claisen condensation between several esters and ketones has been studied and the diketones resulting have been identified.
2. Modifications of proportions and conditions did not change the course of the reaction in the cases studied.

BROMINE DERIVATIVES OF CERTAIN MIXED ETHERS AND SOME OF THEIR REACTIONS

BY L. CHAS. RAIFORD AND LOUIS H. HOWLAND

RECEIVED DECEMBER 23, 1930 PUBLISHED MARCH 6, 1931

Previous work[1] in this Laboratory has shown that in the bromination of certain phenyl alkyl ethers the hydrogen bromide liberated may split them unless sodium acetate is present, and that the splitting is more pronounced when the alkyl radical is connected through a secondary or tertiary[2] carbon atom.

In cases where, as indicated below, the phenyl radical could not be further brominated under the conditions already described, and where, in consequence of this, no "nascent hydrogen bromide"[3] was produced during attempts at bromination, splitting of these ethers was not observed. Nevertheless, it was a matter of interest to test the behavior of such ethers toward hydrogen bromide under several conditions.

Graebe and Martz[4] found that heating trimethoxygallic acid with 48% hydrobromic acid in an open vessel surrounded by boiling water removed the methyl radical from position 4 to the extent of 90%. In the present work that method did not give satisfactory results. Refluxing 2,4,6-

---

[10] Conrad and Gast, **Ber., 31, 1339 (1898).**

[1] Raiford and Birosel, THIS **JOURNAL, 51, 1776 (1929).**

[2] In the tertiary butyl derivative splitting occurred although sodium acetate was present. This may be due to a tendency of the ether to split off the unsaturated hydrocarbon isobutylene. Konowalow [*Z. physik. Chem.*, **1,** 67 **(1887)**] observed such a change in the study of tertiary amyl acetate.

[3] The small amount, if any, produced by the action of bromine on the alkyl radical of the ether was not detected and was disregarded.

[4] Graebe and Martz, *Ann.*, 340, 220 (1905).

tribromophenyl isobutyl and isoamyl ethers with constant boiling hydrobromic acid over a free flame for three and fourteen hours, respectively, caused splitting to the extent of 5 and 12%, while the pentabromo compounds were not affected. These low yields suggested the use of "nascent" hydrogen bromide. Its action was tested in different ways, and examination of Table II (see Experimental Part) will show that the most pronounced effect was obtained by the action of the bromide at an elevated temperature.

In the present work an attempt was made to brominate 2,4,6-tribromophenyl-β,γ-dibromo n-propyl ether[5] with pure bromine, catalyzed by aluminum bromide,[6] in order to secure the corresponding pentabromophenyl derivative. The ether was split and pentabromophenol was obtained. The action was found to be general[7] for the ethers here studied, as indicated in tabular form below.

In previous work it was noted that treatment of phenyl allyl ether with an excess of bromine saturated the aliphatic radical and introduced but two atoms of bromine into the phenyl nucleus, and that these took positions 2 and 4. The structure of this tetrabromo derivative was proved by bromination of 2,4-dibromophenyl allyl ether which, in turn, had been prepared from 2,4-dibromophenol. In the present work this conclusion has been confirmed by further examination of the above indicated tetrabromo compound, and by the study of other similar cases. Thus, the 2,4-dichloro, 2,6- and 3,5-dibromophenyl allyl ethers were treated at 0° in the presence of sodium acetate with a chloroform solution of bromine (1:1 by volume), in excess of that required to saturate the allyl radical and to substitute all available positions in the phenyl group, after which the mixture was allowed to stand at room temperature for about a week. In the first two cases the side chain only reacted, while in the last one both side chain and nucleus were attacked, although the latter was substituted by only two bromine atoms. These results tend to show that in the phenyl allyl ethers when any two of the *o,o,p*-positions have been substituted by bromine no more can be introduced by the method here used.

Claisen[8] found that the allyl ethers of many phenols were readily rearranged by heat, in almost quantitative yield, into the corresponding allylphenols, in which the allyl radical enters the ortho or para position. In subsequent work[9] *p*-bromophenyl and 2,4-dichlorophenyl allyl ethers

---

[5] Raiford and Birosel, THIS JOURNAL, 51, 1778 (1929).

[6] Pfeiffer and Haack [*Ann.*, 460, 170 (1928)] found that certain aryl methyl ethers form addition products (molecular compounds) with aluminum bromide, and that these compounds were demethylated by heating for several hours in presence of benzene.

[7] In many cases the pentabromophenol was mixed with a brown powder that could not be identified. The amount formed was greater at boiling point than at room temperature.

[8] Claisen, *Ber.*, 45, 3157 (1912).

[9] Claisen, *Ann.*, 418, 84 (1919)

were found to rearrange. In the present work a small yield of the phenol was obtained from the 2,4-dichlorophenyl derivative, but attempts to rearrange the dibromo compounds were unsuccessful. Likewise, the phenyl alkyl ethers failed to rearrange.

The β,γ-dihalogenated products shaw a number of interesting properties. All of them absorb moisture from the air so rapidly and to such an extent that samples for analyses cannot safely be weighed in open vessels. They also hold alcohol strongly, and those crystallized from this liquid were dried under reduced pressure at elevated temperatures over extra long periods of time to secure samples for analyses.[10] The compounds were further characterized by a study of their behavior toward alcoholic potash. In each case the elements of hydrogen bromide were removed from the side chain, and the corresponding propargyl ether was obtained in nearly quantitative yield. These ethers showed the characteristic properties of acetylene derivatives in the formation of unstable cuprous, mercuric and silver salts, the latter of which were isolated in combination with one molecular proportion of silver nitrate

Experimental Part

The phenyl alkyl ethers indicated below were prepared by Claisen's method,[11] from phenol and the required alkyl halide. The product was then extracted with a solution of caustic alkali to remove phenol, and the ether purified in a suitable way. The tribromo derivatives were obtained by treatment of the ethers with an excess of bromine in chloroform solution,[12] in the presence of sodium acetate. The behavior of these products toward hydrogen bromide is shown in tabular form below.

Preparation of Pentabromophenyl Ethers.—The pentabromophenol used as starting material was prepared by Bodroux's[13] method, modified as follows. One molecular proportion of melted phenol was dropped slowly with stirring into 1.5 times the theoretical amount of bromine in which about 1% aluminum had been dissolved, and the mixture was allowed to stand for twenty-four hours. Unchanged bromine and aluminum salt were extracted by hydrochloric acid solution of potassium bromide, and the phenol by 10% solution of sodium hydroxide. The product was crystallized from benzene or carbon tetrachloride.

---

[10] The tendency to absorb alcohol raised the question of the replacement of halogen by the alkoxy radical, as observed by Hell and Gunthert [*J. prakt. Chew.*, *52*, 195 (1895)]. The products of the present work were repeatedly boiled with alcohol without change in composition.

[11] Claisen and Eisleb, *Ann.*, 401, *36* (1913).

[12] When a mixture of 2,4,6-tribromophenyl n-propyl ether and more than five times its weight of pure bromine was allowed to stand in an open Erlenmeyer flask for three days at room temperature, a small yield of tetrabromo derivative was obtained. Failure to lose bromine when treated with alcoholic potash indicated that the halogen was not in the alkyl group. *Anal.* Subs., 0.2708: AgBr, 0.4526. Calcd. for $C_9H_8OBr_4$: Br, 70.79. Found: Br, 71.02.

[13] Bodroux, *Bull. soc. chim.*, [3] *19*, 756 (1898).

The alkyl ethers of pentabromophenol were prepared by Claisen's methods (with the exceptions noted in the table) with the modification that excess of alkyl halide was used. No reaction was obtained with tertiary butyl nor with tertiary amyl halide.

TABLE I

PENTABROMOPHENYL ALKYL ETHERS[a]

	Alkyl	Formula	Crystal form	Yield, %	M. p., ° C.	Halogen,[e] % Calcd.	Halogen,[e] % Found
1	Isopropyl	$C_9H_7OBr_5$	Short needles[d]	Nearly quant.	86	75.47	75.38
2	*n*-Butyl[b]	$C_{10}H_9OBr_5$	Irreg. plates[d]	Nearly quant.	79–80	73.39	73.26
3	Isobutyl	$C_{10}H_9OBr_5$	Short needles[d]	45	92–93	73.39	73.30
4	*Sec.*-butyl[b]	$C_{10}H_9OBr_5$	Fibrous masses[d]	25	57–58	73.39	73.34
5	Isoamyl[c]	$C_{11}H_{11}OBr_5$	Fine needles[d]	Nearly quant.	64–65	71.55	72.68

[a] The methyl, ethyl and n-propyl ethers of this series were obtained by Bonneaud [Bull. *soc. chim.*, [4] 7, 777 (1910)] by the action of the potassium salt of pentabromophenol on the required alkyl halide. No higher yield than 22% was recorded and the ethyl compound contained 1.32% more bromine than calculated. Lucas and Kemp [THIS JOURNAL, **43**, 1661 (1921)] reported an 80% yield of this product from the action of the moist pink silver salt of pentabromophenol on ethyl iodide. Derivatives containing tertiary alkyl radicals have not yet been obtained. [b] The Claisen method was here modified to the extent of adding sodium iodide as well as the required alkyl bromide. Cf. Raiford and Colbert, *ibid.*, 48, 2658 (1926). [c] Obtained by refluxing an aqueous potassium hydroxide solution of the phenol with the required alkyl halide. [d] Crystallized from ligroin (80–100°). [e] Brown and Beal, THIS JOURNAL, **45**, 1291 (1923).

Methods of Splitting the Ethers

1. A glacial acetic acid solution of the ether and phosphorus tribromide to which the calculated amount of water was gradually added was heated under a return condenser.

2. The mixture indicated in 1 was heated in a sealed tube at 135–150° for twelve to fifteen hours. The phosphorus tribromide was contained in an inner tube and did not come in contact with the remainder of the mixture until after the outer tube was sealed.

3. Bromine was dropped into a benzene solution of the ether in which some iodine was present as a catalyst.

4. A mixture of the ether, excess of bromine and about 1% of aluminum in the form of bromide was allowed to stand at room temperature for two days.

The products isolated in these experiments were tribromo- and pentabromophenol, respectively. No attempt was made here to recover any aliphatic halogenated product that might have been formed.

[a] The pentabromophenol was mixed with a brown amorphous solid that was not identified. Treatment at the boiling point of the mixture gave a lower yield of phenol and in some cases a larger quantity of the brown solid, which possibly was formed from the phenol.

[b] Split by boiling with bromine in the absence of aluminum bromide to give high yields of pentabromophenol and some resinous material.

Substituted Phenyl Allyl Ethers

2,4-Dichlorophenyl Allyl Ether.—This was obtained by treatment of the corresponding dichlorophenol in acetone solution with potassium carbonate and with excess of allyl bromide by Claisen's[14] general method. The product distilled as an almost colorless oil at 144–145° and 25 mm.

Anal. Subs., 0.2821: AgCl, 0.3988. Calcd. for $C_9H_8OCl_2$: Cl, 34.97. Found: Cl, 34.95.

3,5-Dibromophenyl Allyl Ether.—When the required phenol[15] was treated with allyl bromide as indicated above an almost quantitative yield of ether was obtained: b. p. 145° at 10 mm.

Anal. Subs., 0.2970: 20.4 cc. 0.1 *N* $AgNO_3$. Calcd. for $C_9H_8OBr_2$: Br, 54.79. Found: Br, 54.73.

2,6-Dibromophenyl Allyl Ether.—2,6-Dibromo-4-nitrophenol was reduced as directed by Mohlau and Uhlmann,[16] and the amino group replaced by hydrogen as follows. One-third of a molecular proportion of the amino compound was dissolved in a mixture of 750 cc. of 95% alcohol and 100 cc. of benzene, after which 50 cc. of concentrated sulfuric acid was added slowly with shaking. This mixture was placed in a suitable flask bearing a Y-tube, one arm of which was connected to a reflux condenser, while the other served for the introduction of sodium nitrite. Fifty grams of the finely powdered salt was slowly added. After reaction was apparently over, the mixture was refluxed for two hours, and then allowed to stand in a warm place for several hours. The product obtained by steam distillation and crystallization from dilute alcohol agrees in properties with that described in the literature. By treatment with excess of allyl bromide it was converted into the ether, which distilled at 132–133° at 10 mm.

Anal. Subs., 0.3423: 23.44 cc. 0.1 N $AgNO_3$. Calcd. for $C_9H_8OBr_2$: Br, 54.79. Found: Br, 54.74.

---

[14] Claisen and Eisleb, Ann., 401, 36 (1913).

[15] This was prepared from pentabromophenol by Kohn and Fink's [*Monatsh.*, 44, 188 (1923)] method

[16] Mohlau and Uhlmann, Ann., 289, 94 (1896).

Pentabromophenyl Allyl Ether.—Pentabromophenol was converted to the ether by treatment with a large excess of allyl bromide as described. Crystallization from petroleum ether (80–100°) gave short colorless needles; m. p. 167–168".

Anal. Subs., 0.2016: 17.96 cc. 0.1 *N* $AgNO_3$. Calcd. for $C_9H_5OBr_5$: Br, 75.61. Found: Br, 75.57.

The β,γ-Dibromo Derivatives.—The above-mentioned compounds were next subjected to the action of excess of bromine as follows. The ether was dissolved in chloroform, finely powdered dried sodium acetate added, the flask placed in an ice-bath and the mixture stirred while there was added gradually slightly more bromine than was required to saturate the side chain and substitute all available positions on the nucleus. The mixture stood for several days, the solvent and excess of bromine were distilled off, water was added to dissolve salts, and the ether extracted with a suitable solvent. The physical constants and analytical data for these products are given in Table III.

TABLE III

PHENYL-β,γ-DIBROMOPROPYL ETHERS

Substituted phenyl	Formula	Crystal form	Yield, %	M. p., °C	Halogen,[d] % Calcd.	Found
2,4-Dichloro-	$C_9H_8OCl_2Br_2$	Oil	95	Distilled at 188 (10 mm.)	63.59	63.3
2,3,4,5-Tetrabromo-	$C_9H_6OBr_6$	Nearly[a] colorless prisms	97	123–124	78.68	78.68
2,6-Dibromo-	$C_9H_8OBr_4$	Colorless needles[b]	96	4849.5	70.77	70.60
Pentabromo-	$C_9H_5OBr_7$	Colorless needles[c]	94	122–123	81.27	81.29

[a] Crystallized from acetic acid. [b] Purified with much difficulty, first by distillation and afterward by repeated crystallization from alcohol. [c] Crystallized from ligroin (80–100°). [d] Brown and Beal, THIS JOURNAL, 45, 1291 (1923).

Action of Alcoholic Potash on the Ethers.—Weighed portions of the β,γ-dibromopropyl ethers were dissolved in hot alcohol, and an alcoholic solution of potassium hydroxide added. After the first vigorous action was over the mixture was refluxed for one hour,[17] the liquid cooled, acidified with nitric acid, and diluted to a measured volume. Duplicate samples of the solution were withdrawn, boiled with measured volumes of standard silver nitrate solution in excess of that required by the bromide ion present and the unchanged silver salt determined by titration. From the values so obtained the weight of bromine removed by alkali in each case was estimated, and the decomposition percentage calculated. The remainder of the acid liquid was extracted with ether, the extract dried with anhydrous sodium sulfate, the solvent distilled off, and the propargyl ether purified in a suitable way. The results are given in the accompanying table.

Salts of the Ethers.—The silver salts were precipitated as nearly colorless solids by mixing alcoholic solution of silver nitrate and the required ether, as directed by Béhal.[18] The cuprous salts were obtained as yellow solids by pouring alcoholic solutions of the ethers into ammoniacal solution of cuprous chloride, while the mercuric salts were prepared as gray precipitates by the use of Nessler's reagent. Analytical data for these compounds are given in Table V.

---

[17] When 2,3,4,5-tetrabromophenyl β,γ-dibromo-*n*-propyl ether, described above, was subjected to this treatment, the amount of bromine removed was greater than that corresponding to the loss of two molecular proportions of hydrogen bromide from the side chain, which suggested that some halogen had been lost from the phenyl nucleus, possibly from one of the meta positions. The product was not obtained in the pure form, but it was shown to be an ether, and found to give metallic derivatives.

[a] Halogen determined by the Carius method.

Summary and Conclusions

1. The hydrogen bromide evolved in the bromination of phenyl alkyl ethers may split them unless sodium acetate is present. The splitting is most complete when the alkyl group is connected through a secondary or tertiary carbon atom.

2. Phenyl allyl ethers containing two or more bromine atoms in the nucleus could not be rearranged by heat.

3. Under most conditions studied in this work the action of bromine on phenyl allyl ether saturates the side chain and substituted two positions in the phenyl radical.

4. The ethers here studied which have bromine in the β,y-positions in the side chain react with alcoholic potash and lose two molecular proportions of hydrogen bromide to give the corresponding propargyl compounds. The latter form cuprous, mercuric and silver salts.

5 Further work is in progress in this Laboratory.

IOWA CITY, IOWA

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

THE CATALYSIS OF POLYMERIZATION BY OZONIDES

BY RAY C. HOUTZ AND HOMER ADKINS

RECEIVED DECEMBER 26, 1930 PUBLISHED MARCH 6, 1931

In view of the important part oxygen apparently plays in the drying of oils, and in the polymerization of various substances such as styrene and isoprene,[1] it seemed worth while to study the action of ozonides in accelerating polymerizations. In addition to the metal halides which are well known as polymerization catalysts, many apparently unrelated materials have been claimed to catalyze the polymerization of dienes, such for example, as alkaline earth alkyls,[2] glycerol, starch, urea,[3] organic peroxides, acid anhydrides, metal oxides and per-salts,[4] and the products obtained by ozonizing isoprene.[5] Since the completion of the experimental work discussed in this paper, Conant and Tongberg[6] have shown that a partially ozonized sample of isoprene polymerized more rapidly at ten to twelve thousand atmospheres' pressure than did unozonized isoprene.

The material used as a catalyst in this investigation was a mixture of the ozonides of two octylenes known as "diisobutylene."[7] It was prepared by passing a mixture of 5% ozone and 95% oxygen into the hydrocarbon at 0–5° without a solvent. The reaction was considered complete when quantitative absorption of the ozone ceased, as shown by the effect of the issuing gas on starch–iodide paper. The product was a viscous, pale yellow oil, having on the average n_D^{25} 1.4425; d_{25}^{25} 0.9707. It was miscible with the common organic solvents and exploded if heated above 50–60°. Upon standing, it decomposed slowly with effervescence, losing its yellow color and explosiveness, decreasing markedly in viscosity, density, and refractive index, and increasing in acidity.

Since the formation of polymers results in an increase in the viscosity of a liquid or solution, viscosity measurements were made in order to compare the rates of polymerization.[8] In general, the method consisted in sealing the samples in test-tubes from which the air had been displaced by a stream of nitrogen. The viscosity of each sample was measured at 25°

using an Ostwald viscometer. The tubes were allowed to stand for a time, then broken open and the viscosity redetermined. Each accepted flow-time was the average of four to six trials which checked within 0.1 or 0.2 seconds. Freshly made ozonide was always used in preparing the samples.

The flow time for water of viscometer (a) was 149.4 sec., for (b) 59.3 sec. and for *(c)* 50.6 sec.

Polymerization of Styrene.[9]—Preliminary experiments showed that a small concentration of the ozonide caused styrene to polymerize rapidly, the mixture becoming almost solid in the course of a week. A study was then made of the effect of catalyst concentration on the rate of polymerization. Solutions containing from 0 to 4% ozonide in styrene were placed in a thermostat at 25°. The rates of viscosity increase of styrene using various amounts of catalyst are shown in Fig. 1. The viscometer first used has a water-flow time of **59.3** seconds, but as the viscosities increased the flow times became too large to be convenient, so another having a much shorter *flow* time was employed. The flow times shown in Fig. 1 are all

---

[9] Cf. Staudinger and Heuer, *Ber.*, **63,** 222 (1930).

calculated to the first viscometer on the basis of the flow times of sulfuric acid through the two viscometers. The data in Fig. 1 show that increased concentration of ozonide up to 2% was very effective in increasing the rate of polymerization but that increasing the concentration of catalyst beyond this amount had little effect. The 0.5% curve seems to indicate that an induction period was necessary, since nearly two hundred hours elapsed before a rapid viscosity increase began. Stobbe and Posnjak[8] found that styrene which had stood for fourteen days was polymerized more rapidly bv heat and light than freshly distilled styrene. Probably styrene becomes activated toward polymerization upon standing.

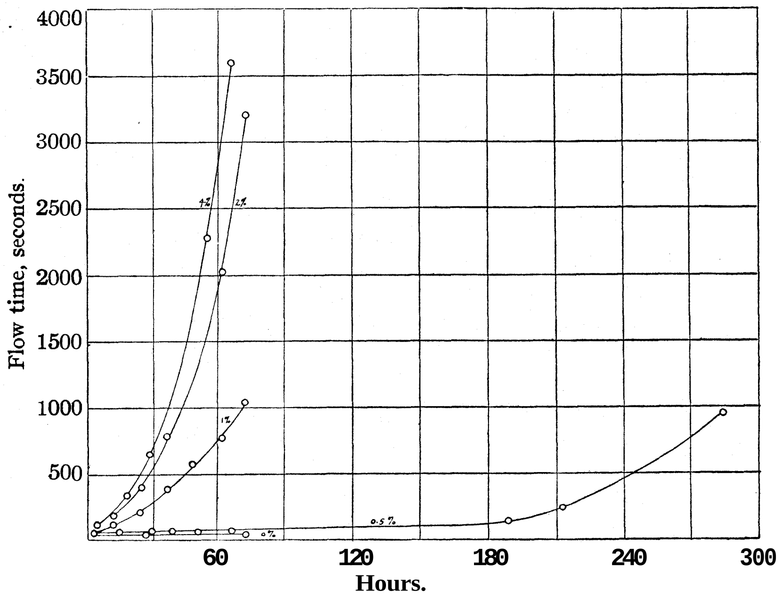

Fig. 1.—Relation of concentration of ozonide to rate of polymerization of styrene. The viscosities at 25° of four samples of styrene containing 0.5, 1, 2 and 4%, respectively, of diisobutylene ozonide are plotted against the time in hours elapsing after the addition of the latter to the styrene.

To determine whether the catalyst was active at elevated temperatures, tubes containing 0, 1 and 4% ozonide were sealed and placed in a steam jacket (nearly 100°) for thirty minutes. The contents of the tubes containing 1 and 4% ozonide had become almost solid. The styrene in the tubes containing no ozonide had thickened considerably, but less than those into which the catalyst had been introduced. The polymerization of styrene was also studied in toluene solution, at both room temperature and 100°. An abstract of the data is given in Table I. The changes in viscosity show that the catalyst was active toward styrene in toluene solution, at both temperatures.

Polymerization of **2,3-Dimethylbutadiene-1,3.**—Solutions containing from 0 to 4% ozonide in freshly distilled dimethylbutadiene were made and left in sealed tubes at room temperatures for forty-four days. The viscosity increases noted were as follows: for 0% ozonide, 63.5, 67.5%; 0.125% ozonide, 83.0, 81.0%; 0.25% ozonide, 93.5, 90.5%; 0.5% ozonide, 100, 99%; 1.0% ozonide, 118, 114%; 2.0% ozonide, 114, 111%; 4.0% ozonide, 117, 122%. It is apparent that the catalytic power of the ozonide toward the diene increased with increasing concentration, but that increments became decreasingly effective, just as was found in the case of styrene.

Polymerization of **"Methylpentadiene."**—Tubes were sealed containing 0.0 and 3.0% of ozonide in methylpentadiene, and allowed to stand for ninety days at room temperature. The increases in viscosity were as follows: 0% catalyst, 1.2% increase; 3% catalyst, 10.4% increase. This result was confirmed by the fact that there was much more of the sticky, rubber-like polymer left on evaporation of the sample containing 3% ozonide than there was from the sample containing no ozonide.

Polymerization of **Indene.**—Samples were sealed and allowed to stand for thirty days. After measuring viscosity they were resealed and left for one hundred and twenty days longer. The percentage increases in viscosity during thirty days were as follows: 0% ozonide, 0.3, 0.7%; 2% ozonide, 12.9, 14.0%; at the end of one hundred and fifty days, 0% ozonide. 3.0, 2.7%; 2% ozonide, 50.5, 56%. The data in Table I show that the ozonide is catalytically active toward indene at 100° as well as at room temperature, and also in toluene solution.

Polymerization of **Furfuryl Alcohol.**—Since furfuryl alcohol turns dark with the formation of resinous products on contact with air, the effect of the ozonide on this substance was studied both in air and in nitrogen. Tubes were sealed and allowed to stand at room temperature for forty days. In the tubes containing nitrogen, the viscosity increases were as follows: 0% catalyst, 1.0, 2.1%; 2% catalyst, 45.6, 47.2%. In the tubes containing air: 0% catalyst, 21.6%; 2% catalyst, 62.4, 66.4%. The percentage of increase in the tubes containing both catalyst and air is approximately the sum of the separate effects of catalyst and air. Since the ozonide liberates some oxygen as it decomposes on standing, the polymerizing effect may be due merely to the presence of the liberated molecular oxygen.

Attempted Polymerization of Other Compounds.—Solutions containing 2% ozonide in trimethylethylene and diisobutylene were sealed and allowed to stand for three to four months. No significant viscosity change had occurred during that time. Stilbene and saligenin were studied similarly in solution using dibutyl ether, dioxane, and toluene as solvents. When no significant viscosity change occurred in three months at ordinary temperatures, higher temperatures were employed (60 and 100°). Viscosity changes in all cases were too small to be significant.

Deterioration of Catalyst.—A sample of ozonide which had stood for several months was found to be active toward styrene. If the ozonide itself is concerned with the catalytic effect, fresh samples should be more active than old ones. If, on the contrary, decomposition products are more active, the catalytic power should increase somewhat on standing. To test this point, the catalytic power of the ozonide was measured on five successive days and again after an interval of twelve days, by noting the viscosity increase produced in freshly distilled styrene samples in twenty-four hours. Each day a fresh solution of the ozonide in styrene was made, and the viscosity increase produced in twenty-four hours noted. Both ozonide and solutions were kept in a thermostat at 25°. The results are plotted in Fig. 2. The decrease in viscosity of the ozonide was very rapid for about three days and during this time the catalytic power decreased rapidly. If decrease in viscosity may be taken as a measure of the decomposition of the ozonide, the latter parallels the decrease in catalytic power, indicating that the ozonide itself, rather than decomposition products, is concerned with the catalysis of polymerization. If ozonization of diisobutylene is stopped just at the point at which quantitative absorption ceases, the ozonide has a very high viscosity. If stopped before this point is reached, the product is much less viscous, due, no doubt, to the presence of diisobutylene. If ozonization is carried beyond this point, the product is also less viscous. This may be due to the formation of perozonides and oxidation products, as indicated by the work of Brus and Peyresblancques.[10]

Preparation of Reagents.—Diisobutylene was prepared as by Edgar.[11] Styrene was prepared as by Abbot and Johnson.[12] 2,3-Dimethylbutadiene-1,3 was prepared from pinacol in 60% yield.[13] Stilbene was prepared essentially according to the method of Hell.[14] Saligenin (*o*-hydroxybenzyl alcohol, m. p. 84°) was obtained by hydrogenation of salicylaldehyde over nickel.[15] The aldehyde (56 g.) was prepared from 250 g. of phenol by the method of Reimer and Tieman.[16] Trimethylethylene (34–38°) was obtained from tertiary amyl alcohol.[17] Methylpentadiene was prepared by the dehydration of 2-methylpentadiol-2,4. The latter was obtained by the reduction of diacetone alcohol. Eighty-three grams of the diol were dehydrated using 1.4 g. of aniline

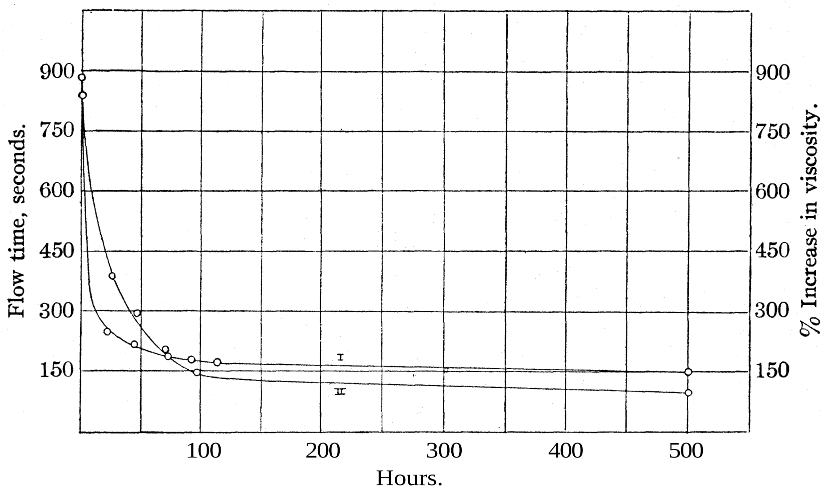

Fig. 2.—Relation of age to catalytic activity of ozonide. In curve I the viscosity of diisobutylene ozonide (expressed in flow time in seconds) is plotted against the time in hours that had elapsed after its preparation. In curve II there is plotted the percentage increase in the viscosity after twenty-four hours at 25° of a sample of styrene containing 2% of ozonide, against the hours that had elapsed between the preparation of the ozonide and its addition to the sample of styrene.

hydrobromide as a catalyst as in the preparation of 2,3-dimethylbutadiene-1,3. The oil layer was found to boil at 72–128°. The formation of some of a methylpentenol was indicated by the fact that the weight of the water layer was low as well as by the boiling range of the product. An attempt to complete the dehydration with oxalic acid resulted in the formation of dark, high-boiling products. About 15 g. of olefin boiling at 74–76° was collected as a mixture of two possible methylpentadienes.

Summary

A mixture of the ozonides of two octylenes has been found to catalyze the polymerization of styrene, indene, 2,3-dimethylbutadiene-1,3, a methylpentadiene, and furfuryl alcohol. It has been found to be inactive as a polymerization catalyst toward stilbene, o-hydroxybenzyl alcohol, trimethylethylene, and the mixture of octylenes from which it is made. The catalyst was active at room temperature and 100° and in a solution in toluene. The ozonide underwent a change on standing especially during the first two days after its preparation and lost a large part of its catalytic power.

CHARACTERIZATION OF ALKYL HALIDES AND ORGANOMAGNESIUM HALIDES[1]

BY A. M. SCHWARTZ AND JOHN R. JOHNSON

RECEIVED DECEMBER 26, 1930 PUBLISHED MARCH 6, 1931

Since organomagnesium halides react smoothly with aryl isocyanates to produce substituted amides that are usually crystalline solids, this reaction is suitable for the identification of organomagnesium halides and of halides that can be converted into these. Gilman and his collaborators[2] have used phenyl and α-naphthyl isocyanates for this purpose and have pointed out that a-naphthyl isocyanate enjoys some advantages over phenyl isocyanate. The most important of these appears to be the fact that the resulting a-naphthyl amides can be purified more readily than the anilides. This disadvantage attending the use of phenyl isocyanate can be minimized by avoiding an excess of the isocyanate and is more than counterbalanced, in our experience, by the fact that only a small number of the a-naphthyl amides are described in the literature. Of the ten α-naphthyl amides prepared by Gilman and Furry, five had not previously been reported. On the other hand, the anilides of all of these

---

[1] A paper presented at the St. Louis Meeting of the American Chemical Society, April 18, 1928. The present report contains additional data not included in the preliminary paper.

[2] Gilman and Furry, THIS JOURNAL, 50, 1214 (1928). This article gives an excellent review of previous work dealing with the action of aryl isocyanates on organometallic halides.

acids have been described in the literature. For purposes of identification, with a minimum preparation of new compounds, it appears preferable to use phenyl isocyanate.

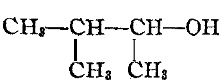
In the present study the alcohols were used as the principal starting materials, since the method lends itself to the characterization of certain secondary and tertiary alcohols and alkyl halides that cannot be identified by the usual methods. All of the isomeric propyl, butyl and amyl alcohols were carried through the series of reactions indicated below

$$R{-}OH \xrightarrow[PX_3]{HX} R{-}X \xrightarrow[\text{ether}]{Mg} R{-}MgX \xrightarrow[H_2O]{C_6H_5NCO} R{-}CO{-}NH{-}C_6H_5$$

In addition to this complete series of alcohols, several other alcohols and alkyl halides were examined. The details of these preparations are shown in Table I. In practice, this method is limited principally by the yield in the conversion of the halide into the organomagnesium halide.

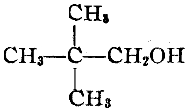
In general, the anilides proved to be satisfactory derivatives for identification, but in several instances the melting points of isomeric compounds differ by only a few degrees. In these cases it is necessary to prepare authentic specimens of known anilides and to use mixed melting point determinations to establish the identity of the unknown anilide. Tests of the mixed melting point procedure showed that unlike anilides of approximately the same melting point gave a marked depression of the melting point when mixed together.

Two of the isomeric amyl alcohols, 3-methylbutanol-2 (I) and 2,2-dimethylpropanol-1 (II) suffered an intramolecular rearrangement in the course of the above series of reactions. Both of these alcohols gave the anilide of dimethylethylacetic acid (111), identical with that obtained from *tert.*-amyl alcohol



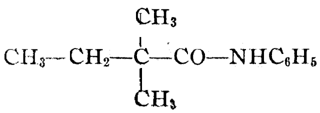
$$CH_3{-}\underset{CH_3}{CH}{-}\underset{CH_3}{CH}{-}OH$$

I



$$CH_3{-}\overset{CH_3}{\underset{CH_3}{C}}{-}CH_2OH$$

II



$$CH_3{-}CH_2{-}\overset{CH_3}{\underset{CH_3}{C}}{-}CO{-}NHC_6H_5$$

III

It is probable that this rearrangement occurred in the conversion of the alcohols into the corresponding chlorides since the chlorides agree in physical properties with *tert.*-amyl chloride. Although several special methods were used in the preparation of the chlorides, such as the action of thionyl chloride in the presence of pyridine,[3] we did not obtain any anilide other than that of dimethylethylacetic acid.

In the case of allylmagnesium bromide[4] the resulting anilide was an

oil that could not be crystallized or distilled. On warming with very dilute sulfuric acid the oil was converted to a solid, from which crotonic anilide was isolated by repeated crystallizations. In this case the original anilide was probably impure vinylacetic anilide, and the subsequent treatment effected a rearrangement to form the more stable compound in which the double bond is conjugated with the carbonyl group

$$CH_2{=}CH{-}CH_2{-}MgBr \xrightarrow{C_6H_5NCO} CH_2{=}CH{-}CH_2{-}CO{-}NHC_6H_5 \longrightarrow CH_3{-}CH{=}CH{-}CO{-}NHC_6H_5$$

It seemed of interest to investigate the behavior of an optically active alkyl halide, in which the halogen is directly attached to the asymmetric

[a] The yields of RMgX are significant because the application of this method of identification is limited in practice by the successful transformation of the halide into RMgX. The yields tabulated here are merely those of typical preparations under ordinary conditions and are not usually the highest that have been attained. Data on the yields of RMgX from a variety of halides, using a standardized procedure, are found in papers by Gilman and his collaborators [THIS JOURNAL, 45, 2462 (1923); 51, 1576 (1929)].

[b] For comparison and checking, this anilide was also prepared from a pure specimen of the corresponding acid obtained by an independent synthesis

[c] The purification of this anilide was difficult and involved an unusually great loss of material.

[d] The structure of this anilide does not correspond to that of the original alcohol; an intramolecular rearrangement occurred in this series of reactions.

carbon atom. For this purpose d-2-bromooctane was chosen, and the resulting anilide was compared with that obtained from dl-2-bromooctane. The optically active halide was found to give a completely inactive anilide, dl-2-methyloctanoic anilide, identical in all respects with that obtained from the racemic halide.[5]

Experimental

Alcohols.—*n*-Propyl, isopropyl and n-butyl alcohols were obtained by fractional distillation of commercial products of high purity. With these exceptions all of the alcohols were prepared synthetically by the conventional methods (usually by Grignard syntheses) and were carefully purified. In a number of supplemental experiments we used specimens of various isomeric amyl alcohols furnished by the Sharples Solvents Corporation, who kindly supplied us with generous samples of these materials.

Alkyl Halides.—The primary and secondary alcohols were usually converted to the bromides, since the primary and secondary alkyl bromides react with magnesium more readily than the chlorides and give higher yields than the iodides. In supplementary trials on a small scale, several chlorides and iodides were used. The tertiary alcohols (and a few of the more reactive primary and secondary alcohols) were converted to the chlorides.

The straight-chain primary bromides were prepared by refluxing the alcohols with a solution of hydrobromic and sulfuric acids obtained by passing sulfur dioxide into a mixture of bromine and ice,[6] without any additional sulfuric acid. The branched chain and secondary bromides were prepared by refluxing the alcohols with 48% aqueous hydrobromic acid without the addition of sulfuric acid. Addition of the latter may lead to the production of isomeric bromides in some cases, and it is extremely difficult to separate these by fractional distillation The tertiary alcohols were converted to the chlorides by shaking with concd. hydrochloric acid? Octanol-2 and cyclohexanol were converted to the bromides by the use of phosphorus tribromide.

Organomagnesium Halides.—The Grignard reagents were prepared according to the conventional methods; a sufficient quantity of ether was used so that the resulting solutions contained from 0.5 to 1.0 mole of RMgX per liter. After standing for at least twelve hours, the solutions were decanted through a plug of glass wool and titrated with standard acid to determine the yields.[8]

Reaction with Phenyl Isocyanate.—A solution of slightly less than the theoretical amount (usually 0.90 mole) of phenyl isocyanate, dissolved in ten volumes of ether, was added dropwise to a solution of the organomagnesium halide, with shaking. It is important to avoid any hydrolysis of the isocyanate and to insure a complete reaction, in order to obtain a pure anilide. The reaction mixture was allowed to stand with occasional shaking for an hour (except for very small runs, which could be hydrolyzed after a few minutes). Hydrolysis was effected by adding, cautiously, cold water containing a little hydrochloric acid. It is necessary to shake the resulting mixture thoroughly in order to obtain a complete hydrolysis of the magnesium derivative of the anilide. The

---

[5] We have not yet determined whether the racemization occurs in the formation of the Grignard reagent or in the reaction of the latter with phenyl isocyanate. From theoretical considerations it appears more likely that racemization occurs in the formation of the Grignard reagent from the secondary alkyl halide.

[6] "Organic Syntheses," John Wiley and Sons, Inc., New York, 1921, Vol. I, p. 5.

[7] *Ibid.*, Vol. VIII, 1928, p. 50.

[8] Gilman, Wilkinson, Fishel and Myers, THIS JOURNAL, 45, 150 (1923).

ether layer was separated[9] and dried with magnesium sulfate; the crude anilide remained after distilling off the solvent. The anilides were usually crystallized from ethyl ether, petroleum ether, or methyl alcohol. It is most satisfactory to effect purification by crystallization from two different solvents; the best results were obtained by a crystallization from petroleum ether followed by ethyl ether. Methyl alcohol can be used for anilides that do not respond to purification by these solvents. The resulting anilides are white crystalline solids with sharp melting points. In a few cases it was necessary to use decolorizing charcoal to obtain colorless products. The yields of the crude anilides were usually from 80–90% of the theoretical quantity, based upon the phenyi isocyanate. The losses in subsequent purification varied from 10–50%.

Procedure for Identification of Alkyl Halides.—In a dry test-tube, provided with a *cork* bearing a calcium chloride tube, is placed 0.4 g. (17 milliatoms) of magnesium turnings. A small crystal of iodine is added and the tube is heated gently until the iodine has reacted completely. The tube is allowed to cool and a solution of 1–2 g. (approximately 10 millimoles) of the dry alkyl halide in 4–5 cc. of dry ether is added. With many halides the reaction starts vigorously and it is necessary to cool the tube in a bath of cold water. In these cases it is preferable to add slowly the solution of the alkyl halide to the magnesium. If the reaction does not start spontaneously, the tube is heated gently by immersion in a beaker of warm water. After the reaction has started[10] the ether is maintained in gentle ebullition until the alkyl halide has reacted completely. After cooling, about 10 cc. of dry ether is added and the unreacted magnesium is allowed to settle. The solution is decanted quickly into another dry test-tube of large capacity, and 4–5 cc. of a 10% ethereal solution of phenyl isocyanate (3–4 millimoles) is added dropwise, with shaking. The tube is protected from atmospheric moisture and allowed to stand for a few minutes with intermittent shaking. The reaction mixture is poured *cautiously* into 20 cc. of ice water containing 1 cc. of concd. hydrochloric acid, and the mixture is agitated thoroughly. The ether layer is separated,[9] dried over anhydrous magnesium sulfate and evaporated. The residual crude anilide is crystallized from appropriate solvents, and if necessary decolorized by the addition of a little decolorizing carbon.

Summary

1. The conversion of a series of alcohols into the corresponding alkyl halides and organomagnesium halides has been investigated.

2. It has been found satisfactory to characterize these organomagnesium halides by reaction with phenyl isocyanate. The resulting anilides are crystalline solids that are suitable for identification purposes.

3. The application of this method to certain branched chain alcohols is limited by the fact that intramolecular rearrangements may lead to anilides that do not correspond in structure to the original alcohol.

4. An optically active halide, d-2-bromooctane (in which the halogen

---

[9] With anilides that are very slightly soluble in ether, a portion of the product separates as a crystalline precipitate and remains suspended at the interface. This portion was removed by filtration, dried and combined with the fraction obtained from the ether layer.

[10] In working with small quantities, difficulty is sometimes experienced in starting the reaction. In refractory cases, the reaction can often be initiated by the addition of a small quantity of Gilman's magnesium--copper alloy, that has been activated by heating with an equal weight of iodine.

is directly attached to the asymmetric carbon atom) led to a completely inactive anilide.

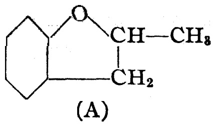
PROPARGYL ETHERS OF PHENOL

BY CHARLES D. HURD AND FRANK L. COHEN

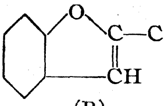
RECEIVED DECEMBER 29, 1930 PUBLISHED MARCH 6, 1931

In contrast to the considerable information concerning the pyrolysis of allyl aryl ethers,[1] little is known concerning the propargyl aryl ethers. Whereas the former tpye changes on refluxing into o-allylphenols, the latter has been reported[2] to yield nothing but nondescript resins. Thus only tars were found when phenyl propargyl ether or p-bromophenyl propargyl ether was refluxed alone or refluxed in diamyl ether.

For the rearrangement of the propargyl ethers to follow the course of the allyl ethers, the anticipated product would be o-hydroxyphenylallene, rather than o-propargylphenol. It appears to be the gamma carbon of the unsaturated chain which becomes attached to the aromatic nucleus during the rearrangement. Thus, just as $C_6H_5OCH_2CH{=}C^*H_2$ rearranges into ortho $HOC_6H_4C^*H_2CH{=}CH_2$, so it might be anticipated that C_6H_5O-$CH_2C{\equiv}C^*H$ would change into ortho $HOC_6H_4C^*H{=}C{=}CH_2$. Furthermore, since 2-methylcoumaran, (A) is a by-product from the pyrolysis of the allyl ether, it might be anticipated, that 2-methylcoumaron, (B), would result from the propargyl ether. Both hydroxyphenylallene and methylcoumaron are structures which might be expected to polymerize readily. It is conceivable that either or both of these substances were the precursors of the tar which was noticed from the pyrolysis of propargyl phenyl ether.



(A)

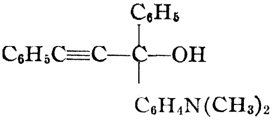


(B)

In extending this subject we endeavored to synthesize the phenyl ethers of the following propargyl alcohols and to study their pyrolysis:

Triphenylpropargylalcohol	$C_6H_5C{\equiv}C{-}C(C_6H_5)_2OH$
Trimethylpropargyl alcohol	$CH_3C{\equiv}C{-}C(CH_3)_2OH$
γ-Methylpropargyl alcohol	$CH_3C{\equiv}C{-}CH_2OH$
1-Phenylethinylcyclohexanol-1	$C_6H_5C{\equiv}C{-}C(CH_2)_5OH$

α,γ-Diphenyl-α-*p*-dimethylaminophenylpropargyl alcohol



$$C_6H_5C{\equiv}C{-}\underset{C_6H_4N(CH_3)_2}{\overset{C_6H_5}{C}}{-}OH$$

---

[1] This topic is summarized in Hurd, "The Pyrolysis of Carbon Compounds," The Chemical Catalog Co., New York, 1929, pp. 214–228.

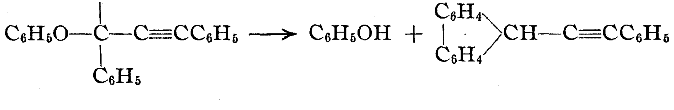
[2] Powell and Adams, THIS JOURNAL, 42, 654 (1920).

Of these compounds, only the first and third appear to have been described previously.

The first three of these alcohols were converted into the chlorides by phosphorus trichloride. The fourth reacted with phosphorus pentachloride but the reaction product did not analyze correctly for the desired halide. This reaction is being studied further. All attempts to convert the fifth alcohol into its chloride were unsuccessful. Dry hydrogen chloride, concd. or dilute hydrochloric acid, and phosphorus tri- and pentachlorides were all tried with variations in temperature and concentration. It seemed, however, that even small amounts of acid were sufficient to give rise to tarry materials from which nothing could be isolated, not even the original alcohol. In the absence of evidence to the contrary, it has been assumed that the propargyl chlorides, $R-C\equiv C-CR_2Cl$, did not rearrange[3] into the chloroallenes, $RCCl=C=CR_2$

Synthesis of the Phenyl Ethers.—With trimethylpropargyl chloride and with y-methylpropargyl chloride it was possible to synthesize the respective phenyl ethers by heating in acetone solution with phenol and potassium carbonate. This is analogous to the method which is commonly used in making the allyl ethers. In contrast to this, it was necessary to use sodium phenoxide to effect reaction with triphenylpropargyl chloride. Even more resistant was the material which was considered (temporarily, at least) to be 1-phenylethinylcyclohexyl chloride. In fact, no satisfactory reaction with phenol or sodium phenoxide could be achieved in spite of several modifications of conditions.

Pyrolysis of the Ethers.—All three of the ethers were found to decompose on heating, but none was found to pyrolyze into an ortho substituted phenol. In fact, distinct differences of reaction mechanism were apparent in all three cases. Triphenylpropargyl phenyl ether was the most resistant to heat, but at 300° it pyrolyzed into phenol and 9-phenylethinylfluorene



$$C_6H_5O-\underset{C_6H_5}{\overset{C_6H_5}{C}}-C\equiv CC_6H_5 \longrightarrow C_6H_5OH + \begin{matrix}C_6H_4\\ | \\ C_6H_4\end{matrix}\!\!>CH-C\equiv CC_6H_5$$

The yield was about 45%. This reaction is similar evidently to the pyrolysis of triphenylmethyl chloride,[4] wherein hydrogen chloride was detached at temperatures above 200° and 9-phenylfluorene formed. Similar also is the production of phenyl-a-naphthofluorene by refluxing diphenyl-a-naphthylchloromethane[5] with zinc chloride in acetic acid.

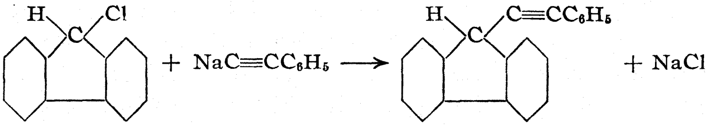
[3] See Willemart, *Compt. rend.*, 187, 385 (1928); 188, 1172 (1929).

[4] Hemilian, *Ber.*, 7, 1208 (1874); 11, 202, 837 (1878); E. and O. Fischer, *Ann.*, 194, 257 (1878); Schwarz, *Ber.*, 14, 1522 (1881); Nef, *Ann.*, 309, 167 (1899).

[5] Ullmann and Mourawiew-Winigradoff, *Ber.*, 38, 2213 (1905).

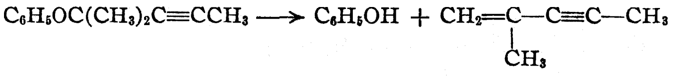
Although it is easy to picture the production of 9-phenylethinylfluorene and 9-phenylfluorene from triphenylpropargyl phenyl ether and triphenylmethyl chloride, respectively, no ready explanation suggests itself as to why other triphenylpropargyl derivatives such as the chloride[6] or acetate[7] fail to undergo a similar type of pyrolysis and yield 9-phenylethinylfluorene. Instead, these substances give rubrene, $C_{42}H_{28}$ (m. p. 331'). An intermediate compound, $C_{42}H_{29}Cl$, which is capable of quantitative conversion into rubrene, is isolable from the chloride by careful heating, but no mention has been made of phenylethinylfluorene. Robin reported that traces only of rubrene were obtained on heating triphenylpropargyl benzoate or triphenylpropargyl methyl ether, but that fair amounts of a yellow hydrocarbon of m. p. 245" were isolated from these substances. We found no rubrene in the pyrolytic products of triphenylpropargyl phenyl ether, but we did isolate traces of a solid melting between 240–250°, which was presumably the same as Robin's compound.

To prove the structure of 9-phenylethinylfluorene, its synthesis was effected from fluorene through fluorenone, 9-hydroxyfluorene and 9-chlorofluorene. This last was condensed with sodium phenylacetylide



The 9-phenylethinylfluorene thus synthesized was identical with the product of the pyrolysis.

Turning now to trimethylpropargyl phenyl ether, it was found to be much more susceptible to heat. Its temperature of decomposition was 160°, as compared to 300° which was required for the triphenylpropargyl phenyl ether. Tar formation was marked, but there was an appreciable yield of phenol and methyl-2-pentene-1-ine-3, in accordance with the equation



$$C_6H_5OC(CH_3)_2C{\equiv}CCH_3 \longrightarrow C_6H_5OH + CH_2{=}\underset{\displaystyle CH_3}{\underset{|}{C}}{-}C{\equiv}C{-}CH_3$$

The ene–ine compound, C_6H_8, was also isolated as a by-product in the synthesis of trimethylpropargyl alcohol and of trimethylpropargyl chloride. Depending on the temperature used, yields of the ene–ine from the alcohol reached as high as 60%. No doubt higher yields could be obtained with facility. This hydrocarbon, b. p. 75–77°, represents an extremely interesting type inasmuch as it possesses conjugation of the rare ene–ine type rather than of the common diene type. Its conjugation was attested to by

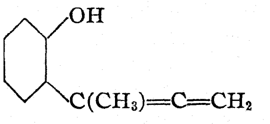
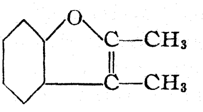
the fact that sodium caused it to polymerize to a black, rubber-like substance in the course of a few hours.

The pyrolysis of γ-methylpropargyl phenyl ether was necessarily different from the other ethers since it possessed no α-phenyl group to give rise to fluorene formation and no α-methyl group to yield a conjugate eneine. Phenol was detected as a reaction product, but only in traces. No gas was evolved. Instead, the chief reaction product was a tar, possessing a molecular weight of about 400. Since the molecular weight of the original ether, or of its isomers such as



or



is 146, this suggests a trimer (mol. wt. 438) as the major component of the tarry mixture. In this polymerization process, most of the original unsaturation was consumed since bromine (in chloroform solution) was absorbed only in trivial amounts. Whether or not the tar was produced as the result of prior allene formation cannot be stated, but if such was the case it is fairly certain that none of the allene escaped the polymerization process.

Experimental Part

Phenylacetylene.—This was prepared by the method of "Organic Syntheses," Vol. VI. An alteration, noted in Volume VIII, p. 124, was the use of potassium hydroxide (2 parts) and sodium hydroxide (1 part) for the fused alkali rather than the former alone. The phenylacetylene was carefully fractionated and the fraction boiling at 140–141° (750 mm.) used. For the work described below, this was an essential step. The material was converted into sodium phenylacetylide by Nef's[8] method. In our use of this salt, it was not removed from the ether wherein it was made.

Phenylethinyl Phenyl Ketone.—Nef's directions[9] were followed for the synthesis of this ketone from sodium phenylacetylide and benzoyl chloride. After purification by vacuum distillation, for a time the ketone resisted solidification. Finally, a solid, m. p. 53–55°, was obtained in 74% yield. Nef's value was 49–50°. André,[10] who prepared this ketone from benzoyl bromide and sodium phenylacetylide, also reported a melting point of 49°. That the value is higher than any of these, namely 65–66°, is shown below.

To effect another synthesis of this ketone, the following reactions were developed

$$C_6H_5C{\equiv}C{-}COCl + C_2H_5OH \longrightarrow C_6H_5C{\equiv}C{-}CO_2C_2H_5 + HCl$$

$$C_6H_5C{\equiv}C{-}CO_2C_2H_5 + C_6H_5MgBr \longrightarrow C_6H_5C{\equiv}C{-}CO{-}C_6H_5 + C_2H_5OMgBr$$

Ethyl cinnamate was converted into phenylpropiolic acid by Perkin's[11] method and this acid changed into the acid chloride in 74% yield by thionyl chloride.[12] We found that

direct esterification of propiolic acid with ethanol and hydrogen chloride (Perkin's method) was impractical because of low yields (33%). Double this yield was obtained from the acid chloride.

Ethyl **Phenylpropiolate.**—A solution of phenylpropiolyl chloride (39 g.) in absolute alcohol (80 cc.) was refluxed for four hours. Then the solution was poured into water and an oil separated. This was extracted with ether, washed with dilute sodium carbonate solution, then with water, dried, and fractionally vacuum-distilled. The yield of the ester was 28.4 g., which is 65% of the theoretical.

Phenylethinyl Phenyl Ketone.—A solution of 0.15 mole of phenylmagnesium bromide in 150 cc. of dry ether was prepared. To this, 10 g. of ethyl phenylpropiolate (0.057 mole) in 100 cc. of dry ether was added slowly. After standing for two hours, the solution was poured into cold, dilute sulfuric acid for hydrolysis. The ether layer was separated and allowed to evaporate at room temperature. A very thick oil was obtained. It failed to crystallize by itself in the cold after two days, but the addition of a little petroleum ether to the surface of the oil caused it to set to a solid mass of very fine crystals. These were filtered off and washed with a small amount of petroleum ether. When dry, the crystals of phenylethinyl phenyl ketone weighed 10 g.; this is an 85% yield. These crystals melted at 43–54" and after several recrystallizations from alcohol the melting point was raised to 65–66°. The boiling point at 15 mm. was found to be 200–202°. This confirms André, who reported 200–205° at 14 mm. Inasmuch as the melting point differed from the older value, the pure material was analyzed.

Anal. Subs., 0.1415: CO_2, 0.4513; H_2O, 0.0621. Calcd. for $C_{15}H_{10}O$: *C*, 87.4; H, 4.89. Found: C, 87.0; H, 4.87.

Although the yields in this synthesis were quite satisfactory, Nef's method involves the use of simpler intermediates and is to be preferred for that reason. It is interesting to note that Wilson and Hyslop[13] synthesized triphenylpropargyl alcohol, rather than phenylethinyl phenyl ketone, by the interaction of ethyl phenylpropiolate and phenylmagnesium bromide. In their procedure, the reaction mixture was kept in a freezing solution of ice and salt during the mixing and the duration of the experiment was "overnight" instead of two hours. Otherwise their steps were very similar to ours.

Synthesis of **Triphenylpropargyl** Alcohol.—In addition to Wilson and Hyslop's method, three other plans have been recorded for the synthesis of this alcohol. (1) Phenylethinyl phenyl ketone[14] plus phenylmagnesium bromide, with a reported yield of "excellcnt." (2) Benzophenone[15] plus phenylethinylmagnesium bromide, in 79% yield. (3) Benzophenone[16] plus sodium phenylacetylide. Nef's yield in this reaction was 54%.

After using all of these methods we reached a preference for the last. However, with Nef's directions very poor yields (0–10%) were obtained. The trouble seemed to be largely in the purification process. It was found that crystallization was a poor method for removing the impurities so, in order to minimize them, the reacting materials were carefully purified before use. Under these conditions the reaction mixture was almost colorless and subsequent crystallization and purification without distillation of unreacted materials was possible. The yields were increased to 65–70% of the theoretical.

To a mixture of 0.1 mole of freshly prepared sodium phenylacetylide in 100 cc. of

---

[13] Wilson and Hyslop, J. *Chem. Soc.*, **123,** 2612 (1923).

[14] Kohler, Am. *Chem. J.*, 38, 561 (1907).

[15] Hess and Weltzien, ***Ber.***, 54, 2518 (1921).

dry ether was added 18.2 g. (0.1 mole) of benzophenone. A very slight heat of reaction which seemed to continue for some time was insufficient to keep the ether rrfluxing. To hasten the reaction, the mixture was refluxed vigorously for six to eight hours. The reaction proceeded smoothly with the formation of the sodium salt of triphenylpropargyl alcohol, which was soluble in ether. When the mixture became a clear solution, the reaction was assumed to be completed but the refluxing was usually continued for an extra hour. The reaction mixture was almost colorless.

After cooling to room temperature, the mixture was poured with stirring into 500 cc. of normal sulfuric acid. Without separating the layers, the ether was allowed to evaporate at room temperature. The light yellow oil which remained was composed of triphenylpropargyl alcohol, phenylacetylene and benzophenone. The mixture was cooled to 0° whereupon the oily layer became a thick sirup. In the course of a few hours at this temperature crystals slowly formed until finally the layer was solid. This solid was broken up and filtered, then washed with petroleum ether and dried. The yield of crude material was 20–22 g., which was 71–74% of the theoretical. One crystallization from benzene and petroleum ether was sufficient to obtain a product which melted at 78–80°. The yield of triphenylpropargyl alcohol thus purified was 16–18 g., or 65–70% of the theoretical.

Trimethylpropargyl Alcohol.—Methylacetylene, prepared from 250 g. of propylene bromide'? and alcoholic potassium hydroxide, was conducted through a long, well-cooled condenser and then through three cold phosphorus pentoxide traps. The dry gas was then passed into a 500-cc. solution of 1.0 mole of ethylmagnesium bromide in ether. The rate of addition of the methylacetylene was such that a gentle but steady refluxing of the ether was induced, with the formation of ethane and methylethinylmagnesium bromide. Although methylacetylene which is prepared from propylene bromide contains some allene, no trouble is caused thereby since the allene cannot react with ethylmagnesium bromide.

The reaction mixture of ether, methylethinylmagnesium bromide and excess ethylmagnesium bromide was cooled to 0° and to it 1 5 moles (87 g.) of acetone was added slowly. The Grignard addition compound was decomposed by cold dilute hydrochloric acid and the ether layer was washed, dried and distilled under reduced pressure. Methyl-2-pentine-3-01-2 was isolated as a colorless liquid boiling at 75–77' (15 mm.). The yield was 47 g. (47% of the theoretical). The index of refraction, n_D^{20}, was 1.4193.

Anal. Subs. 0.2041: CO_2, 0.5472; H_2O, 0.1836. Calcd. for $C_6H_{10}O$: C, 73.4; H, 10 2. Found: C, 73.2; H, 10.2.

Methyl-2-pentene-1-ine-3.—In this synthesis of trimethylpropargyl alcohol, part of the alcohol was always dehydrated with the formation of methyl-2-pentene-1-ine-3, $CH_2{=}C(CH_3){-}C{\equiv}C{-}CH_3$. The yield of hydrocarbon depended on the temperature at which the reaction occurred, and yields as high as 60% were obtained. No efforts were made to improve this yield. No doubt it would he possible to obtain almost quantitative yields by heating the alcohol with oxalic acid dihydrate, since t-butyl alcohol (a related tertiary alcohol) is easily dehydrated in this manner. The methylpentenine was also isolated as a by-product in the preparation of methyl-2-chloro-2-pentine-3, but in much smaller amounts. This hydrocarbon was also one of the chief pyrolytic products of trimethylpropargyl phenyl ether (see below). It was a colorless liquid which boiled at 75–77" and which gave a value of 1.4002 for the index of refraction, n_D^{20}.

Anal. Subs., 0.2148, 0.1407: CO_2, 0.7070, 0.4630; H_2O, 0.3800, 0.1254. Calcd. for C_6H_8: C, 89.94; H, 10.06. Found: C, 89.66, 89.75; H, 9.82, 9.94.

[17] Hurd, Meinert and Spence, THIS JOURNAL, 52, 1141, second method (1930).

γ-Methylpropargyl alcohol **(butine-2-ol-1)** was synthesized by **Yvon's**[18] method from **trioxymethylene** and methylethinylmagnesium bromide. It was collected in 16% yield at **137–140"**; n_D^{20} **1.4497.** Yvon reported a yield of **25%.** Various modifications were tried with no better success. These included the use of gaseous formaldehyde, the use of an excess of Grignard reagent, or the variation of temperature or time of reaction.

1-Phenylethinylcyclohexanol-1.—Twenty-five grams of freshly distilled phenylacetylene **(0.25** mole) was converted into its sodium salt. To this **was** then added slowly **25** g. **(0.25** mole) of cyclohexanone. A vigorous reaction resulted. Then the mixture was refluxed until a clear solution was obtained after which it was hydrolyzed with dilute hydrochloric acid and the ether layer separated. The water layer was extracted with a small quantity of ether and the ether extracts combined. After drying over sodium sulfate, the solution was fractionated. Eighteen grams of a mixture of phenylacetylene and cyclohexanone was obtained, then 1-phenylethinylcyclohexanol-1 distilled as a thick, colorless sirup, b. p. 166–169° at **14** mm. After several hours at room temperature this material crystallized to a white solid which melted at 58–60°. The yield was **25.1 g.,** or **50%.**

α,γ-Diphenyl-α-p-dimethylaminophenylpropargyl Alcohol.—Sodium phenylacetylide was made from **33** g. of phenylacetylene (0.33 mole), and **75** g. **(0.33** mole) of p-dimethylaminobenzophenone[19] in 150 cc. of benzene was added. The mixture was refluxed until all of the solid had disappeared (four hours). After completion of the reaction, the mixture was poured into cold water and the benzene layer washed to remove the sodium hydroxide formed. The benzene solution was then dried and the solvent distilled. The black, tarry material which remained was extracted with petroleum ether. Most of the impurities were removed by this method. A light colored solid was obtained which, on recrystallization from benzene, gave a fine white crystalline material of m. p. 144–145°. The yield was 55 g., or 50%.

Anal. Subs. **0.2841, 0.4020: 0.100** N HCl, 8.50, **12.20.** Calcd. for $C_{23}H_{21}ON$: **N, 4.28.** Found: **N,** 4.14, 4.22.

The **Propargyl Chlorides—Triphenylpropargyl** chloride was **prepared**[20] from phosphorus trichloride and the alcohol in benzene.

Trimethylpropargyl Chloride.—To a solution of **20.0** g. of **trimethylpropargyl** alcohol (0.2 mole) in **50** cc. of **dry** ether was added **13.7** g. of phosphorus trichloride **(0.1** mole). The reaction mixture was maintained at **0°** for one hour and at room temperature for two hours. After this time the ether solution was decanted from the phosphorous acid and distilled. The fraction which boiled at 35–65° and 47 mm. was collected, washed with cold water, dried and redistilled. Trimethylpropargyl chloride (methyl-2-chloro-2-pentine-3) was obtained as a light yellow liquid, b. p. **57-61°** at **47** mm.; n_D^{20} **1.4143.** The yield was 6.6 **g. (33%).**

Anal. Subs., **0.2358, 0.2510:** cc. of $N/10$ $AgNO_3$, **19.9, 20.4.** Calcd. for C_6H_9Cl: **Cl, 30.43.** Found: **Cl,** 30.48, 30.65.

γ-Methylpropargyl Chloride **(Chloro-1-butine-2).**—To **10.0** g. of **butine-2-ol-1** (0.14 mole), dissolved in **50** cc. of dry ether, was added **10.0** g. of phosphorus trichloride **(0.07** mole). **A** vigorous reaction began immediately and in one hour it was completed. After standing for eight hours at room temperature, the ether solution was decanted from the phosphorous acid, washed quickly with cold water, dried and distilled. **Chloro-1-butine-2** was obtained as a light yellow liquid, b. p. **81–84'.** The yield was **5.4 g.,** which is 44% of the theoretical.

The Phenyl Ethers

Triphenylpropargyl Phenyl Ether.—Five grams (0.015 mole) of triphenylpropargyl chloride was added to 50 cc. of absolute ether. The chloride was only slightly soluble. To this mixture was then added an ether solution containing the sodium phenoxide obtained by treating 2.5 g. of phenol with a slight excess of sodium. A finely divided precipitate of sodium chloride settled to the bottom and a clear solution was obtained. After filtration the ether was evaporated off, thereby leaving a mass of yellow crystals which was washed with cold water and with cold absolute alcohol. The crystalline material was recrystallized from ether; m. p. 90–90.5". The yield of the ether was 70% of the theoretical, or 4.3 g.

Anal. Subs., 0.1628: CO_2, 0.5346; H_2O, 0.0901. Calcd. for $C_{27}H_{20}O$: C, 89.68; H, 5.59. Found: C, 89.54; H, 5.79.

Trimethylpropargyl Phenyl Ether.—An ether solution containing 50 cc. of dry ether, 5 g. (0.04 mole) of trimethylpropargyl chloride and 30 cc. of acetone was made and to it was added 5 g. of potassium carbonate and 3.3 g. (0.04 mole) of phenol. The mixture was refluxed for four hours. Fifty cc. of ether was then added and the ether solution washed with dilute alkali to remove unreacted phenol. The ether solution was dried and fractionally distilled. After removal of the ether and the unreacted trimethylpropargyl chloride, a clear and rather viscous yellow oil remained; n^{20}_{D} 1.3408. All attempts to purify the oil by distillation brought about pyrolysis. The yield was 4.8 g., which was 69% of the theoretical. For identification, its molecular weight was determined.

Mol. wt. Subs. 0.2040; benzene, 21.96; freezing point lowering, 0.150". Calcd. for mol. wt. of $C_{12}H_{14}O$: 174. Found: 340. Subs., 0.1694, 0.2421; acetic acid, 26.23, 26.23; freezing point lowering, 0.150°, 0.220". Found: mol. wt., 167.9, 168.6.

y-Methylpropargyl Phenyl Ether.—Four grams (0.055 mole) of chloro-1-butine-2 was dissolved in 50 cc. of absolute ether, and to this solution were added 5.0 g. of potassium carbonate, 10 cc. of acetone and 4.6 g. (0.055 mole) of phenol. After the first vigorous reaction, the mixture was refluxed for six hours. The ether solution was then carefully washed with dilute alkali to remove unreacted phenol. After washing with water and drying, the mixture was fractionally distilled. γ-Methylpropargyl phenyl ether was obtained as a colorless oil, b. p. 123–126° at 25 mm.; n^{20}_{D} 1.3894. A 57% yield (4.6 g.) was realized in the preparation.

Anal. Subs. 0.1442: CO_2, 0.4340; H_2O, 0.0920. Calcd. for $C_{10}H_{10}O$: C, 82.13; H, 6.90. Found: C, 82.15; H, 7.08.

Pyrolysis of the Ethers

Triphenylpropargyl Phenyl Ether.—One gram of the pure ether was heated in a test-tube by means of a large salt-bath. The temperature was raised slowly and uniformly to 310°. At 230° the compound darkened appreciably. At a bath temperature of 252" the reaction temperature ascended from 248 to 256°, indicating a slight exothermic reaction. The noticeably vigorous change occurred at 295°, however, when the vapor of phenol was evolved in appreciable amounts (0.12 g.). The temperature of 310" was maintained for about ten minutes, which was about five minutes after the evolution of a gas had ceased. Then the bath was allowed to cool slowly to room temperature.

A red, glassy material was obtained which, on pulverizing, became a light yellow powder which fused between 85–98°. By extraction with petroleum ether a soluble portion was obtained which after recrystallization melted at 98–100°. This was 9-

phenylethinylfluorene, and it was formed in 45–50% yields. The fraction which was insoluble in petroleum ether was crystallized from benzene. Less than 0.01 g. of red crystals was obtained, m. p. 240–250°.

Synthesis of 9-Phenylethinylfluorene.—Fluorene in acetic acid was oxidized[21] with sodium dichromate to fluorenone, and the latter reduced[a] in alkaline alcoholic solution to 9-hydroxyfluorene by zinc dust. Thionyl chloride was then used to effect the change into 9-chlorofluorene.[22b] Respectively, the yields in the three operations were 50, 87 and 76%.

A slight excess of sodium was added to 3 0 g. of phenylacetylene in 50 cc. of dry ether. The excess of sodium was mechanically removed after completion of the reaction. To the sodium phenylacetylide thus prepared was added three g. of 9-chlorofluorene (0.015 mole). The mixture immediately assumed a dark brown coloration. It was refluxed for three hours and then the solution was filtered to remove the unreacted sodium phenylacetylide and sodium chloride. Evaporation of the filtrate yielded a brown, crystalline solid. The pure 9-phenylethinylfluorene was readily obtained from this as a yellow solid which melted at 98–100" by crystallization from petroleum ether. The yield was 2 g., or 50%.

Anal. Subs., 0.1627: CO_2, 0.5649; H_2O, 0 0750. Calcd. for $C_{21}H_{14}$: C, 94.69; H, 5.31. Found: C, 94.54; H, 5.19.

Phenylethinylfluorene was also synthesized from the 9-hydroxyfluorene. One gram of the latter was dissolved in 50 cc. of dry ether and to it was added 2 g. of phenylacetylene. The mixture was chilled to 5–10° and 5 cc. of concd. sulfuric acid was added slowly while the solution was stirred vigorously. After washing the solution with a little water to remove the sulfuric acid, the solution was evaporated, leaving crude 9-phenylethinylfluorene as a yellow solid. After recrystallization there was 1 g. of pure product (m. p. 98–100°), which was a 65% yield.

Trimethylpropargyl Phenyl Ether.—In a test-tube which was heated by an oil-bath was placed 3.5 g. of trimethylpropargyl phenyl ether. The test-tube was connected to an efficient condenser and the temperature of the bath was carefully raised. At 160° the substance darkened materially and it was maintained at that temperature for half an hour. A small amount of vapor was at once apparent. This condensed and was collected as a colorless liquid. It proved to be methyl-2-pentene-1-ine-3. The yield of it was 0.8 g., a 43% yield.

The material which remained in the test-tube became a black tar after a few minutes and no further decomposition was evident as the heating was prolonged. Extraction of this tar with alkaline solution yielded 0.35 g. of phenol (as tribromophenol). This was 20% of the theoretical. The tarry, alkali-insoluble residue weighed 2.1 g.

γ-Methylpropargyl Phenyl Ether.—Three grams of y-methylpropargyl phenyl ether was heated slowly in a test-tube immersed in a large oil-bath. The temperature was raised slowly to 215–220° without any apparent decomposition and at this point a natural reflux seemed to occur. After one-half hour at this temperature, the material had become much darker and after one and a half hours it was black. When cooled, a thick, black and tarry material was obtained.

Extraction of the tar thus formed with dilute alkali gave less than 0 1 g. of phenol as tribromophenol. The tar was but slightly soluble in ether whereas benzene dissolved it readily. To ascertain the complexity of the tar, its molecular weight was taken and found to be about 400.

Summary

New syntheses of phenylethinyl phenyl ketone (benzoylphenylacetylene) and of ethyl phenylpropiolate have been developed.

A homolog of propargyl alcohol, $RC{\equiv}C{-}CH_2OH$, and four trisubstituted analogs, $RC{\equiv}C{-}CR_2OH$, were synthesized. Three of these were converted into the corresponding propargyl chlorides and then to the phenyl ethers. These ethers were subjected to pyrolysis.

Triphenylpropargyl phenyl ether pyrolyzed into phenol and 9-phenylethinylfluorene, which was synthesized for purposes of identification from fluorene. Both trimethylpropargyl alcohol and trimethylpropargyl phenyl ether decomposed on heating into phenol and a conjugated "ene–ine" hydrocarbon, namely, methyl-2-pentene-1-ine-3. When refluxed, γ-methylpropargyl phenyl ether changed primarily into a tar, the apparent molecular weight of which was 400. No simple allenes were found although they may have been the precursors of the tars. Should propargyl aryl ethers have been found to rearrange like allyl aryl ethers, allenes would have been expected.

RESEARCHES ON PYRIMIDINES. CXX. THE ACTION OF OZONE ON URACIL

BY TREAT B. JOHNSON AND ROBERT B. FLINT[1]

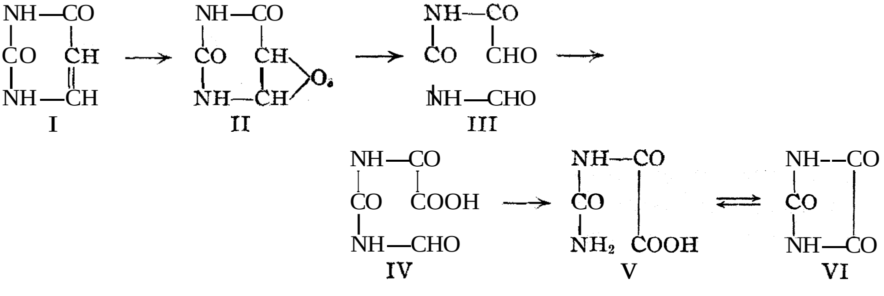
RECEIVED JANUARY 6, 1931 PUBLISHED MARCH 6, 1931

In order to develop a new technique for determining the constitution of nucleic acids, and also known glucosidic combinations containing pyrimidine and purine cycles, the authors decided to investigate the action of ozone on pyrimidines of the uracil type, and to follow this up later with a study of the behavior of certain purines of biochemical interest toward this same reagent. So far as the authors are aware, the behavior of heterocycles of these two types toward ozone has never been investigated. Since both cycles are characterized structurally by the presence of ethylene or unsaturated groupings, it might be predicted that pyrimidines and purines would be very reactive toward ozone, and be broken down at the double bond by this reagent with formation of unique acyclic, ureide constructions possessing immediate biochemical interest. In this paper we now describe the behavior of the pyrimidine "uracil" I when allowed to interact with ozone in glacial acetic acid at ordinary temperature.

[1] Constructed from a dissertation presented by Robert Barnett Flint to the Graduate School of Yale University in June, 1930, in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

Uracil I is not readily attacked by ozone in glacial acetic acid or 85% formic acid at ordinary temperature. If, however, the pyrimidine is suspended in either solvent, and washed ozone generated by passing oxygen gas through an ozonizing unit is bubbled into such a suspension for several hours, the uracil is finally completely destroyed and several products are formed as a result of the ozone action. The two major compounds produced are the ureides oxaluric acid V, and formyl-glyoxyl-urea III. Other degradation products formed along with these are urea, oxalic and formic acids and an unknown pyrimidine. The data already obtained indicate that uracil interacts with ozone in a normal manner to form first a true ozonide as expressed by formula II. This addition product is, however, very unstable and all attempts to isolate it were unsuccessful. In both acetic and formic acid solutions it undergoes decomposition rapidly under the experimental conditions employed, giving as the first product of reaction the new ureide *formyl-glyoxyl-urea* as represented by formula III. This represents the chief product of reaction and is the first member of its type to be described. The corresponding ureide acid, formyloxaluric acid IV, has been described by Gorski,[2] who prepared it by interaction of formylurea with oxalic acid.

The second ureide formed in relative amount is oxaluric acid V, which probably results by oxidation and subsequent hydrolysis of formyl-glyoxyl-urea III. The urea, oxalic acid and formic acid formed in the ozone reaction may all be accounted for as resulting from oxidation and hydrolytic changes of this ureide III. The only positive experimental evidence in favor of the formation of a pyrimidine is the response to a murexide color test. The quantity formed is very small, and thus far we have secured no data which would suggest its constitution. These various transformations of uracil are expressed by the formulas



The observation that oxaluric acid V is *a* product of reaction by ozonization of uracil is of biochemical interest as it introduces new chemical evidence in favor of the assumption that this pyrimidine may be one source of oxaluric acid, which is known to be a product of metabolism

---

[2] Gorski, *Ber.*, *29*, 2046 (1896).

and has been shown to occur in human urine.[3] The source of this ureide in metabolism has generally been attributed to the destructive oxidation of purines or uric acid. At the present time we have very little information regarding the mechanism of molecular degradation when uracil is oxidized and destroyed in body metabolism.[4]

It is our purpose to determine the generality of this type of change by applying the treatment with ozone to a series of derivatives of uracil. The reaction opens up an important and practical procedure for determining the constitution of pyrimidine compounds belonging to the uracil series.

Experimental Part

Preparation of Uracil.—The uracil used in this research was prepared from urea. malic acid, and fuming sulfuric acid in accordance with a modification of the method developed by Davidson and Baudisch,[5] which has been applied in this Laboratory with success by several workers. Four hundred cubic centimeters of 13% fuming sulfuric acid is cooled to 0° and, while the acid is stirred mechanically, 100 g. of malic acid added at such a rate that the temperature of the mixture does not rise above 5°. After the malic acid has been added, the mixture is cooled to 0° and constantly stirred while 100 g. of finely pulverized urea is rapidly added. The temperature rises rapidly to 50° and at 60° there is a vigorous evolution of carbon monoxide. The temperature of the reaction mixture is maintained at 85° for forty-five minutes, then it is cooled and finally poured over 1200 g. of crushed ice. The uracil is precipitated by this treatment and is completely deposited after twenty-four hours. It is purified by crystallization from hot water. The yield averages about 59% of the theoretical quantity.

Interaction of Uracil with Ozone in Glacial Acetic Acid.—Five grams of uracil is suspended in 100 cc. of glacial acetic acid and ozonized oxygen, previously washed with a 5% aqueous solution of sodium hydroxide and finally with concentrated sulfuric acid, is bubbled through the suspension for fourteen to sixteen hours. The uracil slowly dissolves and at the end of the reaction period only a light suspension of crystalline material remains undissolved in the acetic acid. As the reaction approaches completion, the suspended material is tested at fifteen-minute intervals for the presence of uracil by the Wheeler and Johnson[6] method employing bromine water and barium hydroxide. When the characteristic purple precipitate no longer appears after this treatment, the ozone transformation is considered complete. Our methods of separating and identifying the products of this reaction are described below.

Identification of Oxaluric Acid, V.—The reaction product, which was insoluble in the acetic acid after completion of the ozone treatment (above), weighed 0.6 g., and it melted before purification at 183–187° with decomposition. After purification by recrystallization from 95% alcohol, in which it is difficultly soluble, or from glacial acetic acid, it decomposed when heated at 205–215°. It was difficultly soluble in water, but was soluble in alkaline solution and interacted to form insoluble barium and silver salts. Ammonia was evolved when the ureide was warmed in alkaline solution and oxalic acid was shown to be formed by hydrolysis. Urea was also identified in the solution by means

of the Fossc[7] xanthydrol reagent. In fact, the compound agreed in all its properties with those described for oxaluric acid by Biltz and Topp.[8]

Anal. Calcd. for $C_3H_4O_4N_2$: N, 21.21. Found: N, 21.07, 20.91.

The identity of this ureide was further confirmed by the formation of its ethyl ester, which was prepared by digesting the acid in alcohol acidified with sulfuric acid. The ester separated in the form of needles and after purification by crystallization from ether it melted at 177° with decomposition.

Anal. Calcd. for $C_5H_8O_4N_2$: N, 17.50. Found: N, 17.57.

Identification of Formyl-glyoxal-urea, 111.—After separation of the oxaluric acid by filtration (ozone–uracil reaction), the acetic acid was removed by heating at 50°, when we obtained 4.5 g. of a colorless crystalline substance. This was apparently a mixture of several products and all attempts at purification by crystallization from alcohol, chloroform, benzene, ethyl acetate and ether were unsuccessful. By use of hot, glacial acetic acid we succeeded in separating 2.4 g. of a definite crystalline substance which melted constantly at 162°. This was characterized by the following properties: solubility in water, giving a solution which reacted acid to litmus and in 95% alcohol and also dilute potassium carbonate solution; insoluble in ether, benzene and chloroform.

No insoluble barium salt was formed by the action of barium hydroxide, but addition of silver nitrate to an alkaline solution of the compound gave immediately a colorless, flocky precipitate of a silver salt. The warming of a solution of this silver salt in ammoniacal solution led to the production of a bright silver mirror on the walls of the glass receptacle. The silver salt was prepared by precipitation in neutral solution, washed with water, alcohol and ether and finally dried at 80°. This gave on analysis the following results for nitrogen and silver.

Anal. Calcd. for $C_4H_3O_4N_2Ag{\cdot}H_2O$: N, 10.41; Ag, 40.14. Found: N, 10.38; Ag, 39.98.

The compound melting at 162° reduced Fehling's solution immediately on warming and also interacted with Tollens' reagent to form *a* silver mirror, but there was no apparent reaction with Schiff's reagent. Application of the murexide test was negative and it produced no color when introduced into ferric chloride solution, proving that we were not dealing here with formylallanturic acid.[9] The compound was decomposed by digestion with dilute sulfuric acid with formation of formaldehyde and urea. Some of the compound melting at 162° was warmed with dilute nitric acid and the solution then evaporated to dryness. In this residue was easily identified oxalic acid. This exhaustive study of the properties of this substance formed from uracil by the action of ozone led us to conclude that we were dealing with the hitherto unknown acyclic ureide, *viz.*, *formyl-glyoxyl-urea*, 111 The identity of the compound was further established by analysis.

Anal. Calcd. for $C_4H_4O_4N_2$: C, 33.33; H, 2.8; N, 19.44. Found: C, 33.52; H, 3.0; N, 19.37, 19.33.

An attempt to prepare a phenylhydrazone of formyl-glyoxyl-urea was unsuccessful. The ureide interacted with phenylhydrazine in acetic acid solution at ordinary temperature giving a product which melted after purification at 144–145°. It crystallized from alcohol in colorless plates and was identified as formylphenylhydrazine.[10]

Anal. Calcd. for $C_7H_8ON_2$: N, 20.59. Found: N, 20.49.

An attempt to prepare the phenylhydrazone by interaction in absolute alcohol was also unsuccessful. The reaction was applied with 5 cc. of phenylhydrazine, 65 cc. of alcohol and 0.5 *g.* of formyl-glyoxyl-urea. This solution was digested on the steam-bath for three hours, cooled and then diluted with water, when a crystalline substance separated on standing. This was purified by crystallization from absolute alcohol and separated in the form of yellow needles decomposing at 221°. A nitrogen determination by the Dumas method gave a value of 29.5%. In sodium hydroxide solution this dissolved with formation of a deep blue coloration which was discharged by acidification with hydrochloric acid. On adding alkali the blue color was regenerated. Behrend and Grünewald[9] have described a phenylhydrazine derivative of acetylallanturic acid which possesses similar properties. The structure of this compound will be determined and discussed in a later paper.

The acetic acid filtrate from which formyl-glyoxyl-urea was separated by crystallization was examined further for secondary products of ozonization. The possibility of the presence of an ozonide here was eliminated by the fact that no iodine was liberated when the residue obtained after evaporation of the acetic acid was treated with potassium iodide. The presence of oxalic acid and urea was easily detected, and we also observed that this residue gave a pronounced murexide test, indicating the presence of an unknown pyrimidine combination. We were unable, however, to separate a definite pyrimidine combination from this residue.

Formation of Formyl-glyoxyl-urea from Uracil by the Action of Ozone in 85% Formic Acid Solution.—Five grams of uracil was suspended in 100 cc. of 85% formic acid and ozonized oxygen bubbled through the suspension for twenty-three hours. The uracil dissolved and was completely destroyed by action of the ozone. After evaporating the formic acid solution at 50" we obtained a crystalline residue containing urea, oxalic acid and formyl-glyoxyl-urea. Two grams of the latter ureide melting at 162" was obtained by fractional crystallization from glacial acetic acid. This corresponds to a yield of 31% of the theoretical. By ozonization of uracil in glacial acetic acid the yield of this ureide is raised to 38% of the theoretical.

Summary

1. Uracil and ozone interact in glacial acetic acid at ordinary temperature to form chiefly two compounds, *viz.*, formyl-glyoxyl-urea and oxaluric acid.

2. Part of the uracil molecule is completely broken down with formation of urea, oxalic and formic acids.

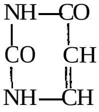
RESEARCHES ON PYRIMIDINES. CXXI. THE ACTION OF OZONE ON SOME DERIVATIVES OF URACIL

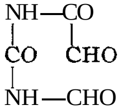
BY TREAT B. JOHNSON AND ROBERT B. FLINT[1]

RECEIVED JANUARY 6, 1931 PUBLISHED MARCH 6, 1931

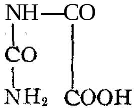
In the previous paper from this Laboratory dealing with pyrimidine chemistry,[2] the authors described the behavior of uracil I toward ozone. It was shown that this pyrimidine cycle can be broken down by the action of ozone without destruction of the ureide structure, and with formation of definite oxidation products characteristic of the constitution of uracil. The characteristic ureides produced by ozonization were identified as oxaluric acid III and formyl-glyoxyl-urea II. Besides these two ureides practically the only other products of reaction were urea, formic and oxalic acids. The definite course of the reaction, its ease of application, and the character of the products formed by decomposition of the pyrimidine were so promising that it seemed desirable to study the action of ozone on other derivatives of uracil. Any transformations of this character, which will serve for determination of the constitution of uracil derivatives, should prove of immediate practical value in many of our problems dealing with cell chemistry, and now calling for solution. In this paper we describe new applications of this reaction, and report on the action of ozone on 4-methyluracil, 4-phenyluracil, thymine, 5-bromouracil, 5-nitrouracil and 1,3-dimethyl-5-bromouracil.



I



II



III

As in the case of uracil, all these pyrimidines interact with ozone in glacial acetic acid at ordinary temperature with destruction of the pyrimidine ring, but without complete degradation of the molecule. The ureide configuration of the original pyrimidine is preserved in some form in every case. As already known, 4-methyluracil is attacked by potassium permanganate in acid solution with formation of trihydroxydihydromethyluracil which Behrend and Osten[3] showed is transformed by more intensive oxidation into acetyloxaluric acid V and finally acetylurea and oxalic acid. With ozone 4-methyluracil reacts also with ring cleavage giving a 67% yield of acetyl-glyoxyl-urea represented by formula VI.

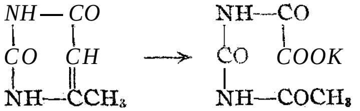
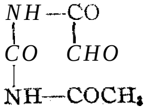
[3] Behrend and Osten, *Ann*, 343, 133 (1905)

No evidence was obtained of the formation of oxaluric acid, as was observed in the case of uracil, or any acetyl-oxaluric acid V.



IV V



VI

4-Phenyluracil reacts with ozone to give the corresponding benzoylglyoxylurea VII, while thymine underwent a more intensive degradation under similar experimental conditions, giving an excellent yield of formylurea VIII. In this respect the thymine degradation corresponds to that of 4-methyluracil, which has been shown to break down by intensive oxidation with potassium permanganate, giving acetyl-urea. Pyruvic acid, $CH_3COCOOH$, if formed in the ozonization of thymine, was apparently destroyed by oxidation, as delicate tests for this ketone acid did not reveal its presence in the reaction mixture. Urea was formed to some extent in all cases examined and was easily detected by means of Fosse's reagent, "xanthydrol."[4]

Especially interesting was the behavior of 5-bromouracil, 5-nitrouracil, and 1,3-dimethyl-5-bromouracil toward ozone. The only one of these three derivatives which favored the formation of an acylic ureide was 1,3-dimethyl-5-bromouracil. This gave an oxidation product having the composition and properties of dimethyloxaluric acid, IX. We did not succeed in detecting in the reaction mixture any cholestrophan or dimethyl-parabanic acid. The corresponding monomethyl-oxaluric acid has been shown to be formed by oxidation of α- and β-dimethyluracil with potassium permanganate.[6] 5-Bromouracil, on the other hand, reacted with ozone under similar conditions giving an excellent yield of parabanic acid, while 5-nitrouracil was decomposed to form urea, oxalic acid and the two ureides, parabanic acid and oxaluric acid.

Ring closure to form parabanic acid in the ozonization of 5-bromouracil and 5-nitrouracil represents only the end of a series of reactions. After removal of this cycle from the reaction products, both residues responded to qualitative tests indicating the presence of formyl-oxaluric acid. Formic acid, urea and oxalic acid were identified after hydrolysis, but we were unable to separate the formyl-oxaluric acid in either case.

[5] Behrend and Dietrich, Ann., 309,271 (1899).

Experimental Part

In studying the action of ozone on the pyrimidines incorporated in this research we have operated according to a general procedure, as follows. A definite quantity of the respective pyrimidine is suspended in a known volume of glacial acetic acid and dry ozonized oxygen is then bubbled through the suspension at ordinary temperature until the transformation of the respective pyrimidine is complete. In the majority of cases solution of the pyrimidine in the acetic acid takes place very slowly, and it is necessary to pass ozone through the acid solution for several hours before the reaction is brought to completion. Acetic acid has proved to be the best solvent for our work; no products of reaction are formed which discolor the acid, and also no resinous substances are produced which interfere with the identification of the characteristic products of reaction.

The Action of Ozone on 4-Methyluracil, IV.—The methyluracil which was used in this research was made according to the directions of Biltz and Heyn[6] by condensing ethyl acetoacetate with urea in the presence of hydrochloric acid. The proportions used during ozonization were 5 g. of the pyrimidine and 100 cc. of glacial acetic acid. The pyrimidine suspended in the acetic acid slowly dissolves during the ozone treatment, and at the end of fourteen hours the reaction is complete and a clear colorless solution is obtained. On allowing this solution to evaporate in a current of air at 50° until the acetic acid was removed, we obtained a crystalline residue which weighed 6.0 g. Purification was effected by crystallization from absolute alcohol, when we succeeded in separating 4.2 g. of a crystalline substance which melted at 150°. Repeated crystallizations failed to raise this melting point. This was identified as ***acetyl-glyoxyl-urea*** and the yield obtained corresponded to 67% of the theoretical.

Anal. Calcd. for $C_5H_6O_4N_2$: N, 17.72. Found: N, 17.40, 17.52, 17.44.

Acetyl-glyoxyl-urea is soluble in water and moderately soluble in 95% alcohol and glacial acetic acid. It is insoluble in ether, benzene, chloroform and ethyl acetate. An aqueous solution of the ureide gives no precipitate of calcium oxalate when warmed in ammoniacal solution with calcium chloride. The ureide reduces Fehling's solution immediately on warming and reacts with Tollens' reagent to form a silver mirror and gives no blue color with ferric chloride. Five-tenths of a gram of the ureide was warmed in dilute hydrochloric acid solution, when it was completely decomposed with formation of urea. The latter was identified by precipitation with xanthydrol according to Fosse's[4] method. The same experiment was repeated, but with the addition of a small amount of nitric acid. Under these conditions complete hydrolysis took place with formation of urea and also oxalic acid, which was identified by precipitation as calcium oxalate.

The alcohol filtrate from which acetyl-glyoxyl-urea was separated by crystallization was found to contain free urea and oxalic acid. We obtained no evidence in this case of the formation of oxaluric acid, as was observed when uracil was treated with ozone.[2]

The Action of Ozone on 4-Phenyluracil.—4-Phenyluracil was synthesized according to the directions of Johnson and Hemingway[7] by condensation of thiourea with ethyl benzoylacetate, when 2-thio-4-phenyl-6-oxypyrimidine is formed. Desulfurization of the latter pyrimidine by the action of chloroacetic acid yields quantitatively the 4-phenyluracil melting at 270°. The proportions used for ozonization were 5 g. of the

---

[6] Biltz and Heyn, **Ann.**, 413, 109 (1917).

[7] Johnson and Hemingway, THIS JOURNAL, 37, **378** (1915)

pyrimidine and 100 cc. of glacial acetic acid. The pyrimidine suspended in the acetic acid interacts readily with ozone and at the end of seven hours a colorless solution was obtained and the pyrimidine ring was completely destroyed. The acetic acid was then removed by evaporation in a current of air at 50°, when we obtained a sirupy residue which we again dissolved in 10 cc. of glacial acetic acid, and allowed to stand in an ice chest for about twelve hours. Two grams of a crystalline compound separated in the form of prisms which melted at 168°. This was identified as benzoyl-glyoxyl-urea. This ureide is insoluble in cold water, chloroform, benzene and ether, and soluble in hot water, alcohol and ethyl acetate.

Anal. Calcd. for $C_{10}H_8O_4N_2$: N, 12.73 Found: N, 12.80, 12.61.

This ureide reacted in a normal manner with Fehling's and Tollens' solutions, showing the presence of an aldehyde group in the compound. No oxalic acid was produced by hydrolysis with hydrochloric acid, but benzoic acid was easily identified, and separated on cooling in colorless crystals melting at 122°. Urea was separated and identified by means of Fosse's reagent (xanthydrol). When nitric acid was added to the hydrochloric acid and the ureide then subjected to hydrolysis, oxalic acid was formed as a product of reaction. This was identified by precipitation as calcium oxalate.

Action of Phenylhydrazine on Benzoyl-glyoxyl-urea.—One-half gram of the ureide was dissolved in a mixture of 5 cc. of phenylhydrazine, 5 cc. of 50% acetic acid and 15 cc. of water. There was a reaction at ordinary temperature and on standing a crystalline substance separated. After purification by crystallization from alcohol, this melted at 168" and was identified as benzoylphenylhydrazine.[8] A mixture of this substance and benzoylphenylhydrazine prepared according to Fischer's directions melted at the same temperature.

Anal. Calcd. for $C_{13}H_{12}ON_2$: N, 13.21. Found: N, 13.22.

After separation of the benzoylphenylhydrazine, the reaction mixture was allowed to stand at room temperature for several days, when a yellow substance separated which was purified by crystallization from boiling absolute alcohol. It separated, on cooling, in the form of yellow needles which melted at 221°. This compound was found to be identical with the substance obtained by interaction of phenylhydrazine with formyl-glyoxyl-urea,[2] and also with acetyl-glyoxyl-urea described above. No change in the melting point (221°) was produced when mixtures of the three different preparations were heated in capillary tubes.

The Action of Ozone on Thymine.—The proportions used for the ozone reaction were 3.5 g. of the pyrimidine suspended in 50 cc. of glacial acetic acid. The thymine was attacked immediately by the ozone and after bubbling ozonized oxygen through the suspension for five hours, the thymine had dissolved and was completely decomposed. The acetic acid was then evaporated as usual in a stream of air at 50°, when we obtained 2.6 g. of a semi-crystalline residue. From this was separated by crystallization from absolute alcohol 1.0 g. of formylurea, corresponding to a yield of 40% of the theoretical. It melted at 168°.[9] When this ureide was dissolved in dilute sulfuric acid, urea was formed, and when the vapor evolved on distillation was conducted into a solution of silver nitrate, there was an immediate reduction with formation of metallic silver. Urea was also produced by digesting the ureide in aqueous solution.

Anal. Calcd. for $C_2H_4O_2N_2$: N, 31.82. Found: N, 31.62, 31.73.

The alcohol filtrates obtained after purification of formylurea were combined and evaporated to dryness. In this residue was detected urea by precipitation with xan-

---

[8] Fischer, *Ann.*, 190, 125 (1878).

[9] Gorski, *Ber.*, 29, 2046 (1896).

thydrol. Baudisch's[10] test for pyruvic acid failed to reveal the presence of this ketone acid, indicating that it had been destroyed by oxidation.

Action of Ozone on **5-Bromouracil.**—Ozone reacted immediately with bromouracil when bubbled through a suspension of 5.0 g. of the pyrimidine in 100 cc. of glacial acetic acid. Bromine was liberated in this reaction and at the end of eleven hours the bromouracil was completely destroyed. After evaporation of the acetic acid there was obtained 3.6 g. of a crystalline residue from which we obtained by crystallization from acetic acid 1.2 g. of parabanic acid melting with decomposition at 238 to 244°.

Anal. Calcd. for $C_3H_2O_3N_2$: N, 24.56. Found: N, 24.55, 24.42.

In the filtrate left after crystallization of the parabanic acid was detected urea and oxalic acid. We did not succeed in identifying formylurea or oxaluric acid as products of the reaction.

Action of Ozone on **5-Nitrouracil.**—5-Nitrouracil was prepared according to the directions of Johnson and Matsuo[11] and treated with ozone according to the technique already described. The action of ozone was very slow and it required twenty-eight hours before the complete destruction of 3 g. of nitrouracil was accomplished. Evaporation of the acetic acid gave 2.3 g. of a crystalline residue which yielded after washing with alcohol and water 0.5 g. of oxaluric acid decomposing at 205–215°.

Anal. Calcd. for $C_3H_4O_4N_2$: N, 21.21. Found: N, 21.10.

From the alcohol extract was separated by crystallization 1.3 g. of a crystalline substance which yielded by further purification 1.0 g. of parabanic acid melting at 238–242°. When mixed with pure synthetic parabanic acid no change in melting point was observed.

Anal. Calcd. for $C_3H_2O_3N_2$: N, 24.56. Found: N, 24.48.

Urea was also detected in the final residues by means of the Fosse reagent (xanthydrol).

The Action of Ozone on **1,3-Dimethyl-5-bromouracil.**—This bromine derivative of 1,3-dimethyluracil is easily obtained by direct bromination of the dimethylppimidine in aqueous solution, and was obtained in the form of prisms melting at 186°. Johnson and Clapp[12] reported a melting point of 181–182°. Ownization of this pyrimidine (2.8 g.) was not complete under twelve to thirteen hours' treatment. The liberation of bromine was noticeable during the change and after evaporation of the acetic acid a residue of 1.4 g. was obtained. The only products identified were urea, oxalic acid and the hitherto unknown ureide *dimethyl-oxaluric acid.* This was purified by crystallization from absolute alcohol and melted at 124–125°. The acid is soluble in water and glacial acetic acid.

Anal. Calcd. for $C_5H_8O_4N_2$: N, 17.50. Found: N, 17.55.

Summary

1. The behavior of 4-methyluracil, 4-phenyluracil, thymine, 5-bromouracil, 5-nitrouracil and 1,3-dimethyl-5-bromouracil toward ozone has been investigated.

2. In every case the pyrimidine ring is destroyed with formation of characteristic ureide constructions and simple oxidation products. In no case is the urea configuration of the respective pyrimidines destroyed by the ozone treatment.

---

[10] Baudisch, THIS JOURNAL, 45, 2978 (1923).

[11] Johnson and Matsuo, *ibid.*, 41, 783 (1919).

[12] Johnson and Clapp, *J. Biol. Chem.*, **5**, 49 (1909).

3. The application of ozonization makes possible an improved technique for determining the structure of uracil compounds. The advantages gained experimentally become apparent when one is called upon to separate and identify the products of oxidation.

4. The urea configuration of the pyrimidine nucleus is not destroyed by the action of ozone.

THE EFFECT OF SUBSTITUENTS ON CERTAIN PHYSICAL PROPERTIES OF BENZENE PICRATE[1]

BY O. L. BARIL AND E. S. HAUBER

RECEIVED JANUARY 6, 1931 PUBLISHED MARCH 6, 1931

Only a few of the aromatic hydrocarbons may be identified from their picrates. The reason for this is that very few aromatic hydrocarbons form picrates which are stable and can be purified by crystallization from suitable solvents. Most of the aromatic hydrocarbons form picrates which are decomposed by solvents or on standing in air.

The influence of substituents on the color of benzene picrate was studied by Franzen.[2] From a study of the absorption spectrum of a mixture of picric acid and a number of aromatic hydrocarbons and their halogen derivatives, he found that an increase in the number of alkyl groups in general causes an increase in the depth of the color produced. He also found that m-derivatives are the brightest, and that *p*-derivatives are the darkest.

Compounds of picric acid with aromatic hydrocarbons were studied by Efrenov[3] by means of thermal analysis of the binary mixtures. He found that molecular quantities of the substances usually reacted, but diphenyl, diphenylmethane and triphenylmethane do not give picrates.

Kendall[4] explains the existence of the picrates by the formation of oxonium salts. The existence and stability of the addition compounds were determined from the freezing-point curve. The melting point was determined by distectic points on the fusion curve, *i.* e., the temperature at which crystallization begins. The molecular composition of the picrates was found to be of the general type 1:1.

In our study with picrates, we have prepared the picrates of several

---

[1] Some of the experimental results described in this paper are taken from a thesis submitted to the Faculty of Holy Cross College by E. S. Hauber in partial fulfilment of the requirements for the degree of Master of Science.

aromatic hydrocarbons, and have taken a melting point of the picrate formed before decomposition took place. The colors of the picrates in the same series were compared in an effort to determine whether or not the substitution of different groups on the benzene ring had any effect on the color of the picrate. In preparing the picrates, a method was used which may be applied to the preparation of picrates of all aromatic hydrocarbons. Wherever possible, the color and the melting points of these picrates were compared with those which could be prepared and purified by crystallization from suitable solvents.

Experimental

All temperatures given are uncorrected.

Picric acid containing 3% of water was dried in an oven at 100° for six hours. All liquid hydrocarbons were dried over anhydrous calcium chloride for twenty-four hours and were freshly distilled. Solid hydrocarbons were crystallized from suitable solvents until they gave a sharp melting point. Equimolecular quantities of the hydrocarbon and picric acid were heated until fusion took place. The melting point of the addition compound was the temperature at which crystallization began, which is in reality the freezing point. The method for the determination of the freezing point was that of Beckmann. A large test-tube containing the two constituents was placed under a reflux condenser. The test-tube was surrounded by a larger test-tube immersed in a bath of concentrated sulfuric acid. The temperature of the sulfuric acid bath was cooled, after fusion took place, at the rate of about one-half a degree per minute below 100°, and at about one to two degrees per minute above 100°. Three determinations were made of each picrate. Wherever possible, these picrates were compared in color and melting point to picrates prepared according to Mulliken.[5] Many picrates prepared could not be found in the literature.

General Procedure.—Ten millimoles of the hydrocarbon and ten millimoles of picric acid were intimately mixed in a test-tube and placed under a reflux condenser. A thermometer was inserted in the mixture. The mixture was gently heated in the sulfuric acid bath until fusion took place, and the bath was then cooled slowly. The freezing point of the picrate was taken on solidification of the mixture. The same mixture was liquefied and the freezing point taken three times in succession in order to check on compound formation.

Aliphatic Derivatives **of** Benzene.—The picrates of the aliphatic derivatives of benzene were prepared from equimolecular amounts of the hydrocarbon and picric acid according to the Beckmann method.

[a] Schultz, Wurth, *Chem. Centr.* I, ***1443*** (1905). [b] This stable picrate crystallizes from boiling alcohol [A. Tohl, ***Ber.***, 21, 905 (1888)]. [c] This stable picrate crystallizes from boiling alcohol [Jacobson, ***ibid.***, 20, 898 (1887)]. [d] This picrate loses hexamethylbenzene at 100–110°. Alcohol removes picric acid. Friedel and Crafts [*Ann. chim.*, [6] **10**, 417 (1887)].

The picrates in Table I are all unstable, decomposing in air, excepting the tetra-, penta- and hexamethylbenzene picrates, which decompose slightly above their melting points. The position of the methyl groups in dimethylbenzene does not have any appreciable effect on the color of the picrates. Separation of the methyl groups in trimethylbenzene raises the melting point of the picrate.

The isomers of the polymethylbenzenes such as cumene and *p*-cymene form no picrates, as all attempts to prepare them failed.

Benzene derivatives containing a double bond in the side chain such as styrene and indene form very explosive picrates.

Hydroxy Derivatives of Benzene.—The hydroxy derivatives of benzene yield picrates which crystallize into beautiful yellow to red crystals from a deep red solution. These equimolecular compounds are highly dissociated on fusion, as is evidenced by the flatness of the maximum on the freezing point curve.[7]

The picrates of the hydroxy derivatives of benzene were prepared from equimolecular amounts of the hydrocarbon and picric acid according to the Beckmann method. All formed needle crystals.

Naphthalene and Anthracene Derivatives.—The picrates of the naphthalene and anthracene derivatives were prepared from equimolecular

[a] This picrate crystallizes from ethyl acetate in yellow prisms and plates, from ethyl ether in yellow crystals, and from ethyl alcohol in monoclinic prisms and needles. [b] Flat needles from ethyl alcohol. [c] Red needles from alcohol or ether. Decomposes on fusion at 92.8". [d] This picrate crystallizes from ethyl ether in red-brown prisms, and it is unstable.

amounts of the hydrocarbon and picric acid according to the Beckmann method. The picrates were also prepared from a solution of the hydrocarbon and picric acid in boiling alcohol, and their physical properties were compared with the physical properties of the picrates prepared according to the Beckmann method. The colors and melting points of the corresponding picrates were found to be identical.

Although the melting points of the β-naphthalene derivatives are higher than those of the α-naphthalene derivatives, the β-naphthalene picrates have a lower melting point than the corresponding a-naphthalene picrates.

Summary

The addition of hydroxyl groups to benzene picrate lowers the melting point and deepens the color of the picrate formed. The addition of methyl groups to benzene picrate raises the melting point of the product and deepens the color of the picrate less than the hydroxyl group. The addition of methyl groups to a side chain of benzene picrate gradually increases the melting point and deepens the color of the picrate, and this increase is more rapid than when a corresponding number of methyl groups are substituted in the ring. The symmetrical trihydroxy- and trimethylbenzene picrates are the darkest, and the color of the picrates becomes lighter as we approach the 1,2,3-derivatives. The same deepening in color was obtained with the methyl derivatives of naphthalene. The β-naphthalene picrates possess lower melting points than the α-naphthalene picrates. Unsaturation in the side chain yields a very unstable picrate. The heavier the molecule the deeper the color of the picrate.

THE CATALYTIC HYDROGENATION OF ORGANIC COMPOUNDS OVER COPPER CHROMITE

BY HOMER ADKINS AND RALPH CONNOR

RECEIVED JANUARY 9, 1931 PUBLISHED MARCH 6, 1931

Nickel has been the only base metal catalyst which has offered much promise for the hydrogenation of pure organic compounds in the liquid phase, although several oxides and mixtures of oxides have been used for the hydrogenation of carbon monoxide in the gas phase at temperatures above 300°. In connection with a study of the action of some of these oxides in inducing the condensation of acetaldehyde at 360°,[1] it seemed advisable to investigate them with respect to their efficiency for catalyzing hydrogenations in the liquid phase. This latter study has resulted in the discovery that a combination of copper and chromium (oxides) is in many

---

[1] **Adkins,** Kinsey and **Folkers,** *Ind. Eng. Chem.,* **22,** 1046 **(1930).**

ways very much superior to any catalyst known to the authors for the hydrogenation of several types of organic compounds.

The catalyst used in this investigation was prepared by decomposing copper ammonium chromate. This procedure is described for the preparation of catalysts containing a "hydrogenating metal" and chromium by Lazier.[2] The examples cited in the patents involve the use of the catalysts zinc and manganese chromite for the reaction of carbon monoxide and hydrogen in the vapor phase at 300 atmospheres and 400° to form methanol and higher alcohols.

Preparation of Catalyst.—Ammonium hydroxide was added to a solution of 126 g. (0.5 mole) of ammonium dichromate (Mallinckrodt) in 500 ml. of water until the color of the solution changed from orange to yellow. The volume of the solution was now 650 ml. The solution was allowed to come to room temperature and a solution of 241.6 g. (1.0 mole) of cupric nitrate trihydrate (Mallinckrodt) in 300 ml. of water was added with stirring. The red-brown precipitate was filtered with suction and dried overnight in an oven at 100–110°. It was then finely powdered, transferred to a porcelain casserole, and decomposed by heating the casserole in the flame of a Bunsen burner. After decomposition had begun, the heat of reaction was sufficient almost completely to decompose the chromate. When spontaneous decomposition had ceased, the casserole was heated with the free flame until fumes ceased to be evolved and the contents was black and so finely powdered as to be almost like a liquid. During this heating, care was taken to keep the material well stirred and to rotate the flame in order to avoid local superheating. The product was allowed to cool and then suspended in 200 ml. of a 10% solution of acetic acid. The suspension was filtered with suction, washed thoroughly with water, dried for twelve hours in an oven at 100–110°, and finely powdered. The yield of catalyst was 113 g.

Experimental Results.—There is recorded in Table I a summary of the data obtained in hydrogenating a representative list of 21 organic compounds. There are given in Columns 1, 2 and 3 the names and amounts of compound subjected to the action of hydrogen and the weight of catalyst. In five or six cases the amount of catalyst used (4 to 7 g.) is considerably in excess of that which it was necessary to use. These excessive amounts were used before the very great potency of the catalyst was realized. The temperature at which the temperature controller was set is given in the fourth column of the table. In the case of a majority of the compounds hydrogenation was so rapid and the reaction so exothermic that the temperature was for a few minutes as much as 15° above the recorded temperature. The time, if any, required for the hydrogenation after the contents of the bomb reached the designated temperature is given in column 5. The pressure of hydrogen during the hydrogenation was from 100 to 150 atmospheres. The yields of products given in the last column represent the amount of the indicated product when allowance was made for the mechanical losses in handling the reaction mixture. That is, a

N-Benzalaniline	.47	2	175	0.4	Phenylbenzylamine	100

100% yield means that no other product was formed in detectable amounts and that none of the original compound remained unhydrogenated. It has been demonstrated repeatedly that the mechanical losses can be reduced to 2% or less in this type of hydrogenation if precautions are taken to wash out the bomb, liner and filtered catalyst with a solvent.

Only five of the compounds referred to in Table I failed to give such quantitative hydrogenations. The yield of ethyl β-hydroxybutyrate was low (77%) when ethanol was not used as a solvent because of the formation of 16% of ethyl β-(β′-hydroxybutyryloxy)-butyrate and 7% of dehydroacetic acid.[3] A hydrogenation of the acetoacetic ester in ethanol resulted in a quantitative formation of the corresponding β-hydroxy ester. Eight per cent. of toluene was formed in the hydrogenation of benzaldehyde, while there were some tar-like condensation products in the hydrogenation of *m*-nitrobenzene. Pyridine was completely hydrogenated, as indicated by the amount of hydrogen absorbed, but only 50% of it was recovered as piperidine, there being an equal amount of a condensation product b. p. 143.5–147.5° (3.5 mm.). Furfuryl alcohol gave only a 70% yield of pen-

[3] *Cf.* Adkins, Connor and Cramer, THIS JOURNAL, 52, 5192 (1930).

tanediols, as there was a 10% yield of amyl alcohol along with some methyltetrahydrofuran and tetrahydrofurfuryl alcohol. The 70% yield of pentanediols was composed of 4 parts of the 1,2-glycol and 3 parts of the 1,5-glycol. Toluene, phenol, aniline, and furoic acid could not be hydrogenated under the conditions described in this paper for the hydrogenation of compounds referred to in Table I.

Discussion of Experimental Results.--Some of the characteristics of copper chromite in the catalysis of hydrogenation in the liquid phase may be described as follows. Numerous aldehydes and ketones may be quantitatively and rapidly hydrogenated to the corresponding alcohols. This holds true not only for aliphatic carbonyl compounds but also for aromatic ones, and for keto esters and a keto alcohol. A carbinol group adjacent to a benzenoid ring may be completely reduced. Nitro groups may be quantitatively converted to primary amines without the simultaneous formation of secondary amines. An alkene linkage in a hydrocarbon as well as in an acid or ketone may be hydrogenated without otherwise modifying the organic compound. Pyridinoid rings and carbon to nitrogen double bonds as in anils may be readily hydrogenated. The furanoid ring in furyl alcohol may be readily broken with the formation of 1,2- and 1,5-pentanediols in good yields. The copper chromite catalyst is not active toward cyanides or toward benzenoid nuclei and thus offers a means for the selective hydrogenation of compounds containing these groups which are so readily reducible over nickel catalysts.

The copper chromite catalyst possesses certain advantages over nickel catalysts. It is not nearly so sensitive as nickel to sulfur or halogen containing impurities in the compound to be hydrogenated. For example, the pinacolone, benzophenone, acetophenone and ethyl α-methyl-β-ketovalerate used for the hydrogenations referred to in Table I were of so poor a quality that they could not be hydrogenated over nickel. Its lesser sensitivity toward deactivation probably accounts for the fact that it is much more active after it has begun to act than is nickel despite the fact that nickel is active at lower temperatures. No special apparatus such as a reduction furnace is needed and the catalyst need not be freshly prepared before use. The catalyst ready for use does not change on standing in contact with air or moisture. In fact, it apparently need not be treated with any more care than would be accorded to such a reagent as sodium chloride. Less labor is involved in its preparation and smaller quantities may be used for reductions than is the case with the nickel catalyst. A sample of the catalyst may be used repeatedly, that is to say, it is not rapidly deactivated during use. The copper chromite catalyst is very much less active than is nickel toward carbinol groups adjacent to benzenoid rings so that it is more useful than nickel for the conversion of carbonyl groups adjacent to such a ring to the corresponding alcohol.

The rate of hydrogenation of acetone over copper chromite is very much more rapid at higher pressures. With an average pressure of 35 atmospheres the hydrogenation of 1.73 moles with 1 g. of catalyst had proceeded to the extent of only 17% in thirty minutes, while at a pressure of 148 atmospheres 60% of the acetone was hydrogenated, while at 212 atmospheres the reaction was 95% complete in the same length of time. At the end of one hour the percentage of hydrogenation was 22, 92 and 100% for the three pressures given above. The rate of hydrogenation at the lowest pressure was practically a linear function of the time.

Zinc chromite has also been used as a catalyst for hydrogenation but it is much less active than copper chromite and has been found to catalyze condensation. For example, 58 g. of acetone with zinc chromite required a temperature of 200° for a reasonable rate of hydrogenation (five and one-half hours) with 7.5 g. of catalyst and there was found almost one half as much mesityl oxide as propanol-2. Similarly, seven hours did not suffice far the complete hydrogenation of 75 g. of benzaldehyde and a condensation product, benzyl benzoate, was formed in considerable amount.

Summary

A new catalyst (copper chromite) has been tested in the hydrogenation of a group of twenty-one organic compounds in the liquid state. It has been shown to be quite superior in several respects to any catalyst hitherto used.

MADISON, WISCONSIN

[A COMMUNICATION FROM THR LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

THE CATALYTIC HYDROGENATION OF ESTERS TO ALCOHOLS

BY HOMER ADKINS AND KARL FOLKERS

RECEIVED JANUARY 9, 1931 PUBLISHED MARCH 6, 1931

The only general method which has been used for the reduction of esters to the corresponding primary alcohols has been that involving the use of sodium and alcohol. This process was originated by Bouveault and Blanc[1] and in its various modifications has been used in the transformation of a large variety of acids, through their esters, to the corresponding primary alcohols. This reaction, however, leaves much to be desired in many cases because of low yields, difficulties of operation, and undesirable side reactions. In view of the importance of this reaction, a search for a catalyst and experimental conditions under which the reduction could be brought about by the use of hydrogen has been in progress for some time in this Laboratory. Recently this search has been successful and a method

[1] Bouveault and Blanc, *Bull. soc. chim.*, [3] 31,668 (1904).

is now available whereby various types of esters may be directly hydrogenated, as indicated in Equation 1, to the corresponding alcohols in excellent yields.

$$RCOOC_2H_5 + 2H_2 = RCH_2OH + C_2H_5OH \qquad (1)$$

The experimental methods and apparatus used in this study were the same as those previously described.[2] The catalyst, "copper chromite," was prepared as described in the preceding paper.[3]

The data on the hydrogenation of seven esters are recorded in Table I. The hydrogen pressure during the hydrogenations approximated 220 atmospheres and the temperature was 250°. The products from all the hydrogenations were subjected to fractional distillation through a Widmer column in order to separate the desired alcohol from the accompanying ethanol. In the case of ethyl valerate and ethyl cinnamate there was 1.4 and 4.5% of unreduced ester in the respective reaction mixture after hydrogenation, but in no other case was there **any** residual ester. The hydrogen absorption, as measured in each case, was from 0.03 to 0.07 mole of hydrogen above that required for the hydrogenation of the ester. This discrepancy was probably due to the diffusion of hydrogen through the walls of the bomb. The yields of alcohols given are those actually obtained, having the indicated boiling or melting point, except in the case of n-amyl alcohol, where two applications of catalyst were necessary and there was a mechanical loss. Allowance was made for the weight of product so lost in calculating the yield given in the table for this alcohol.

TABLE I

HYDROGENATION OF ESTERS

Ester		Catalyst,	Time,		
Name	Mole	g.	hrs.	Yield, %	Alcohol
Ethyl laurate	0 13	3	1 8	97 5	Lauryl (m. p. 24°)
Ethyl myristate	15	5	2 0	98 5	Myristyl (m. p. 37.5–38°)
Ethyl valerate	27	5	13 0	(94 1)	*n*-Amyl (b. p. 135–136.5°)
Ethyl cinnamate	.21	3	9	83 1	Phenylpropyl (b. p. 111–12, 8 mm.)
Ethyl trimethylacetate	23	5	1 5	88 3	*Tert.*-butylcarbinol (b. p. 111–111 5, 738 mm.)
Ethyl succinate	44	7	6 5	80 5	Tetramethyleneglycol (b. p. 106, 3 5 mm.)
Ethyl 2,2-dimethyl-3-hydroxybutyrate	.21	4	0.1	98.0	Isobutyl (b. p. 106–107.5°)

It seems unnecessary to add anything to the results given in the table for the seven esters except to point out that ethyl 2,2-dimethyl-3-hydroxybutyrate during hydrogenation underwent cleavage between the 2 and 3

---

[2] Adkins and Cramer, THIS JOURNAL, 52, 4349 (1930).

[3] Adkins and Connor, *ibid.*, 53, 1091 (1931).

carbon atoms with the formation of two molecules of ethyl and one molecule of isobutyl alcohol as shown in Equation 2.

$$CH_3CHOHC(CH_3)_2COOC_2H_5 + 3H_2 = 2CH_3CH_2OH + (CH_3)_2CHCH_2OH \qquad (2)$$

Unsuccessful attempts were made to hydrogenate malonic and phenylacetic esters. Both of these esters reduced the catalyst so that it was inactive for the hydrogenation of esters. It is hoped that work now in progress will make it feasible to reduce such esters.

Other catalysts for the hydrogenation of esters have been used in this Laboratory but none of them have proved as effective as copper chromite. For example, the nickel catalyst obtained by reducing nickel chromite catalyzed the hydrogenation of ethyl laurate to the extent of only 40% after seven hours at 250°.

Summary

Ethyl laurate, myristate, valerate, cinnamate, trimethylacetate and succinate have been hydrogenated over a copper chromite catalyst with the formation of the corresponding alcohols in yields of from 80 to 98%. The carbethoxy group in 2,2-dimethyl-3-hydroxybutyrate was hydrogenated to a carbinol group, and in addition the molecule underwent cleavage between the 2 and **3** carbon atoms.

STUDIES ON a-CAMPHOR DERIVATIVES. II. THE IDENTITY OF DIHYDRO-TERESANTALIC ACID WITH 7-π-APOCAMPHAN-CARBOXYLIC ACID

BY TORSTEN HASSELSTRÖM

RECEIVED JANUARY 9, 1931 PUBLISHED MARCH 6, 1931

In a previous paper the complete synthesis of 7-T-apocamphancarboxylic acid has been reported.[1] The present investigation was undertaken in order to prove the identity of this acid with dihydro-teresantalic acid. The preparation of dihydro-teresantalic acid itself was accomplished by new methods which furnish further evidence of the structure of the π-camphor derivatives.

By adding hydrogen chloride to teresantalic acid the trimethylene ring is opened and chlorodihydro-teresantalic acid formed.[2] This action of hydrogen chloride, however, does not yield a homogeneous product.[3] Rupe and Tomi[4] have investigated the action of hydrogen chloride on the methyl ester of teresantalic acid and found that two different chlorodi-

---

[1] Hasselstrom, *Ann. **Acad.** Fenn., 30, 12* (1929).

[2] Muller, ***Arch.** Pharm.,* 238, 366 (1900).

[3] Semmler and Bartelt, *Ber., 40,* 3140 (1907).

[4] Rupe and Tomi, *ibid.,* 49, 2563 (1916).

hydro-teresantalic methyl esters were formed; namely, a labile liquid form which easily split off hydrogen chloride, and a more stable solid form which could be distilled without decomposition. The removal of hydrogen chloride from both forms gives the methyl ester of iso-teresantalic acid. Thus iso-teresantalic acid and teresantalic acid are stereoisomeric compounds.

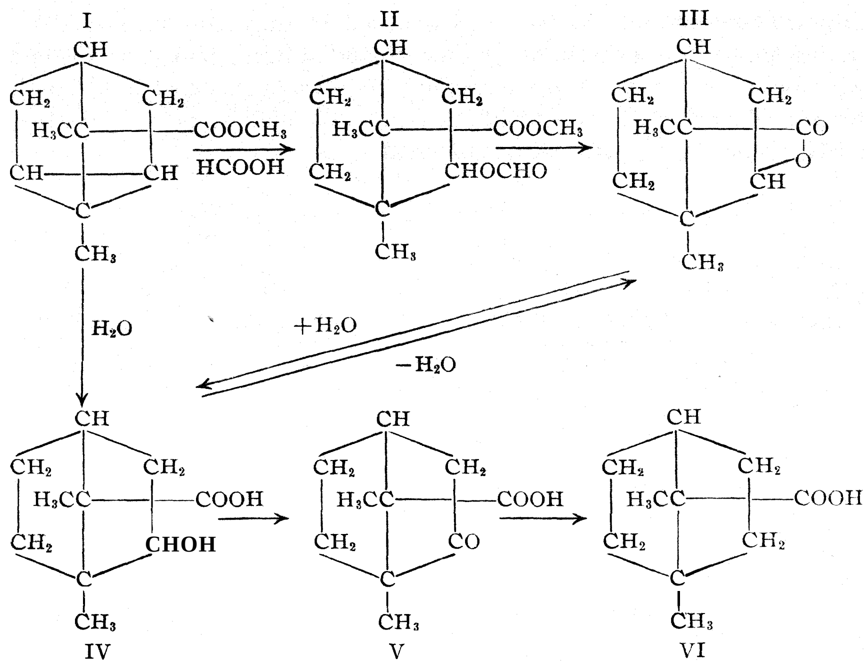
By the action of dilute alkali on chlorodihydro-teresantalic acid, Muller[2] obtained a lactone, which Semmler and Bartelt[5] later converted into the corresponding hydroxy acid and glycol. The action of formic acid on teresantalic acid results in the partial formation of a lactone, which is not identical with Muller's previously prepared lactone. Semmler and Bartelt explained the formation of their lactone by the addition and splitting off of formic acid and suggested that the lactone formed does not have the carboxyl group located in the bridge but in the ring. In order to obtain further data on this lactone formation, the preparation of dihydro-teresantalic acid was first accomplished from Semmler and Bartelt's lactone.

The teresantalic methyl ester (I) was used as starting material, instead of the free acid. This was done in order to prevent, if possible, the formation of the formate of π-norborneol. This reaction resulted in a good yield of the lactone of 2-hydroxy-7-n-apocamphan-carboxylic acid (111), from which the hydroxy acid (IV) was 'prepared by saponification with alkali. The melting points of the lactone and the hydroxy acid corresponded with those given by Semmler and Bartelt.[5] By oxidation with potassium permanganate in alkaline solution an optically active keto acid (V) was obtained, the semicarbazone of which, when treated according to the method of Wolff,[6] gave a good yield of nearly optically inactive dihydro-teresantalic acid (VI). Furthermore, the dihydro-teresantalic acid had the same melting point as the synthetically prepared 7-s-apocamphan-carboxylic acid[1] and did not give a depression by the mixed melting point test. Thus this reaction completes the synthesis of a dihydro-teresantalic acid which is identical with 7-s-apocamphan-carboxylic acid.

The action of formic acid on the methyl ester of teresantalic acid shows that the trimethylene ring is split without a rearrangement of the symmetric system and also that the carboxyl group remains in the bridge Whether or not an intermediate formate of dihydro-teresantalic methyl ester (II) is formed during this reaction was not evident. The splitting of the trimethylene ring might perhaps take place by the addition of water according to the well-known reaction of Bertram and Walbaum. The saponification of the ester group might be a secondary reaction of saponification and therefore the formation of the lactone would be due to the primary hydroxy acid (IV).

[5] Semmler and Bartelt, *Ber.*, **40**, 4465 **(1907)**

[6] Wolff, *Ann.*, **394**, *86* **(1912).**



There still remains the question of the difference between the Semmler–Bartelt and the Muller lactones. The reaction of dilute alkali on chloro-dihydro-teresantalic acid might, during the splitting of hydrogen chloride, cause a rearrangement The lactone of Muller might here react as an intermediate product in the conversion of the teresantalic series into the santene series, since the formation of lactone, thus obtained, is accompanied by more or less santene.[2] This explanation would agree with the hypothesis that the rearrangements in the true camphor series are due to an intramolecular tertiary mobile halogen or hydroxyl atom.[7] Further investigations of Muller's lactone will be necessary to provide more evidence.

Additional work was carried out on the preparation of dihydro-teresantalic acid. The crude mixture of chlorodihydro-teresantalic methyl ester (VII) was reduced to dihydro-teresantalol (VIII). This reaction was carried out with aluminum amalgam in moist ether solution at room temperature, in order to prevent the splitting off of hydrogen chloride, which readily occurs according to Rupe and Tomi.[4] As the isolated product contained chlorine, the reduction was continued by the method of Bouveault and Blanc, by means of metallic sodium and alcohol. The

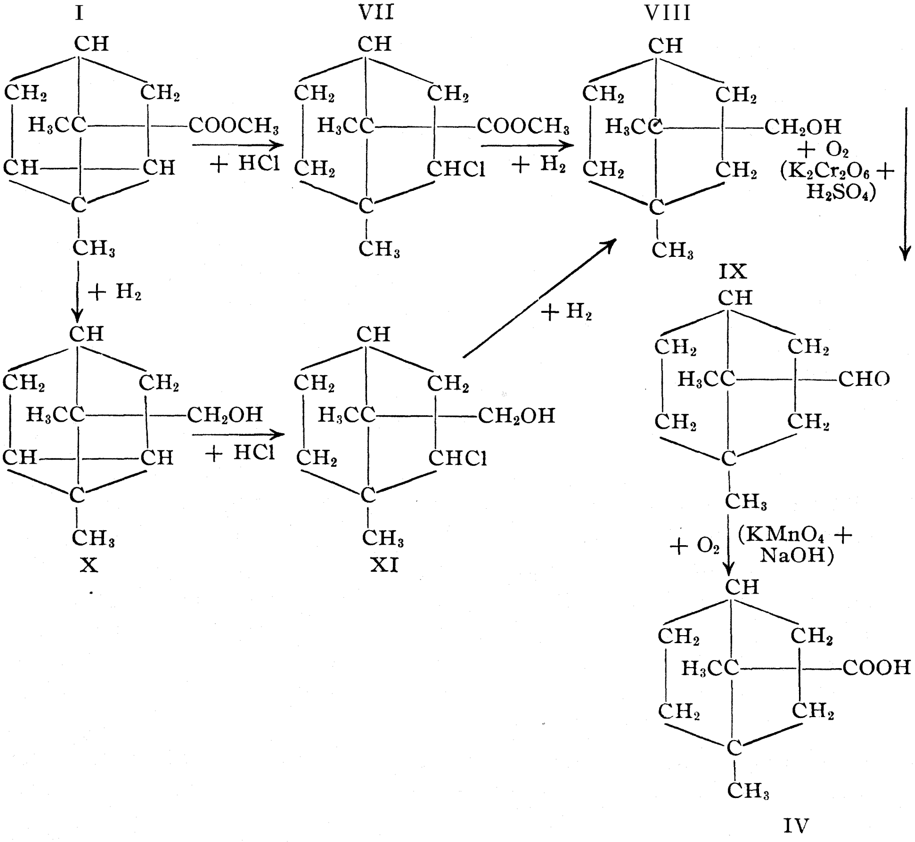
[7] (a) Meerwein and van Emster, Ber., 53, 1815 (1920); *ibid.*, 55, 2500 (1922); (b) Hasselstrbm, Ann. Acad. Fenn., 20, 2 (1923); (c) Komppa and Hasselstrom, *ibid.* 24, 14, *(d)* 15 (1925); (e) 26, 2, (f) 13 (1926); (g) 30, 13 (1929).

dihydro-teresantalol obtained was oxidized to dihydro-teresantalal (IX) with a mixture of potassium dichromate and sulfuric acid. By oxidation with potassium permanganate this aldehyde was converted into dihydro-teresantalic acid (VI), which did not depress the melting point of the previously prepared dihydro-teresantalic acid.



In order to obtain a more convenient method for the preparation of dihydro-teresantalic acid, the methyl ester of teresantalic acid was reduced to teresantalol (X) and the chlorodihydro-teresantalol (XI) obtained by the addition of hydrogen chloride was reduced to dihydro-teresantalol (VIII). However, the addition of hydrogen chloride to teresantalol seems to be accompanied by side reactions, since a solid and a liquid form of chlorodihydro-teresantalol were obtained. Further investigations of the liquid chloride, to determine whether or not a rearrangement to the santene type had taken place, were not made. The solid form of chlorodihydro-teresantalol was reduced by sodium and alcohol to dihydro-teresantalol.

The complete synthesis of dihydro-teresantalic acid, combined with the work of Ruzicka and Liebl,[8] completes the evidence for the structure of teresantalic acid.

These investigations on the a-camphor series will be continued.

Experimental

Raw Material.—The teresantalic acid was obtained from Schimmel and Co. by the courtesy of Fritzsche Bros., New York City. The purification was carried out by crystallizing the crude acid once from dilute acetic acid. The melting point was 156–157°, which corresponds with the data obtained by previous investigators.

Semmler and Bartelt's **Lactone: Lactone** of 2-Hydroxy-7-R-apocamphan-carboxylic Acid.—The methyl ester of teresantalic acid was prepared by the action of methyl sulfate on the sodium salts of teresantalic acid in water solution, according to the data given by Rupe and Tomi.[4]

To a solution of 30 g. of teresantalic methyl ester in 90% formic acid was added 5 cc. of water. The reaction mixture was allowed to boil under a reflux for one hour. After cooling to room temperature, the solution was poured into 500 cc. of a mixture of water and ice. During the treatment a solid mass separated. The product was filtered and dried on a porous plate: yield, 20 g, It was recrystallized from ethyl acetate and melted between 190–191°. Thus the melting point of the lactone corresponded to that given by Semmler and Bartelt.

An oil was obtained as a by-product. This is probably identical with the formate of π-norborneol. However, the amount was too small for an investigation.

Hydroxy Acid from Semmler **and** Bartelt's **Lactone (2-Hydroxy-7-T-apocamphan-**carboxylic Acid).—Two grams of Semmler and Bartelt's lactone was boiled under a reflux until dissolved with 150 cc. of **2%** sodium hydroxide solution. After cooling, the hydroxy acid was precipitated with dilute sulfuric acid. It was filtered and dried upon a porous plate. The crude acid was crystallized from ethyl acetate and melted at 195–196°. This melting point of the hydroxy acid corresponds to that given by Semmler and Bartelt.

Ketodihydro-teresantalic Acid (2-Keto-7-n-apocamphan-carboxylic Acid).—Five grams of the lactone was saponified by 100 g. of an alkaline solution containing 2% of sodium hydroxide. After dissolving, little by little, 120 cc. of permanganate solution, containing 8 g. of potassium permanganate, was added to the boiling solution. The mixture was stirred vigorously. The manganese dioxide was filtered off after the color of the permanganate had disappeared. The filtrate was evaporated on a boiling water-bath until 30 cc. of solution remained. After cooling, the mixture was made acid. The precipitate had all the properties of the original material. The filtrate was extracted repeatedly with ether and the ether solution dried with anhydrous sodium sulfate. After evaporating the ether, a pale yellow oil remained. This gradually solidified: yield, *4.3* g. The oil was dissolved in water, filtered, and gave a more insoluble hydroxy acid. By standing overnight, the keto acid crystallized in colorless plates. Repeatedly recrystallized from water, the acid melted at 269–270°.

Anal. Calcd. for $C_{10}H_{14}O_3$: C, 65.89; H, 7.75. Found: C, 66.10; H, 7.77. *Rotation.* $[\alpha]^{28}_{D}$ $-55°$ (0.52, $\alpha = 2.7°$, in 10% alcohol solution).

In comparison, the 2-keto-7-π-apocamphan-carboxylic acid previously prepared by complete synthesis melted at 249–250°.[1]

The semicarbazone of 2-keto-7-π-apocamphan-carboxylic acid was prepared in **the**

---

[8] Ruzicka and Liebl, *Helv. Chim. Acta*, **9,** 140 (1926).

usual way. It melted at 204–205°, with decomposition, after one recrystallization from dilute alcohol.

7-π-Apocamphan-carboxylic Acid (Dihydro-teresantalic Acid).—Sodium ethylate was prepared in a bomb tube from 0.6 g. of sodium and 3 cc. of absolute alcohol. To the hot solution was added 0.5 g. of the crude semicarbazone of 2-keto-7-π-apocamphan-carboxylic acid. After closing the tube, the mixture was heated at 170–180" during fifteen hours. After cooling, the mixture was diluted with water and the dihydro-teresantalic acid precipitated by dilute sulfuric acid. The crude acid was recrystallized from dilute alcohol and melted at 228–229° (corr.). The acid was nearly optically inactive.

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.42; H, 9.52. Found: C, 71.35; H, 9.37.

In comparison, the dihydro-teresantalic acid obtained by complete synthesis melted at 229–230°.[1] No depression of the mixed melting point was obtained.

Dihydro-teresantalol (π-Borneol).—By the method of Rupe and Tomi,[4] teresantalic methyl ester was converted into chlorodihydro-teresantalic methyl ester. The oil obtained partly solidified on cooling, but the solid a-form was not separated from the labile liquid a-form, on the assumption that the α- and the a-forms are stereoisomeric compounds. Rupe and Tomi found that the hydrochlorides, by splitting off hydrogen chloride, gave the same iso-teresantalic acid, which easily was converted into teresantalic acid. Therefore the crude mixture of the chloro esters was used and the reduction carried out in such a way that the splitting off of hydrogen chloride from the labile a-form would be prevented as much as possible.

Aluminum amalgam was prepared from 25 g. of aluminum. To this moist aluminum amalgam was added 25 g. of chlorodihydro-teresantalic methyl ester, dissolved in 200 cc. of ether. After standing overnight, the mixture was filtered and the ether evaporated. The residue was a colorless oil, which. gave a strong chlorine reaction. The product was therefore dissolved in 250 cc. of absolute alcohol and the reduction continued with 25 g. of sodium according to the well-known method of Bouveault and Blanc. When the reaction was complete, water was added and the solution extracted with ether repeatedly. The ether solution was dried and, after evaporation, the residue was distilled, b. p. 214–216"; yield, 18 g. The crystalline alcohol, after removal of some oil, melted at 171°, which corresponded with Semmler and Bartelt's previously found figure.[3] The oily part was not further investigated.

Dihydro-teresantalal.—One gram of π-borneol dissolved in 10 *g.* of benzene was added to a solution of 1 g. of potassium dichromate, 1.1 g. of sulfuric acid and 10 cc. of water. The mixture was shaken and heated on a boiling water bath until the liquid became green. After cooling, the benzene layer was separated, dried, and the benzene evaporated. The residue gave a positive test for aldehyde with ammoniacal silver solution. The aldehyde was treated with semicarbazide mixture. The semicarbazone obtained was recrystallized from dilute alcohol and melted at 212–213° with decomposition.

Anal. Calcd. for $C_{11}H_{19}N_3O$: C, 63.16; H, 9.14. Found: C, 63.23, H, 8.9.

The aldehyde, recovered by adding dilute hydrogen chloride to the semicarbazone and distilling the mixture with steam, melted at 166.5–167.5°.

Dihydro-teresantalic Acid from Dihydro-teresantalal.—Six grams of dihydro-teresantalal was oxidized at room temperature with 9 g. of potassium permanganate and 6 g. of sodium hydroxide dissolved in 200 cc. of water. The mixture was shaken for twelve hours and the reaction mixture then decolorized with alcohol. The manganese dioxide was filtered off and the filtrate evaporated to about 50 cc. The dihydro-teresantalic acid was precipitated with dilute sulfuric acid and recrystallized from dilute alcohol;

m. p. 229–230°, and no melting point depression when mixed with the previously prepared acid; yield, 4.2 g. The acid was nearly optically inactive.

Chlorodihydro-teresantalol.—Two grams of teresantalol (m. p. 114°), prepared according to Semmler and Bartelt,[3,8] was dissolved in methyl alcohol and the solution saturated with dry hydrogen chloride. The reaction mixture was cooled with a mixture of ice and salt. After standing for forty-eight hours, the mixture was poured on ice and extracted with ether. The ether solution was washed with water and a dilute sodium bicarbonate solution. After evaporation of the ether, a crystalline compound and an oil were obtained. However, the liquid part was formed in such small quantity that its further investigation was impossible. The solid part, 2-chloro-7-a-borneol melted as crude at 125–126° with decomposition.

Dihydro-teresantalol.—Two grams of 2-chloro-7-T-borne was dissolved in 30 cc. of absolute ethyl alcohol and reduced with 5 g. of metallic sodium. The reaction mixture was diluted with water and extracted with ether. After evaporating the ether, dihydro-teresantalol was obtained, m. p. 171°, and did not give any melting point depression when mixed with the previously prepared dihydro-teresantalol.

The semicarbazone of dihydro-teresantalal prepared from dihydro-teresantalol obtained by oxidation of 7-T-borneol melted at 213–214° with decomposition, thus corresponding with the previously found melting point.

Summary

1. It is proved that dihydro-teresantalic acid is identical with 7-π-apocamphan-carboxylic acid.

2. The action of formic acid on teresantalic methyl ester results in a lactone which has the carboxyl group in the ring and not in the bridge.

3. The reactions of teresantal derivatives seem to be accompanied by side reactions, which may be due either to the formation of stereoisomeric compounds or to a rearrangement of the teresantal nucleus to the santene series.

4. The complete synthesis of dihydro-teresantalic acid completes the evidence for the structure of teresantalic acid.

AN ATTEMPTED SYNTHESIS OF A TRICYCLIC SYSTEM PRESENT IN MORPHINE

BY RICHARD H. MANSKE[1]

RECEIVED JANUARY 12, 1931 PUBLISHED MARCH 6, 1931

The intricate sociological and political problems as well as the chemical aspects serve to give to morphine a position that is unique among organic compounds. With the collaboration of the Committee on the Study of Drug Addiction sponsored by the Rockefeller Foundation the author undertook the investigation of some synthetic methods which might possibly lead to a synthesis of at least a portion of the morphine skeleton. It may be stated at once that the projected program was not completed, but the results are now recorded because the author is temporarily engaged in other problems.

In view of the complex structure of morphine, any attempt at a final synthesis is desirably preceded by a series of preliminary syntheses each devoted to only a portion of the whole molecule. The object of such procedure is to determine not only whether or not the anticipated reactions are feasible experimentally, but the optimum conditions for each stage in the process. There are three homocyclic and two heterocyclic systems in the molecule, one of these containing a nitrogen bridge. Naturally occurring examples of the latter are rare, and are in general difficult to synthesize, and although the homocyclic systems present difficulties, it was felt that the crux of the synthesis lay in the availability of the nitrogen ring system.

It has been the object of the present work to synthesize the simplest example of such a structure, and the adjoining example (I) was chosen with this in mind, especially in view of the fact that a portion of the Robinson morphine structure is here represented.[2,3] Two possible syntheses suggested themselves and the preliminary stages were conveniently carried on concurrently, especially in view of the fact that the now readily available ethyl α-cyano-β-phenylacrylate is the obvious starting point in both procedures.

In the one series β-phenyladipic acid was synthesized from phenylsuccinic acid by the well-known stages involving the reduction of the ester to the glycol, converting this first into the dibromide, then into the dicyanide and ultimately hydrolyzing the latter. The yields in several of the stages were excessively poor so that the small amount of 1-keto-1,2,3,4-tetrahydronaphthalene-4-acetic acid (II) ultimately obtained by

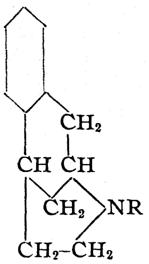
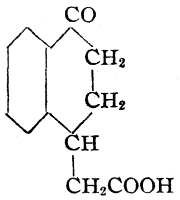
[2] Cahn and Robinson, *J. Chem. Soc.*, **909** (1926).

[3] It is of considerable interest that the alkaloids of *Sinomenium* acutum, and particularly sinomenine, have been assigned consitutions closely related to morphine by Goto and by Kondo and their collaborators, *cf.*, *e.* g., *Ann.*, 470, 224 (1929).

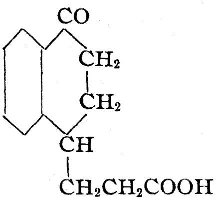
ring closure of the acyl chloride with aluminum chloride was neither sufficient for further syntheses nor was it obtained in a satisfactory state of purity. In view of the fact that a small quantity of a tricyclic diketone (IV) was isolated from the Friedel–Crafts reaction product, it is almost certain that the acidic fraction is a mixture of the two possible keto acids, although von Braun, Bayer and Cassel[4] in an analogous case succeeded in isolating only the six-membered ring compound.



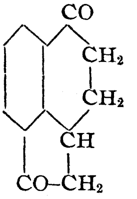
I



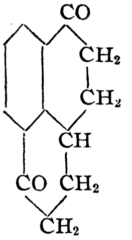
II



III



IV



V

In the second series the synthesis of γ-phenylpimelic acid from β-phenylglutaric acid by an analogous series of reactions proceeded somewhat more satisfactorily although much remains to be desired in the matter of yields. Furthermore, ring closure by means of the Friedel–Crafts reaction proceeded smoothly enough and purification of the resulting product, namely, 1-keto-1,2,3,4-tetrahydronaphthalene-4-propionic acid (III) presented no difficulties. There can be no question in this case of ambiguity of structure, a statement which also applies to the synthesis of hydrind-1-one-3-acetic acid, which was inter *alia* prepared from β-phenylglutaric acid by the same general method. The easy accessibility of the latter keto acid is conducive to its further study and the author hopes to place on record such an investigation in the near future.

As in the previous case a neutral product was obtained during the Friedel–Crafts reaction, examination of which proved it to be the tricyclic diketone (V). The two examples are of some theoretical interest because of the fact that in general it is rare that two carbonyl groups will enter the benzene ring except under drastic experimental conditions.

[4] Von Braun, Bayer and Cassel, Ber., 60, 2602 (1927).

The present observations are undoubtedly due to the particularly suitable orientation of the reacting groups.

Experimental Part

Phenylsuccinic Acid.—The procedure of Baker and Lapworth[5] for the preparation of phenylsuccinic acid is somewhat inadequate when large quantities are desired. The direct addition product of hydrogen cyanide and ethyl **a-cyano-p-phenylacrylate**[6] does not always crystallize. It is therefore extracted with ether from the acidified solution, the ether solution is thoroughly washed with water and the solvent distilled, the last small amount under reduced pressure. The residual addition product from 600 g. of unsaturated ester is heated overnight on a steam cone in a 5-liter round-bottomed flask with a mixture of 1200 cc. of concentrated hydrochloric acid and 800 cc. of water and then heated under reflux until hydrolysis and decarbonylation are complete. The mixture is then evaporated over a large Bunsen burner until unpleasant bumping commences, diluted to 4 liters with hot water, treated with norit and filtered hot. The mixture is rapidly cooled with vigorous stirring and when crystallization is complete the acid is filtered off on a large Biichner funnel, washed with iced water, drained as thoroughly as possible and then washed with about 800 cc. of benzene in small portions. The latter treatment serves to remove a greenish fluorescent material which is difficult to remove otherwise. The yield is 375 to 395 g. A further 20 g. may be obtained from the mother liquor and washings but the product is difficult to purify. As thus obtained the acid was used for the preparation of the ethyl ester, esterification being quantitatively effected by an adaptation of the continuous alcohol-carbon tetrachloride process recommended by Clarke and Davis[7] for the preparation of ethyl oxalate. The pure ester is a viscous liquid boiling at 175° (16 mm.).

β-Phenylglutaric Acid.—The preparation of β-phenylglutaric acid from the addition product of ethyl sodiomalonate in absolute alcohol to ethyl α-cyano-β-phenylacrylate by hydrolysis and decarboxylation was satisfactorily accomplished only by vigorous boiling with 48% hydrobromic acid.[8] The use of concentrated hydrochloric acid and of sulfuric acid of various concentrations was never satisfactory. In the former case boiling for ten days did not effect complete hydrolysis. **A** typical preparation is the following. A solution of 5 g. of sodium in 150 cc. of absolute[9] alcohol is treated with 170 g. of dry

---

[5] Baker and Lapworth, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1928, Vol. VIII, p. 88.

[6] α-Cyano-β-phenylacrylic acid may be esterified in 90% yield as follows. The acid (**346** g.), absolute alcohol (690 cc.) and sulfuric acid (45 cc.) are heated under reflux for eleven to twelve hours (optimum yield). The mixture is cooled in ice, and the crystalline ester filtered off and washed with cold alcohol (290–300 g.). The mother liquor is evaporated somewhat and yields a second crop (100–110 g.) of less pure product, but sufficiently pure for the preparation of phenylsuccinic acid.

[7] Clarke and Davis, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1922, Vol. II, p. **23.**

[8] Avery and Bouton, ***Am. Chem.* J.,*20,*** 510 (1898).

[9] Smith, **J. *Chem.*** *Soc.,* 1288 **(1927),** has provided a general technique which suffices to remove the last traces of water from commercial "absolute" alcohol when the most exacting requirements are to be met. Instead of ethyl succinate, the less expensive ethyl phthalate (27.5 g.) is added to a liter of "absolute" alcohol in which 7 g. of sodium has been dissolved. The mixture is heated under reflux for about an hour and then distilled, taking precautions to exclude atmospheric moisture throughout the entire procedure.

ethyl malonate. The still warm mixture is treated with 200 g. of **ethyl-α-cyano-β-**phenylacrylate (dried in a vacuum desiccator) in one portion, heated gently under reflux for twenty minutes, cooled, acidified to Congo red and the addition product extracted with ether and thoroughly washed with water. (It has been noted repeatedly that about 16 to 21% of the theoretical quantity of sodium is amply sufficient and in fact the yield is always better than if a whole mole be used. It may also be pointed out that ethyl cyanoacetate seems to add to the unsaturated ester with equal facility but the resultant ester is much more resistant to hydrolysis, presumably because of the consumption of a mole of acid during the hydrolysis of the additional cyano group) The oily addition product freed as far as possible from ether is heated with 360 cc. of 48% hydrobromic acid (a larger proportion of 40% acid is not as satisfactory and requires longer boiling) gently at first and vigorously after about an hour. Hydrolysis is generally complete in twenty-four to thirty hours. The mixture is diluted to one liter with hot water, boiled for some time with a generous portion of norite, filtered and cooled. The acid is filtered off, washed with cold water and with benzene (yield, 170–180 g.). Further purification*" by recrystallization from water is tedious and never yields an acid in compact well-formed crystals. However, if it is dissolved in one and one-half times its volume of boiling ethyl acetate and while still hot treated with an equal weight of benzene, slow cooling yields hard stout glistening prisms melting sharply at 140–141°[10] The recovery is well over 80%, and in the preparation of large quantities the yield of pure acid varies between 75 and 85% when the various mother liquors are worked over.

Continuous esterification by means of alcohol–carbon tetrachloride yields the pure ethyl ester quantitatively as a colorless semi-viscous liquid boiling at 188° (18 mm.).

2-Phenylbutane-1,4-diol.—Seventy grams of sodium is introduced into a 3-liter round-bottomed flask immersed in cold water, fitted with a stirrer, reflux condenser protected by a drying tube, and a dropping funnel. A solution of 62.5 g. of ethyl phenylsuccinate in 800 cc. of absolute alcohol[9] is added at the maximum rate just so that the reaction does not get out of control. When all has been added and the vigor of the reaction has subsided somewhat, the cooling water is gradually heated to boiling and the stirrer is started. In the course of about two hours the sodium has dissolved. The mixture is treated with 400 cc. of water and 800 cc. of solvent is distilled off through a short column. The remaining small amount of alcohol is removed at a water pump and the glycol then extracted from the cooled residue with a mixture of equal quantities of ether and benzene. Three successive extractions with liberal quantities of solvent suffice and when a series of runs are made the volume of solvent can be greatly reduced by using the later extracts from one run for the first extraction of the next. The solvent from the combined and cautiously washed extracts is distilled off and the residue distilled. The crude glycol is collected at 150–180° (4 mm.) and the yield from 625 g. of ester is 210 to 220 g. As thus prepared it has been used for the subsequent preparation of the dibromide. Redistillation through a short column yields a viscous colorless oil of faint but pleasant odor reminiscent of rose, b. p. 165" (4 mm.). Attempts to obtain the glycol crystalline failed. On chilling, it set to a solid glass at −10°.

Anal. Calcd. for $C_{10}H_{14}O_2$: C, 72.29; H, 8.43. Found: C, 72.61; H, 8.39.

A characteristic derivative is the *bis-phenylurethan* obtained in the usual way. After two recrystallizations from alcohol, in which it is sparingly soluble when cold, it melted sharply at 113°.

Anal. Calcd. for $C_{24}H_{24}O_4N_2$: N, 6.93. Found: N, 7.03.

2-Phenyl-1,4-dibromobutane.—A mixture of 200 g. of the crude glycol and 100 cc. of acetic anhydride was saturated with a stream of dry hydrogen bromide. The heated

---

[10] All melting points are corrected.

mixture was allowed to cool to room temperature and after twenty-four hours was again saturated with hydrogen bromide and finally heated on a steam-bath for several hours. The cooled product was copiously diluted with ether, thoroughly washed with water and with sodium bicarbonate solution, dried over calcium chloride, the solvent removed and the residue distilled under reduced pressure. The yield of a mobile heavy product boiling at 173–175° (16 mm.) varies from 275 to 295 g. The dibromide loses hydrogen bromide readily and in the course of several days turns dark and turbid. Further purification to a stable colorless product was not attempted.

β-Phenyladipic Acid.—A solution of 110 g. of sodium cyanide in 100 cc. of water and 500 cc. of alcohol was treated with 292 g. of the above dibromide and heated under reflux for twelve hours, during which time the heavy oil gradually dissolved and sodium bromide separated. The dark mixture was filtered through a layer of charcoal and the residue washed with alcohol. The alcohol in the filtrate was distilled off and the mixture extracted with ether–benzene. The solvent from the washed and dried solution was removed and the residue distilled under reduced pressure. An appreciable low-boiling fraction was discarded. The higher-boiling fraction (100 g.) was obtained at 190–200° (4 mm.) and hydrolyzed without further purification by an excess of aqueous alcoholic potassium hydroxide. Removal of the solvent, extraction of an appreciable amount of unsaponifiable product, and final acidification yielded to ether extraction a colorless oily acid which on cooling set to a semi-solid mass. Benzene was added and the colorless crystals filtered off and washed with the same solvent, in which the acid is practically insoluble; yield, 35 g. One recrystallization from ether–benzene yielded well-formed rhombic plates of β-phenyladipic acid, m. p. 146°. The acid is readily soluble in acetone, ether or alcohol, but practically insoluble even in hot water.

Anal. Calcd. for $C_{12}H_{14}O_4$: C, 64.86; H, 6.31. Found: C, 65.53; H, 6.28.

1-Keto-1,2,3,4-tetrahydronaphthalene-4-acetic Acid. II.—A mixture of 35 g. of β-phenyladipic acid and 100 g. of phosphorus pentachloride, which liquefied in a short time, was heated for three hours on a steam cone and then freed of volatile fractions at a water pump. The residue was diluted with 300 cc. of carbon disulfide and treated with 26 g. of anhydrous aluminum chloride in small portions. The mixture was gently warmed for fifteen minutes, then cooled and the supernatant layer of carbon disulfide decanted. The dark residue was decomposed with ice and dilute hydrochloric acid, and the reaction products extracted with ether. The ether solution was thoroughly washed with water and then the acid products were removed by shaking with several successive portions of aqueous sodium bicarbonate.

There remained in the ethereal solution a small amount of a neutral substance which was obtained as an oil on removal of the ether. In the course of several days it crystallized for the greater part. The adhering oil was largely removed on a porous plate and the still somewhat yellow resinous mass recrystallized from a large volume of petroleum ether–benzene (90:10). The substance was thus obtained in minute needles (yield, about 0.5 g.) melting at 149°. Its mode of preparation together with its physical properties and analyses show the substance to be 4,9-diketo-1,2,3,4-tetrahydroacenaphthene, IV.

Anal. Calcd. for $C_{12}H_{10}O_2$: C, 77.42; H, 5.38. Found: C, 77.62; H, 5.24.

The acidic products present in the sodium bicarbonate extract from the ethereal solution were recovered by acidification and extraction with ether. Attempts to obtain either the free acid or the methyl ester in a state of homogeneity were unsuccessful. In view of the isolation of the above diketone it is quite certain that there is present a mixture of the two theoretically possible isomers.

3-Phenylpentane-1,5-diol.—Using the same technique and the same molecular proportions as with the lower homolog, this glycol was obtained in a 60% yield based on the crude product distilling at 175–185° (5 mm.). Redistillation yielded a colorless viscous oil of faintly pleasant odor boiling at 174° (4 mm.).

Anal. Calcd. for $C_{11}H_{16}O_2$: C, 73.33; H, 8.89. Found: C, 73.44; H, 8.80.

Recrystallization of the *bis-phenylurethan,* prepared in the usual way, first from alcohol and then from benzene yielded stout well-defined prisms melting at 112–113°.

Anal. Calcd. for $C_{25}H_{26}O_4N_2$: N, 6.70. Found: N, 6.76.

3-Phenyl-1,5-dibromopentane.—Of the various procedures that were tried to convert the glycol into the dibromide, only the acetic anhydride–hydrogen bromide method gave encouraging results. Following the details given for the lower homolog, from 160 g. of the glycol there was obtained 230 g. of crude dibromide, b. p. 177–182° (16 mm.), the greater portion distilling at 180'. As thus obtained it loses hydrogen bromide readily, and in the course of several days darkens appreciably. It was characterized by conversion to *3-phenyl-1,5-diphenoxypentane,* the conversion being readily effected by heating for several hours with an excess of aqueous alcoholic sodium phenate. Removal of solvents and steam distillation to remove some volatile oily impurities yielded a viscous product which crystallized in the course of several days. After pressing out on porous tile it was twice recrystallized from benzene–petroleum ether and was thus obtained in stout prisms, m. p. 72°, sparingly soluble in alcohol.

Anal. Calcd. for $C_{23}H_{24}O_2$: C, 83.13; H, 7.23. Found: C, 82.91; H, 7.12.

It may be mentioned here that several attempts to obtain the lower homolog in an analogous way yielded only uncrystallizable oils. There appears to be a much greater tendency for the elimination of hydrogen bromide due to the greater stability of the conjugated system thus produced.

γ-Phenylpimelic Acid.—The conversion of the above dibromide to the dicyanide and subsequent hydrolysis to the acid proceeded with much better yields than in the preparation of β-phenyladipic acid. From 264 g. of the dibromide and 95 g. of sodium cyanide in aqueous alcohol there was obtained 156 g. of crude dinitrile, b. p. 200–215" (4 mm.). It was at once converted into the acid by hydrolysis with excess potassium hydroxide in dilute alcohol. Removal of the solvent and extraction of the alkaline liquid with several portions of ether to remove a small amount of unsaponified product and subsequent acidification and extraction with ether yielded, after drying and evaporation of the solvent, a colorless viscous oil which crystallized readily in contact with benzene. The yield of product, m. p. 83–84°, after filtering and washing with benzene, was 132 g. A further small amount was recovered from the mother liquor. Recrystallization from ether–benzene yielded stellate aggregates of fine needles melting at 84°. Recrystallization from water is difficult on account of the low melting point but stout prisms can be obtained in the course of several months. The acid is only very sparingly soluble in cold water and but slightly when hot.

Anal. Calcd. for $C_{13}H_{16}O_4$: C, 66.10; H, 6.78. Found: C, 65.89; H, 6.78.

1-Keto-1,2,3,4-tetrahydronaphthalene-4-propionic acid, 111.—Without modification this keto acid was obtained from γ-phenylpimelic acid by the procedure above outlined for the lower homolog. From 94.4 g. of the acid, 84 g. of phosphorus pentachloride, 60 g. of aluminum chloride, and 300 cc. of carbon disulfide, there was obtained 48 g. (53%) of slightly colored crystalline acid melting at 105–106°. It is readily soluble in benzene and sparingly in ether, and was easily recrystallized by cautious addition of ether to a concentrated solution in benzene. As thus obtained it consisted of large colorless plates melting sharply at 108–109°.

Anal. Calcd. for $C_{13}H_{14}O_3$: C, 71.56; H, 6.42. Found: C, 71.54; H, 6.27.

The methyl ester was prepared in the usual way as a colorless viscous oil after distillation, but it could not be induced to crystallize.

Hexahydrobenznaphthene-α,α'-dione, V.—Corresponding to the diketo compound obtained from β-phenyladipic acid there was obtained, in the ethereal extract from the preparation of the ketonaphthalenepropionic acid, a neutral product after the removal of the acids by extraction with sodium bicarbonate solution. The dried ether solution on evaporation yielded a pale brown oil which crystallized on cooling. Filtration and cautious washing with ether, in which the compound is sparingly soluble, and recrystallization from a concentrated solution in benzene by the cautious addition of ether, gave colorless stout prisms (5 g.) which melted sharply at 111°.

Anal. Calcd. for $C_{13}H_{12}O_2$: C, 78.00; H, 6.00. Pound: C, 77.55; H, 5.82.

Characterization by the preparation of the dioxime in alkaline solution with excess hydroxylamine yielded the desired substance in minute needles from acetone, m. p. 253–254° with darkening. The dioxime is readily soluble in hot acetone but only sparingly so in hot alcohol or acetic acid.

Anal. Calcd. for $C_{13}H_{14}ON_2$: N, 12.17. Found: N, 11.55.

Hydrind-1-one-3-acetic Acid.—In the course of a preliminary investigation this compound was obtained in unsatisfactory yield by treating β-phenylglutaric anhydride[11] dissolved in nitrobenzene with finely powdered aluminum chloride. The procedure which was ultimately found to give satisfactory and consistent yields was analogous to that used in the preparation of the corresponding tetralone derivatives.

A mixture of 208 g. of β-phenylglutaric acid and 420 g. of phosphorus pentachloride was gently warmed on a steam cone until reaction was complete. The phosphorus oxychloride and excess pentachloride were removed in vacuo at 100° and the cooled residue treated with 200 cc. of carbon disulfide. The addition of 140 g. of powdered aluminum chloride in small portions induced a vigorous elimination of hydrogen chloride. When reaction was complete the carbon disulfide was removed at a water pump and the dark tarry residue decomposed with ice and hydrochloric acid. The crystalline product was filtered off, thoroughly washed with cold water, freed of neutral products by solution in sodium bicarbonate and reprecipitation (yield, 178 g.). Small quantities may be recrystallized from hot water, in which it is sparingly soluble, and it is then obtained in large colorless rhombic plates melting at 155°. Larger quantities may be recrystallized from benzene–petroleum ether.

Anal. Calcd. for $C_{11}H_{10}O_3$: C, 69.48; H, 5.26. Found: C, 69.43; H, 5.26.

Methyl Hydrind-1-one-3-acetate.—The crude acid (190 g.) dissolved in 700 cc. of absolute methanol was heated under reflux for fifteen hours with 15 cc. of concentrated sulfuric acid. Addition of water, extraction with ether–benzene, thorough washing, finally with aqueous sodium bicarbonate and removal of solvent, yielded a dark oil which was distilled under reduced pressure. The fraction boiling at 175–180° (18 mm.) weighed 130 g. and solidified completely on cooling. Recrystallized from benzene–petroleum ether it consisted of large rhombic plates melting sharply at 54°.

Anal. Calcd. for $C_{12}H_{12}O_3$: C, 70.59; H, 5.88. Found: C, 69.96; H, 5.86.

Addendum

In view of the low yields that were obtained in the preparation of the phenyl-glycols it was necessary to submit the method of reduction to a thorough examination to ascertain its validity. It had been observed that the toluene method described by Marvel and Tanenbaum,[12] which

---

[11] Adams and Noller, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1925, Vol. V, p. 17.

[12] Marvel and Tanenbaum, THIS JOURNAL, 44, 2648 (1922).

gave rather good yields in the case of δ-phenoxybutyl alcohol, did not improve the yields perceptibly when applied to the preparation of the phenyl-glycols. It has indeed been found that even in the preparation of the phenoxy-alcohol yields as good as previously recorded may be obtained by reducing ethyl γ-phenoxybutyrate (104 g.) with sodium (70 g.) in large pieces and absolute alcohol (650 cc.). At first the mixture is cooled to keep the reaction under control and then heated on a steam cone to dissolve the sodium completely. No stirring whatever is necessary. The alcohol is isolated in the usual way.

In one experiment where the ester contained considerable quantities of γ-phenoxybutyronitrile there was isolated also δ-phenoxybutylamine and a solid substance remained in the distillation flask which on recrystallization from benzene consisted of colorless needles and melted sharply at 94–95°. Analysis proved it to be α-phenoxybutyr-δ-phenoxybutylamide, $C_6H_5OCH_2CH_2CH_2CONHCH_2CH_2CH_2CH_2OC_6H_5$.

Anal. Calcd. for $C_{20}H_{25}O_3N$: C, 73.40; H, 7.65; N, 4.28. Found: C, 73.40; H, 7.78; N, 4.27.

ε-Phenoxyamyl Alcohol, $C_6H_5OCH_2CH_2CH_2CH_2CH_2OH$.—Ethyl δ-phenoxyvalerate (108 g.) in alcohol (800 cc.) was reduced as above described with sodium (70 g.). The alcohol isolated in the usual way was obtained as a colorless rather viscous oil, b. p. 164–166° (17 mm.), which on cooling in ice solidified completely. At room temperature it remelted, yield, 75%. It was characterized by the preparation of the phenylurethan, which was obtained in stout prisms melting at 93–94°.[13]

In conclusion it may be pointed out that ethyl sebacate when reduced by the same molecular proportions of sodium gave 1,10-dihydroxydecane in 77% yield.

Summary

1. An attempt, thus far unsuccessful, has been made to effect the synthesis of a portion of the morphine nucleus.

2. The preparation of some intermediates, notably, β-phenyladipic and γ-phenylpimelic acids, is described.

3. Two unusual cases of the easy introduction of two carbonyl groups into the benzene ring by means of the Friedel–Crafts reaction have been discovered.

4. A note regarding the reduction of esters with sodium is appended.

STUDIES IN THE DIPHENYL ETHER SERIES.
II. PREPARATION AND STRUCTURE OF SOME SULFONIC ACIDS AND RELATED DERIVATIVES[1]

BY C. M. SUTER

RECEIVED JANUARY 12, 1931 PUBLISHED MARCH 6, 1931

The sulfonation of diphenyl ether and its derivatives has been very little investigated. Hoffmeister[2] found that the action of concentrated sulfuric acid on diphenyl ether gave a disulfonic acid, but the positions occupied by the acid groups were not determined. The same acid[3] had been made previously but was considered to be a derivative of diphenyl. It has recently been found[4] that aminosulfonic acid sulfonates diphenyl ether to the ammonium 4-phenoxybenzenesulfonate. A number of sulfinic acids have been used as intermediates in the preparation of phenothioxin derivatives.6 Apparently no thiol substitution products have been previously investigated.

The structure of the disulfonic acid was determined by bromination of its barium salt in water solution, the bromo-monosulfonate first formed giving upon further bromination the 4,4′-dibromodiphenyl ether of known[6] structure. Since this method of determining structures has been employed previously with sulfonic acids of certain aromatic hydrocarbons,[7] phenols,[8] and amines[9,8b] without any inconsistencies becoming evident, the two sulfo groups occupy the 4,4′-positions.

The acid obtained by monosulfonation of diphenyl ether was found to give derivatives with properties which did not correspond to those reported by Quilico[4] for the compound obtained by him. However, upon repetition of his work, the products obtained by the various sulfonation methods were found to be identical.

An attempt to prepare 4-hydroxydiphenyl ether by fusion of the sodium sulfonate with sodium hydroxide was unsuccessful, as the ether linkage is broken during the reaction.

Bromination of sodium 4-phenoxybenzenesulfonate might conceivably result either in replacement of the sulfo group or substitution in the second benzene ring. Actually the latter takes place to the apparent exclusion of the former, as no 4-bromodiphenyl ether was found. A small amount of 4,4′-dibromodiphenyl ether was formed due to the further reaction with bromine of the bromosulfonic acid which is the primary product. Since this acid is also formed by sulfonation of 4-bromodiphenyl ether, the position of the bromine is evident. Its sodium and ammonium salts are only slightly soluble in water, as little as 12 mg. of sodium or ammonium ion in 10 cc. of solution giving a heavy crystalline precipitate with 1 cc. of a one molar solution of the acid. As much as 50 mg. of potassium gave no precipitate under similar conditions.

The action of excess chlorosulfonic acid upon diphenyl ether gives the 4,4′-disulfonyl chloride. It is apparently not possible to make the monosulfonyl chloride in this way, further sulfonation always occurring. 4-Bromodiphenyl ether reacts to give the 4′-sulfonyl chloride under the proper conditions, an excess of chlorosulfonic acid or a temperature higher than 25 or 30° leading to further sulfonation. The structure of this sulfonyl chloride is indicated by its formation from 4-phenoxybenzenesulfonyl chloride by bromination.

The 4-phenoxybenzenesulfinic acid prepared by reduction of the corresponding sulfonyl chloride was found to be quite unstable and could not be obtained in the pure state. Titration of the freshly prepared acid required 80% of the theoretical amount of alkali, while in three days this had dropped to about 50% of that calculated. The decomposition products have not been investigated.

The 4-thioldiphenyl ether when first distilled was odorless but developed the smell of hydrogen sulfide in a few hours. This was due to the decomposition of a trace of some impurity present since after standing for six months the evolution of hydrogen sulfide had ceased and the product had practically the same melting point as at first. A water solution of its sodium salt is rapidly oxidized by the oxygen of the air, crystals of the disulfide being deposited. This is also formed by oxidation of an alcohol solution of the thiol with iodine.

The sulfur analyses were made with a Parr bomb, and nitrogen was determined by the Kjeldahl method. All temperatures are corrected unless otherwise specified.

Experimental

Bromination of Barium Phenoxybenzene-4,4′-disulfonate.—To a solution of 11.8 g. (0.025 mole) of the salt 2 in 1 liter of water at 50° was added with stirring 4 g. (0.025 mole) of bromine. When the color of the bromine had disappeared, the precipitate which contained the sulfonic acid and sulfuric acid as a mixed salt was filtered off and treated with two 500-cc. portions of 0.5 normal sodium carbonate solution. The combined filtrates upon cooling deposited the slightly soluble sodium 4-bromophenoxybenzene-4'-sulfonate as thin colorless plates. The yield was 5 g., which is 57% of the theoretical.

Anal. Calcd. for $C_{12}H_8BrO_4SNa$: S, 9.12. Found: S, 8.92, 8.90.

The p-toluidine salt was obtained as small colorless plates melting at 245–247°.

Anal. Calcd. for $C_{19}H_{18}BrNO_3S$: N, 3.21. Found: N, 3.06, 3.02.

Bromination of Sodium 4-Bromophenoxybenzene-4'-sulfonate.—A bromination similar to the above gave an 84% yield of 4,4'-dibromodiphenyl ether which melted at 55–56". By recrystallizing from petroleum ether, it was obtained as large colorless needles melting at 59–60°. The value reported in the literature[6] is 60.5".

Monosulfonation of Diphenyl Ether.—This was carried out in various ways. Sulfonation in acetic acid solution with chlorosulfonic acid or in acetic anhydride with concentrated sulfuric acid was found to be better than the direct action of concentrated sulfuric acid without a solvent because this latter method gives considerable quantities of the disulfonic acid. This occurs because the monosulfonic acid first formed is soluble in concentrated sulfuric acid and is further sulfonated before the almost insoluble diphenyl ether has all reacted.

To a mixture of 170 g. (1 mole) of diphenyl ether and 100 cc. of acetic anhydride was added gradually with shaking 69 cc. (1.2 mole) of 95% sulfuric acid. After an hour on the steam-bath, the solution was poured into 1 liter of ice water. The unchanged ether (27 g.) was filtered off and the sodium sulfonate precipitated by adding 80 g. of sodium hydroxide in 250 cc. of water. There was obtained 212 g. of the dry salt, which is 93% of the theoretical based upon the diphenyl ether actually used. This product has the same characteristics as that obtained by Quilico[4] from his sulfonation product. The p-toluidine salt was obtained from dilute methanol as colorless needles melting at 221–222°.

Anal. Calcd. for $C_{19}H_{19}NO_4S$: N, 3.92. Found: N, 3.93, 3.87.

Bromination of Sodium 4-Phenoxybenzenesulfonate.—To a solution of 27 g. (0.1 mole) of the salt in 1 liter of water at 50° was added 16 g. (0.1 mole) of bromine. Separation of a precipitate began at once. After an hour the reaction mixture was heated to boiling to dissolve all water-soluble material and the solution decanted from a small amount of oil which solidified upon cooling. This, after crystallizing from petroleum ether, gave 5 g. of 4,4'-dibromodiphenyl ether. No monobromodiphenyl ether was found. Upon cooling the water solution, there separated 19.5 g. of sodium 4-bromophenoxybenzene-4'-sulfonate.

Fusion of Sodium 4-Phenoxybenzenesulfonate with Sodium Hydroxide.—This was carried out under different conditions, none of which gave an appreciable yield of 4-hydroxydiphenyl ether. A mixture of 27 g. of the sodium salt and 100 g. of sodium hydroxide was heated at 260° for fifteen minutes and then dissolved in water. There was recovered 10 g. of unchanged sodium salt and upon acidifying with hydrochloric acid a small amount of a flocculent precipitate separated. This was too small in quantity for examination. Phenol and sodium sulfite were present in considerable amounts in the solution. A similar fusion carried out at 300° gave no products insoluble in water when the reaction products were treated like the above.

4-Phenoxybenzenesulfonyl Chloride.—Heating a mixture of 181 g. (0.66 mole) of the sodium sulfonate with 70 g. (0.33 mole) of phosphorus pentachloride under reflux at 170–180° for ten hours gave 125 g. of an oil of which upon fractionation 95 g. or 54% of the theoretical amount boiled at 205–207° (uncorr.) under 12 mm. pressure. This solidified upon cooling and crystallized from petroleum ether as colorless needles melting at 45–46°. Treatment of the sodium salt of the acid obtained by Quilico's method in the same manner gave the same sulfonyl chloride, although he reports it to be an oil.

Anal. Calcd. for $C_{12}H_9ClO_2S$: S, 11.92. Found: S, 12.09.

The amide was made by treatment of the sulfonyl chloride with a mixture of ammonium hydroxide and alcohol. It was purified by crystallizing its sodium salt from water, redissloving in water and acidifying with acetic acid. It melted at 128–129°; previously[4] reported, 88°.

Anal. Calcd. for $C_{12}H_{11}NO_3S$: N, 5.52. Found: N, 5.59, 5.79.

The anilide obtained from a mixture of the sulfonyl chloride with aniline and 10% sodium hydroxide solution melted at 86–88°.

Anal. Calcd. for $C_{18}H_{15}NO_3S$: N, 4.31. Found: N, 4.26.

Sulfonation of 4-Bromodiphenyl Ether. (a) With Sulfuric Acid.—A mixture of 25 g. (0.1 mole) of 4-bromodiphenyl ether and 11 cc. (0.2 mole) of 95% sulfuric acid was warmed on the steam-bath until it was homogeneous, poured into 400 cc. of water, and sodium hydroxide added to precipitate the sodium salt. There was obtained the theoretical yield of the 4'-sulfonate identical with that from bromination of the mono- and di-sulfonic acid salts. For precipitation tests with sodium, potassium, and ammonium ions, a reaction mixture similar to the above was diluted to 100 cc. with water and 1-cc. portions of this solution added to 10 cc. of the solution to be tested. As little as 12 mg. of sodium as sodium nitrate gave a precipitate within a few minutes, while 9 mg. gave a slight precipitate after standing for twelve hours; 10 mg. of ammonium also gave a slight precipitate after twelve hours; 100 mg. of potassium gave a precipitate within half an hour, 75 mg. after twelve hours, and 50 mg. gave no precipitate.

(b) With Chlorosulfonic Acid.—To 25 g. (0.1 mole) of 4-bromodiphenyl ether was added with shaking 15 cc. (0.22 mole) of chlorosulfonic acid. The thick oily mixture was poured into ice water and the solid acid chloride filtered off. The yield was 16 g. of product which crystallized from petroleum ether as plates melting at 81–82°. The water-soluble sulfonation products did not include the monosulfonic acid, as they gave no insoluble sodium salt.

The same sulfonyl chloride was obtained in 91% yield by bromination of 4-phenoxybenzenesulfonyl chloride in carbon tetrachloride solution.

Anal. Calcd. for $C_{12}H_8BrClO_3S$: S, 9.23. Found: S, 9.35.

The amide was obtained from dilute methanol as colorless plates melting at 131–132°.

Anal. Calcd. for $C_{12}H_{10}BrNO_3S$: N, 4.25. Found: N, 4.20.

The corresponding anilide after crystallizing from dilute methanol several times melted at 108–109°.

Anal. Calcd. for $C_{18}H_{14}BrNO_3S$: N, 3.47. Found: N, 3.52.

Phenoxybenzene-4,4'-disulfonyl Chloride.—To 85 g. (0.5 mole) of diphenyl ether was added with shaking 200 cc. of chlorosulfonic acid. After two hours the mixture was poured into 2 liters of water and the crude disulfonyl chloride filtered off. The yield was 160 g. or 88% of the theoretical of material which crystallized from petroleum (90–120°) as colorless needles melting at 128–129°.

Anal. Calcd. for $C_{12}H_8Cl_2O_5S_2$: S, 17.45. Found: S, 17.35.

The diamide crystallized from hot water, in which it is somewhat soluble, as shiny plates melting at 158–160°.

Anal. Calcd. for $C_{12}H_{12}N_2O_5S_2$: N, 8.53. Found: N, 8.56, 8.75.

4-Phenoxybenzenesulfinic Acid.—A mixture of 13.5 g. (0.05 mole) of the sulfonyl chloride, 6.5 g. (0.05 mole) of sodium sulfite, and 6 g. of sodium carbonate in 75 cc. of water was refluxed for half an hour to complete the reaction. The mixture was filtered to remove a small amount of water-insoluble material and the solution cooled. There separated 9.8 g. of colorless needles of the sodium sulfinate. This was recrystallized once from hot water.

Anal. Calcd. for $C_{12}H_9O_3SNa$: Na, 8.97. Found: Na, 8.98, 8.97.

By acidifying the filtrate after removal of the sodium sulfinate, there was obtained a chalky white precipitate which was not the sulfinic acid. When heated, it darkened above 180° with no definite melting point. Titration with standard alkali gave an equivalent weight approximately twice that of the sulfinic acid. It is planned to investigate this and similar products further.

Adding acid to a water solution of the sodium sulfinate precipitated an oil which soon solidified. After drying for several hours, a sample of this was titrated with standard alkali.

Anal. Calcd. for $C_{12}H_{10}O_3S$: 0.5049 g. requires 21.8 cc. of 0.099 *N* NaOH. Found. 17.6 cc. After standing for three days in a desiccator, another sample was titrated. 0.1973 g. requires 8.43 cc. of 0.011 *N* NaOH. Found: 4.11 cc.

Another similar sample showed a drop in melting point from 100–101° to 91–93° in forty-eight hours. Because of this instability, further attempts to obtain the acid in a pure condition were not made.

4-Thioldiphenyl Ether.—To a mixture of 70 g. of concentrated sulfuric acid and 210 g. of crushed ice was added with stirring 27 g. (0.1 mole) of the sulfonyl chloride and then 35 g. of zinc dust, the temperature being kept below 0°. After standing for two hours, the mixture was refluxed for two and one-half hours, filtered from a little unchanged zinc, and extracted with benzene. The benzene was evaporated and the residue distilled under reduced pressure. The yield was 12 g. or 60% of the theoretical of a colorless oil boiling at 178–180° at 20 mm., which solidified upon cooling and melted at 19–22". The product thus obtained always gave a low sulfur analysis even after repeated distillation. Recrystallizing from petroleum ether by cooling the solution to −10° gave colorless plates of a pure product melting at 21–22°.

Anal. Calcd. for $C_{12}H_{10}OS$: S, 15.86. Found: S, 15.67.

A sample was also titrated in alcohol solution with standard sodium hydroxide using phenolphthalein as the indicator.

Anal. Calcd. for $C_{12}H_{10}OS$: 0.2132 g. requires 10.7 cc. of 0.099 N alkali. Found: 10.5 cc.

The disulfide was formed by oxidation of a water solution of the sodium salt of the thiol by air, or by treatment of an alcoholic solution of the thiol with iodine. It crystallized from methanol as colorless plates which melted at 47–48°.

Anal. Calcd. for $C_{24}H_{18}O_2S_2$: S, 15.95. Found: S, 15.90.

Summary

The sulfonation of diphenyl ether with both sulfuric acid and chlorosulfonic acid has been studied and the structures of the products formed have been determined by replacement of the sulfo groups with bromine. In all cases, sulfonation occurs in the para positions when these are unoccupied by other groups.

The sulfinic acid and thiol have been obtained by reduction of 4-phenoxybenzenesulfonyl chloride. The sulfinic acid was found to be very unstable.

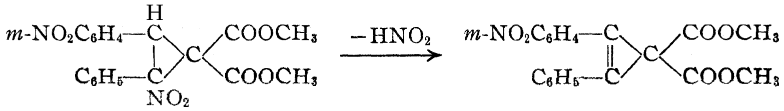
STUDIES IN THE CYCLOPROPENE SERIES. I. DIPHENYLCYCLOPROPENEDICARBOXYLIC ACID

BY S. F. DARLING AND E. W. SPANAGEL

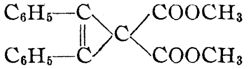
RECEIVED JANUARY 12, 1931 PUBLISHED MARCH 6, 1931

In connection with a study of the behavior of nitrocyclopropane derivatives with bases Kohler and his students[1] have postulated the presence of a substituted cyclopropene derivative intermediate between the nitrocyclopropane and the end-product. Later they actually succeeded in isolating a new type of cyclopropene derivative[2] (I) as the first product of the action of sodium methylate on the nitrocyclopropane (II). This



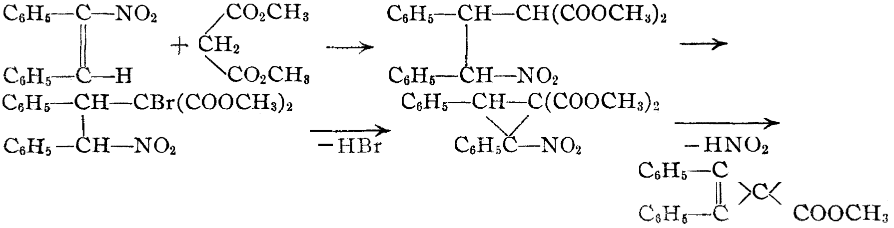
II I

substance suggests many new problems for study but the presence of the nitro group in one of the benzene nuclei is undesirable in certain cases. We have therefore prepared another cyclopropene derivative (III) differing

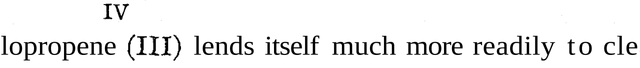


III

from the cyclopropene (I) in that both phenyl groups are unsubstituted. The reactions which lead to this substance are as follows



The proof of the structure of this new cyclopropene derivative is analogous to the proof of the constitution of (I). The corresponding dibasic acid (IV) on oxidation with potassium permanganate in alkaline solution forms dibenzoylmethane. Therefore we may write the following reaction



IV

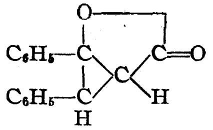
The cyclopropene (III) lends itself much more readily to clean cut reactions than the cyclopropene derivative (I); however, its preparation

---

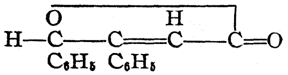
[1] Kohler, THIS JOURNAL, 44, 624 (1922).

[2] Kohler, *ibid.*, 52, 1174 (1930).

entails many difficulties and low yields result. The work described in this paper is confined to the study of the effect of heat on the dibasic acid (IV). This compound melts to a clear, pale yellow liquid at about 190°, with the evolution of carbon dioxide. If this clear melt after cooling is manipulated with appropriate solvents a good yield of a new substance whose composition corresponds to the loss of one molecule of carbon dioxide from the dibasic acid, is obtained. Contrary to our expectations this substance proved to be a lactone instead of a mono basic acid. A little reflection about the matter shows that two formulas for this lactone are probable; the cyclic lactone (V) and the corresponding open-chain unsaturated lactone (VI).

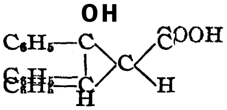


V



VI

In order to assign the more probable formula to this lactone we have converted it into the corresponding hydroxy acid and subjected this substance to ozonization. There is little doubt that the hydroxy acid derivable from a substance of formula (VI) would form benzoin as one of the products of ozonization. Benzoin could easily be isolated and identified. The hydroxy acid related to a substance of formula (V) should resist ozonization or at most undergo a little general oxidation. The hydroxy acid remained almost totally unchanged in the presence of a moderate stream of ozone and over 75% of the material was recovered unchanged after being subjected to a rapid stream of 6% ozone for three hours. Little doubt therefore remains that the lactone should be represented by formula (V) and the hydroxy acid by formula (VII). Substances of this type are practically unknown; in fact previous attempts to introduce hydroxyl groups in the cyclopropane ring have led to open-chain compounds. We hope that additional work with cyclopropene derivatives will further characterize this little-known class of compounds.



VII

Experimental Part

The a-Bromo Compound Formed by Indirect Bromination.—Ten grams of dimethyl β,γ-diphenyl-γ-nitro-ethyl-malonate, prepared according to the method of Kohler and Barrett,[3] was suspended in 30 cc. of dry methyl alcohol and to this was added 1.3 *g*. of sodium as sodium methylate. This caused the substance to dissolve and to form a light yellow solution. This solution was cooled and poured slowly into a cold solution of excess bromine in 25 cc. of *dry* methyl alcohol. The crystals of bromine compound separated promptly and were purified by crystallization from methyl alcohol, from which solvent they separate in stout, colorless crystals which melt at 117–118°. The yields vary between 70 and 80% of the theoretical.

---

[3] Kohler and Barrett, THIS JOURNAL, 48, 1770 (1926).

Dimethyl α-Bromo-β,γ-diphenyl-γ-nitro-ethyl-malonate.—This substance is isomeric with the bromine compound prepared by Kohler and Barrett[3] by direct bromination of the nitro ester.

Anal. Calcd. for $C_{19}H_{18}O_6NBr$: C, 52.3; H, 4.1. Found: C, 52.1; H, 4.2.

Preparation of the Nitrocyclopropane.—Thirty grams of the above bromine compound was pulverized and added to a solution of 30 g. of potassium acetate in 250 cc. of dry methyl alcohol. The mixture was refluxed for thirty minutes, during which time the substance dissolved, the solution developed a yellow color, and potassium bromide separated. The solution was cooled and to it was added enough water to dissolve the potassium bromide. After standing for several hours the solution deposited 6–7 *g.* of pure nitrocyclopropane derivative, which melted at 129°. The mother liquor was removed by decantation and after further standing it deposited the isoxazoline oxide, melting point 140°, previously described by Kohler and Barrett.[3] After removal of the oxide the solution sometimes deposited a crop of unchanged isomeric bromine compound when the crude bromine compound was used instead of the pure substance melting at 117–118°.

Dimethyl 1,2-Diphenyl-2′-nitro-3,3′-cyclopropane Dicarboxylate.—This substance separates from methyl alcohol in large, lustrous plates which melt at 129".

Anal. Calcd. for $C_{19}H_{17}O_6N$: C, 64.2; H, 4.8. Found: C, 64.0; H, 4.8.

Preparation of the Cyclopropene Diester.—Five grams of nitrocyclopropane was dissolved in 60 cc. of hot, dry methyl alcohol and to this was added 1 g. of sodium as sodium methylate. The solution was refluxed for fifteen minutes, during which time sodium nitrite separated. In one experiment the sodium nitrite was filtered off and identified. However, in most cases water was added to the cold solution until it precipitated the cyclopropene ester. The yield is about 1–1.5 g. Some cyclopropene dibasic acid can be recovered by acidification of the mother liquors.

Dimethyl 1,2-Diphenyl-3,3′-cyclopropene Dicarboxylate.—After several crystallizations from a mixture of ether and petroleum ether the substance was pure. It separates in beautiful, colorless prisms which melt at 140–142°.

Anal. Calcd. for $C_{19}H_{16}O_4$: C, 74.0; H, 5.2. Found: C, 74.1; H, 5.5.

The Cyclopropene Dibasic Acid.—Two-tenths gram of the cyclopropene ester was refluxed for ten minutes with excess methyl alcoholic potash. The alcohol was removed and the cold solution was acidified. An oil separated which soon solidified. After purification from a mixture of ether and petroleum ether the substance separated in stout, colorless needles which melted with the evolution of carbon dioxide at about 190°.

Anal. Calcd. for $C_{17}H_{12}O_4$: C, 72.9; H, 4.3. Found: C, 73.1; H, 4.6.

Oxidation of the Dibasic Acid.—One-tenth gram of the cyclopropene dibasic acid was dissolved in excess 10% sodium carbonate solution to which was added potassium permanganate solution until the purple color persisted. The solution was cleared with sodium sulfite solution and finally acidified with dilute hydrochloric acid. The substance which separated was extracted with ether and the ethereal solution shaken with a saturated solution of copper acetate. The pale green copper compound which separated melted at 295–300° with decomposition after crystallization from benzene. The copper derivative of dibenzoylmethane melts at 294–301° with decomposition. The remainder of the copper compound was shaken with water containing a small amount of dilute acid and an ether upper layer. The ether layer after evaporation deposited a substance which melted at 75–77°. A mixed melting point with a known sample of dibenzoylmethane showed no depression.

Addition of Bromine to the Cyclopropene Diester.—Two-tenths gram of cyclopropene ester in chloroform solution absorbed bromine from a 5% solution of bromine in carbon tetrachloride in direct sunlight. The solvent was removed under diminished pressure and the oil which remained crystallized after manipulating with methyl alcohol. It separates in small, colorless crystals from methyl alcohol which melt at 194–5° with decomposition.

Dimethyl 1,2-Dibromo-1,2-diphenyl-3,3′-cyclopropane Dicarboxylate.—*Anal.* Calcd. for $C_{19}H_{16}O_4Br_2$: C, 48.7; H, 3.4. Found: C, 49.0; H, 3.4.

Decomposition of the Cyclopropene Dibasic Acid. The Lactone.—Two-tenths gram of the cyclopropene dibasic acid was melted in a Pyrex test-tube heated by means of a sulfuric acid bath and maintained at the decomposition point until the carbon dioxide was all evolved. The clear melt was cooled and then taken up in ether, from which it soon separated in colorless crystals. It melts at 149–151°.

Anal. Calcd. for $C_{16}H_{12}O_2$: C, 81.3; H, 5.1. Found: C, 81.2; H, 5.6.

Hydrolysis of the Lactone.—Six-tenths gram of lactone was dissolved in 10 cc. of methyl alcohol to which had been added excess potassium hydroxide solution. A deep purple solution resulted which became lighter as the solution was heated on the water-bath. After removal of the methyl alcohol, which was gradually replaced by water, the clear solution was cooled and acidified. A substance separated which was crystallized from a mixture of ether and petroleum ether. It separates in small, octahedral crystals which melt at 146–148°.

1,2-Diphenyl-2-hydroxy-3-cyclopropane Carboxylic Acid.—Anal. Calcd. for $C_{16}H_{14}O_3$: C, 75.5; H, 5.5. Found: C, 75.1; H, 5.6.

Ozonization of the Hydroxy Acid.—Four-tenths gram of the hydroxy acid was ozonized cautiously in ethyl bromide for half an hour, after which almost the whole of the material was recovered unchanged. Finally another 0.4 g. was ozonized in a rapid current of 6% ozone for three hours after which more than 0.3 g. was recovered unchanged. Ozone therefore has no effect on the compound.

Summary

1. Another cyclopropene derivative has been prepared.
2. The dibasic acid obtained from this cyclopropene diester loses carbon dioxide at its decomposition point to form a cyclopropane lactone.

APPLETON, WISCONSIN

THE INDUCTION OF THE REACTION BETWEEN CHLORINE AND BENZENE BY ETHYLENE

BY T. D. STEWART AND M. H. HANSON

RECEIVED JANUARY 13, 1931 PUBLISHED MARCH 6, 1931

In the reaction between ethylene and chlorine Stewart and Smith[1] postulated a chain mechanism of the type

$$C_2H_4 + Cl_2 \longrightarrow C_2H_4Cl_2^* \xrightarrow{Cl_2} C_2H_3Cl_3 + HCl + \text{Heat} \qquad \text{(Ia)}$$

$$C_2H_4Cl_2^* \xrightarrow[\text{Wall}]{O_2} C_2H_4Cl_2 + \text{Heat} \qquad \text{(Ib)}$$

$$C_2H_4Cl_2^* \xrightarrow[Cl_2]{C_2H_4} 2C_2H_4Cl_2^* \qquad \text{(Ic)}$$

in which the starred formulas represent an intermediate compound, presumably an activated ethylene dichloride.

The experiments described here were first designed to determine whether this intermediate would induce a reaction in other reacting systems, or itself undergo a reaction with other substances (than chlorine). For instance, in the presence of benzene, a Friedel–Crafts reaction is possible between the intermediate and benzene, or in the presence of both benzene and benzoyl chloride, benzophenone might be formed. Thorough search for these reactions has shown no indication of them. Oxidations of the reaction products by alkaline permanganate or chromic acid have yielded only traces of materials which could be considered aromatic carboxylic acids. Similarly, when the reaction between ethylene and chlorine was carried out in the presence of a mixture of benzoyl chloride and benzene, no trace of benzophenone could be found.[2]

However, when benzene is used as a solvent for the chlorine-ethylene reaction, considerable benzene hexachloride is always formed, usually a mixture of the stereoisomeric forms, with the a-form (m. p. 157°) predominating.

$$C_6H_6 + 3Cl_3 \longrightarrow C_6H_6Cl_6$$

This reaction has long been known as one susceptible of induction by light,[3]

---

[1] Stewart and Smith, THIS JOURNAL, 51, 3091 (1929); 52, 2869 (1930).

[2] The reaction mixture was distilled to remove ethylene dichloride and benzene, the residue completely hydrolyzed in dilute alkali, and the alkaline solution extracted with benzene. The residue from this extract, distilling above 100°, yielded no oxime soluble in dilute alkali but insoluble in neutral water solution (10 cc.).

[3] Faraday, Ann. Chem., [2] 4,472 (1825); Slator, *Z. physik. Chem.*, 45, 540 (1903). Luther and Goldberg, *ibid.*, 56, 43 (1906), state that light is necessary even in boiling benzene. They studied the inhibiting effect of oxygen, from which Alyea (Ref. 6) estimates the quantum efficiency as about seventy-five moles per quanta.

alkali,[4] iodine[6] and alpha particles.[6] The first and last of these have been shown to have a chain mechanism. The efficiency of the induction by ethylene is then of particular interest and the effect of the physical conditions of the experiments upon this efficiency of importance.

The above reaction is not the sole reaction. Considerable hydrogen chloride is often formed, indicating some substitution. In our experience phenyl chloride is not a product. When little or no hydrogen chloride is formed the product is cleanly crystalline, but otherwise it is contaminated by gummy higher chlorinated substitution products of benzene. There are thus two criteria as to the nature of the reaction itself. The substitution reaction is favored by low chlorine concentrations in the photochemical and presumably so in ethylene-induced reactions. No attempt is made here to formulate the actual products of substitution (see Equation II′c below).

A Provisional Mechanism.—The experimental results may be correlated by means of the following series of steps, in which chain mechanisms for both the ethylene–chlorine and benzene–chlorine reactions are assumed, but without precise specification of the mechanism of chain propagation.

$$C_2H_4 + Cl_2 \longrightarrow C_2H_4Cl_2^* \begin{cases} \xrightarrow[\text{Wall, } O_2]{C_6H_6} C_2H_4Cl_2 + \text{Heat} & \text{IIa} \\ \xrightarrow[Cl_2]{C_2H_4} 2C_2H_4Cl_2^* \ldots\ldots \longrightarrow C_2H_4Cl_2 + \text{Heat} & \text{IIb} \\ \xrightarrow[3Cl_2]{C_6H_6} C_6H_6Cl_6^* + C_2H_4Cl_2 \xrightarrow[3Cl_2]{C_6H_6} 2C_6H_6Cl_6^* & \text{IIc} \\ C_6H_6Cl_6^* \xrightarrow[\text{Wall, } O_2]{C_6H_6} C_6H_6Cl_6 + \text{Heat} & \text{IId} \end{cases}$$

Reaction IIc might better be written as follows

$$C_2H_4Cl_2^* \xrightarrow[Cl_2]{C_6H_6} C_6H_6Cl_2^* + C_2H_4Cl_2 \xrightarrow{Cl_2} C_6H_6Cl_4^* \begin{cases} \xrightarrow{Cl_2} C_6H_6Cl_6^* \ldots\ldots & \\ \xrightarrow{-HCl} C_6H_5Cl_3(?) + \text{Heat} & \text{II}'\text{c} \end{cases}$$

Other possibilities present themselves, such as reaction Ia, but in numerous fractional distillations, no fractions corresponding to the tri- and tetrachloroethanes have been observed. This reaction is believed to

---

[4] Matthews, Trans. *Chem. Soc.*, 59, 166 (1891). Luther and Goldberg (Ref. 3, p. 55) state that alkali serves as a catalyst even with the total exclusion of light.

[5] Müller, J. *Chem. Soc.*, **15**, 41 (1862), states that the use of iodine as a catalyst results largely in substitution products.

[6] Alyea, THIS JOURNAL, 52, 2743 (1930).

have been inhibited by the benzene. Another type reaction, suggested to us by Professor G. N. Lewis, presumes no ethylene dichloride formed.

$$C_2H_4Cl_2^* + C_6H_6 + 2Cl_2 \longrightarrow C_6H_6Cl_6^* + C_2H_4 \ldots.$$

We have not observed conditions wherein little or no ethylene is used up. Moreover, when ethylene and chlorine react in the presence of ethylene dichloride (no benzene), the course of the substitution reaction approximates that of Equation Ia, since the hydrogen chloride produced never exceeds, in moles, the ethylene used up, which it might do if the hypothetical intermediate acted simply as a chlorinating reagent. The appearance of ethylene dichloride as an isolable product would tend to eliminate this type of mechanism as a major step in the process. The rupture of the benzene–chlorine chains by ethylene (or chlorine) is probable.

Experimental Results

The main observation was the proportion of total chlorine used up which reacted with the benzene. This was measured by weighing the non-volatile products formed and by noting the molal ratio of chlorine to ethylene reacting. This ratio would be unity if the chlorine reacted solely with the ethylene, and only by addition (see above). Any excess of chlorine used up, as shown by a value of this ratio greater than unity, is taken to mean reaction with benzene.

The Homogeneous Reaction between Ethylene and Chlorine Dissolved in Benzene.—The reagents were dissolved separately, and equal volumes of the solutions mixed and allowed to stand for two hours or more in the dark. The results were very discordant, but a few conclusions may be drawn. (1) The presence of glass wool or glass beads in the reaction mixture causes no difference in the molal ratio of total chlorine to ethylene used up, or in the nature or amount of the product. (2) This molal ratio varied from 1.7 to 2.2 when the chlorine concentration lay between 0.3 and 0.42 M and the ethylene concentration changed from 0.042 *M* (initial) to zero. In one experiment, with the chlorine within the above limits, but with the initial ethylene concentration at 0.013 M, this ratio was 10. When both were low (chlorine 0.036 M, ethylene 0.0043 M) the ratio was 1.26, very little of the chlorine reacting with benzene. (3) In all cases the amount of non-volatile residue was close to that predicted on the assumption that it consisted of benzene hexachloride and was formed from that excess of chlorine over ethylene indicated by the above ratios (little or no phenyl chloride was formed). But the product was always gummy in character, and the hydrogen chloride production was much higher than in experiments to be described later. (4) In the absence of ethylene the disappearance of chlorine is represented by the following figures.

Time (hours)	0	16	40	68
Chlorine concentrations (m./l.)				
(a) Dark	0.431	0.447	0.444	0.431
(b) Diffused light	...	.372	.346	.326
(c) Dark	.0347	.0357	.0364	.0352

These solutions were all quiet; the reaction in diffused light is enormously hastened by constant shaking, but in the dark is unaffected (Expts. 2a and 2b, Table II). The variations above suggest analytical difficulties in part. Eventually these analyses could be reproduced to 1%. There is no evidence to indicate that diffused light affects the reaction induced by ethylene, since the ethylene-induced reaction was the same (in two hours) in the dark and in diffused light.

The homogeneous reaction is then attended by an undue amount of benzene substitution even at high chlorine concentrations, and a low efficiency of induction except in one case, which suggested that the efficiency of induction might be a function of the ethylene concentration, *i. e.*, higher at lower ethylene concentrations. This would be expected on the basis of the competitive effect of Equations IIb and IIc.

Experiments with Chlorine Dissolved in Benzene and the Ethylene Introduced into the Vapor Phase. I. Bubbler Experiment.—In the first experiments dry ethylene gas was bubbled through the chlorine–benzene solution. The reaction vessel was essentially a glass tube, about 1 cm. in diameter and 25 cm. long, with smaller glass tube connections at each end. When filled with the solution and placed in a gently sloping position the bubbles of gas traveled the length of the tube, in contact with both the wall and the solution. The rate of flow varied from one to two cubic centimeters per minute, so that most of the gas entering was absorbed. The bubbles seemed to decrease to one-half or one-third their original volume, but the fraction of entering gas which was recovered was usually less than one-tenth This seemed to indicate that a large proportion of the reaction took place at the entrance and exit. The point of interest is that in these experiments the ethylene partial pressure in the gas phase was high, and varied probably from two-tenths to five-tenths of an atmosphere. Table I gives a summary of the results. The average chlorine concentration varied in the different experiments. The hydrogen chloride formed should be considered a maximum, and of significance only as indicating very little substitution, for analytical reasons (see Experimental Part). The weight of product is not consistent with the amount of chlorine and ethylene used. This also involves an analytical difficulty (see footnote, Table II) and is not considered to alter the major conclusion that this method of introducing the ethylene leads to a definite reaction between the chlorine and benzene, to the extent of about half the total reacting chlorine, with comparatively little substitution.

TABLE I

EXPERIMENTS WITH BUBBLES

Vol. of solution, 73 cc.; temp., 22–23°; semi-darkened room. Time: Expt. A, 45 min.; Expts. B, C, D, 4 hours. In Expts. A, B and C the reaction vessel was cleaned by solvents and air-dried at 100°; in Expt. D, by ignition in dry oxygen. Product was recovered as residue upon evaporation at room temperature and 3 mm. pressure.

Expt.	Concn. of Cl_2 moles/liter Initial	Final	Moles of reactants Cl_2	C_2H_4	Ratio Cl_2/C_2H_4	Moles HCl (at end)	Product, g.
A	0.425	0.313	0.00814	0.00318	2.56	0.00137	0.411
B	.853	.406	.0326	.0149	2.19	.00250	1.45
C	1.437	.978	.0335	.0152	2.20	.00715	2.36
D	1.297	.782	.0375	.0158	2.37	....	2.51

II. Shaker Experiments.—In these experiments, summarized in Table II, a large glass tube, sealed at both ends and provided with a side tube in the center, was the reaction flask. It was partly filled with the chlorine–benzene solution, connected to the ethylene supply through a three-way stopcock in the side tube, and placed on a rocker which caused the gas bubbles present to travel the length of the tube about once every second. The gas space could be varied at will and could be filled initially (by solution displacement) with ethylene, air or nitrogen. The ethylene supply was under constant pressure, and the gas flowed in as fast as the ethylene was used up. The initial partial pressure of the ethylene varied from about four-tenths of an atmosphere (Expts. 1, 3, 4) to about thirty centimeters of water (Expts. 5, 6), and varied greatly in single experiments, except in Expt. 6. This lack of constancy was due to decreasing vapor pressure of the solution, permitting more ethylene to enter, offset by the accumulation of any inert gas in the ethylene supply, and the production of hydrogen chloride. The difference in Expts. 3 and 4 could then be due to the difference in the volume of the gas phase in which the larger volume favored maintenance of a high ethylene partial pressure.

An attempt to hold this variable within narrow limits was made in subsequent experiments, by first filling the vapor phase with nitrogen to a total pressure of one atmosphere, and then allowing the ethylene to flow in at a pressure greater than this by 30 cm. of water. However, the rapidly decreasing chlorine partial pressure permitted the increase of the ethylene partial pressure, so that in Expt. 6 this was, in part, corrected for by closing the ethylene entrance periodically and opening the nitrogen entrance, thus allowing nitrogen to replace the accumulated ethylene in the gas phase. This was done six times during the experiment, and resulted in a marked increase in the proportion of chlorine reacting with the benzene. Any valid estimate of the ethylene partial pressure is impossible, but since the rate of solution of ethylene in benzene is low, and the rate of reaction is low, it may be assumed to be 30 ± 15 cm. of water in Expt. 6.

In diffused daylight (Expt. 2a) benzene alone reacts with chlorine at an appreciable rate (when shaken), but not in a darkened room (Expt. 2b). Experiment 1, then, cannot be compared strictly with subsequent experiments in which the reaction vessel as well as the room was darkened. The partial pressure of the ethylene appears to be an important factor in determining the proportion of chlorine reacting with benzene. Over 90% of the reacting chlorine reacts with benzene at low ethylene partial pressures. The effect of changing chlorine concentration upon this result has not yet been ascertained, but from the results given in Table I it would appear that at chlorine concentrations above 0.3 M the ethylene partial pressure is the major variable. No induction period was looked for. From previous work, the presence of oxygen would tend to reduce the length of any benzene–chlorine chain for a photochemically induced reaction, but its effect upon the ethylene-induced reaction is as yet undetermined. The walls have some effect upon the reaction, as evidenced by the low induction ratio in the homogeneous reactions as compared to the heterogeneous, and by the faster photochemical reaction in diffused light brought about by shaking.[7] However, immersed glass beads or glass wool

[a] In Expt. 5 the reaction mixture as a whole, instead of an aliquot portion, was treated with standard bisulfite and the excess bisulfite titrated with standard iodine as usual. The mixture then stood overnight before titrating the acid present. By morning this unusually large proportion of acid was present, and the yield of solid products, although cleanly crystalline, was lower than usual. It is thought that this may possibly be a function of the time of standing of the reaction mixture with water. Since the isolated products do not yield acid in contact with water, the experiment suggests either an unknown variable in the original reaction or possibly an unstable product first formed which reacts slowly with water to yield acid and water-soluble or volatile products, but which might change to water-stable products on standing. The isolated product did not appear to differ from that derived from other experiments, except that it was crystalline, whereas the presence of much acid is usually accompanied by gummy residues upon evaporation.

---

[7] The effect of boiling the solution, mentioned by Luther and Goldberg (Ref. 3) may be related to an agitation factor.

have little or no effect, hence the gas–wall interface, if any, would appear to be the important one.

Preparation of Materials.—The ethylene was generated from ethylene dibromide and zinc, washed with alcohol and stored over water. A drying train including phosphorus pentoxide was interposed between the reservoir and the reaction flask. When necessary for accuracy in measuring the gas volumes, a nitrometer was used as a reservoir. Analysis showed up to 1% of air or other inert gas.

A tank of chlorine containing less than one mole per cent. of hydrogen chloride was used. Blackened bottles contained the benzene, into which the chlorine was passed slowly, usually overnight.

The benzene was distilled from chromic acid and sulfuric acid mixture, washed and distilled from solid potassium hydroxide and finally from sodium wire.

Analysis.—Benzene was saturated with ethylene in a bubbler and the ethylene pressure used to force the solution up into a pipet. The measured solution was then delivered below a bromine solution in carbon tetrachloride at −20°. After standing tightly stoppered in the dark for six hours (in two hours the reaction was 75% complete) the excess bromine was titrated, using aqueous potassium iodide and thiosulfate. Appropriate blanks showed no conflicting reactions with the benzene. At 22" the saturated solution was 0.084 *M*, and this value agreed closely with a direct measurement of the volume of gas dissolved. In the homogeneous reaction experiments the containers had a small gas phase to minimize volatilization. More dilute solutions were prepared by diluting the saturated stock solutions.

Chlorine in benzene cannot be analyzed for by adding aqueous potassium iodide and titrating the iodine. Errors as high as 30% are involved. The analysis was made by delivering pipetted samples below the surface of a known volume of standard 0.1 *N* sodium acid sulfite solution (standardized against iodine solution) and back-titrating the excess. The hydrogen chloride formed was estimated from the same sample by subsequently titrating the total acid present with standard alkali, using phenolphthalein, and subtracting from this total the acid found in the reaction

$$HSO_3^- + Cl_2(\text{or } I_2) + H_2O \longrightarrow SO_4^= + 2Cl^- (\text{or } I^-) + 3H^+$$

By suitable blanks the ratio (in equivalents) of acid formed to bisulfite used up was determined. It was usually very close to the theoretical value of 1.5, and constant. However, any error in this ratio caused a very large error in the acid calculated as formed in the reaction studied, and this, together with slight (1%) uncertainties in the analysis for chlorine, made the estimate of the amount of substitution very uncertain. The values given in the text are probably high.

The normality of a bisulfite solution is reasonably constant if the volume of solution is large, if air admitted to the solution is drawn through a similar solution, and if the buret and reservoir do not form a closed system. This last proviso eliminated some anomalous changes in normality, that is, each time the buret was emptied air from the room (not from the reservoir) was admitted to the buret. The difficulty seemed real and is probably connected with the auto-oxidation problem of sulfites.

The benzene hexachloride was purified and analyzed for chlorine; no evidence of the presence of $C_6H_5Cl_7$, which has similar properties and could have been formed, was observed.

Summary

Benzene hexachloride, together with substitution products, is formed when ethylene gas is passed into a benzene solution of chlorine in the dark. A mixture of the various stereoisomers is obtained, with the a-form (m. p.

157°) predominating. The molal ratio of total chlorine reacting to ethylene reacting varies from two to eleven in the present experiments, and is greater the lower the partial pressure of ethylene. This is explained on the basis of chain mechanisms for both the ethylene–chlorine and benzene–chlorine reactions, the latter being induced by and acting as an inhibitor of the former.

In homogeneous solution the above ratio, with chlorine in large excess, is approximately two. A higher proportion of the chlorine is used in substitution than in the heterogeneous reactions.

No evidence of a Friedel–Crafts type of reaction between the ethylene chloride formed and benzene could be found. In a mixture of benzene, benzoyl chloride and chlorine no benzophenone was formed with introduction of ethylene.

THE REDUCTION POTENTIALS OF SOME HIGHER BENZOLOGUES OF THE QUINONES

BY LOUIS F. FIESER AND EMMA M. DIETZ

RECEIVED JANUARY 15, 1931 PUBLISHED MARCH 6, 1931

With the view of applying certain new tests to the theories of the structure of anthracene, we have prepared three angular dibenz-anthraquinones,[1] and determined their reduction potentials. It seemed appropriate to include in this study other quinones derived from tetra- or pentacyclic hydrocarbons, and we have thus examined potentiometrically most of the known compounds of this type.

We were fortunate in securing a sample of picenequinone through the kindness of Professor Frederick D. Chattaway of Oxford University, while the chrysene used in the preparation of the 5,6-quinone was furnished by the Gesellschaft fur Teerverwertung through the courtesy of the late Dr. R. Weissgerber. The other derivatives of 5,6-chrysenequinone, as well as the 6,12-isomer, were prepared by the synthesis of Beschke and Diehm.[2]

The results of the electrometric titrations are summarized in the accompanying table. The nature of the titrating reagent indicates the method of titration employed; in most cases it was found expedient to reduce the quinone catalytically and to titrate the reductant with an oxidizing agent. While satisfactory results were easily obtained with the tetracyclic quinones, the very sparing solubility of the pentacyclic compounds presented a serious obstacle. With the very dilute solutions slight sources of error have a magnified effect upon the potentials. It

was further found that electrode equilibrium was established very slowly in the titrations with these compounds; 'a steady value sometimes was reached only after a period of one hour. The consequent errors are reflected in the divergence of the separate determinations of the normal potential, E_0, particularly in the case of picenequinone. Because of the added uncertainty indicated by the wide deviation of the slope of the titration curve (ΔE_1 and ΔE_2) from the theoretical value ($\Delta E = 17.8$ mv.), the potential found for this compound is regarded as only an approximation.

The Structure **of Anthracene.**—It has been pointed out[4] that the abnormally low reduction potential of anthraquinone may be interpreted as an indication of the unusual reactivity of the anthracene nucleus. According to current theories, the seat of this reactivity may be either an ortho-quinonoid grouping of the double bonds or a para bond between the meso carbon atoms. While it is not easy to predicate the implications of the para-bond theory, for such a structure is purely hypothetical, the ortho-quinones are well-known substances and rational predictions of the properties of the benzologues of anthracene can be constructed from the assumption of the ortho-quinonoid structure of the hydrocarbon.

On the basis of this theory the attachment to anthrahydroquinone of a phenylene group in the angular position, as in I, should stabilize the

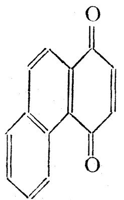
II



III

compound, in the sense of decreasing its tendency to undergo oxidation and thus relieve the tension in the ortho-quinonoid nucleus (q). This follows from the fact that β-naphthoquinone is more stable, in the same sense, than o-benzoquinone. This stabilizing effect of the added phenylene group would be expected to result in an increase in the oxidation–reduction potential of the system of which 1,2-benz-anthrahydroquinone is the reductant. The question of the possible influence of the extra benzene ring present in the oxidant, II, on the nature of the anthraquinone molecule can be readily answered by comparing 1,4-phenanthrenequinone, III, and 1,4-naphthoquinone. The latter compounds differ in just the way that 1,2-benz-anthraquinone differs from anthraquinone; a quinonoid ethylene linkage is in one case a part of a naphthalene ring, in the other case it is incorporated in a benzene nucleus. The potential of the naphthalene-containing compound, III, is the higher by 40 mv.[5]

If the extra phenylene group had no influence on the character of the reductant in question, the potential of the system from 1,2-benzanthraquinone would be expected to be 40 mv. higher than that from anthraquinone (E_0 = 0.155 v.),[6] or 0.195 v. The actual potential is 0.228 v., 73 mv. above that of the parent compound It is reasonable to attribute the extra increment to the stabilizing of the o-quinonoid system of the reductant, in the manner indicated.

In the case of the dibenz-anthraquinones, IV and V, the second angular phenylene may be expected to have the same influence on the nature of the oxidant as the first such group, and this would give an increase in the potential of 40 mv. over that of 1,2-benzanthraquinone. Examination

[5] Fieser, **This Journal**, 51, 3101 (1929). The difference in the potentials is erroneously reported in Table II of this paper as amounting to 30 mv.

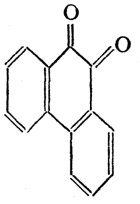
[6] Conant and Fieser, *ibid.*, 46, 1858 (1924).

of the o-quinonoid formula for one of the reductants, such as VI, reveals the fact that while the first phenylene group, p, is in a position to stabilize the quinonoid structure in the anthracene nucleus, the second group, p′, cannot be attached at the same time to the quinonoid ring and therefore cannot influence its reactivity. According to the theory, then, the angular dibenz-anthraquinones should differ in potential from the monobenz-derivatives by approximately 40 mv., and not by the larger figure of 73 **mv.** which represents the effect of a single phenylene group. The results given in the table show that the difference for the two quinones, IV and V, amounts to **36** mv. and 40 mv., respectively, and the good agreement with the predictions based upon the o-quinonoid theory of the structure of anthracene constitutes an argument in support of this theory.

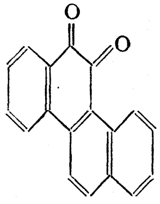
While the p-bond theory leads to no precise predictions of the effect of attaching an angular phenylene group to anthracene, it does imply that a second such group would have exactly the same influence as the first, for the p-bond formula is symmetrical. The present results show, however, that this is not the case and that, contrary to the *p*-bond theory, anthracene appears to have an unsymmetrical structure. It is unfortunate that the potential differences upon which these arguments are based are not more pronounced. The above conclusions appear justified, but they lack the weight to which they might otherwise lay claim.

The linear benz- and dibenz-anthraquinones offer an interesting field for a continuation of the present study, but it was found that these compounds, for reasons which will be apparent from a forthcoming publication, are not amenable to potentiometric study.

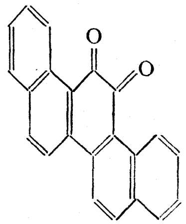
Benzologues of 9,10-Phenanthrenequinone.—5,6-Chrysenequinone, VIII, and picenequinone, IX, do not differ appreciably in potential from phenanthrenequinone, VII. While it is surprising that the added phenylene groups appear to have no influence, an adequate interpretation of the relationship will only be possible when the potential of the parent compound is more fully understood.



E_0 = 0.471 v.
VII



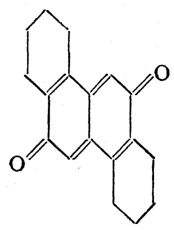
E_0 = 0.465 v.
VIII



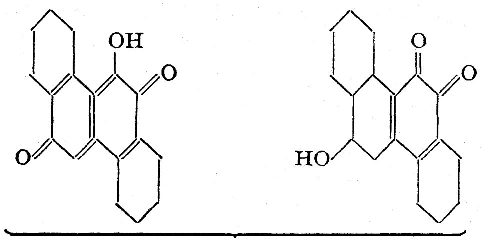
E_0 = 0 474 v.
IX

Amphi-chrysenequinone.—It is of interest to compare this substance, X, with amphi-naphthoquinone. The reduction potential of the latter compound has been estimated by an indirect method to be 0.758 mv.[7] By the inclusion of two of the quinonoid linkages of this substance in benzene rings the molecule is greatly stabilized and the potential is decreased by 0.366 v., or 0.183 v. for each such ring. This appears to be fairly consistent with the fact that the potential of *p*-benzoquinone is lowered 0.224 v. by the attachment to it of one phenylene group.

Hydroxy-chrysenequinone may conceivably exist in two tautomeric forms, XIa and XIb. Beschke and Diehm[2] have advanced chemical evidence in support of the ortho-quinonoid structure, XIb, and the electrochemical evidence confirms this view. If the structure of the compound were that of an amphi-quinone, the potential should be in the neighborhood of 0.120 v. below that of amphi-chrysenequinone (effect of a quinonoid hydroxyl), that is, about 0.272 v. Since this differs from the actual value by over 0.1 v. it is obvious that the amphi-quinonoid structure is excluded. If, on the other hand, the compound has the structure of XIb, it would be expected to differ in potential from ortho-chrysenequinone to about the same extent that 3-hydroxy-phenanthrenequinone differs from the unsubstituted quinone, or 0.053 v. The potential predicted on this basis is 0.465 − 0.053 = 0.412 v., and the figure is in fairly good agreement with the actual value of 0.391 v. The ortho-quinonoid formula is further supported by the fact that the ether, which is assuredly ortho-quinonoid, is just 0.027 v. higher in potential than the hydroxy compound. Such a relationship is entirely normal.



$E_0 = 0.392$ v.
X



$E_0 = 0.391$ v.
XIa XIb

While the structure of hydroxy-amphi-chrysenequinone is thus established beyond question, the potential of this substance presents a striking anomaly. When Beschke and Diehm prepared the compound for the first time, they advanced the view that the substance must exist in that tautomeric form which has the lower reduction potential. This general principle has been elaborated and applied in a number of instances by one of us,[8] and the generalizationinvariably has been confirmed. Beschke and Diehm had no means of estimating adequately the relative potentials

---

[7] Fieser, THIS JOURNAL, 52, 5204 (1930).

[8] Fieser, *ibid.*, 50, 439 (1928).

of the two tautomeric forms, but it is now clear that they were in error in considering that the ortho-quinonoid form would have the lower potential. The present results show that the stable tautomer is the one having the higher reduction potential, and the case thus constitutes a definite exception to-the rule. The only suggestion which we can now offer in explanation of the failure of the hydroxyquinone to change over into a thermodynamically more stable tautomer is that there is some steric resistance to such a change.

Summary

A potentiometric study of the benzologues of anthraquinone and phenanthrenequinone has led to the following significant conclusions. (1) The potentials of the benz- and dibenz-anthraquinones lend support to the ortho-quinonoid theory of the structure of anthracene. (2) Hydroxy-chrysenequinone constitutes an exception to the rule that when a quinone can exist in two forms the one of lower potential will predominate.

THE OXIMES OF ALPHA, BETA-UNSATURATED KETONES AND THE BECKMANN REARRANGEMENT

BY A. H. BLATT

RECEIVED JANUARY 17, 1931 PUBLISHED MARCH 6, 1931

The work of Meisenheimer and others has brought into question the long-accepted assumption that in the Beckmann rearrangement a shift occurs between the oximino hydroxyl group and the hydrocarbon residue spatially adjacent—a cis migration—and has given new prominence to the view that the shift is between groups spatially removed—a *trans* migration. The original evidence to this effect was furnished by the ring opening of triphenyl isoxazole;[1] the bulk of the evidence, however, has come from the study of ring closure in appropriately substituted ketoximes.[2]

Although the chief evidence for the idea of a *trans* migration has come from the study of ring closure, there is one class of ketoximes, the oximes of α,β-unsaturated ketones, whose behavior seems incompatible with a *trans* migration.[3]

[3] Von Auwers has discussed these oximes in a preliminary notice [*Ber.*, 62, 1320 (1929)] and has outlined a series of researches on the oxime configurations and the relation between configuration, substituents and ease of ring closure. The present work was outlined and started several years ago It was completed recently without knowl-

Two α,β-unsaturated ketones, benzalacetophenone[4] and dypnone[6] have been studied in some detail. Since the facts are similar in both cases it will be necessary to review only the former. When benzalacetophenone is treated with hydroxylamine hydrochloride, the product is an oxime. To this oxime, which furnishes cinnamanilide when it undergoes the Beckmann rearrangement, Henrich, on the basis of a cis migration, assigned the structure (I) and the designation of labile oxime.

V

When benzalacetophenone is treated with hydroxylamine hydrochloride and an excess of alkali it furnishes, in poor yield and among other products, a substance which Henrich formulated as the isomeric stable oxime (II). This stable oxime, however, is surprisingly unreactive. In contrast to the labile oxime it does not yield an acetyl derivative, nor does it give an addition product with phenyl isocyanate, nor can it be made to undergo a Beckmann rearrangement. In view of its unreactivity Henrich considered an alternative formulation as 3,5-diphenyl isoxazoline (III). This cyclic formula, however, he rejected because he felt it to be inconsistent with the fact that on reduction with sodium and boiling alcohol both the stable and labile oximes give the same product (IV), whereas in Henrich's opinion the isoxazoline should have given the amino alcohol (V). This behavior on reduction has not seemed to the present writer to be sufficient for the rejection of the isoxazoline formula, inasmuch as so little is known of the general behavior on reduction of this type of heterocyclic compounds. And since a decision between the oxime and isoxazoline formulas is a prerequisite for further discussion, our experiments started with this question.

Most of the workers who preceded Henrich had used the isoxazoline formula for the stable oxime and Claus[4c] had shown that this stable oxime could be oxidized to the known 3,5-diphenyl isoxazole—a fact which at least balances Henrich's reduction as structural evidence. To decide definitely between the oxime and isoxazoline formulas we treated the stable oxime with methylmagnesium iodide after the method of Zerewitinoff, believing that no matter how inert the oximino hydroxyl group it

should certainly evolve methane with this reagent. However, the stable oxime from benzalacetophenone yields no gas; hence it has no active hydrogen and it is to be written, therefore, as the isoxazoline (III).

The facts now available are that benzalacetophenone in acid solution yields an oxime, in alkaline solution an isoxazoline. The inferences from these facts are that the true oxime has the syn phenyl configuration (I) assigned it by Henrich, that the isomeric oxime is unstable and on formation goes into the isoxazoline (111), and that in the Beckmann rearrangement of the true oxime there is a cis shift between the hydroxyl and phenyl groups. A more detailed study for the purpose either of confirming these inferences or of discovering new facts which would bring the rearrangement of α,β-unsaturated ketoximes into line with the other oximes constitutes the balance of this article.

I. The Configuration of the True Oximes

For determining whether the true oximes of α,β-unsaturated ketones possess the *syn* phenyl configuration, corresponding to (I), or the ***anti*** phenyl configuration, corresponding to (II), benzalacetophenone oxime is unsatisfactory; it is obtained in poor yield, it crystallizes with difficulty, and the cyclic products to be expected from it are symmetrical and give no clue to the way in which ring closure has taken place. Consequently we turned to other unsaturated ketones, benzal-*p*-bromo-acetophenone and benzal-o-chloro-acetophenone, and prepared from them the corresponding true oximes—that is, oximes which on rearrangement give substituted anilides of cinnamic acid.

The oxime of benzal-o-chloro-acetophenone, if it has the *syn* phenyl structure (VI), corresponding to that assigned by Henrich to the true oxime of benzalacetophenone, might be expected to lose halogen acid when treated with alkali and yield a benzisoxazole. Actually it does not lose halogen acid even on prolonged boiling with alcoholic potash. This fact, while not conclusive, because of the possible inactivity of the chlorine, does make necessary serious consideration of the alternative configuration. Using the more readily available oxime of benzal-*p*-bromo-acetophenone it was possible to secure definite evidence as to configuration by closing the ring on the side toward the double bond. When this oxime is brominated in chloroform solution it takes up two atoms of bromine, yielding a dibromide (VIII), which either by the action of alkali or of heat loses hydrogen bromide and is converted into 3-#-bromophenyl-5-phenyl isoxazole (IX). The structure of the isoxazole was shown by its synthesis from the dibromide of benzal-*p*-bromo-acetophenone.[6] This ring closure is explicable only if the oxime has the ***anti*** phenyl configuration (VII).

---

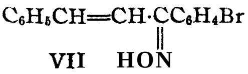
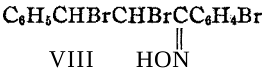
VI



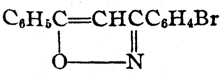
$C_6H_5CH{=}CH{\cdot}\underset{\underset{\text{HON}}{\|}}{C}C_6H_4Br$

VII



$C_6H_5CHBrCHBr\underset{\underset{\text{HON}}{\|}}{C}C_6H_4Br$

VIII



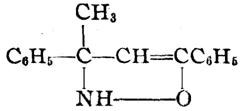
IX

Since the oxime (VII) is the analog of all the oximes of α,β-unsaturated ketones so far examined (it like all the others gives an anilide of cinnamic acid on rearrangement), one must conclude that the true oximes of these α,β-unsaturated ketones have the *anti* phenyl configuration and undergo a *trans* shift in the Beckmann rearrangement.

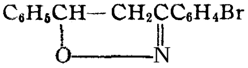
II. The Mechanism of Formation of the Isoxazolines

With the *anti* phenyl configuration assigned to the true α,β-unsaturated ketoximes, it becomes of interest to learn whether these oximes are intermediate steps in the formation of the isoxazolines. We have, therefore, treated the true oximes of dypnone and of benzal-p-bromoacetophenone with hydroxylamine hydrochloride and excess alkali (the conditions under which the isoxazolines are formed directly from the ketones) and found that the oximes are unaffected. Neither are they converted into isoxazolines by heating with alcoholic alkali. It would seem then that the oximes are not intermediate in the formation of the isoxazolines.

Since the isoxazolines are formed directly from the ketones only in alkaline solution and since free hydroxylamine is known to add to unsaturated carbonyl compounds,[7] the 1,4-addition of the reagent followed by ring closure immediately suggests itself as a possible mechanism. This mechanism can be tested in the case of dypnone for here the isoxazoline if formed through simple 1,4-addition would have the structure (X), and it would possess an active hydrogen atom. Actually the isoxazoline is inert toward the Grignard reagent.



X



XI

Similarly, if the isoxazoline from benzal-*p*-bromo-acetophenone were formed through 1,4-addition, the nitrogen would be attached to the carbon atom adjacent to the phenyl group. Actually, the nitrogen is attached to the carbon atom adjacent to the *p*-bromophenyl group (XI), as is shown by the oxidation of the isoxazoline to 3-*p*-bromophenyl-5-phenyl isoxazole (IX). Consequently, the simple 1,4-addition of hydroxylamine is eliminated as a mechanism.

---

[7] Posner, *Ann.*, 389, 1 (1912).

It appears likely that the isoxazolines are formed as a result of a rather complex process, perhaps involving the addition of a molecule of hydroxylamine to two molecules of unsaturated ketone.[4d] For the present, however, it must suffice to emphasize, in view of the *anti* phenyl configuration assigned to the true oximes, that these oximes are not intermediates in the formation of the isoxazolines.

III. The Sulfuric Acid Rearrangement of the Oximes

Since it has been established that the so-called stable oximes of α,β-unsaturated ketones are in reality isoxazolines, a reaction first noted by Henrich[4e] must be reinterpreted. Henrich showed that the true oximes of benzalacetophenone and dypnone when dissolved in concd. sulfuric acid, heated and then poured on ice gave the stable oximes; restated, the true oximes rearrange to isoxazolines. This is, in effect, a new type of oxime rearrangement. We have confirmed Henrich's observations using dypnone and have further found that in this and other cases simple solution in sulfuric acid followed by pouring on ice suffices to bring about the rearrangement. The reaction is a remarkably clean one. In fact, since the oximes are the sole reaction product using the ketone and hydroxylamine hydrochloride, while the isoxazolines are only one of the many products formed in alkaline solution, it is frequently more satisfactory to prepare the isoxazolines via the oximes and sulfuric acid than from the ketones directly.

It is, of course, hazardous to use this rearrangement as structural evidence but it may be pointed out that the rearrangement is certainly not incompatible with the anti phenyl configuration. From appearances at least the rearrangement would seem to involve halochromic salt formation on the part of the oxime, followed by rearrangement of the cation in the strongly acid medium to yield a more basic product.

The expenses of this research have been defrayed by funds privately contributed.

Experimental Part

$C_6H_5CH{=}CHCOC_6H_5$ and $C_6H_5C(CH_3){=}CHCOC_6H_5$

3,5-Diphenyl isoxazoline and **3,5-diphenyl-5-methyl** isoxazoline were prepared according to the directions of previous workers.[4c,e] Treated in a Zerewitinoff apparatus with an excess (6 moles) of methylmagnesium iodide in isoamyl ether, there was no evolution of gas even on warming.

When dypnone oxime, prepared according to Henrich's directions,[4e] was boiled with alcoholic sodium hydroxide—2.0 g. of oxime in 150 cc. of alcohol containing 1.5 g. of sodium hydroxide—80% of the oxime was recovered. No isoxazoline could be detected.

Another sample of dypnone oxime was shaken with a small volume of concd. sulfuric acid. There was a noticeable evolution of heat as the oxime dissolved to yield a deep yellow solution. As soon as all the material had gone into solution the reaction mixture was poured onto cracked ice. The precipitated solid melted, after drying, at 75–78°

and a mixture with the pure 3,5-diphenyl-5-methyl isoxazoline (78°) melted at 77–78°. The yield was quantitative.

$C_6H_5CH{=}CHCOC_6H_4Cl$-*o*[8]

The unsaturated ketone was made by condensing benzaldehyde and o-chloro-acetophenone according to the directions in "Organic Syntheses" for benzalacetophenone.[9] The *o*-chloro-acetophenone was obtained by the hydrolysis of ethyl o-chlorobenzoyl acetate.[10] Since the benzal-*o*-chloro-acetophenone, which was obtained in good yield as a yellow oil, could not be induced to crystallize, it was converted directly to the oxime. For this purpose 12.12 g. of unsaturated ketone was dissolved in 100 cc. of alcohol and 7.0 g. of hydroxylamine hydrochloride (100% excess) in 25 cc. of water was added. The resulting solution was boiled for five hours, left overnight, then ether and water were added. The ether layer was worked up in the usual manner and yielded the oxime upon slow evaporation after the addition of petroleum ether. The oxime is reluctant to crystallize and the yield is poor. For analysis the material was twice crystallized from ether and petroleum ether.

Anal. Calcd. for $C_{15}H_{12}ONCl$: C, 69.9; H, 4.7. Found: C, 69.8; H, 4.8.

Benzal-*o*-chloro-acetophenone oxime crystallizes in small cubes. It is very soluble in all the common solvents save petroleum ether. On melting, this oxime shows a peculiar behavior; the most carefully purified material melts over a wide range, 110–124° heating at a rate of 2° per minute, to give a yellow melt; compare the behavior of the oxime of benzal-*p*-bromo-acetophenone below.

Beckmann Rearrangement.—Phosphorus pentachloride in excess was added to 1.0 g. of the oxime dissolved in 10 cc. of absolute ether. The reaction flask was cooled in ice water until the initial precipitate had redissolved, then the solution was poured on ice and the product taken up in ether. On evaporation of the ether, white crystals melting at 134–136° were obtained. These crystals did not depress the melting point of a sample of the o-chloro-anilide of cinnamic acid prepared from the acid chloride and *o*-chloro-aniline.

Anal. Calcd. for $C_{15}H_{12}ONCl$: C, 69.9; H, 4.7. Found: C, 69.8; H, 4.8.

The o-chloro-anilide of cinnamic acid is quite soluble in acetone and ether. It crystallizes well from methyl and ethyl alcohols in very fine colorless needles when its solutions in these solvents are diluted with hot water. The anilide melts at 136–137°.

Action of Alkali on the Oxime.—To a solution of 2.0 g. of potassium hydroxide in 25 cc. of methyl alcohol there was added 0.761 g. of oxime. The reaction mixture was boiled for five and one-half hours, during which time a red color developed. The solution was then diluted with 125 cc. of water, acidified with dilute nitric acid and left overnight. Next day the precipitate was removed by filtration and the chloride ion in the filtrate determined by a Volhard titration. Only 0.69 cc. of 0.1 N silver nitrate solution—corresponding to the removal of 2.3% of the chlorine—was required. The precipitate weighed 0.70 g. and when crystallized slowly from ether and petroleum ether it yielded the characteristic cubes of the original oxime, which was identified by a melting point and a mixed melting point determination.

$C_6H_5CH{=}CHCOC_6H_4Br$-*p*

Preparation of the Oxime.—A solution of 0.05 mole of unsaturated ketone was prepared by dissolving 14.35 g. of the ketone in 150 cc. of hot alcohol. After the addition of a drop of hydrochloric acid to neutralize any alkali occluded during the preparation of

the ketone, 5.3 g. (0.075 mole) of hydroxylamine hydrochloride dissolved in 25 cc. of water was added and the reaction mixture boiled for four hours. Hot water was then added to incipient cloudiness. On cooling, the oxime crystallized in fine white needles. which were filtered and dried. The yield was 13.0 g. or 86%. By concentrating the filtrate and adding water another gram of material was obtained. For analysis the oxime was recrystallized from alcohol.

Anal. Calcd. for $C_{15}H_{12}ONBr$: C, 59.6; H, 4.0. Found: C, 59.7; H, 4.0.

Benzal-*p*-bromo-acetophenone oxime (VII) is quite soluble in the common organic solvents; crystallizes well from 95% alcohol or more dilute alcohol in extremely fine needles. These needles—perfectly colorless—melt over a wide range, 138–150°, to a yellow liquid. Repeated crystallization does not affect the melting point and a fractional crystallization accompanied by a microscopic examination of the crystals showed them to be homogeneous. A small sample of the pure oxime was kept at 150° for one-half hour. During this time an odor of benzaldehyde or benzonitrile was noticeable. The yellow melt, on cooling, gave a solid discolored yellow, apparently the oxime accompanied by decomposition products. No isoxazoline could be detected.

Action of Alcoholic Alkali on the Oxime.—Two grams of the oxime was dissolved in 25 cc. of alcohol containing 2.0 g. of potassium hydroxide and the solution was boiled for four hours. It developed a yellow color and an odor indicating that some hydrolysis had taken place. However, by adding water to complete precipitation, 1.75 g. of oxime was recovered and there was no evidence of the formation of isoxazoline.

Action of Hydroxylamine on the Oxime.—When 3.0 g. of the oxime was dissolved in 35 cc. of hot alcohol, a solution of 1.05 g. of hydroxylamine hydrochloride and 2.0 g. of potassium hydroxide in 10 cc. of water added, and the reaction mixture boiled for three hours there was no conversion to the isoxazoline. On working up the products of the reaction 80% of the oxime was recovered.

Beckmann Rearrangement.—Phosphorus pentachloride in excess was added to 2.0 g. of the oxime in 25 cc. of absolute ether. After the initial precipitate had redissolved the reaction mixture was poured onto ice, ether added and the ethereal solution washed with water, sodium carbonate solution and dried. On evaporation of the ether, 1.6 g. of solid, discolored yellow, was obtained. This material was purified by crystallization from alcohol. It then melted at 188–189°. The *p*-bromo-anilide of cinnamic acid was prepared from the acid chloride and *p*-bromo-aniline. It melted at 191° and a mixed melting point with the rearrangement product was 189–190°.

Anal. Calcd. for $C_{15}H_{12}ONBr$: C, 59.6; H, 4.0. Found: C, 59.3; H, 4.1.

Bromination of the Oxime.—When 5.2 g. of the oxime was dissolved in 100 cc. of chloroform and 2.8 g. of bromine in the same solvent was added, a dibromo-oxime (VIII) was formed. The crude material, obtained by pumping off the chloroform, weighed 7.3 g., was discolored red and melted with vigorous decomposition at about 150°. It was purified by crystallization from chloroform and petroleum ether, from which it separates in splendid clusters of fine needles melting, with decomposition, at about 155°.

Anal. Calcd. for $C_{15}H_{12}ONBr_3$: Br, 51.9. Found: Br, 51.3.

The dibromo-oxime is difficultly soluble in the ordinary solvents and if their boiling points are at all elevated it seems either to react with the solvent or to lose hydrogen bromide. With alcoholic alkali the dibromo-oxime eliminates hydrogen bromide to yield 3-p-bromophenyl-5-phenyl isoxazole (IX) but the reaction is not clean cut—doubtless because the greater part of the material follows the more complex course recently outlined for α,β-dibromo ketones by Kohler and Addinall.[11] Thus when

---

[11] Kohler and Addinall, THIS JOURNAL, 52,3728 (1930).

0.842 g. of dibromo-oxime was added to 25 cc. of hot methyl alcohol containing 2.0 g. of potassium hydroxide, a brilliant orange solution resulted. Some of the material seemed not to enter into the reaction but to persist as a heavy oil; the oxime is only slightly soluble in methanel. Soon after the addition of the dibromide glistening flat plates of isoxazole began to separate from the solution. After three hours' boiling the reaction mixture was diluted to 150 cc. with distilled water and left overnight. Next day it was acidified with dilute nitric acid, which discharged the color, and filtered. The filtrate in a Volhard titration required 31.75 cc. of 0.1 N silver nitrate solution, corresponding to the elimination of 87% of the aliphatic bromine in the dibromide. The precipitate when crystallized from hot ethyl acetate yielded 0.1 g. of 3-*p*-bromophenyl-5-phenyl isoxazole (IX), which was identified by its melting point, 178–179°, and a mixed melting point with a specimen prepared from the dibromide of benzal-*p*-bromo-acetophenone—see below. The ethyl acetate filtrate contained material which gave a copper salt with aqueous copper acetate.

Action of Heat on the **Dibromo-oxime (VIII).**—Either as the pure solid or in solution the dibromo-oxime when heated loses hydrogen bromide to form the isoxazole (IX). One gram of pure dibromide in a small flask connected to a water pump was heated to 150° until the evolution of hydrogen bromide ceased. The evolved gases reddened litmus paper and produced a yellow precipitate when passed into silver nitrate solution. The dark red melt solidified on cooling. It was crystallized from acetic acid and yielded 0.3 g. of isoxazole. The filtrates deposited an additional small quantity of isoxazole. The isoxazole was identified by its melting point and a mixed melting point. The yield was 50%. The same conversion to the isoxazole can be brought about by heating the dibromo-oxime in glacial acetic acid. Thus 0.5 g. of the dibromooxime in 20 cc. of glacial acetic acid was boiled for thirty minutes. On concentrating and cooling the solution 0.17 g. of isoxazole was obtained.

Synthesis of **3-*p*-bromophenyl-5-phenyl-isoxazole (IX).**—To a suspension of 8.9 g. of the dibromide of benzal-*p*-bromo-acetophenone[12] and 2.8 g. of hydroxylamine hydrochloride in 150 cc. of alcohol, there was added 6.6 g. of potassium hydroxide in 15 cc. of water. A yellow color immediately developed and in a few minutes glistening white plates resembling naphthalene began to precipitate. After forty-five minutes the reaction mixture was cooled and filtered, then the precipitate washed thoroughly with water and dried. The yield of crude material, which was practically pure, was 3.6 g For analysis the isoxazole was crystallized from ethyl acetate.

Anal. Calcd. for $C_{16}H_{10}ONBr$: C, 60.0; H, 3.3. Found: C, 60.0; H, 3.7.

3-p-Bromophenyl-5-phenyl isoxazole (IX) is insoluble in cold alcohol and ether, slightly soluble in acetone and chloroform. It crystallizes well from glacial acetic acid, benzene or ethyl acetate. The pure material melts at 178–179°.

Preparation of 3-p-Bromophenyl-5-phenyl **Isoxazoline** (XI). A. From the Ketone.—A solution of 2.1 g. of hydroxylamine hydrochloride (0.03 mole) and 4.0 g. of potassium hydroxide in 20 cc. of water was added to a solution of 5.6 g. of benzal-p-bromo-acetophenone (0.02 mole) in 70 cc. of alcohol. After boiling for one and one-half hours, during which time the solution turned orange in color while colorless glistening crystals began separating, the reaction mixture was left overnight. Next day the precipitate of isoxazoline was filtered and dried; yield, 1.9 g. or 30%. The filtrate on dilution with water yielded other products which in view of the known complexity of the alkaline reaction were not studied.

B. From the **Oxime.**—One gram of benzal-*p*-bromo-acetophenone oxime was shaken with 20 cc. of concd. sulfuric acid. The oxime dissolved giving a yellow solution.

---

[12] Weygand and Bauer, ***Ann.,*** 459, 138 (1927).

After standing overnight the sulfuric acid was poured onto ice and the colorless precipitate filtered and dried. It weighed 0.85 g., melted at 137–139° and caused no depression in the melting point of the isoxazoline prepared directly from the ketone. For analysis the material was crystallized from alcohol.

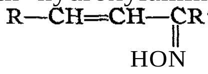
Anal. Calcd. for $C_{15}H_{12}ONBr$: C, 59.6; H, 4.0. Found: C, 59.7; H, 4.2.

3-*p*-Bromophenyl-5-phenyl-isoxazoline (XI) is moderately soluble in and crystallizes well from the ordinary solvents. In appearance the glistening flat plates of the isoxazoline closely resemble the isoxazole. However, the solubility of the isoxazoline in alcohol is considerably greater than the isoxazole. The pure isoxazoline melts at 138–139°.

Oxidation of the Isoxazoline (XI) to the Isoxazole (IX).—A solution of 2.0 g. of the isoxazoline in 100 cc. of glacial acetic acid was heated to 80° and 1.3 g. (200% excess) of chromic oxide was added. The reaction mixture was stirred for forty-five minutes, then poured into 400 cc. of cold water. The resulting precipitate was filtered and washed with water and a small amount of cold alcohol. It was then boiled with an amount of alcohol insufficient for complete solution. The hot alcoholic solution was separated from the solid residue by filtration. The residue crystallized from ethyl acetate furnished 0.25 g. of pure isoxazole. The first crop of crystals from the alcoholic filtrate was likewise isoxazole and weighed 0.25 g. The identity of these two sets of material was shown by a mixed melting point with the pure isoxazole. The second and third crops of crystals from the alcoholic filtrate weighed 0.6 g. and were slightly impure isoxazoline, as shown by their melting points. The balance of the material apparently had been further oxidized.

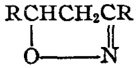
Summary

Certain α,β-unsaturated ketones when treated with hydroxylamine hydrochloride yield oximes of the general configuration



$$R{-}CH{=}CH{-}\underset{\underset{HON}{\|}}{C}R'$$

. These oximes undergo a *trans* shift in the Beckmann rearrangement and when dissolved in concd. sulfuric acid rearrange in a different manner to yield the isomeric isoxazolines



$$\begin{array}{l}RCHCH_2CR' \\ \;\;|\qquad\quad \| \\ \;\;O{-}{-}{-}{-}N\end{array}$$

. The so-called stable oximes of these α,β-unsaturated ketones are in reality isoxazolines, and are formed through a process which does not involve either the true oxime as an intermediate or the simple 1,4-addition of hydroxylamine to the ketone.

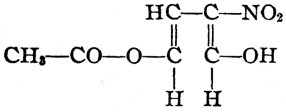
THE STRUCTURE OF NITROFURAN AND THE MECHANISM OF NITRATION IN THE FURAN SERIES

BY B. T. FREURE AND JOHN R. JOHNSON

RECEIVED JANUARY 19, 1931 PUBLISHED MARCH 6, 1931

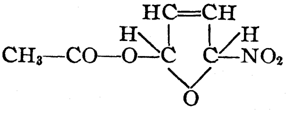
The nitration of furoic acid,[1] furfural diacetate,[2] 2-methylfuran[3] and many other furan derivatives, leads to the formation of nitro compounds in which it is reasonably certain that the nitro group has entered an *alpha* position. The nitration of furan itself gives a crystalline nitrofuran which Marquis[4] has formulated as β-nitrofuran. Since his work does not constitute an unequivocal demonstration of the position of the nitro group, and a large amount of indirect evidence would lead one to expect an α-nitrofuran, the validity of his formula is doubtful. The present study was undertaken with the object of establishing the structure of this nitrofuran and elucidating the mechanism of the nitration process.

In the nitration of furan, which is effected in the presence of acetic anhydride, there is formed an intermediate nitroacetate. This product corresponds in composition to the addition of a molecule of nitric acid and a molecule of acetic acid, with the elimination of a molecule of water. On treatment with pyridine, the unstable nitroacetate loses a molecule of acetic acid and is transformed into a crystalline nitrofuran. Marquis[4] found that the intermediate nitroacetate is decomposed by warm water with the production of nitrous and acetic acids and maleic dialdehyde, and this observation led him to formulate the intermediate product as an open-chain enol (I), produced by rupturing the oxygen bridge of the furan ring. It is difficult to concede that the formation of maleic dialdehyde is valid evidence for assigning the nitro group to the β-position and for assuming an open-chain enol structure. It seems more reasonable to assign to the intermediate nitroacetate a closed chain structure (II), which would be produced by 1,4-addition of nitric acid and subsequent acetylation. A similar 1,2-addition would give an alternative closed chain structure (III).

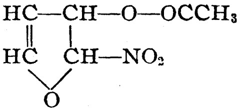


$$\begin{array}{ccc} & HC & C\text{—}NO_2 \\ & \| & \| \\ CH_3\text{—}CO\text{—}O\text{—} & C & C\text{—}OH \\ & | & | \\ & H & H \end{array}$$

I



II



III

The formation of maleic dialdehyde can be explained more simply from the ring structures (II and III) than from the open-chain enol (I)

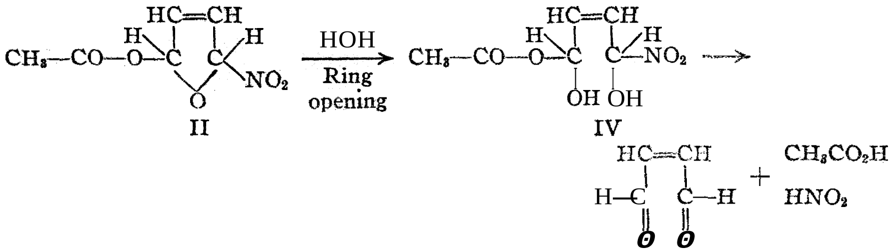
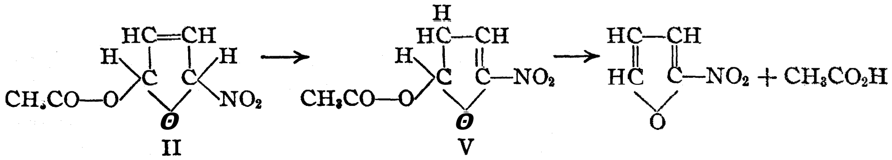
[2] Gilman and Wright, THIS JOURNAL, 52, 2550 (1930).

[3] Ref. 1, p. 1118.

[4] Marquis, *Ann. chim. phys.*, [8] 4, 216 (1905).

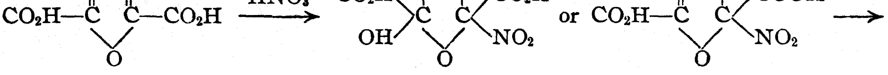


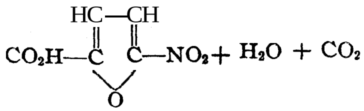
The decomposition of the unstable α-hydroxy nitro compound (IV) into an aldehyde and nitrous acid is analogous to the transformation of a-hydroxycarboxylic and α-hydroxysulfonic acids into aldehydes. The transformation of the intermediate nitroacetate (II) into 2-nitrofuran by the action of pyridine can be explained by 1,4-elimination of acetic acid or by a preliminary rearrangement into an isomeric nitroacetate (V), followed by 1,2-elimination of acetic acid



This type of rearrangement may be expected to occur readily since this shift of the double bond brings it into conjugation with the double bond of the nitro group. This reaction is analogous to the migration of the double bond from the β,γ- to the α,β-position in unsaturated carboxylic acids.

The behavior of certain substituted furan derivatives on nitration furnishes additional evidence for the formulation of the intermediate product as a ring compound. Although esters of furoic and furylacrylic acids form intermediate nitroacetates, the free acids do not form any intermediate product that can be isolated. It is highly probable that this difference is due to a greater lability of the intermediate product rather than to a fundamental difference in the mechanism of nitration. This view is supported by the observation that the nitration of furan derivatives containing a carboxyl group in the alpha-position often results in a displacement of the carboxyl group by the nitro group. Since the esters of these acids do not show this behavior, the decarboxylation is readily explained by the great instability of the intermediate a-nitro carboxylic acid





There is at present no direct evidence that favors the postulation of 1,4-addition of nitric acid rather than 1,2-addition. In the course of the present work one of the intermediate nitro compounds (obtained from methyl furoate) has been isolated in a pure state as a stable white crystalline solid. We hope to determine the structure of this intermediate compound in order to ascertain whether 1,4- or 1,2-addition has taken place.

In establishing the structure of the nitrofuran obtained by Marquis, 5-nitrofuroic acid was used as a reference substance. The position of the nitro group in this compound has been established with reasonable certainty by its formation from dehydromucic acid (furan-2,5-dicarboxylic acid) through the displacement of one carboxyl group and from 5-sulfofuroic acid through displacement of the sulfonic acid group.[5] It should suffice, therefore, to decarboxylate 5-nitrofuroic acid and to compare the resulting 2-nitrofuran with the compound produced by the direct nitration of furan. Accordingly, nitrofuroic acid (m. p. 185–185.5°) was decarboxylated by heating with copper bronze, in the presence of organic bases. The resulting 2-nitrofuran (m. p. 28.8–29.2°) proved to be identical with a specimen of nitrofuran (m. p, 28.8–29.2°) obtained from furan by nitration. Consequently, the nitrofuran described by Marquis should be designated as 2-nitrofuran instead of 3-nitrofuran.[6] Thus the nitration of furan occurs in an alpha position, in conformity with many furan derivatives and with its sulfur analog, thiophene.

Experimental

5-Nitrofuroic Acid.—This acid was prepared by hydrolysis of methyl or ethyl 5-nitrofuroate with strong sulfuric acid. Our experience showed that the yields were improved by using a solution of two parts by volume of concd. sulfuric acid in three parts of water, instead of the more concentrated acid (1:1) used by Marquis. In a typical preparation 55 g. of pure methyl 5-nitrofuroate was refluxed for fifty minutes with a solution of 250 cc. of concd. sulfuric acid in 375 cc. of water. The resulting 5-nitrofuroic acid after recrystallization from hot water melted at 185–185.5° (corr.) and weighed 40 g. (79% yield).

Intermediate Nitroacetate from Methyl Furoate.—In studying the nitration of

---

[5] Hill and White, *Am. Chem. J.*, 27, **193** (1902).

[6] This result has been anticipated by Rinkes (Ref. 1) who obtained a nitrofuran. m. p. 27.9°, by displacement of the carboxyl group of 2-furoic acid. He concluded that this product was 2-nitrofuran and showed that it was identical with the nitrofuran obtained by nitration of furan. To the intermediate nitroacetate, Rinkes assigns an open-chain enol formula which differs from that of Marquis merely in the position of the nitro group. We prefer to assign to this intermediate product a structure which differs from that of Marquis in the position of the nitro group and in having a closed chain (dihydrofuran) structure.

methyl furoate in acetic anhydride, it was observed that a white crystalline intermediate product could be obtained, along with a liquid product, if the excess of acetic anhydride was removed by prolonged contact with water. Although Marquis has described methyl 5-nitrofuroate, he did not report the isolation of this crystalline intermediate product.

A cooled solution of 50 g. of pure methyl furoate in 75 g. of acetic anhydride was added to a solution of 125 g. of fuming nitric acid (sp. gr. 1.50) in *200* g. of acetic anhydride, prepared and maintained at −5°. The temperature of the reaction mixture was kept at −5° during the course of this addition (two hours) and the resulting solution was stirred at −5° for two hours after all of the methyl furoate had been added. The reaction mixture was poured onto 500 g. of cracked ice and **2.5–3** liters of water was added. After stirring vigorously for twenty to thirty minutes the original viscous oil changed to a waxy mass containing white crystals and adhering drops of oil. This mass was separated and washed thoroughly, by stirring with cold water until the washings were free from acid. The waxy mass was pressed thoroughly on a suction filter in order to free the crystals from the adhering oil. The crystalline portion was washed with cold sodium bicarbonate solution and freed from alkali by repeated washing with cold water. After purification by several crystallizations from absolute methyl alcohol, the intermediate nitroacetate formed colorless needles which melted at **95.9°** (corr.) in a capillary tube; on the electric bar[7] the crystals melted at 96.3° (corr.). This compound is very slightly soluble in petroleum benzine, and sparingly soluble in cold ether, carbon tetrachloride and methyl or ethyl alcohol. It is very soluble in acetone and in hot methyl or ethyl alcohol and glacial acetic acid.

Anal. Calcd. for $C_8H_9O_7N$: C, 41.54; **H, 3.93.** Found: C, 41.67, 41.48; **H, 3.89, 3.92.**

Upon catalytic hydrogenation, in the presence of platinum, the nitroacetate takes up approximately **2.5** moles of hydrogen. We have not yet studied the reactions of the reduced product.

This intermediate nitroacetate does not give an enol test with ferric chloride solution and does not decolorize a solution of bromine in carbon tetrachloride at 20°. The nitro-acetate shows the characteristic reducing action of aldehydes, with Fehling's solution and with ammoniacal silver oxide. It is decomposed on heating with water; on warming with pyridine it is converted almost quantitatively, by an ***endothermzc*** reaction, into methyl 5-nitrofuroate. The latter, after one crystallization from methyl alcohol, formed colorless crystals, m. p. 81.6° (corr.). This product is evidently purer than that obtained by Marquis, who reported a melting-point of 78.5°.

In addition to the crystalline nitroacetate described above, there was obtained an almost equal quantity of a heavy yellow oil, which was obtained from the crystals by pressing on a suction filter and by adding water to the mother liquors from the crystallization of the solid nitroacetate. This oil was dissolved in ether, washed free from acid by means of cold sodium bicarbonate solution, and finally freed from alkali by repeated washing with cold water. The ether solution was allowed to stand at 0° for several days in order to separate an additional quantity of the crystals. After filtering these off and evaporating off the solvent under reduced pressure, there remained a yellow viscous oil from which no further quantity of crystals could be separated. On warming the oil with pyridine, a violent ***exothermic*** reaction occurs and the solution becomes very deeply colored (almost black). On pouring this into water, a highly colored insoluble precipitate is formed, from which only 25–30% of the calculated quantity of methyl 5-nitrofuroate could be isolated. The fact that a violent exothermic reaction occurs on

---

[7] **Dennis and Shelton,** THIS JOURNAL, 52, 3128 **(1930).**

treatment with pyridine, indicates that the oil contains a substance more reactive than the crystalline nitroacetate. The formation of methyl 5-nitrofuroate may be due to the presence of the crystalline nitroacetate dissolved in the oil.

Decarboxylation of 5-Nitrofuroic Acid: 2-Nitrofuran.—Five grams of the pure dry acid (m. p. 185–185.5°), 10 g. of high-boiling coal tar bases (b. p. 145–165° at 15 mm.) and 1 g. of copper–bronze (Kahlbaum's Naturkupfer C) were placed in a Wood's metal bath at 160–180°, and the temperature was finally raised to 220" after the original vigorous decomposition had subsided. The procedure was similar to that used for the decarboxylation of the halogenated furoic acids.[8] The distillates from several runs were combined and subjected to steam distillation. The volatile products were extracted with ether and the extract was washed thrice with cold dilute hydrochloric acid to remove any bases. After washing with cold water until the washings were free from acid, the ether solution was dried over anhydrous sodium sulfate. After removal of the solvent under diminished pressure, the residual crude 2-nitrofuran was dissolved in the minimum amount of petroleum benzine (b. p. 60–70°) at 50°. The warm solution was decanted from a small tarry residue and cooled to 0°, with vigorous stirring. The faintly pink crystals of 2-nitrofuran were filtered with suction, washed with a little of the cold solvent and then recrystallized in the same manner. The purified 2-nitrofuran formed almost colorless crystals melting at 28.8–29.2° (corr.). From 27 g. of 5-nitrofuroic acid there was obtained 2.8 g. of 2-nitrofuran (14% yield).

Nitration of Furan: 2-Nitrofuran.—The nitration of furan was carried out in acetic anhydride, according to the procedure of Marquis. After several crystallizations from petroleum benzine (b. p. 60–70°), the product formed pale yellow crystals, m. p. 28.8-29.2' (corr.). The identity of this nitrofuran with the specimen of 2-nitrofuran resulting from the decarboxylation of 5-nitrofuroic acid was established by a microscopical examination of the crystals and a mixed melting point determination. A mixture of the two substances in equal amounts melted at 28.8–29.2" (corr.), which is the melting point of the original pure substances.

Microscopical Examination of **2-Nitrofuran.**[9]—Two samples of this compound, one prepared by the direct nitration of furan and the other by nitration of furoic acid and subsequent decarboxylation, exhibited exactly the same optical properties.

2-Nitrofuran was found to be very soluble in xylene at room temperature but it yielded well formed crystals from this solvent when cooled to 0°. With this treatment, long, slender prisms were obtained as well as some smaller parallelograms. Both the prisms and the parallelograms were of two types, which will be designated as "type A" and "type B." Type A crystals were rectangular in shape, varying in length from squares to long prisms. In these, extinction was parallel. Type B crystals were parallelograms having an acute angle of about 68°. These, also, varied greatly in length. In this type, extinction was oblique to the direction of elongation and parallel to the shorter side. It was evident that the prisms were merely elongations of the shorter types. Type B crystals of both samples showed a marked tendency to form twins on the longer

---

[8] Shepard, Winslow and Johnson, THIS JOURNAL, 52,2083 (1930).

[9] The authors are indebted to Mr. P. P. McClellan for carrying out this microscopical examination.

side. Interference figures indicated that the crystals were biaxial, hence they must belong to the monoclinic system. The trace of the optic plane was parallel to the shorter side of type B crystals.

Summary

2-Nitrofuran has been prepared by the decarboxylation of 5-nitrofuroic acid and has been shown to be identical with the nitrofuran obtained from furan by nitration. The latter had been incorrectly formulated by Marquis to be 3-nitrofuran.

Evidence is presented to support the view that the intermediate nitroacetates, produced in the nitration of various furan derivatives in acetic anhydride solution, are ring structures rather than open chain enols.

The mechanism of the nitration process is suggested tentatively to be a 1,4-addition to the furan ring, without scission of the oxygen bridge.

THE ACTION OF PHENOL ON BENZOYLDIPHENYLMETHYL BROMIDE

BY C. FREDERICK KOELSCH[1]

RECEIVED JANUARY 21, 1931 PUBLISHED MARCH 6, 1931

In a recent paper Schuster[2] reported that the reaction between benzoyldiphenylmethyl bromide and phenol gave phenylbenzoin monophenyl ether

$$(C_6H_5)_2CBrCOC_6H_5 + C_6H_5OH \longrightarrow HBr + \underset{(I)}{(C_6H_5)_2C(OC_6H_5)COC_6H_5} \qquad (1)$$

Subsequent treatment of the resulting product with phenylmagnesium bromide was reported to give benzopinacone monophenyl ether

$$(C_6H_5)_2C(OC_6H_5)COC_6H_5 + C_6H_5MgBr \longrightarrow (C_6H_5)_2C(OC_6H_5)C(OH)(C_6H_5)_2 \qquad (2)$$

A reaction such as that indicated in (1) would be remarkable indeed, since it is well known that phenol reacts in an acidic environment with certain compounds containing labile halogens to form nuclear substitution products; for example, phenol and triphenylchloromethane form *p*-hydroxytetraphenylmethane. It was then supposed that reaction (1) did not proceed as Schuster indicated, but rather

$$(C_6H_5)_2CBrCOC_6H_5 + C_6H_5OH \ \_\quad HBr + \underset{(II)}{(C_6H_5)_2C(C_6H_4OH)COC_6H_5} \qquad (3)$$

To test this supposition, Schuster's work was repeated in this Laboratory.

In the present paper it is shown that the reaction between benzoyldiphenylmethyl bromide and phenol proceeds neither according to (1) nor

---

[1] Du Pont Fellow, 1930–1931.

[2] Schuster, *Ber.*, 63, 2397 (1930).

according to (3). Instead, it is shown that the reaction takes place in the following manner

$$(C_6H_5)_2CBrCOC_6H_5 + C_6H_5OH \longrightarrow \underset{\text{(III)}}{(C_6H_5)_2CHCOC_6H_5} + p\text{-}BrC_6H_4OH \qquad (4)$$

The first evidence that diphenylacetophenone (III) and not phenylbenzoin monophenyl ether (I) or hydroxytriphenylacetophenone (II) was produced in the reaction was obtained by treating the product with alcoholic potassium hydroxide, when potassium benzoate and diphenylmethane were formed

$$(C_6H_5)_2CHCOC_6H_5 + KOH \longrightarrow (C_6H_5)_2CH_2 + C_6H_5COOK$$

Later, it was found that the product, when treated with acetic anhydride and sulfuric acid, gave triphenylvinyl acetate

$$(C_6H_5)_2CHCOC_6H_5 \rightleftarrows (C_6H_5)_2C{=}\overset{OH}{\dot{C}}{-}C_6H_5 \xrightarrow{(CH_3CO)_2O} (C_6H_5)_2C{=}\overset{OCOCH_3}{\dot{C}}{-}C_6H_5$$

Finally, the identity of the product was proved by determining its melting point when mixed with a known specimen of diphenylacetophenone which had been prepared by the reactions[3]

$$C_6H_5CH(OH)COOCH_3 + C_6H_5MgBr \longrightarrow C_6H_5CH(OH)C(C_6H_5)_2OH \xrightarrow{-H_2O} C_6H_5COCH(C_6H_5)_2$$

Further evidence that the reaction proceeds according to Equation 4 was obtained by the isolation of *p*-bromophenol in considerable amounts from the reaction mixture. This compound was identified beyond question by its boiling point and by the melting point and neutral equivalent of the aryloxyacetic acid obtained from it by treatment with chloroacetic acid and sodium hydroxide.

The product of the action of phenylmagnesium bromide on diphenylacetophenone, which melts at 232–233' and not at 219° as Schuster reported, is a,α,β,β-tetraphenylethanol[4]

$$(C_6H_5)_2CHCOC_6H_5 + C_6H_5MgBr \longrightarrow (C_6H_5)_2CHC(C_6H_5)_2OH$$

On treatment with alcoholic potassium hydroxide it gave a mixture of diphenylmethane and benzophenone

$$(C_6H_5)_2CHC(C_6H_5)_2OH \longrightarrow (C_6H_5)_2CH_2 + (C_6H_5)_2CO$$

Schuster noted and was unable to explain the resistance of the hydroxyl group to substitution by bromine on treatment with hydrogen bromide in the compound which he obtained by the action of phenylmagnesium bromide on his supposed phenylbenzoin monophenyl ether. Since it has been pointed out that this reaction product is really α,α,β,β-tetraphenylethanol, and since unreactivity toward such a reagent as hydrogen bromide is apparently a characteristic property of polyphenylethanols,[5] this behavior of the compound in question is not surprising.

Experimental

Benzoyldiphenylmethyl Bromide and Phenol.—The procedure of Schuster for carrying out the reaction between these two compounds was followed closely. Eight grams of benzoyldiphenylmethyl bromide[6] was heated at 100° for three hours with 3.2 g. of phenol. The product, after triturating with dilute sodium hydroxide solution, was crystallized from alcohol, giving 5.25 g. of diphenylacetophenone melting at 135–136°, uncorr. (On heating with concentrated sulfuric acid, diphenylacetophenone gives a deep green solution. The color becomes reddish-brown on dilution.)

The oil obtained on acidification of the sodium hydroxide extract was taken up in ether, dried, and the ether removed. Distillation of the residue at 23 mm. gave two main fractions, both of which solidified. The first (1.2 g.), which boiled at 80–85°, was phenol; the second (1.9 g.), which boiled at 127–130°, was identified as *p*-bromophenol by the preparation of p-bromophenoxyacetic acid from it, which melted at 156–158° and had a neutral equivalent of 228.[7]

Cleavage of Diphenylacetophenone by Potassium Hydroxide.—Three grams of the ketone obtained above was refluxed for twenty hours with a solution of 2 g. of potassium hydroxide in 50 ml. of alcohol. The solvent was removed in a current of air at reduced pressure, water was added, and the mixture was steam distilled. From the distillate was obtained 1.6 g. of diphenylmethane boiling at 145–150° at 25 mm., and melting at 21–23", which gave benzophenone on oxidation with chromic acid. The residue from the steam distillation gave on acidification 1.02 g. of benzoic acid melting at 120–121°; neutral equivalent, 120.

Triphenylvinyl Acetate.—A mixture of 0.5 g. of diphenylacetophenone with 5 ml. of acetic anhydride and 3 drops of concentrated sulfuric acid was heated at 60–70° for twelve hours. The product, on crystallization from dilute acetic acid, melted at 102–104°,[8] and gave diphenylacetophenone on warming with alcoholic sodium hydroxide.

Only unchanged diphenylacetophenone was recovered when an attempt was made to methylate the compound with dimethyl sulfate and alkali in methyl alcohol.

α,α,β,β-Tetraphenylethanol.—To the filtered solution of phenylmagnesium bromide prepared from 20 g. of phenyl bromide in 50 ml. of ether was added 8 g. of diphenylacetophenone. The solution, after refluxing for half an hour, was worked up as described by Schuster, giving a product which on one crystallization from toluene melted at 218–223°. On repeated recrystallization from toluene, this was separated into *α,α,β,β*-tetraphenylethanol melting at 227–229° uncorr. (2.4 g.), and unchanged diphenylacetophenone (4.6 g.).[4]

Cleavage of *α,α,β,β*-Tetraphenylethanol by Potassium Hydroxide.—One gram of the alcohol was refluxed for two hours with 1 g. of potassium hydroxide dissolved in 20 tnl. of alcohol. Water was added after removing the alcohol under reduced pressure, and the mixture was steam distilled. The residue contained only a negligible amount of organic material. The oil in the distillate was taken up in ether; this solution was dried with calcium chloride and treated with the filtered Grignard solution from 3.0 g. of phenyl bromide. Dilute sulfuric acid was added, the ether was removed, and the residue was steam distilled. The distillate contained 0.27 g. of diphenylmethane (calcd. 0.48 g.) identified by oxidation to benzophenone. The non-volatile organic substance was identified as triphenylcarbinol by its melting point (159–160°, uncorr.) and its characteristic color reaction with concentrated sulfuric acid; it weighed 0.65 g., correspondimg to 0.45 g. of benzophenone (calcd. 0.52 g.).

Summary

The reaction between phenol and benzoyldiphenylmethyl bromide gives p-bromophenol and diphenylacetophenone.

The compounds described as phenylbenzoin monophenyl ether and benzopinacone monophenyl ether by Schuster[2] are in reality diphenylacetophenone and $\alpha,\alpha,\beta,\beta$-tetraphenylethanol.

Diphenylacetophenone and $\alpha,\alpha,\beta,\beta$-tetraphenylethanol are smoothly cleaved by alcoholic potassium hydroxide, giving in the one case benzoic acid and diphenylmethane, and in the other benzophenone and diphenylmethane.

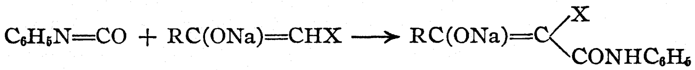
THE COURSE OF ADDITION OF SODIUM ENOL ALKYLMALONIC AND SODIUM ENOL ALKYLCYANACETIC ESTERS TO UNSATURATED ESTERS

BY ARTHUR MICHAEL AND JOHN ROSS

RECEIVED JANUARY 24, 1931 PUBLISHED MARCH 6, 1931

According to the law of chemical neutralization,[1] the course of an addition reaction involving the use of an enolic sodium derivative will be such as to produce a compound in which the sodium is in a better neutralized state. The attainment of the maximal heat of formation in the addition reaction depends upon the neutralization of the positive energy of the metal and this energy factor determines the utmost possible degradation of chemical energy. This generalization is well illustrated in the reactions of sodium enol derivatives with phenyl isocyanate.[2] With the sodium enol derivatives of acetoacetic, malonic, formyl, acetic, benzoylacetic esters and diacylmethane, the reaction takes place smoothly to give in most cases almost quantitative yields of anilides, thus



$$C_6H_5N{=}CO + RC(ONa){=}CHX \longrightarrow RC(ONa){=}C\begin{cases}X\\ CONHC_6H_5\end{cases}$$

I

In these derivatives the a-hydrogen atoms of the enolic sodium mother substances are replaced by the negative $—CONHC_6H_5$ group, and, hence, the sodium atoms are better neutralized in the C-addition products (I). When there is no a-hydrogen atom in the sodium compound, this simple reaction cannot take place. For example, with the sodium enol derivatives of ethylmalonic and ethylacetoacetic esters maximal possible energy degradation is attained by the phenyl isocyanate polymerizing mainly

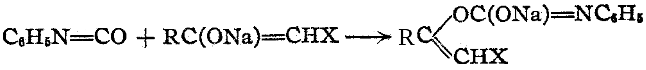
---

[1] Michael. J. *prakt. Chem.*, 60, 293 (1899); THIS JOURNAL, 32, 990 (1910).

[2] Michael, *Ber.*, 38, 22 (1905).

to the much less energetic isocyanurate and a small amount of the same neutral sodium product of destructive decomposition is formed from **each** sodium enolic ester.

A second course of these reactions would be the formation of sodium enol 0-addition products, that is, of sodium enolic urcthan derivatives



II

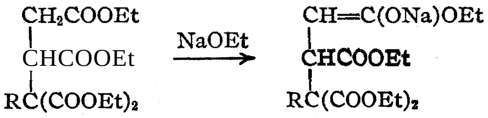
According to the law of chemical neutralization, such a procedure is not possible, since the metal in the compound (II) would be much less neutralized than in the original sodium enolates. Indeed, the tendency to form sodium enol urethans is so slight that sodium ethoxide does not unite with phenyl isocyanate, but entirely converts it into isocyanurate.

Auwers, Kobner and Meyenberg[3] showed that sodium enol alkylmalonic esters readily added to fumaric ester, and, from the addition product upon hydrolysis, obtained a-alkyl tricarballylic acids. The addition reaction was written[4]

$$\mathrm{RCNa(COOEt)_2} + \begin{matrix}\mathrm{CHCOOEt}\\ \| \\ \mathrm{CHCOOEt}\end{matrix} \longrightarrow \begin{matrix}\mathrm{CHNaCOOEt}\\ | \\ \mathrm{CHCOOEt}\\ | \\ \mathrm{RC(COOEt)_2}\end{matrix}$$

III

Since Michael[5] showed that the addition products of sodium enol methylmalonic ester and sodium enol ethylmalonic ester with fumaric ester readily gave sodium derivatives, which could be methylated upon treatment with methyl iodide, it was apparent that the original addition compound could not be a y-alkyl y-carbethoxy tricarballylic ester (111), unless such an ester formed a stable sodium derivative (IV) at the α-carbethoxy group



$$\begin{matrix}\mathrm{CH_2COOEt}\\ | \\ \mathrm{CHCOOEt}\\ | \\ \mathrm{RC(COOEt)_2}\end{matrix} \xrightarrow{\mathrm{NaOEt}} \begin{matrix}\mathrm{CH{=}C(ONa)OEt}\\ | \\ \mathrm{CHCOOEt}\\ | \\ \mathrm{RC(COOEt)_2}\end{matrix}$$

III IV

Michael concluded from his experiments that these esters gave stable enolic sodium derivatives (IV), but the recent examination of such addition reactions with α,β-unsaturated, monobasic olefinic esters[6] made it probable that the alkyl group migrated in the addition of sodium enol alkylmalonic esters to the unsaturated dibasic ester, thus forming compounds containing a malonic ester residue that would give stable sodium

---

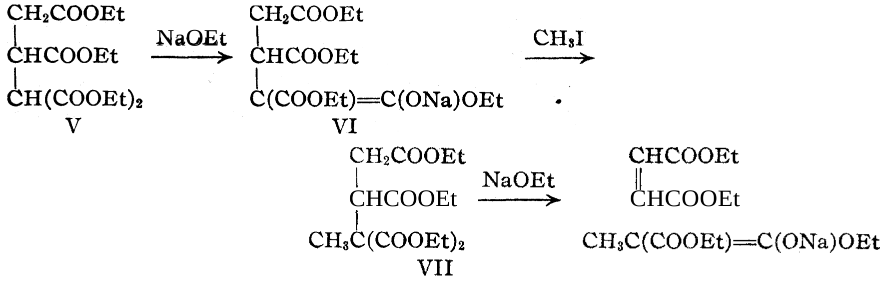
[4] Ethyl is more conveniently represented by Et throughout this paper.

[5] Michael, *Ber.*, **33**, 3731 (1900).

[6] Michael and Ross, THIS JOURNAL, 52,4598 (1930).

enol derivatives and could therefore be alkylated. In order to ascertain whether this had occurred, these reactions were re-examined.

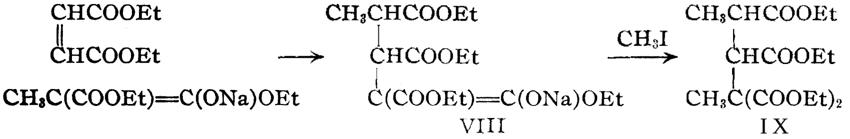
Butane α,β,γ,γ-tetracarboxylic ester (VII) was prepared by methylation of the sodium derivative of propane α,β,γ,γ-tetracarboxylic ester (VI). Upon treatment with anhydrous sodium ethoxide, in ether at 0°, followed by methyl iodide, the butane derivative (VII) mainly underwent retrogression to form fumaric ester and sodium enol methylmalonic ester



$$\begin{array}{l} CH_2COOEt \\ | \\ CHCOOEt \\ | \\ CH(COOEt)_2 \\ \text{V} \end{array} \xrightarrow{NaOEt} \begin{array}{l} CH_2COOEt \\ | \\ CHCOOEt \\ | \\ C(COOEt){=}C(ONa)OEt \\ \text{VI} \end{array} \xrightarrow{CH_3I}$$

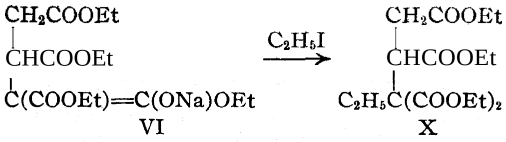
$$\begin{array}{l} CH_2COOEt \\ | \\ CHCOOEt \\ | \\ CH_3C(COOEt)_2 \\ \text{VII} \end{array} \xrightarrow{NaOEt} \begin{array}{l} CHCOOEt \\ \| \\ CHCOOEt \\ \\ CH_3C(COOEt){=}C(ONa)OEt \end{array}$$

The sodium enol methylmalonic ester thus formed was converted by the methyl iodide into dimethylmalonic ester. This course of the reaction is in marked contrast to that of the addition product of sodium enol methylmalonic and fumaric esters, which under parallel conditions methylate to give a quantitative yield of α,γ-dimethyl γ-carbethoxytricarballylic ester (IX).[7] The first addition reaction therefore takes place with migration of methyl, *i. e.*



$$\begin{array}{l} CHCOOEt \\ \| \\ CHCOOEt \\ \\ CH_3C(COOEt){=}C(ONa)OEt \end{array} \longrightarrow \begin{array}{l} CH_3CHCOOEt \\ | \\ CHCOOEt \\ | \\ C(COOEt){=}C(ONa)OEt \\ \text{VIII} \end{array} \xrightarrow{CH_3I} \begin{array}{l} CH_3CHCOOEt \\ | \\ CHCOOEt \\ | \\ CH_3C(COOEt)_2 \\ \text{IX} \end{array}$$

It was further shown that pentane α,β,γ,γ-tetracarboxylic ester (X) prepared by action of ethyl iodide upon the sodium derivative of propane α,β,γ,γ-tetracarboxylic ester (VI) remained unchanged upon treatment in the cold with sodium ethoxide and methyl iodide



$$\begin{array}{l} CH_2COOEt \\ | \\ CHCOOEt \\ | \\ C(COOEt){=}C(ONa)OEt \\ \text{VI} \end{array} \xrightarrow{C_2H_5I} \begin{array}{l} CH_2COOEt \\ | \\ CHCOOEt \\ | \\ C_2H_5C(COOEt)_2 \\ \text{X} \end{array}$$

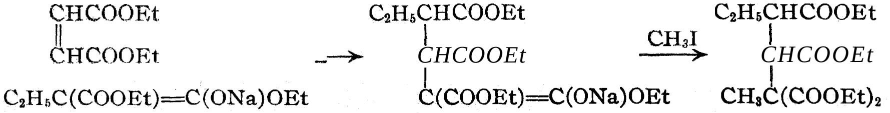
Upon treatment of the addition product of sodium enol ethylmalonic ester to fumaric ester in the cold with sodium ethoxide and methyl iodide, the tetracarboxylic ester is methylated with facility.[8] It therefore follows

---

[7] Michael, Ref. 5, p. 3763.

[8] Michael, *ibid.*, p. 3746.

that in the latter addition reaction the ethyl group has migrated to the a-position, thus

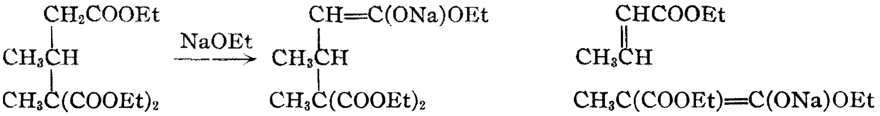


$$\begin{array}{l}\mathrm{CHCOOEt}\\ \| \\ \mathrm{CHCOOEt}\\ \\ \mathrm{C_2H_5C(COOEt){=}C(ONa)OEt}\end{array} \longrightarrow \begin{array}{l}\mathrm{C_2H_5CHCOOEt}\\ | \\ \mathit{CHCOOEt}\\ | \\ \mathrm{C(COOEt){=}C(ONa)OEt}\end{array} \xrightarrow{\mathrm{CH_3I}} \begin{array}{l}\mathrm{C_2H_5CHCOOEt}\\ | \\ \mathit{CHCOOEt}\\ | \\ \mathrm{CH_3C(COOEt)_2}\end{array}$$

XI XII

The retrogression reaction that occurred when the free esters from the addition products of sodium enol alkylmalonic esters to crotonic ester were treated with sodium[9] was later shown by Ingold[10] and Kohler and Butler[11] to take place by the action of sodium ethoxide upon similar addition products. Ingold considered that such reversal of the additive process indicated that the additive process itself was a balanced reaction which proceeded until a definite equilibrium was attained under the conditions in which the reaction was carried out. The following view offers an insight into the mechanism of the retrogression reaction.

Michael[12] explained the formation of acetoacetic ester from ethyl acetate and sodium through the primary formation of $CH_2{=}C(ONa)OEt$ and Scheibler and Marhenkel[13] on isolating this compound, proved the correctness of this view. It therefore seemed probable that the capacity of the ester (XIII) to form a sodium derivative at the α-carbethoxyl group as in (XIV) was due to the near spatial negative influence of the four oxygen atoms upon the C and H_2 of the CH2 group. However, the strong positive influence of the sodium introduced into ester (XIII) must decrease the affinity for each other of the two C atoms of (XIV) attached to the methyl groups, and the very considerable positive free chemical energy of the sodium in (XIV) is able to attain a much better neutralization by the retrogression of (XIV) into sodium enol malonic and crotonic esters.



$$\begin{array}{l}\mathrm{CH_2COOEt}\\ | \\ \mathrm{CH_3CH}\\ | \\ \mathrm{CH_3C(COOEt)_2}\end{array} \xrightarrow{\mathrm{NaOEt}} \begin{array}{l}\mathrm{CH{=}C(ONa)OEt}\\ | \\ \mathrm{CH_3CH}\\ | \\ \mathrm{CH_3C(COOEt)_2}\end{array} \qquad \begin{array}{l}\mathrm{CHCOOEt}\\ \| \\ \mathrm{CH_3CH}\\ \\ \mathrm{CH_3C(COOEt){=}C(ONa)OEt}\end{array}$$

XIII XIV

The intermediate formation of such a sodium derivative as (XIV) is, therefore, not improbable.

That pentane α,β,y,y-tetracarboxylic ester (X) did not undergo retrogression upon treatment with sodium ethoxide and methyl iodide may have been due to incapacity to form such a sodium derivative as in

---

[9] Michael, Ref. 5, p. 3749.

[10] Ingold, J. *Chem. Soc.*, 119, 1976 (1921).

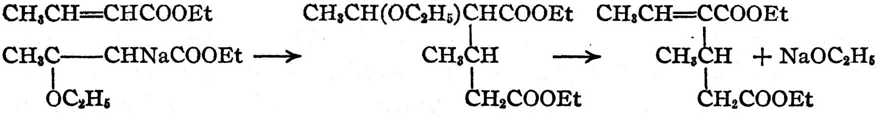
[12] Michael, Ber., 38, 1933 (1905).

[13] Scheibler *and* Marhenkel. Ann., 458, 1 (1927).

(XIV), owing to the influence of the more positive character of the ethyl compared with the methyl group.

It was thought that separation of the ethyl group from the directly attached carbon atom of sodium enol ethylmalonic ester would not take place as readily as the separation of the methyl group of sodium enol methylmalonic ester, and that the difference might be reflected in the yields of addition product obtained. The reaction between sodium enol ethylmalonic and crotonic ester was therefore examined. Contrary to the behavior of sodium enol methylmalonic ester,[6] only slight addition was found to occur; the crotonic ester mainly polymerized to the sodium derivative of a dimeric ester, a-ethylidene β-methylglutaric ester (XV) which v. Pechmann[14] had obtained by the action of sodium ethoxide, and Michael[15] by the action of sodium on crotonic ester. This reaction was expressed by v. Pechmann as follows[16]



$$\begin{array}{l} \mathrm{CH_3CH{=}CHCOOEt} \\ \mathrm{CH_3\underset{\displaystyle OC_2H_5}{\underset{|}{C}}{-\!-}CHNaCOOEt} \longrightarrow \end{array} \begin{array}{c} \mathrm{CH_3CH(OC_2H_5)CHCOOEt} \\ | \\ \mathrm{CH_3CH} \\ | \\ \mathrm{CH_2COOEt} \end{array} \longrightarrow \begin{array}{c} \mathrm{CH_3CH{=}CCOOEt} \\ | \\ \mathrm{CH_3CH} \\ | \\ \mathrm{CH_2COOEt} \end{array} + \mathrm{NaOC_2H_5}$$

XV

The fact that the sodium derivative of enol ethylmalonic ester causes the polymerization of crotonic ester while that of methylmalonic ester does not, is to be attributed to the more energetic state of the metal in the first ester. Addition of sodium enol ethylmalonic ester to crotonic ester would require the migration of the ethyl group, and apparently polymerization of the crotonic ester takes place more readily.

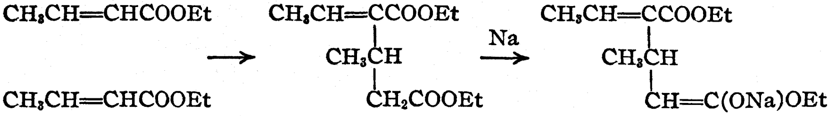
Since no addition product was obtained in the above reaction, attention was directed to the ease of migration of alkyl groups during the addition of sodium enol alkyl cyanacetic esters to unsaturated esters. J. F.

---

[14] V. Pechmann, Ber., 33, 3340 (1900).

[15] Michael, ibid., 33, 3760 (1900).

[16] There is no evidence that crotonic ester unites with sodium ethylate and the existence of the assumed sodium β-ethoxybutyric ester is improbable, apart from the assumption of the direct union of sodium with carbon. The assumed intermediate stage is therefore untenable as is also the last step. since Michael showed that the sodium derivative of the dimeric crotonic ester appears as the final reaction product. The reaction represents a polymerization by addition, resulting in the better neutralization of the sodium



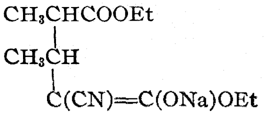
$$\begin{array}{l} \mathrm{CH_3CH{=}CHCOOEt} \\ \\ \\ \\ \mathrm{CH_3CH{=}CHCOOEt} \end{array} \longrightarrow \begin{array}{c} \mathrm{CH_3CH{=}CCOOEt} \\ | \\ \mathrm{CH_3CH} \\ | \\ \mathrm{CH_2COOEt} \end{array} \xrightarrow{\mathrm{Na}} \begin{array}{c} \mathrm{CH_3CH{=}CCOOEt} \\ | \\ \mathrm{CH_3CH} \\ | \\ \mathrm{CH{=}C(ONa)OEt} \end{array}$$

Although the sodium addition product contains the group $—\mathrm{CH{=}C(ONa)OEt}$, it does not suffer retrogression because crotonic ester does not give a sodium derivative. This is an interesting point in support of the theoretical views upon the retrogression reaction discussed above.

Thorpe[17] concluded that in the addition of sodium enol a-cyano propionic ester to β,β-dimethylacrylic ester, the parts of the addendum appeared to be CH_3 and —C(CN)=C(ONa)OEt. Upon examination of the addition of sodium enol α-cyanopropionic ester to crotonic ester, it was found that addition also occurred with migration of the methyl radical to the a-C atom of the latter ester, that is, the addendum functioned as CH_3 and —C(CN)=C(ONa)OEt

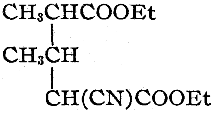
$CH_3CH{=}CHCOOEt$

$CH_3C(CN){=}C(ONa)OEt$



$$\begin{array}{l} CH_3CHCOOEt \\ \quad | \\ CH_3CH \\ \quad | \\ \quad C(CN){=}C(ONa)OEt \end{array}$$

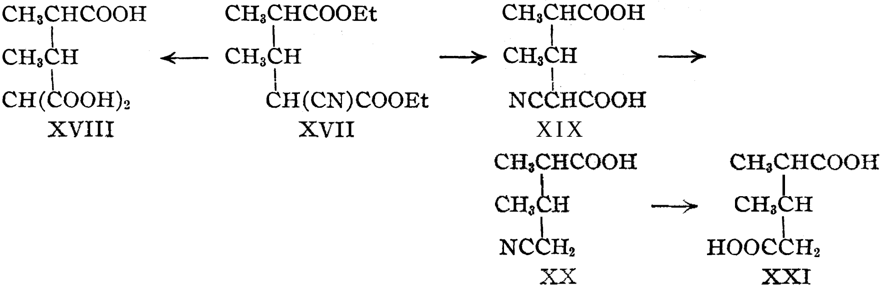
XVI



$$\begin{array}{l} CH_3CHCOOEt \\ \quad | \\ CH_3CH \\ \quad | \\ \quad CH(CN)COOEt \end{array}$$

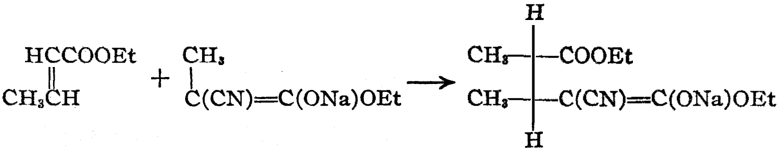
XVII

The product, α,β-dimethyl γ-cyanoglutaric ester (XVII), is apparently a stereomeric form of the cyano ester obtained by the addition of sodium enol cyanacetic ester to tiglic ester.[6] Upon saponification (XVII) gave a sirupy cyano acid (XIX) which upon treatment with hydrochloric acid gave very little α,β-dimethylglutarimide, but mainly a liquid cyano acid (XX). This was converted into trans α,β-dimethylglutaric acid, which was identified by its di-anilide. Hydrolysis of the cyano ester gave a tricarboxylic acid (XVIII), which was not identical with the corresponding acid prepared through the addition of sodium enol cyanacetic ester to tiglic ester, and was therefore apparently a stereomer of that acid



$$\begin{array}{lcllcl} \begin{array}{l} CH_3CHCOOH \\ \quad | \\ CH_3CH \\ \quad | \\ CH(COOH)_2 \end{array} & \longleftarrow & \begin{array}{l} CH_3CHCOOEt \\ \quad | \\ CH_3CH \\ \quad | \\ \quad CH(CN)COOEt \end{array} & \longrightarrow & \begin{array}{l} CH_3CHCOOH \\ \quad | \\ CH_3CH \\ \quad | \\ NCCHCOOH \end{array} & \longrightarrow \\ \text{XVIII} & & \text{XVII} & & \text{XIX} & \\ & & & & \begin{array}{l} CH_3CHCOOH \\ \quad | \\ CH_3CH \\ \quad | \\ NCCH_2 \end{array} \; \longrightarrow & \begin{array}{l} CH_3CHCOOH \\ \quad | \\ CH_3CH \\ \quad | \\ HOOCCH_2 \end{array} \\ & & & & \text{XX} & \text{XXI} \end{array}$$

Considering the addition reaction in each case to take place as a *trans* process,[18] the following stereomeric compounds would be expected to be formed



$$\begin{array}{l} HCCOOEt \\ \quad \| \\ CH_3CH \end{array} + \begin{array}{l} CH_3 \\ | \\ C(CN){=}C(ONa)OEt \end{array} \longrightarrow \begin{array}{c} H \\ | \\ CH_3{-}|{-}COOEt \\ CH_3{-}|{-}C(CN){=}C(ONa)OEt \\ | \\ H \end{array}$$

XXII

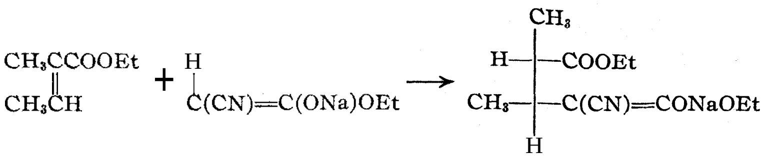
[17] J. F. Thorpe, J. *Chem. Soc.*, 77,923 (1900).

[18] See Michael, J. *prakt. Chem.*, 52,289 (1895); THIS JOURNAL, 40, 1674 (1918).

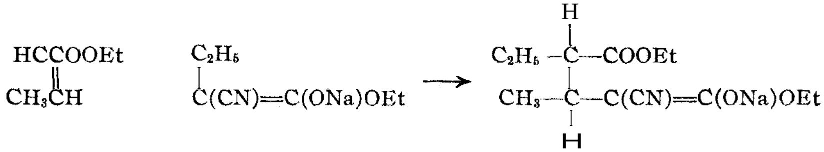


$$\begin{array}{l}CH_3CCOOEt\\ \quad\|\\ CH_3CH\end{array} + \begin{array}{l}H\\ |\\ C(CN){=}C(ONa)OEt\end{array} \longrightarrow \begin{array}{c}CH_3\\ |\\ H{-}|{-}COOEt\\ CH_3{-}|{-}C(CN){=}CONaOEt\\ |\\ H\end{array}$$

XXIII

It agrees with this interpretation, that the addition of sodium enol cyanacetic ester to tiglic ester gave a cyano ester stereomeric with the product of addition of sodium enol a-cyanopropionic ester to crotonic ester.

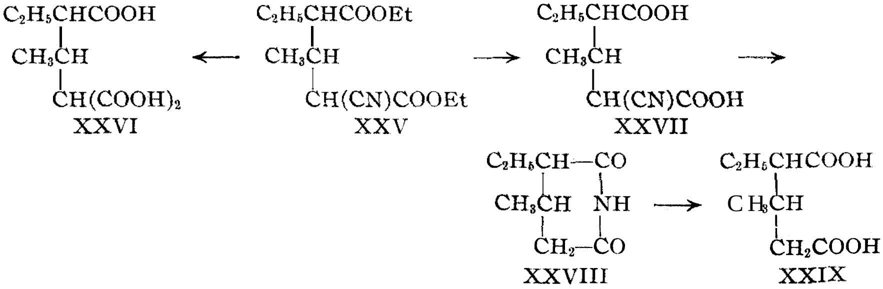
Results parallel to those with sodium enol a-cyanopropionic ester were obtained in the addition of sodium enol a-cyanobutyric ester to crotonic ester. A 33% yield of a-ethyl-B-methyl-y-cyanoglutaric ester (XXV) was obtained from the addition product (XXIV), showing that the parts of the addendum were C_2H_5 and C(CN)=C(ONa)OEt. With *trans* addition the reaction proceeds as follows



$$\begin{array}{l}HCCOOEt\\ \quad\|\\ CH_3CH\end{array} \quad \begin{array}{l}C_2H_5\\ |\\ C(CN){=}C(ONa)OEt\end{array} \longrightarrow \begin{array}{c}H\\ |\\ C_2H_5{-}C{-}COOEt\\ |\\ CH_3{-}C{-}C(CN){=}C(ONa)OEt\\ |\\ H\end{array}$$

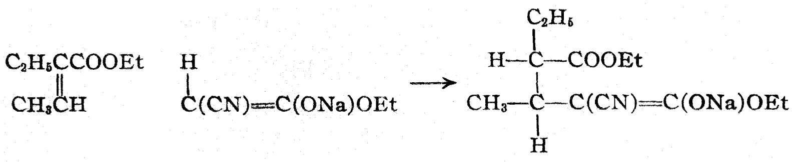
XXIV

Upon saponification of the ester (XXV), a cyano acid (XXVII) melting at 147° was obtained, which upon treatment with hydrochloric acid was almost completely converted into α-ethyl-β-methylglutarimide, m. p. 92°, together with a small amount of a stereomeric imide, m. p. 102°. Since both imides gave the same *cis* α-ethyl-β-methylglutaric acid, m. p. 88° (XXIX), upon hydrolysis, it is considered that they are related to one another as *cis* and *trans* with respect to the methyl and ethyl groups and the plane of the imide ring. Through saponification with caustic potash, the ester (XXV) gave α-ethyl-β-methyl-γ-carboxyglutaric acid (XXVI), melting at 143°. These reactions are represented by



$$\underset{XXVI}{\begin{array}{l}C_2H_5CHCOOH\\ CH_3CH\\ CH(COOH)_2\end{array}} \longleftarrow \underset{XXV}{\begin{array}{l}C_2H_5CHCOOEt\\ CH_3CH\\ CH(CN)COOEt\end{array}} \longrightarrow \underset{XXVII}{\begin{array}{l}C_2H_5CHCOOH\\ CH_3CH\\ CH(CN)COOH\end{array}} \longrightarrow \underset{XXVIII}{\begin{array}{l}C_2H_5CH{-}CO\\ CH_3CH\quad NH\\ CH_2{-}CO\end{array}} \longrightarrow \underset{XXIX}{\begin{array}{l}C_2H_5CHCOOH\\ CH_3CH\\ CH_2COOH\end{array}}$$

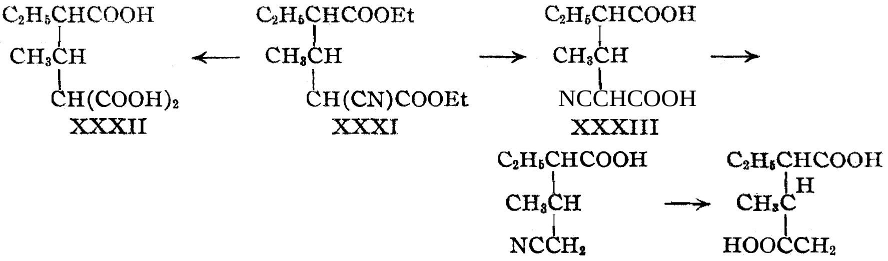
Addition of sodium enol cyanacetic ester to a-ethylcrotonic ester gave a stereomeric form (XXX) of the sodium derivative of the ester (XXIV)



$$\begin{array}{l}C_2H_5CCOOEt\\ \quad\| \\ CH_3CH\end{array} \quad \begin{array}{l}H\\ | \\ C(CN){=}C(ONa)OEt\end{array} \longrightarrow \begin{array}{l} \qquad\;\; C_2H_5 \\ \qquad\quad | \\ \quad H-C-COOEt \\ \qquad\quad | \\ CH_3-C-C(CN){=}C(ONa)OEt \\ \qquad\quad | \\ \qquad\quad H\end{array}$$

XXX

Through saponification with alcoholic potash, the ester from (XXX) yielded a cyano acid, m. p. 132° (XXXIII), and complete hydrolysis led to a tricarboxylic acid (XXXII), melting at 141°. When boiled for thirty minutes with hydrochloric acid, the cyano acid (XXXIII) gave a very small amount of the imide (XXVIII) melting at 92° with a sirupy cyano acid (XXXIV) as the main product. The latter, when completely hydrolyzed, gave trans α-ethyl-β-methylglutaric acid, m. p. 101°



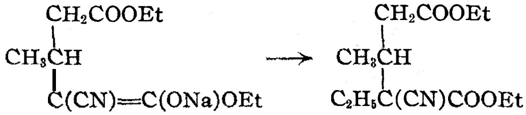
$$\begin{array}{l}C_2H_5CHCOOH\\ \quad | \\ CH_3CH \\ \quad | \\ \quad CH(COOH)_2\end{array} \longleftarrow \begin{array}{l}C_2H_5CHCOOEt\\ \quad | \\ CH_3CH \\ \quad | \\ \quad CH(CN)COOEt\end{array} \longrightarrow \begin{array}{l}C_2H_5CHCOOH\\ \quad | \\ CH_3CH \\ \quad | \\ NCCHCOOH\end{array} \longrightarrow$$

XXXII XXXI XXXIII

$$\begin{array}{l}C_2H_5CHCOOH\\ \quad | \\ CH_3CH \\ \quad | \\ NCCH_2\end{array} \longrightarrow \begin{array}{l}C_2H_5CHCOOH\\ \quad |\,H \\ CH_3C \\ \quad | \\ HOOCCH_2\end{array}$$

XXXIV XXXV

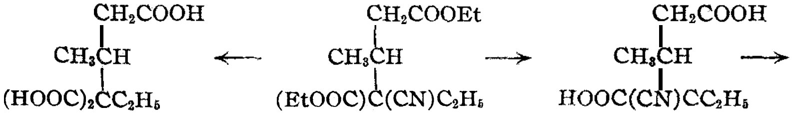
For comparison with the above compounds, β-methyl-γ-ethyl-γ-cyanoglutaric ester (XXXVII) was prepared by the action of ethyl iodide upon the sodium derivative of **β-methyl-γ-cyanoglutaric** ester (XXXVI)



$$\begin{array}{l}\quad CH_2COOEt\\ \quad | \\ CH_3CH \\ \quad | \\ \quad C(CN){=}C(ONa)OEt\end{array} \longrightarrow \begin{array}{l}\qquad CH_2COOEt\\ \qquad | \\ \quad CH_3CH \\ \qquad | \\ C_2H_5C(CN)COOEt\end{array}$$

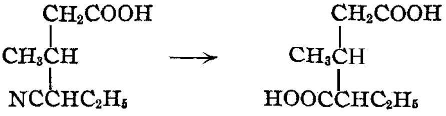
XXXVI XXXVII

From the product of saponification with caustic potash, a cyano acid (XXXIX) was obtained, melting at 139°, which upon treatment with hydrochloric acid gave a sirupy cyano acid (XL) with a very small amount of the two isomeric β-methyl-α-ethylglutarimides, m. p. 92° and m. p. 102°. Upon complete hydrolysis with hydrochloric acid, the cyano acid gave *trans* α-ethyl-β-methylglutaric acid, m. p. 101° (XLI).



$$\begin{array}{l}\qquad CH_2COOH\\ \qquad | \\ \quad CH_3CH \\ \qquad | \\ (HOOC)_2CC_2H_5\end{array} \longleftarrow \begin{array}{l}\qquad CH_2COOEt\\ \qquad | \\ \quad CH_3CH \\ \qquad | \\ (EtOOC)C(CN)C_2H_5\end{array} \longrightarrow \begin{array}{l}\qquad CH_2COOH\\ \qquad | \\ \quad CH_3CH \\ \qquad | \\ HOOC(CN)CC_2H_5\end{array} \longrightarrow$$

XXXVIII XXXVTI XXXIX



$$\begin{array}{l}CH_2COOH\\ |\\ CH_3CH\\ |\\ NCCHC_2H_5\end{array} \longrightarrow \begin{array}{l}CH_2COOH\\ |\\ CH_3CH\\ |\\ HOOCCHC_2H_5\end{array}$$

XL XLI

γ-Ethyl-β-methyl-γ-cyanoglutaric acid (XXXIX) after long boiling with 25% caustic potash, yielded the corresponding tricarboxylic acid (XXXVIII) which could not be obtained crystalline. The difficulty of hydrolysis of this substituted ethyl cyanoacetic acid is undoubtedly due to the influence of the ethyl and $—CH(CH_3)CH_2COOEt$ groups upon the cyanacetic residue. The greater stabilizing influence of the ethyl compared with the methyl group as a substituent is similarly exhibited in the difficulty of saponifying diethylmalonic ester, in comparison with the relative ease of saponification of dimethylmalonic ester.[19]

It would appear from the above reactions that addition of sodium enol cyano esters to a,@-unsaturated esters can take place with the selective synthesis of one of the stereomeric forms. It was shown above that if the primary addition reaction is considered a *trans* process then the addition of sodium enol cyanoacetic ester to a-ethylcrotonic ester would give a cyano ester stereomeric with the product of addition of sodium enol a-cyanobutyric ester to crotonic ester. When both stereomeric forms appeared, as occurred in the additions to cinnamic and a-methylcinnamic esters,[20] it is apparent that racemization had taken place during the addition reaction. This must also be the case when the same single stereomer was formed, as in the addition of sodium enol malonic to tiglic ester and of sodium enol methylmalonic to crotonic ester. McKenzie and Wren[21] and others have connected the presence of the phenyl group as favoring racemization. The action of free alkali or of sodium ethoxide in promoting racemization is well known, so that racemization would be expected to occur in the presence of a strongly alkaline material, such as sodium enol malonic ester. The absence of racemization when the sodium enol cyano esters are added to olefinic unsaturated esters is an indication of the neutrality and stability of the sodium enol cyano ester addition product in these particular cases.

In the addition of sodium enol alkyl cyanacetic esters to crotonic ester, it was noticed that always with the main product varying small quantities of higher boiling esters were formed, which gave a deep red color with alcoholic ferric chloride. Analyses indicated that they consisted of an addition product of one molecule of the alkyl cyanacetic ester to one molecule of crotonic ester. Hydrolysis with hydrochloric acid of the prod-

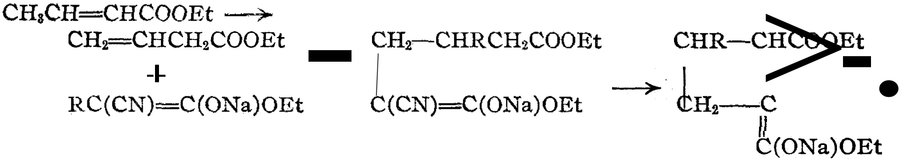
[21] **McKenzie and Wren,** ***J. Chem. Soc.*****, 117, *680*** (1920)

uct from α-cyanopropionic and crotonic esters gave a ketone, which readily gave a semicarbazone. However, the yield of the ketone was very small, and, possibly due to the difficulty experienced in purifying this small quantity of material, the melting point and analysis of the semicarbazone did not correspond well to the expected derivative of a dimethylcyclopentanone. Notwithstanding, it was thought that this ketone might have been derived from an imino compound produced by ring-formation involving the cyano group and the H attached to the a-carbon atom.

Although crotonic ester shows no tendency to change into vinylacetic ester, yet as a hypothesis it may be supposed that in the presence of the energetic sodium enol alkyl cyanacetic ester, crotonic ester may exhibit a tendency to function in its β,γ-form



XLII XLIII

By the action of sodium ethoxide, such δ-cyano esters as (XLII) readily form sodium derivatives of cyclic imino compounds (XLIII) in which the sodium is better neutralized than in the open-chain derivatives.[22]

In a somewhat analogous case, the addition of sodium enol malonic ester to citraconic ester,[23] it has been shown[24] that, as well as the normal addition compound, a-methylpropane-a,&γ,γ-tetracarboxylic ester, there is also formed butane-α,β,δ,δ-tetracarboxylic ester, which would appear to have been produced by addition to itaconic ester. The latter tetracarboxylic ester is readily converted by sodium ethoxide into a cyclopentanone-carboxylic ester and, hence, the product of addition of sodium enol malonic ester to citraconic ester is largely the sodium derivative of this cyclic keto ester, because in this compound the sodium secures better neutralization and in the formation the maximum energy degradation is attained. To achieve this, hydrogen from the methyl group migrates during the reaction with change in the position of unsaturation so that the sitraconic ester functions during the process of addition as does itaconic ester.

The possibility indicated by the formation of high-boiling esters of an apparently cyclic structure, apparently derived from vinylacetic ester and suggesting that addition could take place at the β,γ-carbon atoms of an olefinic ester, was of sufficient interest as to warrant further examina-

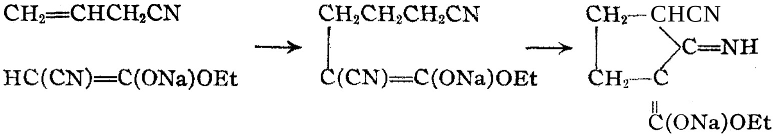
[22] Best and Thorpe, *J. Chem. Soc.*, *95, 685* (1909).

[23] Michael, Ber., **33, 3757** (1900).

[24] Hope, *J. Chem. Soc.*, 101,892 (1912); Ingold, Shoppee and Thorpe, *ibid.*, **1477** **(1926).**

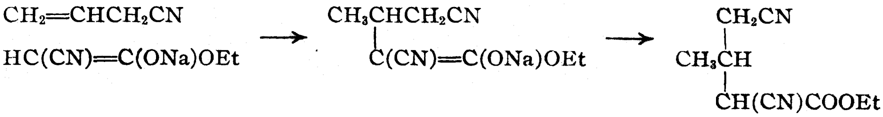
tion of reactions where this type of addition might be expected to be favored.

Allyl cyanide was chosen as a readily accessible β,γ-unsaturated compound of the same type as vinylacetic ester. If this added sodium enol cyanacetic ester in the above manner, then the ethyl compound of 2-imino-3-cyanocyclopentane-1-carboxylate (XLV) would be formed, a compound that has been described by Thorpe and Best.[22]



XLIV XLV

When this reaction was carried out in alcohol, or alcohol-free benzene, none of the cyclic imino compound could be detected. A very good yield of sodium derivative of β-methyl α-carbethoxyglutaronitrile (XLVI) was obtained



$$\begin{array}{l} CH_2{=}CHCH_2CN \\ HC(CN){=}C(ONa)OEt \end{array} \longrightarrow \begin{array}{l} CH_3CHCH_2CN \\ \quad| \\ C(CN){=}C(ONa)OEt \end{array} \longrightarrow \begin{array}{l} \quad CH_2CN \\ \quad\ | \\ CH_3CH \\ \quad\ | \\ \quad CH(CN)COOEt \end{array}$$

XLVI XLVII

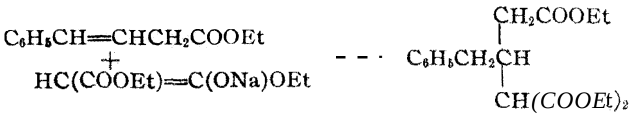
Similarly sodium enol a-cyanopropionic ester and allyl cyanide gave sodium enol α,β-dimethyl-γ-carbethoxyglutaronitrile (XLVIII) by migration of CH_3, although in this case a quantity of resinous material was also formed

$$\begin{array}{l} CH_2{=}CHCH_2CN \\ CH_3C(CN){=}C(ONa)OEt \end{array} \qquad \begin{array}{l} CH_3CHCN \\ \quad\ | \\ CH_3CH \\ \quad\ | \\ \quad C(CN)C(ONa)OEt \end{array}$$

XLVIII

The absence of β,γ-addition with allyl cyanide may be due to the great tendency of this nitrile to rearrange to the more stable α,β-unsaturated isomer. Since styrylacetic acid (β,γ-derivative) is known to be far more stable toward alkali than y-phenylcrotonic acid (α,β-isomer)[25] addition to styrylacetic ester was therefore examined. Vorlander and Strunck showed that sodium enol malonic ester adds to styrylacetic ester apparently through the α,β-derivative to give β-benzyl-γ-carbethoxyglutaric ester (XLIX). However, there is obviously no means of deciding from the structure of the addition product, at which carbon the hydrogen of the addendum had united

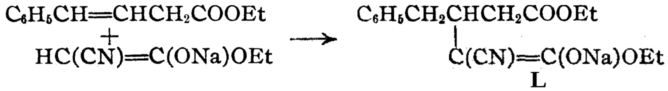
[25] Vorländer and Strunck, *Ann.*, 239, 345 **(1906).**



$$C_6H_5CH{=}CHCH_2COOEt + HC(COOEt){=}C(ONa)OEt \dashrightarrow C_6H_5CH_2\overset{CH_2COOEt}{\underset{CH(COOEt)_2}{CH}}$$

XLIX

We found that sodium enol cyanacetic ester similarly gave the sodium derivative of *β*-benzyl-*γ*-cyanoglutaric ester (L) and no cyclic imino compound was found in the reaction product.

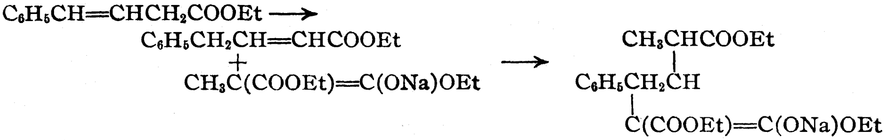


$$C_6H_5CH{=}CHCH_2COOEt + HC(CN){=}C(ONa)OEt \longrightarrow C_6H_5CH_2\underset{C(CN)=C(ONa)OEt}{CH}CH_2COOEt$$

L

Addition of sodium enol a-cyanopropionic ester to styrylacetic ester gave a cyano ester from which no identifiable acids could be obtained after hydrolysis with caustic alkali, nor was there any indication of the formation of an imino derivative.

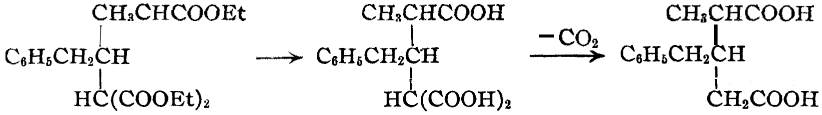
Addition of sodium enol methylmalonic ester to styrylacetic ester gave the sodium derivative of *α*-methyl-*β*-benzyl-*γ*-carbethoxyglutaric ester (LI), showing that migration of the methyl group had taken place as well as apparent addition to the a,@-isomer of styrylacetic ester.



$$C_6H_5CH{=}CHCH_2COOEt \longrightarrow C_6H_5CH_2CH{=}CHCOOEt + CH_3C(COOEt){=}C(ONa)OEt \longrightarrow C_6H_5CH_2\overset{CH_3CHCOOEt}{\underset{C(COOEt)=C(ONa)OEt}{CH}}$$

LI

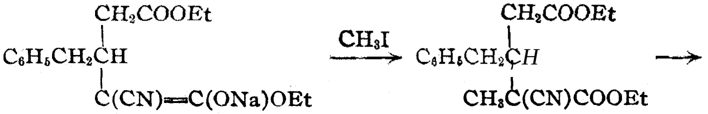
Upon saponification of the ester (LII), two stereomeric tricarboxylic acids were obtained, melting at 195 and 118'. These acids when heated above their melting points lost carbon dioxide and gave the isomeric *α*-methyl-*β*-benzylglutaric acids (LIV), melting at 139 and 97°, respectively.



$$C_6H_5CH_2\overset{CH_3CHCOOEt}{\underset{HC(COOEt)_2}{CH}} \longrightarrow C_6H_5CH_2\overset{CH_3CHCOOH}{\underset{HC(COOH)_2}{CH}} \xrightarrow{-CO_2} C_6H_5CH_2\overset{CH_3CHCOOH}{\underset{CH_2COOH}{CH}}$$

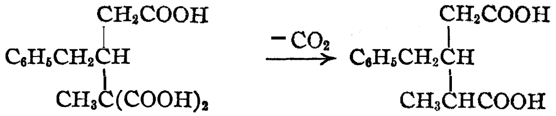
LII LIII Two forms LIV Two forms

By methylation of the sodium derivative of *β*-benzyl y-cyanoglutaric ester (L), *γ*-methyl-*β*-benzyl-*γ*-cyanoglutaric ester (LV) was obtained and this upon hydrolysis gave *γ*-methyl-*β*-benzyl-*γ*-carboxyglutaric acid (LVI), melting at 177°. This acid on heating above 177" gave *α*-methyl-*β*-benzylglutaric acid (LIV), m. p. 139°, which was identical with the acid of the same melting point obtained above.



$$C_6H_5CH_2\overset{CH_2COOEt}{\underset{C(CN)=C(ONa)OEt}{CH}} \xrightarrow{CH_3I} C_6H_5CH_2\overset{CH_2COOEt}{\underset{CH_3C(CN)COOEt}{CH}} \longrightarrow$$

L LV

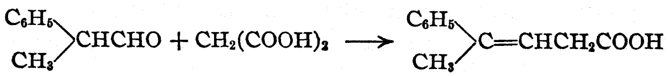


$$\begin{array}{c}CH_2COOH\\ |\\ C_6H_5CH_2CH\\ |\\ CH_3C(COOH)_2\end{array} \xrightarrow{-CO_2} \begin{array}{c}CH_2COOH\\ |\\ C_6H_5CH_2CH\\ |\\ CH_3CHCOOH\end{array}$$

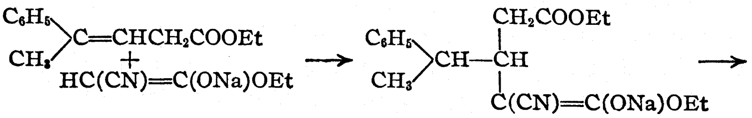
LVI LIV

Evidently to establish the constitution of the tricarboxylic acid, m. p. 118°, and of the dicarboxylic acid, m. p. 97°, derived from it, it was necessary to compare it with γ-methyl-γ-phenyl-β-aceticbutyric acid (LX).

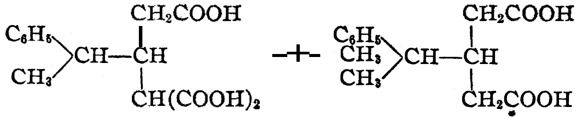
For this purpose hydratropic aldehyde was condensed with malonic acid in the presence of diethylamine, and the ester of the γ-methyl-γ-phenylbutenoic acid (LVII) so obtained was treated with sodium enol cyanacetic ester



LVII



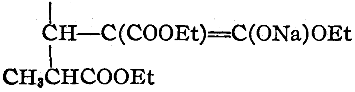
LVIII



LIX LX

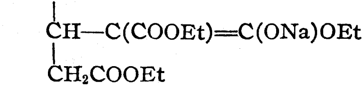
The cyano ester was hydrolyzed to the tricarboxylic acid (LIX) melting at 162°, which upon heating lost carbon dioxide and gave y-methyl-γ-phenyl-β-aceticbutyric acid, m. p. 88° (LX).

In the addition of sodium enol methylmalonic ester to styrylacetic ester, the methyl group evidently assumed the α-position and isomerization of the styrylacetic ester to y-phenylcrotonic ester occurred. This rearrangement may have anteceded the addition but it is more probable that it took place during the process and that it was associated with the maximal neutralization of the positive energy of the sodium. A comparison of the structures of the two possible addition products (LXI) and (LXII)



$$\begin{array}{l}CH_2C_6H_5\\ |\\ CH{-}C(COOEt){=}C(ONa)OEt\\ |\\ CH_3CHCOOEt\end{array}$$

LXI



$$\begin{array}{l}CH_3CHC_6H_5\\ |\\ CH{-}C(COOEt){=}C(ONa)OEt\\ |\\ CH_2COOEt\end{array}$$

LXII

shows that the negative radicals of (LXI) are more symmetrically arranged about the positive nucleus CH—C(COOEt)=C(ONa)OEt and that (LXI) should therefore be the intramolecularly better neutralized compound.

Experimental

A. Addition of Alkylmalonic Esters to Fumaric Ester

Propane-α,β,γ,γ-tetracarboxylic ester was prepared by the addition of malonic ester to fumaric ester in the presence of a small amount of sodium ethoxide;'' yield, 90% of theory, b. p. 187° (5 mm.).

Propane-α,β,γ,γ-tetracarboxylic acid was prepared from the above ester by saponification with 20% barium hydroxide solution and decomposing the sparingly soluble barium salt obtained with acid. The tetracarboxylic acid was extracted with ether and crystallized from the ether solution as a fine powder, m. p. 153°.

Anal. Calcd for $C_7H_8O_8$: C, 38.19; H, 3.64. Found: C. 38.36; H, 3.80.

Butane-α,β,γ,γ-tetracarboxylic ester was obtained by adding 22 g. of propane-α,β,γ,γ-tetracarboxylic ester to an ethereal suspension of anhydrous sodium ethoxide prepared from 1.8 g. of sodium, and methylating by addition of 10 g. of methyl iodide to the solution of sodium derivative, the mixture being cooled in ice. After standing for eight hours at room temperature, the product was worked up in the usual way; yield 21 g. of ester boiling at 180° (3 mm.).

Anal. Calcd. for $C_{16}H_{27}O_8$: C, 55.34; H, 7.78. Found: C, 55.50; H, 7.95.

Upon treatment of this ester with an ethereal suspension of sodium ethoxide, followed by methyl iodide, the main products were those of fission into fumaric and methylmalonic esters; 16 g. of ester was added to sodium ethoxide from 1.2 g. of sodium and after five minutes 8 g. of methyl iodide was added, the whole mixture standing at 0° for twelve hours. Upon working up there were obtained: 10 g. of ester, b. p. 95–120° (10 mm.), fumaric, dimethylmalonic esters; 4 g. of ester, b. p. 120–180° (3 mm.), unchanged ester.

Butane-α,β,γ,γ-tetracarboxylic acid was obtained by saponifying the ester with 20% caustic potash or barium hydroxide solution. The acid was liberated with hydrochloric acid and extracted with ether. It crystallized in transparent nodules from ether or acetone and ligroin and melted at 170°.

Anal. Calcd. for $C_8H_{10}O_8$: C, 41.03; H, 4.27. Found: C, 40.82; H, 4.46.

Butane-β,γ,δ,δ-tetracarboxylic ester is formed when fumaric ester is added to methylmalonic ester in the presence of an equivalent of sodium ethoxide in ethereal solution. This ester was previously obtained by Auwers, Kobner and Meyenberg,[27] and Michael[a] but described as butane-α,β,γ,γ-tetracarboxylic ester. Michael showed that this ester formed a sodium derivative, which readily reacted with methyl iodide and gave a quantitative yield of pentane-β,γ,δ,δ-tetracarboxylic ester and which, upon hydrolysis, gave α,γ-dimethyltricarballylic acid.

Butane-β,γ,δ,δ-tetracarboxylic acid was prepared by saponifying the ester with caustic potash. It was extracted with ether and crystallized from an ether-ligroin mixture in large nodules. There was no change in melting point upon fractional crystallization, so it was concluded that this acid, melting at 176°, was probably a pure stereomeric form. Hope[29] obtained an acid, melting at 155°, which he considered to be a mixture of two stereomeric forms, from the ester obtained in the addition of sodium enol malonic ester to citraconic ester.

Anal. Calcd. for $C_8H_{10}O_8$: C, 41.03; H, 4.27. Found: C, 41.21; H, 4.42.

[29] Hope, J. *Chem. Soc.*, 101, 901 (1912).

Pentane-β,γ,δ,δ-tetracarboxylic acid was prepared by saponification of the ester obtained upon treating the above **butane-β,γ,δ,δ-tetracarboxylic** ester with sodium ethoxide and methyl iodide at 0°. Recrystallized from acetone–ligroin mixture, m. p. 166°.

Anal. Calcd. for $C_9H_{12}O_8$: C, 43.54; H, 4.84. Found: C, 43.28; H, 4.90.

Pentane-α,β,γ,γ-tetracarboxylic Ester.—Prepared by treating sodium enol propane-α,β,γ,γ-tetracarboxylic ester with ethyl iodide, in ethereal solution, in the cold. The ester boiled at 180° (3 mm.).

Anal. Calcd. for $C_{17}H_{29}O_8$: C, 56.51; H, 8.03. Found: C, 56.65; H, 8.00.

Nine grams of ester was added to sodium ethoxide from 0.7 g. of sodium and after five minutes 8 g. of methyl iodide was added, the whole mixture standing on ice for twelve hours. Upon working up, there was obtained 8 g of ester, b. p. 180° (3 mm.), which proved to be unchanged ester, since upon saponification it gave pentane-α,β,γ,γ-tetracarboxylic acid, m. p. 177°.

Pentane-α,β,γ,γ-tetracarboxylic acid was obtained by saponifying the ester with caustic potash. It crystallized from ether in nodules, m. p. 177".

Anal. Calcd. for $C_9H_{12}O_8$: C, 43.54; H, 4.84. Found: C, 43.35; H, 4.77.

Pentane-α,α,β,γ-tetracarboxylic ester was obtained when fumaric ester was added to sodium enol ethylmalonic ester, formed by adding ethylmalonic ester to an equivalent of anhydrous sodium ethoxide suspended in ether. This ester, previously described as pentane-α,β,γ,γ-tetracarboxylic ester, was obtained by Michael,[28] who also showed that it formed a sodium derivative which, upon methylation, gave a quantitative yield of hexane-β,β,γ,δ-tetracarboxylic ester.

Pentane-α,α,β,γ-tetracarboxylic acid was prepared by saponifying the ester with caustic potash. It crystallized from ether or acetone–ligroin in transparent nodules, melting at 179° with decomposition, and, since no separation was obtained upon fractional crystallization, it was concluded that this acid represented a single stereomeric form.

Anal. Calcd. for $C_9H_{12}O_8$: C, 43.54; H, 4.84. Found: C, 43.75; H, 5.05.

Hexane-β,β,γ,δ-tetracarboxylic acid was prepared by saponifying the ester obtained by treating pentane-α,α,β,γ-tetracarboxylic ester with sodium ethoxide and methyl iodide in ether solution at 0°. Recrystallized from acetone–ligroin mixture, m. p. 170°.

Anal. Calcd. for $C_{10}H_{14}O_8$: C. 45.80; H, 5.34. Found: C, 45.72; H, 5.51.

B. Addition of Alkylcyanacetic Esters to Crotonic Ester

Addition of a-Cyanopropionic Ester to Crotonic Ester.—a-Cyanopropionic ester was prepared by methylation of sodium enol cyanacetic ester and freed from unchanged cyanacetic ester by shaking with successive small quantities of 5% caustic potash.

To a solution of 4.7 g. of sodium dissolved in 70 cc. of absolute alcohol, 25.5 g. of a-cyanopropionic ester was added, followed by 23 g. of crotonic ester. The mixture was heated on the water-bath for twenty-four hours. The cooled product was then poured into 500 cc. of ice water containing 13 g. of acetic acid and extracted with ether. The ethereal extract was washed with 10% sodium carbonate, followed by distilled water, the neutral esters dried and fractionated. Some low-boiling material came over first and then two main fractions were collected: 24 g., representing a 50% yield of **γ-cyano-α,β-dimethylglutaric** ester, distilled at 145–148° (3 mm.). This was a colorless liquid, which gave no coloration with alcoholic ferric chloride.

Anal. Calcd. for $C_{12}H_{19}O_4N$: C, 59.75; H, 7.88. Found: C, 59.65; H, 7.95.

Eleven grams of ester, collected between 160 and 185" (3 mm.), gave a deep red coloration with alcoholic ferric chloride. After redistillation, a fraction boiling at 182° (3 mm.) was obtained which was analyzed

And, Calcd. for $C_{12}H_{19}O_4N$: C, 59.75; H, 7.88; N, 5.82. Found: C, 59.47; H, 7.6; N, 5.7.

Upon hydrolyzing 3 g. of this high-boiling ester with hydrochloric acid (1:1), a small quantity of a ketonic compound, b. p. 50–120° (10 mm.), was obtained together with a sirupy acid. The ketonic compound with semicarbazide acetate gave a crystalline semicarbazone within one hour. This was recrystallized from dilute aqueous alcohol and melted at 224".

Anal. Calcd. for $C_7H_{13}ON_3$: C, 54.2; H, 8.38; N, 27.1. Found: C, 54.79; H, 7.34; N, 19.0.

These figures do not correspond with any simple derivative of cyclopentanone.

α,β-Dimethyl-γ-cyanoglutaric acid was obtained by saponification of or,@-dimethyl-γ-cyanoglutaric ester, b. p. 145–148° (3 mm.), with 20% caustic potash containing a small amount of alcohol. Immediately upon warming, the ester dissolved. After acidifying the well-cooled solution, the cyano acid was extracted with ether. It was a sirup which resisted all attempts to make it crystallize

Anal. Calcd. for $C_8H_{11}O_4N$: C, 51.89; H, 5.95. Found: C, 51.56; H, 6.03.

When boiled for one hour with concentrated hydrochloric acid, the above α,β-dimethyl-γ-cyanoglutaric acid gave a small amount of α,β-dimethylglutarimide, m. p. 112°, together with a sirupy cyano acid from which, on treatment with alkali, a liquid α,β-dimethylglutaric acid was prepared. This was characterized as a *trans* derivative by conversion into a,@-dimethylglutaricdianilide The α,β-dimethylglutaric acid was mixed with an excess of aniline and heated at 180° for one hour. The neutral dianilide thus formed crystallized in fine needles from mixture of ether and ligroin and melted at 216°.

Anal. Calcd. for $C_{19}H_{22}O_2N_2$: C, 73.53; H, 7.1. Found: C, 73.27; H, 7.31.

The above α,β-dimethylglutaric dianilide was identical with the dianilide prepared from an authentic sample of the ***trans*** α,β-dimethylglutaric acid.

α,β-Dimethyl-γ-carboxyglutaric acid was prepared by complete hydrolysis of the ester boiling at 147° (3 mm.), or of the above cyano acid by boiling it with 20% caustic potash for eight hours when ammonia ceased to be evolved. The acid solidified on standing and was recrystallized from an ether–ligroin mixture as fine prisms, m. p. 142°.

Anal. Calcd. for $C_8H_{12}O_6$: C, 47.07; H, 5.88. Found: C, 46.95; H, 6.00.

This acid was shown by mixed melting point to ***be not*** identical with the α,β-dimethyl-γ-carboxyglutaric acid, m. p 145°, obtained by condensation of the enolic sodium derivative of malonic or cyanacetic esters with tiglic ester. From the ease of hydrolysis of the parent ester, and the general properties of the acid, it is probable that it is a stereomer of α,β-dimethyl-γ-carboxyglutaric acid.

α,β-Dimethyl-γ-cyanoglutaric acid was obtained as an uncrystallizable sirup by saponifying the addition product of sodium enol cyanacetic ester to tiglic ester.[30]

Anal. Calcd. for $C_8H_{11}O_4N$: C, 51.89; H, 5.95. Found: C, 51.63; H, 6.10.

Upon boiling with concentrated hydrochloric acid, it gave some α,β-dimethylglutarimide, m. p. 113°, together with a cyano acid. Alkali hydrolysis of this acid, however, gave ***trans*** α,β-dimethylglutaric acid, characterized by the dianilide, m. p. 216'.

---

[30] Michael and Ross. Ref. 6. p. 4007.

β,γ-Dimethyl-γ-cyanoglutaric acid was prepared, for comparison with the above cyanoglutaric acids, by the action of methyl iodide upon the sodium derivative of β-methyl-γ-cyanoglutaric ester. It readily crystallized in large prisms, m. p. 152°, and upon boiling with hydrochloric acid gave about equal quantities of α,β-dimethylglutarimide and the trans cyano acid. Thorpe and Young[31] synthesized this acid by the same method, but gave the melting point as 132–133°.

Anal. Calcd. for $C_8H_{11}O_4N$: C, 51.89; H, 6.95. Found: C, 51.78; H, 5.96.

Attempted Addition of Sodium Enol Ethylmalonic Ester to Crotonic Ester.—a-Carboxybutyric ester was obtained by treating sodium enol malonic ester with ethyl iodide, and the product was purified from malonic ester by shaking four times with a third of its volume of 25% caustic potash.

Four and eight-tenths grams of sodium was pulverized and dissolved in 9.5 g. of absolute alcohol in ether solution. To the anhydrous sodium ethoxide, 38 g. of α-carboxybutyric ester was added, followed by 23 g. of crotonic ester and the mixture heated on the water-bath for six hours. The ice-cooled mixture was then washed with water containing a little more than an equivalent quantity of acetic acid. The ether solution was extracted with 10% sodium carbonate, followed by distilled water, dried and the neutral esters distilled; 35 g. of ester boiled up to 150° (25 mm.), consisting mainly of unchanged a-carboxybutyric ester and with some crotonic ester; 7 g. distilled from 140–152° (4 mm.), which consisted of a-ethylidene β-methylglutaric ester (or so-called dicrotonic ester). This was proved by analysis of the acid, m. p. 129°, obtained upon saponification of this ester.[32]

Anal. Calcd. for $C_8H_{12}O_4$: C, 55.82; H, 7.56. Found: C, 56.04; H, 7.3.

There was also obtained 4 g. of ester boiling at 152–159° (4 mm.), which upon saponification gave a sirupy, uncrystallizable acid. The small yield of this material did not permit further examination, although it probably represented the addition product of ethylmalonic to crotonic ester.

Addition of Sodium Enol a-Cyanobutyric Ester to Crotonic Ester.—a-Cyanobutyric ester was prepared from sodium enol cyanacetic ester and ethyl iodide. The product was shaken with successively small amounts of 5% caustic potash in order to remove unchanged cyanacetic ester.

A solution of 4.7 g. of sodium in 70 cc. of absolute alcohol was mixed with 28 g. of α-cyanobutyric ester and then with 23 g. of crotonic ester, and the mixture heated on the water-bath for twenty-four hours. The cooled product was poured into 500 cc. of water containing 13 g. of acetic acid and the solution extracted with ether. The ethereal extract was washed with 10% sodium carbonate, then with distilled water, dried and the neutral esters distilled. About 25 g. distilled up to 140° (15 mm.), which consisted of unchanged esters. The 17 g. that passed over at 153° (3 mm.) proved to be γ-cyano-a-ethyl-P-methylglutaric ester, representing a 33% yield. It was a colorless liquid which gave no color with alcoholic ferric chloride.

Anal. Calcd. for $C_{13}H_{21}O_4N$: C, 61.18; H, 8.23. Found: C, 60.95; H, 8.30.

There was also obtained a fraction of ester, boiling at 160–165° (3 mm.), which gave a deep red coloration with alcoholic ferric chloride. This higher-boiling ester was probably homologous with the similar ester formed in the addition of sodium enol a-cyanopropionic ester to crotonic ester.

Anal. Calcd. for $C_{13}H_{12}O_4N$: C, 61.18; H, 8.23. Found: C, 60.56; H, 8.01.

γ-Cyano-α-ethyl-β-methylglutaric acid was obtained by saponification of the ester,

---

[31] Thorpe and Young, J. Chem. Soc., 83, 357 (1903).

[32] V. Pechmann, Ber., 33, 3340 (1900); and Michael, *ibid.*, 33, 3760 (1900).

b. p. 153' (3 mm.), with alcoholic potash, the mixture being gently boiled until the ester had dissolved. Upon acidifying, the acid was extracted with ether and crystallized in prisms from a mixture of ether and ligroin, m. p. 147". This cyano acid accounted for 60% of the product of saponification; only a residual sirup remained.

Anal. Calcd. for $C_9H_{13}O_4N$: C, 54.26; H, 6.53. Found: C, 54.15; H, 6.7.

α-Ethyl-β-methylglutarimides.—Boiling the above cyano acid with hydrochloric acid (1:1) gave a mixture of two isomeric imides. The tnain product melted at 92° and crystallized in fine needles from an ether–ligroin mixture.

Anal. Calcd. for $C_8H_{13}O_2N$: C, 61.94; H, 8.38. Found: C, 62.16; H, 8.6.

From the mother liquor the second imide melting at 102°, which crystallized in large prisms, was obtained. By boiling the above-mentioned sirupy cyano acid, more of this imide, m. p. 102°, was obtained. This was apparently formed from a stereomeric *cis* form of the a-ethyl-p-methyl-y-cyanoglutaric acid, which may occur in four racemic forms.

Anal. Found: C, 62.05; H, 8.5.

Cis **α-Ethyl-β-methylglutaric** acid was obtained by hydrolysis of the above imide, m. p. 92°, by boiling with hydrochloric acid for six hours. It crystallized in prisms from a mixture of chloroform and ligroin and melted at 88°.

Anal. Calcd. for $C_8H_{14}O_4$: C, 55.18; H, 8.04. Found: C, 55.13; H, 8.16.

α-Ethyl-β-methyl-γ-carboxyglutaric acid was obtained by complete hydrolysis of the ester, b. p. 153° (3 mm.), or of the cyano acid, m. p. 147°, with caustic potash. It crystallized in fine prisms, melting at 143°.

Anal. Calcd. for $C_9H_{14}O_6$: C, 49.53; H, 6.42. Found: C, 49.56; H, 6.53.

Addition of Sodium Enol Cyanacetic Ester to a-Ethyl Crotonic Ester.—To a solution of 2.3 g. in 35 cc. of absolute alcohol, 11.3 g. of cyanacetic ester was added, followed by 14.2 g. of α-ethylcrotonic ester (b. p. 160"). The mixture was heated on the water-bath for twenty-four hours and the material worked up as usual; yield, 60% of addition product.

α-Ethyl-β-methyl-γ-cyanoglutaric ester distilled at 154° (4 mm.).

Anal. Calcd. for $C_{13}H_{21}O_4N$: C, 61.18; H, 8.23. Found: C, 61.06; H, 8.40,

α-Ethyl-β-methyl-γ-cyanoglutaric acid was prepared by saponifying the above ester with alcoholic potash. It crystallized in large prisms, melting at 132".

And. Calcd. for $C_8H_{13}O_4N$: C, 54.26, H, 6.23. Found: C, 54.22; H, 6.08.

Upon boiling the cyano acid with hydrochloric acid, a small amount (5%) of a mixture of the α-ethyl-β-methylglutarimides was obtained, but the main product was a sirupy cyano acid that could not be crystallized. This was apparently or-ethyl-@-methyl-y-cyanobutyric acid, since, upon complete hydrolysis, it gave *trans* or-ethyl-& methylglutaric acid, m. p. 101°. This acid crystallized in large prisms from a mixture of chloroform and ligroin. It had previously been prepared by v. Pechmann,[32] from α-ethylidene-β-methylglutaric acid, who only described one form, which from the above synthesis is apparently the *trans* stereomer.

Anal. Calcd. for $C_8H_{14}O_4$: C, 55.18; H, 8.06. Found: C, 55.25; H, 8.18.

a-Ethyl-@-methyl-γ-carboxyglutaric acid was obtained by complete hydrolysis of the ester, b. p. 154° (4 mm.), or of the cyano acid, m. p. 132°, with caustic potash. It crystallized in needles, m. p. 141°.

And. Calcd. for $C_9H_{14}O_6$: C, 49.53; H, 6.42. Found: C, 49.82; H, 6.69.

Ethylation of γ-Cyano-β-methylglutaric Ester.—γ-Cyano-β-methylglutaric ester was prepared by the addition of crotonic ester to sodium enol cyanacetic ester in alcoholic solution. The ester distilled as a colorless liquid, b. p. 147° (3 mm.).[33] To a suspension of sodium ethoxide prepared by the action of **4.8** g. of absolute alcohol upon **2.5** g. of pulverized sodium, **23** g. of γ-**cyano**-β-**methylglutaric** ester was added. After standing until the formation of the soluble sodium derivative was completed, **17** g. of ethyl iodide was added and the mixture stood for two hours at room temperature. After warming on the steam-bath for half an hour, the product was worked up in the usual way. γ-**Ethyl**-β-**methyl**-γ-**cyanoglutaric** ester boiled at 152° (**4** mm.).

Anal. Calcd. for $C_{13}H_{21}O_4N$: C, **61.18**; H, **8.23**. Found: C, **61.29**; H, **8.42**.

γ-Ethyl-β-methyl-γ-cyanoglutaric acid was obtained through saponification with alcoholic potash. It crystallized from ether–ligroin mixture in long prisms, m. p. 139°. The amount of this cyano acid accounted for 80% of the product of saponification.

Anal. **Calcd.** for $C_9H_{13}O_4N$: C, 5426; H, **6.53**. Found: C, **54.11**; H, **6.63**.

Upon boiling γ-ethyl-β-methyl-γ-cyanoglutaric acid with dilute hydrochloric acid for one hour, there was formed a small amount of the two α-ethyl-β-methylglutarimides (less than 5%), but the main product was a sirupy cyano acid which could not be crystallized. It was apparently α-ethyl-β-methyl-γ-cyanobutyric acid, since, upon complete hydrolysis, it gave *trans* **α-ethyl-β-methylglutaric** acid, m. p. **101°**.

γ-Ethyl-β-methyl-γ-carboxyglutaric acid.—Upon boiling γ-**ethyl**-β-**methyl**-γ-**cyanoglutaric** ester, or the corresponding cyano acid, with 30% caustic potash for twenty-four hours, a sirupy tricarboxylic acid was obtained which could not be crystallized.

Anal. Calcd. for $C_9H_{14}O_6$: C, **49.53**; H, **6.42**. Found C, **49.28**; H, **6.62**.

When boiled with hydrochloric acid, the **tricarboxylic** acid lost carbon dioxide to form a mixture of *cis* and *trans* a-ethyl-j3-methylglutaric acids.

C. Addition to β,γ-Unsaturated Compounds

Addition of **Sodium Enol** Cyanacetic Ester to **Allyl** Cyanide.—Ally1 cyanide was prepared from cuprous cyanide by the method described in "Organic Syntheses" (Vol. VIII, p. 4); **5.7** g. of sodium was dissolved in **85** cc. of absolute alcohol and 28 g. of **cyanacetic** ester added. After cooling, **17** g. of **allyl** cyanide was added and, as there was a noticeable evolution of heat as the solid derivative dissolved, the flask was placed in ice water The mixture was gently **refluxed** upon the water-bath for sixteen hours. The product was cooled, mixed with dilute acetic acid and extracted with ether; **40** g. of **β-methyl-γ-carbethoxyglutaronitrile,** b. p. 160° (**3** mm.), was obtained, being a yield of 90%.

Anal. Calcd. for $C_9H_{12}O_2N_2$: C, 59.99; H, **6.66**. Found: C, **59.75**; H, **6.80**.

When the addition was **carried** out in xylene using alcohol-free sodium **enol cyanacetic** ester, prepared by precipitation from ether solution, the product was the same.

In each case the constitution of the cyano ester was proved by hydrolysis with 20% caustic potash, when β-methyl-γ-carboxyglutaric acid was obtained, m. p. 139° (Ref. **6,** p **4604).**

Addition of Sodium **Enol α-Cyanopropionic** Ester to **Allyl** Cyanide.——Thirty-two grams of a-cyanopropionic ester was added to a solution of 5.7 g. of sodium in absolute alcohol and then 17 g. of **allyl** cyanide, **carrying** out the operation as above. The neutral products, **12 g.,** distilling up to **110°** (**15** mm.), consisted apparently of unchanged material; 17 g. distilled at 152° (3 mm.) which was **α,β-dimethyl-γ-carbethoxyglutaronitrile,** and a resinous residue weighing **12** g. remained in the flask.

Anal. Calcd. for $C_{10}H_{14}O_2N_2$: C, **61.85**; **H, 7.22**. Found: C, **61.72**; H, **7.36**.

Upon hydrolysis with **20%** caustic potash, the cyano ester gave a,@-dimethyl-7-

---

[33] Darbishire and Thorpe, J. *Chem. Soc.*, **87, 1716 (1905).**

carboxyglutaric acid, m. p. 142". This was identified by analysis, direct comparison and a mixed melting point with a sample of the acid, prepared by addition of sodium enol α-cyanopropionic ester to crotonic ester.

Addition of Sodium Enol Cyanacetic Ester to Styrylacetic Ester.—To a solution of **1.2 g.** of sodium in 20 cc. of absolute alcohol, was added **5.8** g. of cyanacetic ester, followed by **9.5** g. of styrylacetic ester, and the mixture heated for sixteen hours on the water-bath. After working up in the usual way, a yield of **10** g. of addition product, boiling at **193°** (3 mm.), was obtained. The formation of enolic compounds could not be detected.

Anal. Calcd. for $C_{17}H_{21}O_4N$: C, **67.33;** H, **6.93.** Found: C, **67.15; H, 7.10.**

β-Benzyl-γ-carboxyglutaric acid was obtained through treatment of the above ester with caustic potash. It crystallized in large transparent prisms, melting at 158° with decomposition. This acid should be identical with the acid obtained by Vorlander and Strunck[34] through the addition of sodium enol malonic ester to styrylacetic ester, although their acid melted at **146°**.

Anal. Calcd. for $C_{13}H_{14}O_6$: C, **58.64;** H, **5.26** Found: C, **58 41;** H, **5.35.**

The above acid gave β-benzylglutaric acid on heating to 165° for thirty minutes. It crystallized in large prisms from an ether–ligroin solution and, like Vorländer and Strunck's acid, melted at **102°**

γ-Methyl-β-benzyl-γ-cyanoglutaric ester was obtained by treatment of the sodium derivative of the above ester in ether solution with methyl iodide. It boiled at 194° (3 mm.).

Anal. Calcd. for $C_{18}H_{23}O_4N$: C, **68.14,** H, **7.25.** Found: C, **68.22;** H, **7.41.**

γ-Methyl-β-benzyl-γ-carboxyglutaric acid was prepared through hydrolysis of the above cyano ester with caustic potash. It crystallized in large prisms from acetone–ligroin mixture and melted at 177° with decomposition.

Anal. Calcd. for $C_{14}H_{16}O_6$: C, **59.99;** H, **5.71.** Found: C, **60.18;** H, **5.93.**

α-Methyl-β-benzylglutaric acid.—This acid was heated at **180°** for thirty minutes and the decomposition product crystallized from a mixture of ether and ligroin. Only one acid was isolated and this melted at 139° after recrystallization.

Anal. Calcd. for $C_{13}H_{16}O_4$: C, **66.1;** H, **6.78.** Found: C, **66.23;** H, **6.90.**

Addition of Sodium Enol Methylmalonic Ester to Styrylacetic Ester.—To a suspension of anhydrous sodium ethoxide prepared from **2.3** g. of sodium, **17.5** g. of methylmalonic ester was added, followed by **19** g. of styrylacetic ester and the mixture was heated upon the water-bath for six hours. After working up as usual, **15** g. of unchanged esters, b. p. up to 120° **(10** mm.) was obtained and **15** g. of the addition product ester, boiling at 197° **(3** mm.) There was also a small amount of high-boiling ester which distilled at 222° (3 mm.).

Anal. Calcd. for $C_{19}H_{26}O_6$: C, **65.13;** H, **7.43.** Found: C, **65.28; H, 7.61.**

α-Methyl-β-benzyl-γ-carboxyglutaric acid.—The ester, boiling at 197° (3 mm.), was saponified with caustic potash. After acidifying, the tricarboxylic acids were extracted with ether. Upon addition of ligroin, an acid crystallized out which melted at **197"** upon purification.

Anal. Calcd. for $C_{14}H_{16}O_6$: C, **59.99;** H, **5.71.** Found: C, **59.71;** H, **6.00.**

A second isomeric α-methyl-β-benzyl-γ-carboxyglutaric acid was obtained from the mother liquor left after crystallizing out the form of m. p 197°. It was recrystallized from chloroform and melted at 118°.

A d . Found: C, **59.81;** H, **5.9.**

---

[34] Vorländer and Strunck, Ann., **345,239 (1906).**

α-Methyl-β-benzylglutaric Acid.—When the a-methyl-p-benzyl-y-carboxyglutaric acid, melting at 195°, was decomposed by heating at 200° for twenty minutes, a mixture of the two forms of a-methyl-p-benzylglutaric acid was obtained. These were separated by crystallization from chloroform–ligroin mixture. The main product was the stereomer, m. p. 139°, identical with the acid obtained above from **γ-methyl-β-benzyl-γ-carboxyglutaric** acid. The other isomer present in small amount melted at 97°.

When α-methyl-β-benzyl-γ-carboxyglutaric acid, m. p. 118°, was heated at 150° for thirty minutes, the product consisted entirely of α-methyl-β-benzylglutaric acid, m. p. 97°.

Anal. Calcd. for $C_{13}H_{16}O_4$: C, **66.10;** H, **6.78.** Found: C, **66.18;** H, **6.95.**

Synthesis of **γ-Methyl-γ-phenyl-β-aceticbutyric** Acid.—Hydratropic aldehyde, prepared by Claisen's method[35] was condensed with malonic acid, by boiling a mixture of the aldehyde and malonic acid in alcoholic solution for six hours in the presence of a few drops of diethylamine. The product was poured into water, and extracted with ether. The acid was extracted from the ether solution by washing with sodium carbonate solution. Upon acidifying with hydrochloric acid an oil was obtained which was taken up in ether. The acid thus obtained was esterified by boiling with absolute alcohol containing a little sulfuric acid. The ester obtained was fractionally distilled and gave two main fractions; γ-methyl-γ-phenylbutenoic ester boiled at 156° **(10 mm.).**

Anal. Calcd. for $C_{13}H_{16}O_2$: C, **76.47;** H, 7.84. Found: C, **76.24;** H, **8.06.**

A smaller amount of the higher-boiling fraction of ester, 175–182° **(10** mm.), was apparently γ-methyl-γ-phenyl-α-carbethoxybutenoic ester.

A d . Calcd. for $C_{16}H_{20}O_4$: C, **69.56;** H, 7.25. Found: C, **69.32;** H, **7.40.**

y-Methyl-y-phenylbutenoic acid was obtained by saponification of the above ester, b. p. 156° **(10 mm.)**; it remained a sirup. Mayer and Stamm[36] previously obtained this acid, m. p. 75–78°, through the action of methylmagnesium iodide upon benzoylpropionic ester.

Anal. Calcd. for $C_{11}H_{12}O_2$: C, **75.00;** H, **6.82.** Found: C, **74.73;** H, **7.06.**

y-Methyl-y-phenyl-a-carboxybutenoic Acid.—Upon saponification of the ester. b. p. 175–182° **(10** mm.), an acid was obtained melting at **151**"with evolution of gas.

Anal. Calcd. for $C_{12}H_{12}O_4$: C, **65.46;** H, **5.45.** Found: C, **65.23;** H, **5.60.**

Addition of Sodium **Enol** Cyanacetic Ester to **γ-Methyl-γ-phenylbutenoic** Ester.—To a solution of **1.2** g. of sodium in 20 cc. of alcohol was added **5.7** g. of cyanacetic ester, followed by **10** g. of **γ-methyl-γ-phenylbutenoic** ester, and the mixture heated for twelve hours upon the water-bath. The product was worked up in the usual manner and 9 g. of ester, b. p. **198'** **(3** mm.), was obtained. This was the addition product, **γ-methyl-**γ-phenyl-α-cyano-β-aceticbutyric ester.

Anal. Calcd. for $C_{18}H_{23}O_4N$: C, **68.14;** H, **7.25.** Found: **C, 68.26;** H, **7.38.**

γ-Methyl-γ-phenyl-α-carboxy-β-aceticbutyric acid was obtained through saponifying the above ester with caustic potash. The acid crystallized in large prisms from an acetone–ligroin mixture which melted at **162'** with decomposition.

Anal. Calcd. for $C_{14}H_{16}O_6$: C, **59.99;** H, **5.71.** Found: C, **60.18;** H. **5.64.**

γ-Methyl-γ-phenyl-β-aceticbutyric acid was prepared by heating the above tricarboxylic acid to 165° for thirty minutes. The acid crystallized from a mixture of ligroin and ether in fine needles melting at 88°.

Anal. Calcd. for $C_{13}H_{16}O_4$: C, **66.10;** H, **6.78.** Found: **C, 66.11;** H, **6.63.**

Summary

1. The course of addition of a derivative of the sodium enol malonic ester type to an α,β-unsaturated ester proceeds according to the law of chemical neutralization. That addition product is therefore formed in which the positive energy of the sodium atom is best neutralized, since the maximal energy degradation is thus realized.

2. It has been shown that in the addition of sodium enol alkyl malonic esters to fumaric ester, the alkyl group migrates so that the addendum parts are alkyl and —C(COOEt)=C(ONa)OEt.

3. In the addition of sodium enol alkyl cyanacetic esters to crotonic ester, the addendum parts are similarly alkyl and —C(CN)=C(ONa)OEt.

4. In the addition to crotonic ester, the yield of addition product was greater in the case of sodium enol methylcyanacetic ester *(50%)* than with sodium enol ethylcyanacetic ester **(33%).** However, the yield of addition product is determined by several complex factors so that it is not possible from these experiments to make any statement regarding the relative ease of migration of the methyl and ethyl groups in these addition reactions.

5. In these reactions, the maximal chemical neutralization of the sodium is realized by the sodium remaining attached to the carbonyl oxygen atom in the malonic or cyanacetic groups. The sodium atom, however, becomes better neutralized than it was in the addendum by the spatial negative influence of the acquired carbethoxyl group.

6. Esters of the type $CHX(COOEt)—CHY—CZ(COOEt)_2$ [where X = R or H, Y = R, H or COOEt and Z = R or H, also R is an alkyl or aryl radical], apparently form enolic sodium derivatives containing the group —CH=C(ONa)OEt, but these immediately decompose to form ethylenic α,β-esters and sodium alkylmalonic esters. The retrogression of the free ester (A) by sodium is probably due to the formation of such an enolic sodium derivative, It would follow from this relationship that the sodium atom involved in the addition reactions specified under 2 and **3** above cannot migrate during the addition process. However, if the single carbethoxyl group of (A) can form an enolate, an amount of sodium corresponding to the relative acidity of the two enolic forms of ester (A) (Z = H), would migrate to the single carbethoxyl group according to the partition principle,[37] and spontaneous retrogression would lead to the re-formation of a further quantity of this sodium enol derivative. Thus, by this process, in agreement with the partition principle, an apparent balanced state would be achieved between the two possible stable sodium derivatives.

7. It has not been found possible to obtain addition to the γ-carbon atom of a β,γ-unsaturated ethylenic ester or nitrile. Addition occurs

---

in the case of allyl cyanide and styrylacetic ester at the α- and β-carbon atoms, with migration of an α-hydrogen atom.

CAMBRIDGE, MASSACHUSETTS

NOTES

Some New *p*-Bromophenacyl Esters.—In using the method of Reid and Judefind [THIS JOURNAL, 42, 1043 (1920)] for the identification of organic acids, we have prepared the following *p*-bromophenacyl esters which are not listed by these authors: trimethylacetate, m. p. 76.5°; isocaproate, m. p. 77.3°; enanthate, m. p. 69.2°; isoheptylate, m. p. 75.5°; pelargonate, m. p. 63.5°.

Preparation of N-o-Chlorobenzoyl-o-chlorobenzenesulfonamide.—Several years ago an investigation was undertaken in this Laboratory having for its object the preparation of diphenic sulfinide ("Diphensaccharin"). It was hoped that this compound might be sweet, or at least that its preparation would throw some light on the general problem of sweet taste *vs.* molecular structure. The method attempted was the internal condensation of chlorobenzoylchlorobenzenesulfonamide by loss of two atoms of chlorine from the molecule.

Preparation of N-o-Chlorobenzoyl-o-chlorobenzenesulfonamide, $ClC_6H_4CONHSO_2C_6H_4Cl$.—Ten grams of o-chlorobenzenesulfonamide was treated with 9.5 g. of o-chlorobenzoyl chloride and the mixture heated (180–190°) in an oil-bath for one hour. The dark brown mass was dissolved in acetone, the solution filtered, and the solid again precipitated by the use of petroleum ether. The solid was heated on a clay plate (70–80°) until it was perfectly dry and odorless. Repeated crystallizations from dilute ethanol or dilute acetic acid finally gave a product with a constant melting point of 154–155°; white platelets, having a faint bitter taste, yield about 11 g.

Anal. Calcd. for $C_{13}H_9O_3Cl_2NS$: C, 47.27; H, 2.72; N, 4.24; Cl, 21.52; S, 9.70. Found: C, 47.24; H, 2.60; N, 4.19; Cl, 21.40; S, 9.76.

In attempting to prepare diphenic sulfinide from the compound named above, it was heated alone and in different solvents, and treated with metals and other reagents under a variety of conditions. Seventy-two experiments were carried out, only two of which gave any indication of success. In these cases the material was heated in amyl alcohol solution with copper powder and sodium iodide.[1] A compound was secured having a melting point of 255–258°. It was contaminated with amyl alcohol, which was removed in part by application of heat. The yield was small and complete purification was not possible. Analysis for sulfur gave 8.67%, while theory calls for 12.35%. The compound had a bitter taste. Repetitions of this experiment did not again yield this compound, and lack of starting materials forced the abandonment of the project. In view of the known instances in which seven- and eight-membered ring compounds have been made from diphenic acid, the failure of this synthesis is without explanation, and seems worthy of report.

The p-Bromoanilides of Isobutyric and Isovaleric Acids.—For purposes of comparison in identification work in this Laboratory it was desired to have samples of the *p*-bromoanilides of a number of the paraffin acids. The most comprehensive list of such p-bromoanilides which appears in the literature is that reported by Robertson [Robertson, *J. Chem. Soc.*, **115**, 1210 (1919)]. This list, however, does not contain the derivatives of isobutyric or isovaleric acids.

The procedure used for the preparation of the *p*-bromoanilides of the acids from acetic to stearic is a modification of Robertson's procedure and is as follows: One gram (1 mol) of the acid or its sodium salt was placed in a small flask or test-tube and treated with 1 mol of thionyl chloride and heated under a reflux condenser for thirty minutes. The reaction mixture was then cooled and treated with 2 mols of *p*-bromoaniline in 30 cc. of benzene. After warming on a steam-bath for a few minutes the benzene solution was cooled, transferred to a separatory funnel, washed twice with water, twice with 5% hydrochloric acid, once with 5% sodium hydroxide and finally with water. The benzene solution was then evaporated to dryness and the remaining bromoanilide recrystallized from ethyl alcohol The melting points and analyses of these derivatives of isobutyric and isovaleric acids are

	M. p., °C.	Bromine, %	
		Calcd.	Found (Carius)
p-Bromoisobutyranilide	150–151	33.03	32.43
p-Bromoisovaleranilide	128–129	31.10	31.12

The *p*-bromoisobutyranilide has been reported by Norton [*Am. Chem. J.*, **7**, 116 (1885)] as melting at 128°. Judging from the low melting point

---

[1] Finkelstein, *Ber.*, **43**, 1530 (1910).

and satisfactory analysis reported for this p-bromoanilide it is quite probable that it was contaminated with some of the ortho isomer, *as* it was prepared by the bromination of isobutyranilide. *p*-Bromoisovaleranilide **does** not appear to have been described previously in the literature.

COMMUNICATIONS TO THE EDITOR

THE α,β,γ-TRIMETHYLGLUTARIC ACIDS

Sir:

In a recent paper Michael and Ross[1] reported the failure to obtain α,β,γ-trimethyl-α-carboxyglutaric acid in a crystalline form. I had obtained this acid[2] and reported it as melting at **144–145'.** Michael and Ross note that 145° is also the melting point of **α,β-dimethyl-γ-carboxy**glutaric acid, which suggests that the two are identical. The fact is that I obtained α,β,γ-trimethylglutaric acid melting at 134° from the decomposition of my acid, whereas α,β-dimethyl-γ-carboxyglutaric acid upon decomposition gives a,@-dimethylglutaric acid melting at 87°.[3]

Michael and Ross obtained α,β,γ-trimethyl-α-carboxyglutaric acid as a sirup which on distillation gave an acid melting at 115–125°. In my work on these compounds I found that it was necessary to obtain the tricarboxylic acid in **a** pure state before decomposing it in order to effect the purification of the **α,β,**y-trimethylglutaric acid. Even so it required ten recrystallizations to reach the melting point of **134'.** The compound which Michael and Ross describe as ***cis*-α,β,**y-trimethylglutaric acid, which according to their statement "softened at 115° and melted at 125°," was probably an impure acid identical with mine, which melted at **134'.** The liquid which they call *trans*-α,β,γ-trimethylglutaric acid was, apparently, the same as the liquid remaining in the mother liquors from the crystallization of the acid melting at 134°. Neither their work nor mine is sufficiently complete to characterize this liquid as a definite chemical individual. Inasmuch as modern theory predicts the occurrence of ***three*** stereoisomeric forms (one racemic and two meso acids) it would, in my opinion, be unfortunate if it should be so described in handbooks.

Michael and Ross attempted to separate their acids into a "cis" and a ***"tram"*** form by converting the "*cis*" form into the anhydride and the imide. Granting free rotation about a single bond *all* three of the possible

THE α,β,γ-TRIMETHYLGLUTARIC ACIDS

Sir:

In the preceding Communication F. E. Ray expresses the opinion that in our recent paper [This journal, 52, 4598 (1930)] (a) certain compounds described were impure and (b) that the method of separation of the α,β,γ-trimethylglutaric acids was not valid.

With respect to his first objection, we would draw attention to the fact that the compounds we described were analytically pure and, in the cases where crystalline, were unchanged in melting points after the third crystallization.

Ray prepared his tiglic ester through methylethylmalonic ester, obtained apparently by methylation and ethylation of sodium enol malonic ester. Besides the methylethylmalonic ester, the reaction product would contain monomethyl or ethyl and dimethyl or diethyl malonic esters, which cannot be completely separated by fractional distillation [Michael, *J. prakt. Chem.*, 72, 537 (1905)]. Ray finally obtained a product which boiled at 100° (30 mm.), which is clearly too high for tiglic ester (b. p. 156° (760 mm.)). The addition compound he prepared from this product through sodium enol cyanacetic ester boiled at 150–170" (30 mm.) and this obviously impure material was methylated. By hydrolysis the product gave a solid acid from which by repeated crystallization, a 145° melting acid was isolated. This was considered to be a-carboxy α,β,γ-trimethylglutaric

---

[4] Since writing this Note, Michael and Ross in a footnote contained in the following Communication to the Editor, p. 1175, have kindly called my attention to a transposition of an analysis in my paper[6] [This journal, 50,562 (1928)]. The silver salt of α,β,γ-trimethyl-α-carboxyglutaric acid was analyzed and found correct (page 662, line 15). Following this is given the titration of the α,β,γ-trimethylglutaric acid, $C_8H_{14}O_4$. This should, of course, have followed the paragraph which describes the preparation of this acid from the malonic acid derivative for which the analysis of the silver salt is given.

In the hope of identifying this α,β,γ-trimethylglutaric acid (m. p. 134°) as the racemic form I have attempted its resolution by means of the brucine and strychnine salts but without success. It may thus be one of the meso forms. As a check to previous work the silver salt of the acid was prepared and analyzed with the following results:

Anal. Subs., 0.0450: Ag, 0.0248. Calcd. for $C_8H_{12}O_4Ag_2$: Ag, 55.6. Found: Ag, 55.1.

This leaves no doubt that the acid melting at 134° is α,β,γ-trimethylglutaric acid.

acid but the formula was not proved by analysis.[1] No yield was given of this acid and it was not clear from the description in his paper that the 145° melting acid was used for pyrogenic decomposition. In his preparation of the tribasic acid through tiglic and sodium enol malonic esters, Ray obtained it as a sirup from which apparently he could obtain the 134° melting dicarboxylic acid more readily than from the 145° melting acid. It is therefore difficult to understand the reference in his letter of "necessity to purify before decomposition." The acid melting at 134° was described as α,β,γ-trimethylglutaric acid, although no analyses of this material are given. We, therefore, cannot attach the importance that Ray does to this substance of unknown composition, obtained from an impure source.

With respect to the second objection, the validity of the method is a well established fact. The stereomeric poly-alkyl dicarboxylic acids do not form anhydrides with equal facility, or of equal stability, and we refer Dr. Ray to the literature of these acids [Perkin and Bone, J. Chem. *Soc.*, 69, 264 (1896); Thorpe and Young, *ibid.*, **83,** 358 (1903), and others].

Since we used this method in the separation of the α,β,γ-trimethylglutaric acids, our products were described as *cis* and *trans* to indicate their origin and relative ease of anhydride formation. It was not relevant to our investigation to separate the possible stereomeric forms of α,β,γ-trimethylglutaric acid; it was sufficient for us to obtain a pure imide, m. p. 90°, and an acid, m. p. 125°, as reference compounds and to indicate further the existence of a *trans* acid form.

STEREOCHEMISTRY OF DERIVATIVES OF DIPHENYL AND ANALOGS

Sir:

Apparently the first suggestion that stereoisomerism of the type observed in the diphenyl series might also occur among binuclear heterocyclic aromatic substances is due to Kermack and Slater,[1] who attempted the resolution of 3-o-nitrophenyl-indole-2-carboxytic acid. A recent publication by Steele and Adams[2] describes the attempted resolution of certain phenylpyridine compounds.

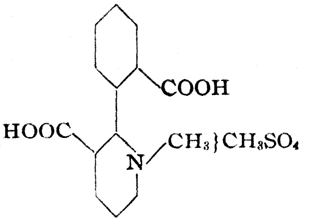
[1] Ray gives no C and H analysis of this acid. Using very small quantities of material he showed by analysis of the silver salt that the silver content agreed with the formula of a tricarboxylic acid $C_9H_{14}O_6$, but titration with 0.1 N alkali indicated a dicarboxylic acid $C_8H_{14}O_4$. Analysis of the silver salt and titration could only indicate the equivalent of the acid. These conflicting analyses cannot indicate whether the acid was methylated; that is, whether the acid was $C_9H_{14}O_6$ or $C_8H_{12}O_6$.

[1] Kermack and Slater, *J. Chem. Soc.*, **36 (1928)**.

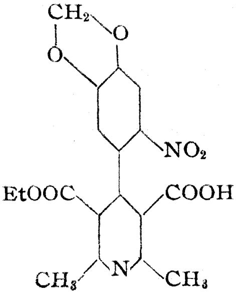
[2] Steele and Adams, THIS JOURNAL, 52, 4528 (1930).

An extensive investigation of such heterocyclic substances as might be expected to exhibit stereoisomerism of diphenyl type has been in progress in these laboratories for some time, but owing to failure to obtain the substances examined in enantiomorphous forms up to the present, publication of results, with the exception of an introductory paper by Chalmers, Lions and Robson,[3] has been so far withheld.

In the 2-phenylpyridine series and the 2-phenylquinoline series attempts have been made to provide a "blocking group" by conversion of the tertiary nitrogen atom into a quaternary salt. Thus, 2-(-o-carboxyphenyl-)-3-carboxypyridine methosulfate (I) has been examined. but its resolution not effected.

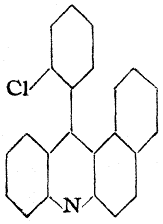


I

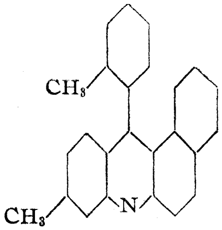


II

Derivatives of 4-phenylpyridine such as (II) have been prepared by the Hantzsch synthesis, and attempts at resolution are in progress. It is worthy of note in this connection that ortho-substituted benzaldehydes react least readily in the Hantzsch synthesis.[4] In the isoquinoline series 1-(-*o*-chlorophenyl-)-isoquinoline methiodide and ethiodide, and 1-(-a-tolyl-)-isoquinoline methiodide and ethiodide have been prepared and converted into the corresponding salts of optically active acids, but these are apparently homogeneous. The acridine compounds (III) and (IV) have also been prepared and examined but not separated into enantiomorphs.



III



IV

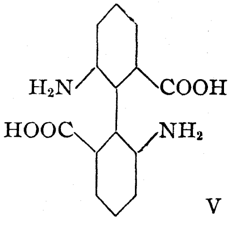
This consistent failure to resolve **a** compound of the phenylpyridine series suggests that the conditions there obtaining are different from those in the diphenyl series, probably owing to the definitely polar character of

---

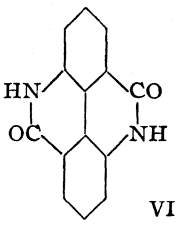
[3] **Chalmers, Lions and Robson, J. Roy.** ***Soc. New South Wales*** **(1930).**

[4] **Hinkel and Madel, J.** ***Chem. Soc.,*** **750 (1929).**

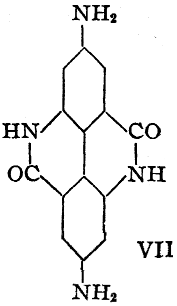
the pyridine nitrogen atom. Undoubtedly, there would be a powerful attraction between this atom and an ortho carboxyl of the benzene ring, leading to pronounced molecular distortion. As yet, the resolution of a derivative of diphenyl having strongly positive groups in the 2,2′-positions and strongly negative groups in the 6,6′-positions has not been effected. 2,2′-Diamino-6,6′-dicarboxydiphenyl (V) passes immediately on its formation into the dilactam (VI).[5] Presumably, in this substance both pyridone rings lie in the same plane as the benzene rings, though this has not definitely been established.



V

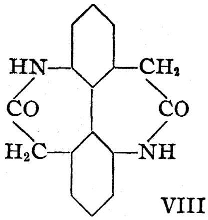


VI

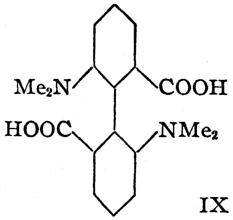


VII

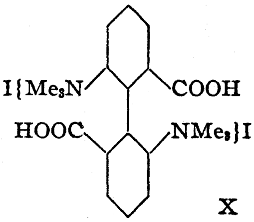
At present the optical homogeneity of (VII) is under examination. It is also proposed to attempt the preparation and resolution of ring homologs of (VI), *e.* g., the dilactam (VIII) in which the benzene rings should lie out of one plane, two configurations thus being possible. Further attempts to resolve 2,2′-tetramethyldiamino-6,6′-dicarboxydiphenyl (IX) and 2,2′-hexamethyldiamino-6,6′-dicarboxydiphenyl dimethiodide (X) and the corresponding betaine (XI) are in progress. The behavior of all these substances may shed some light on the phenomenon in the phenylpyridine series.



VIII



IX



X

Finally, the examination of certain phenylpyrroles and phenylindoles is in progress. According to the obstacle theory it is to be expected that in such binuclear systems the smallest groups which would be effective in preventing free rotation of the nuclei about their common axis must be larger than in the diphenyl series. Hence, the first example chosen for study which is expected to be resolvable is 1-(-*o*-xenyl-)-2,5-diphenylpyrrole-3-carboxylic acid (XII).

THE CRYSTAL FORM OF NICKEL OXIDES

Sir:

In making adsorption measurements of carbon dioxide on nickel oxide, it was found by one of us[1] that the adsorptive properties of the oxide varied quite markedly for different modes of heat treatment.

The nickel oxide was prepared by oxidation of suspended nickelous hydroxide with chlorine gas in basic solution. The black precipitate of the oxide was electrolyzed free of alkali and dried. One sample was outgassed several times at 285°, while the other was not subjected to a temperature of more than 110°.

The first preparation was the poorer adsorbent for carbon dioxide. The adsorption was carried out at 56.5° and the amounts adsorbed were in the approximate ratio of 1:2.5.

This difference of behavior, which was unlikely due to sintering, since the overheated form had rather smaller particle size as indicated by the line-width of the x-ray diagrams referred to below, also could not be explained on the basis of chemical differences, since in the Bunsen test for higher oxides, only traces of such could be found in either case. Both samples corresponded to nickelous oxide.

The substances were then subjected to x-ray analysis by means of the Debye–Scherrer–Hull method.

The overheated oxide corresponded exactly to the previously reported structure for nickelous oxide, being face-centered cubic. The edge of the unit cube was found to be 4.14 Å. (uncorrected), which corresponds to 4.17 Å. as given by the "International Critical Tables."

The structure of the nickelous oxide which had not been heated above 110° was quite different. Although also cubic, the edge of the unit cube was 4.64 Å. (uncorrected). The density was determined as 4.8 as compared to 6.69, given as the density of the ordinary nickelous oxide (Landolt–Bomstein "Tabellen"). The number of molecules in the unit cell

[1] O. G. Bennett, "Thesis," The Johns Hopkins University, 1930.

was calculated as four, with the same accuracy as for the known oxide. However, from a consideration of the intensities of reflection, the face-centered cubic type is not permissible. The complete determination of the atomic coordinates has not been finished as yet.

This form also differs from the ordinary nickelous oxide by causing an unusual amount of fogging on the photographic film when a Debye-Scherrer diagram is taken (Fe-radiation).

Evidently we have found a new cubic modification of nickelous oxide; we have also some evidence for the existence of further modifications. The possibility of the existence of several modifications of nickelous oxide is indicated by the work of Hedvall [Z. *anorg. Chem.*, *92*, 381 (1915)].

This work is being continued and special emphasis is laid on the determination of a possible relation between adsorption, catalysis and structure.

THE FREE ENERGY OF PORMATIOR OF THALLIUM AMALGAMS

Sir:

Recently Tammann has reviewed the subject of heterogeneous equilibria both from the theoretical and the practical standpoint.[1] Besides describing the different types of phase diagrams, he shows how they can be derived from purely thermodynamic considerations, using the surfaces in free energy (*F*)-temperature-composition space taken for the several phases. Successive isothermal planes cut the F-surfaces in curves which define the singular points on isothermal lines across the phase diagram.

These surfaces, however, give only form and characteristics of the general types of diagrams, and have not been applied to any specific systems, since absolute values of F, which are needed for the calculation, have not been obtained, although changes of the free energy are easily measurable.

Nevertheless I believe I have succeeded in calculating a curve for the system thallium–mercury which represents the general form of the intersection of the free energy surfaces for that system with the 20° isothermal plane. I have calculated the free energy of formation of thallium amalgams from the elements, using the data of Richards and Daniels,[2] Lewis and Randall,[3] and Richards and Smyth[4] by a method which I will explain

in detail in the full report. Briefly, the free energy of formation is a linear function of the mole fractions and partial molal free energies of thallium and mercury in amalgamated and free states. If the last-named quantities—partial molal free energies of solid thallium and liquid mercury—were known, the true F-curve could be drawn; they are, however, constants at any given temperature, and enter my equations as products by the first power of the mole fraction, hence the only effect on the F-curve is to subject it to that type of linear transformation known as a "shear." While a "shear" will change certain features of a curve, such as slope, certain other features, in this case more important, are unchanged. The curve is presented (Fig. 1).

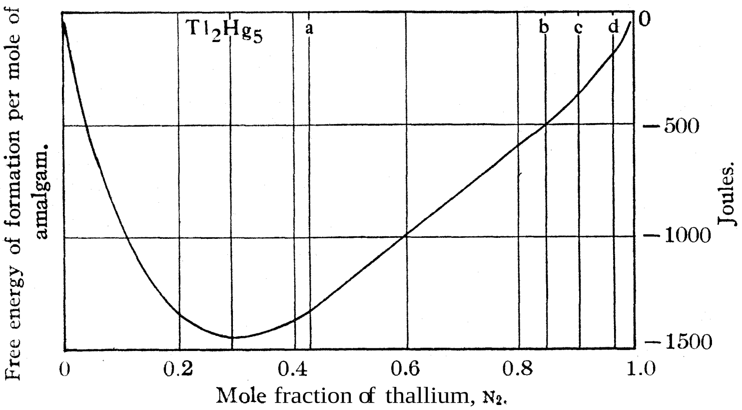

Fig. 1.—Free energies of formation of thallium amalgams

The parts of the curve included between the vertical lines *a* and b, and *c* and d are straight lines, and will remain straight lines after a shear. Straight lines are to be expected, representing the common tangent to the free energy curves of the two phases in equilibrium in these regions. There is also a minimum at $N_2 = 0.285$ which is not to be expected from Tammann's treatment. It coincides, however, with the composition of the known compound Tl_2Hg_5. The appearance of this minimum is all the more surprising since no singular point appears in the e. m. f. curve at this composition, and 20° is five degrees above the melting point of the compound, so that we have it existing in solution only.

Complete details of the method and calculations will be presented in an article to be submitted shortly.

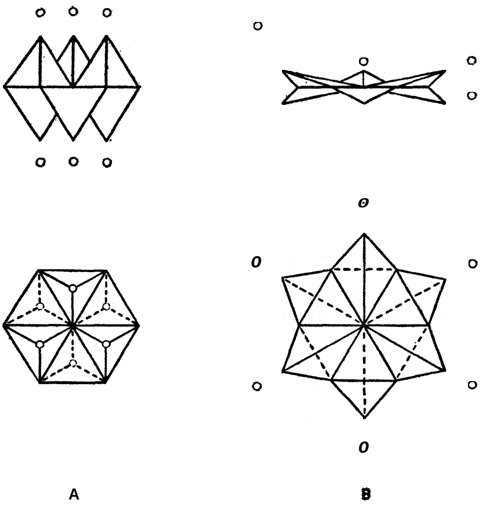
THE OSCILLATING, PUCKERED, CENTROID MODEL FOR THE BENZENE RING

Sir:

Some time ago[1] the writer showed that many of the peculiarities of benzene and its derivatives could be accounted for by assuming a structure for the ring like that postulated by Körner[2] (Fig. 1, A) except for distorted (B) rather than regular tetrahedra. (The tetrahedra represent assumed preferred orientations of valence electrons or orbits.)[3]

The chief argument against this structure was lack of evidence for isomers which would be expected of disubstituted benzene derivatives. It has since been shown[4] that predictions on the basis of that theory that so-called 1,8-disubstitution products of naphthalene would be found to be 1,5-, and vice versa, are incorrect. Moreover, x-ray studies of graphite[6] and of $C(CH_3)_6$[6] have indicated that in these substances the **centers** of the carbon atoms, of a single layer or molecule, lie in or nearly in one plane.



This evidence is satisfied if one assumes that the "tetrahedra" are sufficiently distorted, placing 1,8-substituents in naphthalene closer together than 1,5-substituents, and that there is frequent or constant oscillation between such a puckered form and its mirror image, preventing the isolation of isomers and giving a time-average distribution of x-ray scattering power ("electron density") like that deduced from the observations.

Consideration of such forces as the repulsion between atomic kernels would lead one to expect a tendency toward a puckered rather than a plane ring. With only slight puckering the same factors which are responsible for molecular rotation in the solid state[7] might be expected to

produce the type of oscillation suggested. At sufficiently low temperatures this oscillation should cease. One would expect, therefore, small "humps" in the heat capacity curves of all benzene derivatives (unless oscillation is prevented by external forces), similar to those found[8] for certain of them which have been attributed' to rotation of CH_3 groups.

Another alternative is to assume easy (not necessarily frequent) oscillation and that the orientation of the puckering in a particular molecule in crystalline $C(CH_3)_6$ does not depend on the orientations in surrounding molecules.

The "anomalous" isomerism found among biphenyl derivatives may perhaps be due to non-oscillating puckered rings, rather than to a lack of free rotation about the bond joining them.

X-Ray studies have revealed no cases of two mutually perpendicular planes of symmetry passing through benzene ring centers (as would be expected if the rings were plane), although in several cases a center of symmetry has been found.[9] X-Ray evidence also definitely favors models with equivalent atoms at or oscillating about the corners of a regular hexagon. A satisfactory model must account, moreover, for the synthesis of benzene derivatives, first by methods indicating 1,4-linkages and second, by simple ring closure of a conjugated system.[10] The writer knows of no model, other than that proposed here, which meets these requirements.

From this model one would predict that "electron density" calculations from accurate x-ray intensity data by the method of Fourier Series summations[11] would show the carbon atom "peaks" to be considerably elongated normal to the "plane of the ring."

[1] Abstract of a presentation made at the February meeting of the Washington Section of the American Chemical Society, Washington. D. C.

mum, but there is no sharply defined finite discontinuity in the total heat absorbed. All the examples quoted in the literature (see, *e.* g., the work of F. Simon on ammonium salts, Giauque and Wiebe on hydrogen bromide and iodide, K. Clusius on crystalline nitrogen, oxygen, methane, etc.) occur in the region of very low temperatures, and are for this reason difficult to examine for changes in other physical properties. There exists accordingly some uncertainty as to the exact behavior of a crystal during these apparent inversions, and doubt has been expressed [A. Smits, *Physik. Z.*, (1930)] as to whether the experimental conditions do not account for the anomaly. It is also clear that theoretical explanations of this type of transition [L. Pauling, *Phys. Rev.*, August (1930)] cannot be fully accepted for all cases until our knowledge is more complete.

Sodium nitrate exhibits a gradual transition which ends at approximately 275°. We have examined the changes in heat capacity as shown by differential heating and cooling curves, thermal expansion, the solubility of the salt to its melting point in water, and the x-ray diffraction patterns at various temperatures. Further work on other properties is in progress. The results obtained indicate that the properties of sodium nitrate crystals alter reproducibly over a range of temperatures rather than suddenly at a definite transition point. The expansion coefficient is nearly constant to about 150°, then it gradually increases to a peak value near 275°, followed by a rapid decrease to a normal value beyond 280°. The heat absorption on heating likewise gradually increases to a maximum at 275.5°, while on cooling the heat evolution begins at about 278°. Hysteresis phenomena are completely absent. The change in x-ray patterns is definite but small, and optical examination with a heating microscope shows that the crystals remain optically uniaxial up to the melting point. The solubility curve undergoes a small, but apparently real, change in the transition region. The detailed results of the experimental work will be communicated in the near future.

THE PHOTO-REACTION BETWEEN HYDROGEN AND IODINE MONOCHLORIDE

Sir:

In a note on the reaction between iodine monochloride and hydrogen, D. P. Mellor and T. Iredale[1] have presented some experiments which they believe are contrary to conclusions presented by us in a recent paper.[2]

---

[1] Mellor and Iredale, Nature, 127, 93 (1931).

[2] Rollefson and Lindquist, THIS JOURNAL, 52, 2793 (1930)

We wish to call attention to the fact that their experimental results are not a contradiction of ours, as the conditions were considerably different, and furthermore their results may be interpreted in a manner consistent with our conclusions.

In the first place if we have a group of normal chlorine atoms formed, approximately 2% of them should in time acquire the energy of activation to the $^2P_1$ state by collisions. These atoms would be capable of forming hydrochloric acid by reaction with hydrogen. If, however, the atoms were destroyed by a reaction such as $ICl + Cl = Cl_2 + I$ before they acquired this energy, there would be no hydrochloric acid formation. Therefore, the most favorable conditions for reaction with hydrogen would be with the hydrogen pressure much higher than the iodine monochloride pressure. Mellor and Iredale had this condition in that they had the hydrogen' pressure approximately forty times that of the iodine monochloride, whereas in our experiments of this kind the two pressures were of the same magnitude. Our results were confirmed by Franck and Rabinowitsch,[3] who found no reaction between hydrogen and iodine monochloride when they used an electric spark for excitation.

Mellor and Iredale apparently missed the principal point of our argument, namely, that in a given mixture of iodine monochloride, chlorine and hydrogen, light absorbed by the chlorine started a reaction whereas that absorbed by the iodine monochloride did not. That experimental fact is definite proof that the action of light on chlorine gives a product different from that resulting from iodine monochloride. This point is discussed in detail in our previous paper.

THE REMOVAL OF HYDROGEN HALIDE FROM ORGANIC HALIDES

Sir:

In view of the recent appearance of an article by Semb and McElvain [THIS JOURNAL, 53, 690 (1931)] on the reaction of organic halides with secondary amines, we should like to state that we have been investigating the reaction of organic halides with tertiary amines with the hope of using this reaction to determine the relative ease of removal of hydrogen halide from various organic halides. From the work of Semb and McElvain it is apparent that the usual course of the reaction of organic halides with secondary amines, and in particular with piperidine, is the formation of tertiary amines and that the removal of hydrogen halide takes place to a considerable extent only from tertiary halides. In our work using

---

[3] Franck and Rabinowitsch, *Z. Elektrochem.*, 36,794 (1930).

tertiary amines, and in particular pyridine, the main reaction other than quaternary salt formation appears to be the removal of halogen acid, although rearrangement of the quaternary salt to alkyl pyridine hydrohalides has not been excluded. We have used direct titration with standard alkali to determine the extent of elimination of hydrogen halide and have followed the rate of this reaction for a number of alkyl halides. We hope to be able to publish our results shortly.

CALCULATIONS ON THE VELOCITY OF SOUND IN NITROGEN TETROXIDE

Sir:

In a recent publication, Kistiakowsky and Richards[1] describe an attempt to determine the velocity of the dissociation of nitrogen tetroxide from measurements of the velocity of sound in the gas at 25° and various pressures. Their experimental curve for the change in velocity with pressure is not in good agreement with that calculated from the equation of Einstein[2] giving the velocity of sound in a dissociating gas at frequencies below the critical frequency. Kistiakowsky and Richards attribute the deviation to the inaccuracy of the dissociation data of Bodenstein[3] used in the calculations.

In a forthcoming publication, we report new data on the dissociation of nitrogen tetroxide; we have substituted these data in the theoretical equation and compared the result with the curves of Kistiakowsky and Richards. Einstein's derivation assumes that the gas in question is a perfect gas; this is obviously not true for nitrogen tetroxide. Since we have the pressure coefficient of the equilibrium constant, which varies at 25° according to the equation

$$K_p = 0.1426 - 0.7588\, C^0_{N_2O_4}$$

where

$$C^0_{N_2O_4} = \frac{\text{weight of } (N_2O_4 + NO_2)}{92.02}$$

we can calculate, for any given pressure, the deviation from the ideal condition. Further, from our extrapolation to zero pressure, we have a new value for the heat of dissociation—13,960 calories per mole at constant volume. In making the calculations, we have accepted the values assumed by Kistiakowsky and Richards for the specific heats of nitrogen tetroxide and nitrogen dioxide.

We have plotted the velocity of sound, $V_{\text{theoretical}}$, as calculated from

---

[1] Kistiakowsky and Richards, THIS JOURNAL, 52, 4661 (1930).

[2] Einstein, *Sitzb. Berl. Akad.*, 380 (1920).

[3] Bodenstein, *Z. physik. Chem.*, 100, 68 (1922).

our dissociation data, on a graph similar to that given by Kistiakowsky and Richards on page 4666 (Reference I). The differences between this curve and the curve representing the direct experimental measurements of Kistiakowsky and Richards $V_{\text{experimental}}$ are given in the second column of the following table. In the last column are given the differences based on Bodenstein's data without the pressure corrections for the equilibrium constant.

Pressure in mm.	$V_{\text{experimental}} - V_{\text{theoretical}}$ (in meters/sec)	
	Verhoek and Daniels	Bodenstein
200	2.9	2.2
300	3.0	1.2
400	2.9	0.7
500	2.4	.1
600	1.9	− .3
700	1.5	− .7

While the agreement between the experimental curve and the theoretical curve can hardly be said to be any better using our data, the deviation is nearly constant, and the calculated velocity is always less than the observed velocity. This fact seems to indicate some constant error, either in theory or experiment. In the derivation of Einstein it is assumed that the gas is only slightly absorbing and that the dissociation proceeds according to a unimolecular reaction. It is possible that these assumptions are not sufficiently well satisfied.

NEW BOOKS

Periodisches System. Geschichte und Theorie. (Periodic System: History and Theory.) By DR. EUGEN **RABINOWITSCH,** Gottingen, and DR. ERICH **THILO,** Berlin. Verlag von Ferdinand Enke, Stuttgart, Germany, 1930. **xii + 302 pp. 50** ***figs.*** 16.5 X 24.5 cm.

This is a textbook which takes up the periodic system both from a chemical and physical point of view. It is a welcome addition to our list of textbooks as it collects in one place a considerable amount of related material of great importance to the chemist who is at all interested in theoretical things, and which, as far as the reviewer is aware, has not previously all been brought together in one place in textbook form. It is to be recommended for advanced students of chemistry who wish to (or ought to) learn something about quantum theory (even though it be mostly old quantum theory) and its applications, without wading through too much material of a highly mathematical character. But many people to whom most of the material is already familiar will undoubtedly be glad to find it assembled in simple and readable form, though to them the inclusion of references to original sources would have greatly increased its value.

The book is divided into five parts. The first part is an historical treatment of the ideas leading up to the development of the periodic system. This seems to the reviewer to be very useful, inasmuch as it brings forth clearly the difficulties by which early chemistry was beset (and which are often the student's difficulties) and the methods by which these difficulties were straightened out. The second part treats of electrons, protons and the way they combine to build up nuclei. The fundamental experiments are briefly presented and discussed. The next part takes up the Bohr theory of the atom, and considers the energy states both of hydrogen and the more complicated atoms, the various types of coupling of electrons, the Pauli exclusion principle, etc., and ends with a chapter on wave mechanics. The mathematics is kept to a minimum, and on the whole it is quite clearly written. The fourth part deals in detail with the building-up of the periodic system and the energy diagrams of individual atoms. The fifth part consists of a discussion of the periodicity of the chemical properties of the atoms, and takes up such topics as the Born–Haber cycle, polar and non-polar compounds, etc. It contains much valuable material in tabular form (as do, indeed, other parts of the book). Particularly suggestive is the attempt to calculate the existence limits of ionic compounds, though some of the assumptions involved seem hardly tenable. For example, the reviewer can hardly see how the radius of the ion Ca^+, in a crystal, could be smaller than that of Ca^{++}, but it looks possible that the final results of the calculation would not be much altered if more reasonable values for some of the ionic radii were taken instead of those used by the authors.

There are some misprints in the mathematical portions, and in the lettering of Figs. 43, 46, 48 and 49; on p. *255* "endotherm" is written once for "exotherm." The typography would have been more attractive if italics had been used for mathematical symbols, and it would have been easier to distinguish between *l* and 1.

OSCAR K. RICE

The Study of Crystals. A General Introduction. By T V. BARKER, Fellow of Brasenose College, Oxford. Thomas Murby and Co., 1 Fleet Lane, Ludgate Circus. London E. C. 4, England, 1930. xvi + 137 pp. 195 figs. 15.5 × 25.5 cm. Price, 8/6 net.

The text is accompanied by exercises, descriptions of experiments, and excellent illustrations. Parts of the book on geometrical and physical properties may be used as an elementary laboratory manual; other parts, including the following topics, may be read with profit by more experienced students: crystallization from jellies, space-lattice theory, x-rays, polymorphism, "liquid crystals," isomorphism, equilibria between liquid and crystal phases (this general topic occupies about one-fifth of the book and includes such subjects as reciprocal salt pairs, the microscope as a check on crystallization, mixed-crystals, isodimorphous phases).

Hardness, birefringence and optical orientation are not discussed,

H. E. MERWIN

Systematic Crystallography: An Essay on Crystal Description, Classification and Identification. By T. V. BARKER, Fellow of Brasenose College, Oxford. Thomas Murby and Co., 1 Fleet Lane, Ludgate Circus, London E. C. 4, England, 1930. xi + 115 pp. 76 figs. 16 × 25.5 cm. Price. 7/6 net.

An account is given of a method, which seems as simple as possible, for treating the angular measurements of crystals so that determinative tables can be constructed by listing a minimum number of interfacial angles.

Only slight burdens would be imposed upon describers of new crystals, but the time-consuming task of completing the tables "seems to be a matter for cooperation, personal and financial, and any suggestions toward its fulfilment would be very welcome." The tables will require that many crystals be reoriented and/or have their axial ratios changed. Transformations are based upon the principle of simplest indices, and the pseudo-tetragonal and pseudo-cubic rules.

Appendices contain useful formulas, tables of tangents and multiple tangents, and stereographic nets of 1 and $2^1/_2$ in. radii.

H. E. MERWIN

Chemische Thermodynamik. Einführung in die Lehre von den chemischen Affinitäten und Gleichgewichten. (Chemical Thermodynamics. Introduction into the Study of Chemical Affinities and Equilibria.) By DR. HERMANN ULICH, Professor at the University of Rostock. Verlag von Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1930. xvi + 353 pp. 30 figs. 15.5 × 23.5 cm. Price, unbound, RM. 18.50; bound, KM 20.

In the February, 1930, number of THIS JOURNAL I reviewed a textbook on Thermodynamics by Schottky, Ulich and Wagner. One of the two chemists among the three authors has now written a much simpler text for students interested in the chemical applications, based on the same principles.

These principles are: Consider first the reaction, and build it up from elementary reactions. Then it is only necessary to know the thermodynamical data for these standard elementary reactions. A second step taken in the latter part of the book, is to build up the data of the elementary reaction from data of the substances concerned in it

Other innovations of the book, taken over from the larger work, are the use of the concept of "resistant groups" instead of molecules, especially useful in mixtures with dissociation and association, and the systematic use of "partial" quantities, extended further than by Lewis and Randall.

The outstanding advantage of the book to my mind, however, is that it is the only one that familiarizes the reader both with the American and with the German method of calculating free energies. The former, which is due to Lewis, gives for every substance the entropy at room temperature and needs therefore only relatively small corrections for other temperatures to be made with the help of the specific heats. The German method starts for every solid pure phase with the absolute zero and the Nernst theorem, integrating the specific heats from zero up. This procedure is more fundamental, but much more cumbersome and subject to inaccuracies.

The book contains a comprehensive table of the thermodynamical data of standard reactions.

It is written in an agreeable style and can be well recommended as a textbook. Sometimes the wish to make the book readable seems to have induced the author to use not quite accurate expressions. There is one error, however, in the statement on page 187 that the identity of energy and free energy at the absolute zero is not self-evident, because the entropy might become infinite. This is, however, multiplied with T and it would take an infinite specific heat, which is most unlikely, to overcome this.

K. F. HERZFELD

A Textbook of Organic Chemistry. By A. F. HOLLEMAN, Ph.D., LL.D., D.Sc., F.R.S.E. **Seventh English edition, completely revised with the coöperation of the author. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, 1930. xx + 594 pp. Illustrated. 15.5 X 23.5 cm. Price $3.50.**

A recent musical comedy advises us that "50 million Frenchmen can't be wrong." Be that as it may, it is more than equally safe to assume that when the editions of a book reach the 50's, and this is one of the 52nd, there must be a great deal that is right about it.

The seventh English edition of Holleman's excellent text not only upholds the high standard of its predecessors, but has been revised to include such recent advances in organic chemistry as Haworth's work on the sugars and Robinson's on strychnine. As no pearl is flawless, so no text, to a reviewer, is quite perfect. It is regrettable that in using the Geneva system, two naming schemes have been introduced. Also some may take exception to the author's usage, consistent though it be, of numbers instead of Greek letters, to designate positions of substituents on carbon chains. All the numerous diagrams do not, unfortunately, depict the best modern laboratory technique. No explanation appears for the term fire-damp, and the writer is led to wonder what students think this term means anyway. The element, now generally called beryllium, is unfortunately designated by a less satisfactory name. Nitriles are always called carbonitriles, but with no seemingly adequate reason, and the term saponification, which should be reserved for the alkaline hydrolysis of esters, is too loosely used. It is rather surprising, considering the generally superior quality of this book, that the *trans* shift in the Beckmann rearrangement is not mentioned, and that Paneth's work on free methyl and ethyl is ignored. The possibility of replacing nuclear halogen to give phenol, likewise is not mentioned. The rather objectionable term disodium malonic ester is employed without indicating that it is merely a convenience and is not to be taken literally. The suggested mechanism for the addition of sodium phenolate to a certain acetylenic compound seems to pay too little attention to the effects of conjugated unsaturation; while the formula for carotene does not agree with that which is commonly assigned to this hydrocarbon.

However, to more than offset the points just taken exception to, mention should be made of the splendid correlation between physical and organic chemistry, to the part given to alicyclic compounds, of the unusually good presentation of the carbohydrates, and of the treatment of the Walden inversion. The Svedberg molecular weight method for proteins is described, and the formula for that interesting substance thyroxine is included. Furthermore, there appears a good account of the low temperature distillation of coal.

This volume is, without doubt, one of the best one-volume texts available. It is meaty, but it is digestible.

G. ALBERT HILL

Neuere Torfchemie. (Modern Peat Chemistry.) By PROF. DR. G. STADNIKOFF. Introduction by Wo. Ostwald. Verlag von Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1930. viii + 167 pp. 17 figs. 15.5 × 23.5 cm. Price, unbound, RM. 12.

An industry as old as the preparation of peat for the market for use as a fuel might seem to have but little room for technical improvement, but the author has demonstrated that not only is there much to be done but also that in the last years very notable advance has been made in fundamental knowledge of the chemical and physical relations of peat and of its decomposition products. It might also be assumed that peat has but little immediate interest for the United States since there is but little prospect of any large scale utilization of a low grade fuel. On the other hand, the enormous acreage of peat lands in this country, over 100,000,000 acres, and the fairly large importations of foreign peats, mostly for agricultural uses, together with utilization of considerable domestic peat for purposes other than heating render additions to our knowledge of the properties of peat timely and useful.

The author, who is scientific director for the National Institute for Coal Research at Moscow, has assembled all the pertinent and reliable published data on the water content of peat, the processes and principles of its dehydration, the components of peat and their chemical and physical properties, the bitumen content and its character, the humus content and its components and the liquid products of peat distillation. To this assemblage of data the author has added the results both of technical development and of scientific research in the laboratories of the Soviet jurisdiction during the past ten years. The scientific data are presented for the most part in the form of tables, seventy-seven in number. The whole body of material is clearly presented and discussed without any attempt to develop a particular or personal point of view. In each topic every material advance in scientific knowledge of peat is developed.

On the whole the booklet, small as it **is,** probably presents the most compact and readily accessible body of information available. The text is accompanied by numerous references to the best scientific and technical literature both in Europe and America down to **1930.**

HORACE G. BYERS

Nutrition and Food Chemistry. By BARNARD S. BRONSON, State College for Teachers, Albany, N. Y. John Wiley and Sons, Inc., New York, 1930. viii + 467 pp. 34 figs. 15 X 23 cm. Price, $3.75.

The purpose of this book, as stated by the author in the preface, is to lessen the burden which is carried by human knowledge regarding food and diet due to the mass of accumulated misinformation about this subject. "It is the outgrowth of attempts over a number of years to sift the grain from the chaff in presenting the elements of nutrition and foods to a group of college students with little foundation in physiology and none in organic chemistry." There is a short introductory chapter on "The Organism and its Environment," followed by eighteen chapters covering the following general topics: "Food, and Mechanics of Digestion;" "Chemistry of Digestion;" "Chemical Changes in the Intestine, and Absorption;" "Composition of Foodstuffs," including two chapters on carbohydrates and one covering both fats and proteins; "Fate of the Foodstuffs," two chapters; "Protein Requirement;" "Energy Requirement;" "Inorganic Salts and Acid-Base Balance;" "Vitamins;" "Milk and Milk Products;" "Butter, Oleomargarine, Cheese, Condensed Milk, and Ice Cream;" "Eggs and Meat;" "Vegetable Foods;" "Legumes, Root Crops, and Green Vegetables," and "Fruits." Several appendices cover the subjects of "New York State Milk Standards," "Distribution of Vitamins," in tabular form, "Terms Used in Standardization of Eggs," and tables showing recent analyses of the iron and copper content of foods.

The author has, in general, covered the field in a very clear and pleasing manner, and shows that he has been a very critical student of the many subjects presented. It is perhaps too much to expect a teacher to be absolutely up to date in a field of applied science in which such a large volume of research is being published yearly. Although the author has brought his subject up to the very latest word in certain fields, the book would be benefited by considerable "sifting," as it stands, and will no doubt require considerably more in the future.

A feature of the book which may appeal to many teachers and students is the etymology of many terms, given in footnotes. The book is well illustrated and the text fortified with many valuable tables, taken from numerous sources, all of which are acknowledged.

The author's style is not as uniform as one might wish, suggesting that the various sections of the subject matter were prepared at different times and not re-written for publication. This is borne out by the considerable amount of tautology in the text, which in a few cases has led to diametrically opposing statements.

Although the author has prepared the chemical sections of his text for students with no foundation in organic chemistry, he does not hesitate to introduce structural formulas in the chapters on the composition of carbohydrates, proteins and fats. This may give the text some appeal to students with more advanced chemical training, but the reviewer questions whether it is possible to teach enough organic chemistry in a few pages of text to make heterocyclic structural formulas intelligible to students who have only the most elementary chemical training. Incidentally, the structural formulas for the sugars are not those most generally accepted by biochemists at the present time and the author's explanation of the gamma sugars is hazy.

OXIDATION–REDUCTION POTENTIALS.
III. THE MERCURIC–MERCUROUS ELECTRODE

BY STEPHEN POPOBP, JOHN ALLEN RIDDICK, VERDA IRENE WIRTH AND
LEE DUDLEY OUGH

RECEIVED AUGUST 6, 1930 PUBLISHED APRIL 6, 1931

Carter and Robinson[1] were the first investigators to study the oxidation–reduction potential of the mercuric-mercurous electrode, using the perchlorates of mercury. They measured a series of cells of the type

$$Hg \mid Hg_2Cl_2,\ N\ KCl \mid 0.1\ N\ KCl\ Hg_2(ClO_4)_2,\ Hg(ClO_4)_2 \mid Pt^{+2}$$

assuming that the error due to liquid junction was negligible. The perchlorates of mercury had previously been used by Ley and Heimbucher[3] and later by Linhart[4] and found suitable for electromotive force measurements as they are soluble, easily purified, highly ionized and do not form complex ions to any appreciable extent.

In a previous investigation on the oxidation–reduction potential of the ferric–ferrous electrode,[5] a method has been given for the determination of oxidation–reduction potentials in which the difficulties due to incomplete elimination of liquid junctions and the lack of precise data on the activity of an ion in the presence of other electrolytes have been reduced to a minimum.

In this investigation measurements were made of the cell

$$Pt \mid Hz,\ HClO_4 \mid HClO_4,\ Hg(ClO_4)_2,\ Hg_2(ClO_4)_2 \mid Pt^+$$

The liquid junction was maintained constant by a Lamb and Larson[6] flowing junction. The reproducibility of such a junction was established by MacInnes and Yeh.[7]

Two sets (A and B) of experimental data are presented. In both sets

the concentrations of the perchloric acid were kept the same throughout the cell.

In Set A the ratio of the concentration of the mercuric perchlorate squared to the concentration of the mercurous perchlorate was maintained as near unity as possible. With decreasing concentrations of the mercury salts, within each series, both sides of the cell approach identity, and the liquid junction potential approaches zero. By plotting a function of the potential against the concentration of the mercurous perchlorate and extrapolating to zero concentration of the mercury salt, the liquid junction potentials should also become zero. To obtain the normal oxidation–reduction potential, one must correct for the presence of perchloric acid. By plotting the extrapolated values obtained from the various acidities against the acid concentrations and again extrapolating to zero concentration of perchloric acid, due correction is made for the presence of perchloric acid.

In Set B the concentration of mercuric perchlorate was kept equal to the concentration of the mercurous perchlorate, this procedure enabling one to work with more dilute solutions and to apply the principle of ionic strength. In this set the values of the oxidation–reduction potentials, E' (without any corrections for the activity coefficients), were found to be constant in each acid series although the concentrations of the mercury salts were varied from 0.008 *m* to 0.0005 m. The values of E' in each acid concentration were plotted against the molality of the perchloric acid and the curve extrapolated to zero. In Set B, series VI and VII, the solutions were dilute enough to use the principle of ionic strength and to calculate approximately the activity coefficients. The oxidation–reduction potentials, E'', thus obtained were plotted against the square roots of the ionic strengths and the line extrapolated to zero ionic strength. The two extrapolated values in Set B were checked mathematically using the method of moments[8,9] and the method of the zero sum.[10] The extrapolated values were found to agree very closely with those obtained by the mathematical methods.

Apparatus and Material

1. Cell and Equipment.—Practically the same cell and potentiometric equipment were employed as were used in former studies.[5,11] All e. m. f. measurements were made at 25 ± 0.01°. An Eppley standard cell, No. 30957, the voltage of which was expressed in International volts was used.

2. All water was redistilled from alkaline permanganate in an all-glass still.

3. All perchloric acid was redistilled in an all-glass still under reduced pressure, the first and last fourths being discarded. Air free from carbon dioxide was then passed through the acid to remove any possible trace of free chlorine.

4. Redistilled mercury was passed five times in a fine spray through a mercury purification column containing mercurous nitrate and nitric acid, and then passed three times through a column of distilled water.

5. Mercuric perchlorate was prepared by treating red mercuric oxide with perchloric acid,[12] until the solution was faintly turbid. After filtering, the solution was concentrated in an all-glass vacuum distillation apparatus under about 10 cm. pressure. Glass beads were introduced into the flask to prevent bumping and to serve as a gage to the concentration of the mercuric perchlorate solution. Mercuric perchlorate is very soluble and hence difficult to crystallize. When the density of the solution became such that the glass beads floated, good crystals could be obtained on slow cooling. Crystals produced by fast cooling came out in one solid mass with which it was difficult to work. Slow cooling produced large crystals when a small excess of perchloric acid was present. These crystals could be well drained and were sometimes about 2 cm. in diameter. Several of these large crystals were measured with a contact goniometer giving the angles M M = 120°, and M C = 90°. These indicate crystals in the hexagonal system with the forms $10\bar{1}0$ and 0001. Only the larger crystals could be removed from the solution for examination. Small crystals lose their identity before they can be examined in the air, this being due to the hygroscopic property of the mercuric perchlorate. Crystallization takes place slowly and when complete the glass beads would sink. The supernatant liquid was poured off and the crystals were drained in a centrifuge in special glass centrifuge cups at 800–900 r. p. m. for about twenty minutes. All mercuric perchlorate was at least twice recrystallized.

6. Mercurous perchlorate was prepared by shaking an acidified solution of mercuric perchlorate with an excess of mercury for forty-eight hours at 50". Subsequent analysis in some of the solutions employed showed that the amount of mercuric perchlorate remaining in the solution was negligible. Both mercuric and mercurous perchlorates were kept in dark bottles under an atmosphere of carbon dioxide. The carbon dioxide was passed through silver sulfate solution and cotton before entering the solution.

7. All other chemicals were of the best quality obtainable.

Analytical Methods

All the data for the analyses are given in Table I. Weight burets were used in all titrations.

1. Standardization of Perchloric and Hydrochloric Acids.—The perchloric and hydrochloric acid solutions were standardized against a standard, carbonate-free sodium hydroxide solution, using phenolphthalein as the indicator. The base was standardized against Bureau of Standards potassium acid phthalate. Standardization against potassium acid phthalate had been found to agree closely with the standardization against benzoic acid and against constant boiling hydrochloric acid.[13]

2. Analysis of Mercuric Salt.—The stock mercuric perchlorate solution was standardized by three entirely different methods. The mercuric sulfide method was adopted as the standard.

a. Mercuric Sulfide Method.—A weighed portion of the mercuric perchlorate solution was acidified with 10 cc. of 0.8 *N* perchloric acid and diluted to 75 cc. Hydrogen

---

[12] Chikashige, *J. Chem. Soc.*, 63, 1013 (1895).

[13] Popoff and Neuman, *Ind. Eng. Chem., Anal. Ed.*, 2, 45 (1930).

sulfide was passed for ten minutes. The solution was heated to boiling, cooled, then hydrogen sulfide again was passed until precipitation was complete. The precipitate was filtered through a Gooch crucible, washed with alcohol, carbon disulfide and ether. The carbon disulfide was used to remove any sulfur formed in the oxidation of the hydrogen sulfide. Attempts to employ ammoniacal solutions, etc., as recommended by some, failed to give concordant results. Without the carbon disulfide treatment, the results were very concordant among themselves but higher than the calculated employing pure mercuric chloride as the standard. The precipitate of mercuric sulfide was dried at 105° for one hour. Since the activity product constant of mercuric sulfide is very small (4×10^{-54}), no correction for solubility was made.

b. Potassium Iodide Method.—A solution of potassium iodide was standardized against recrystallized c. p. mercuric chloride. Sodium chloride and perchloric acid were added, the former to retard the formation of mercuric iodide, the latter to give identical conditions in the standardization of the iodide solution as in actual determination of the mercuric ion in the stock solution.

c. Thiocyanate Method.—An approximately 0.1 N solution of potassium thiocyanate was standardized against standard silver nitrate solution using ferric alum as the indicator. Perchloric acid was added for the same reason as in 2b.

The precision of the three methods of determining mercuric ion and the comparison between the three methods are given in Table I, 1 and 2.

Considering the precision of the mercuric sulfide method, one may justify its selection as the standard method, especially after the method was checked using c. p. mercuric chloride as the standard. The other methods were employed as an approximation and a check on a more precise method.

3. Analysis of Mercurous Salt.—The mercurous ion in the stock solution of the mercurous perchlorate was determined by two entirely different methods (see Table I, 3).

a. The Gravimetric Method.—In this method the mercury was precipitated as mercurous chloride with sodium chloride. A correction factor for the solubility and volatility on heating of the mercurous chloride was determined by preparing mercurous chloride, treating a weighed portion of the precipitate under conditions similar to those in the analysis and determining the loss in weight. The filtrate, after the mercurous ion had been precipitated, was treated with hydrogen sulfide, but the amount of the sulfide of mercury obtained was negligible. This method did not give very concordant results in some cases, but the average value agreed with that obtained by the electrometric method.

b. The Electrometric Method.—Mercurous perchlorate was added slowly and with stirring to an excess of sodium chloride solution. The excess sodium chloride was then titrated electrometrically with standard silver nitrate, using a silver–silver chloride electrode. The weight ratio between the sodium chloride and silver nitrate had previously been determined electrometrically. The silver nitrate was standardized against potassium chloride which had been recrystallized three times.

4. Acidity in the Mercury Perchlorate Solutions.—The mercuric and mercurous stock solutions contained free perchloric acid. This acid cannot be determined either electrometrically or colorimetrically employing indicators because of the presence of the mercury salts. The mercury was deposited on mercury cathodes using a current of 0.5 ampere and 3 volts, and the total acid was determined by titration with standard alkali solution. A solution of perchloric acid was electrolyzed using the same kind of electrodes (with free mercury in the solution) as in the analysis for acid in the mercury solution. Since the volume ratios between acid and base (Table I, 4) are the same both before and after electrolysis, it may be concluded that the free acid in the salt solutions can be determined after setting free the mercury on electrolysis by titrating with standard alkali. The acidities of the solutions are given in Table I, 5.

5. Preparation of Solutions of Known Concentration.—The stock solutions of acid and mercury perchlorates were employed for preparing, by weight, the various solutions needed for the cells using the proper buoyancy corrections.

TABLE I

ANALYTICAL METHODS

1. Precision of the Three Methods for Mercuric Ion

HgS method HgS per g. of soln., g.	KI method Weight ratio	KCNS method Weight ratio

$Hg(ClO_4)_2$	0.1099	0.09374	0.01617
$Hg_2(ClO_4)_2$	.06016	.03986	.02030

Experimental Data

Cells of the type

$$\begin{array}{l} \mathrm{Pt} \mid \mathrm{H_2,\ HClO_4} \mid \mathrm{HClO_4,\ Hg(ClO_4)_2,\ Hg_2(ClO_4)_2} \mid \mathrm{Pt}^{+} \\ \quad E_{\mathrm{H}} \qquad\quad E_1 \qquad\qquad\qquad\qquad\qquad\qquad E_a \end{array}$$

were measured. There are three sources of potential in the cell: E_{H}, the potential of the hydrogen electrode; E_a, the potential of the mercuric–mercurous electrode; and E_1, the liquid junction potential.

E_{H} was calculated from the equation

$$-E_{\mathrm{H}} = 0.05915/2 \log (P_{\mathrm{H_2}}/P_{760} \times 1/a\mathrm{H}^{+2}) \qquad (1)$$

$P_{\mathrm{H_2}}$ is the pressure of the hydrogen taken as the barometric pressure, corrected for brass scale, minus the vapor pressure of the acid solutions used. The vapor pressures were computed and taken to be the same as those for hydrochloric acid from the data given in the "International Critical Tables.[14] $a\text{H}^+$ represents the hydrogen-ion activity which was calculated from data of Randall and Young[15] for the mean activity coefficient of hydrochloric acid. Schuhmann[16] states that the mean activity coefficient of perchloric acid may be taken to be the same as that for hydrochloric acid up to one molal. Experimental data, of a somewhat similar nature, show that this conclusion may be correct, at least within the experimental error.

E_a was found from the equation

$$E_a = E_{\text{cell}} + E_H \qquad (2)$$

E_1 cannot be computed at finite concentrations of mercuric and mercurous perchlorates, but if is kept constant in a given cell by a flowing junction.

1. Set A.—In Set A the ratio of the concentration of the mercuric perchlorate squared to that of the mercurous perchlorate was kept equal to one, but the molalities of the mercury salts were varied as shown in Table II. The mercurous ion is considered as a divalent ion.

TABLE II

THE CONCENTRATION OF THE MERCURY SALTS

Cell	Molality of $Hg_2(ClO_4)_2$	Molality of $Hg(ClO_4)_2$
A	0.008100	0.09000
B	.004000	.06324
C	.002000	.04472
D	.001000	.03162

The electromotive force data are given in Table III. The values of E_a in each acid concentration were plotted (Fig. 1) against the molality

OXIDATION–REDUCTION POTENTIALS AT VARIOUS ACID CONCENTRATIONS

Series	**Molality** of $HClO_4$	E'
I	0.4000	0.9012
II	.2000	.9004
III	.1000	.9009
IV	.0500	.9011

2. Set B.—In Set B the concentration of the mercuric salt was kept equal to the concentration of the mercurous, making it possible to work with a solution in which the ionic strength was as low as 0.023. Table V gives the electromotive force data obtained. E' was calculated from the equation

$$E_a = E' - 0.05915/2\ (\log C_{Hg_2^{++}}/C_{Hg^{++}}^2) \qquad (3)$$

where $C_{Hg_2^{++}}$ represents the concentration of the mercurous ion and $C_{Hg^{++}}^2$ represents the concentration of the mercuric ion squared.

3. **The** Activity Coefficients of **Perchloric** Acid.—Following the procedure of Schuhmann[16] but employing flowing junctions, electromotive force measurements were made using four cells of the type

$$\text{Pt} \mid \text{H}_2, \text{HClO}_4 \mid \text{HCl}, \text{H}_2 \mid \text{Pt}^+$$

The acid concentrations were varied from 0.02 to 1 molal, but the concentrations of the acids in each cell were kept the same. After making corrections for the small variations in concentration and for the liquid junction potentials employing Lewis and Sargent's[17] formula

$$E_1 = -0.05915 \log \frac{\Lambda_{\text{H}^+} + \Lambda_{\text{ClO}_4^-}}{\Lambda_{\text{H}^+} + \Lambda_{\text{Cl}^-}}$$

and the more recent data found in the "International Critical Tables"[18] for the equivalent conductances of the two acids, it was found that any corrections for the unequal activity coefficients of hydrochloric and perchloric acids, would lie within the experimental errors for all concentrations except for the one molal acid, this correction being of the order of 1.2 millivolts.

Final Calculations and Discussion

The standard oxidation–reduction potential of the mercuric–mercurous electrode was finally derived from total concentration and from the principle of ionic strength making use of activity coefficients.

1. From Total Concentration.—It was found convenient in Set **A** to work with solutions in which the concentration of the mercuric salt squared was equal to the concentration of the mercurous salt. By suitable plottings (Figs. 1 and 2), the standard oxidation–reduction potential was found to be 0.9011 volt. By working with solutions in which the concentration of the mercuric perchlorate was kept equal to that of the mercurous, Set B, it was found that when dilute enough solutions were employed, plotting similar to that in Fig. 1 was unnecessary. The average values of E' which correspond to each acid concentration are given in Table VI. Figure **3** gives the curve obtained. The extrapolated value, 0.9050, was checked mathematically using the methods of moments and the zero sum and it was found to be 0.9045.

TABLE VI

VARIATION OF E' WITH ACIDITY

.02	.9038

---

[17] Lewis and Sargent, THIS JOURNAL, 31, 363 (1909).

[18] "International Critical Tables," Vol. VI, 1929, p. 242.

2. From **the** Principle of **Ionic** Strength.—In Set B it was possible to work with solutions whose ionic strength was small enough to enable us to use the equation of Bronsted and La Mer[19] for the activity coefficient of a divalent ion given by the equation

$$-\log \mathbf{f} = 0.5\, z^2\sqrt{\mu} \qquad (4)$$

This Equation 4 does not hold except in solutions whose ionic strength is of the order of 0.01 or less, but since the calculations involving the diameter of the ions, the dielectric constant, the distance of closest approach of the two ions, and others are somewhat uncertain, it was decided to calculate the coefficients by Equation 4 and then to plot the values of E^n (see Table VII), from the equation

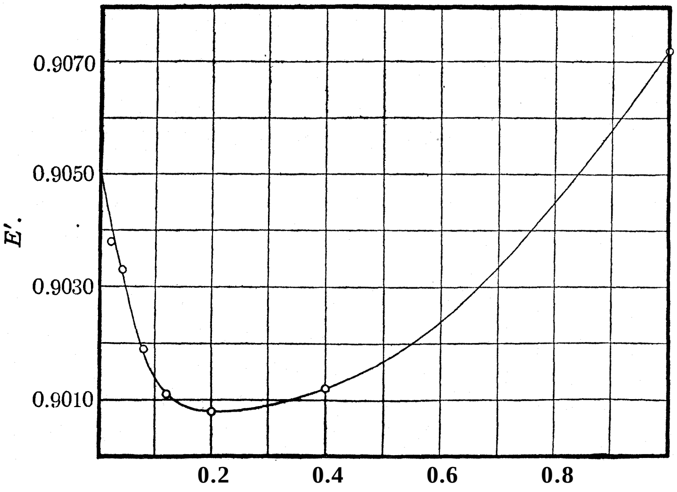

Fig. 3.—The standard oxidation–reduction potential from total concentration.

$$E_{n} = E^{w} - 0.05915/2\left(\log \frac{C_{\mathrm{Hg_2^{++}}}}{C_{\mathrm{Hg^{++}}}^{2}}\right) - 0.05915/2\left(\log \frac{\gamma_{\mathrm{Hg_2^{++}}}}{\gamma_{\mathrm{Hg^{++}}}^{2}}\right) \qquad (5)$$

against the square root of the ionic strength. This plot is given in Fig. 4. On extrapolating the straight line, the value for E_0 was found to be 0.9045.

---

[19] Brönsted and La Mer, This journal, 46, 555 (1924).

This value was checked mathematically as formerly and was found to be 0.9042.

3. Effect of Acidity and Concentration of Mercury Salts.—When the concentration of the perchloric acid was varied from 0.02 to 1 molal, the oxidation–reduction potential of the mercuric–mercurous electrode went through a minimum at about 0.2 m. Since the effect on the potentials of changing the concentration of the mercury salts (keeping the mercuric equal to the mercurous) from 0.008 to 0.0005 m is practically negligible in each acid series, one may conclude that the liquid junction potentials are negligible. This conclusion seems justified since the potential remains the same even in 0.02 *m* perchloric acid, in which the liquid junction potential should be the largest.

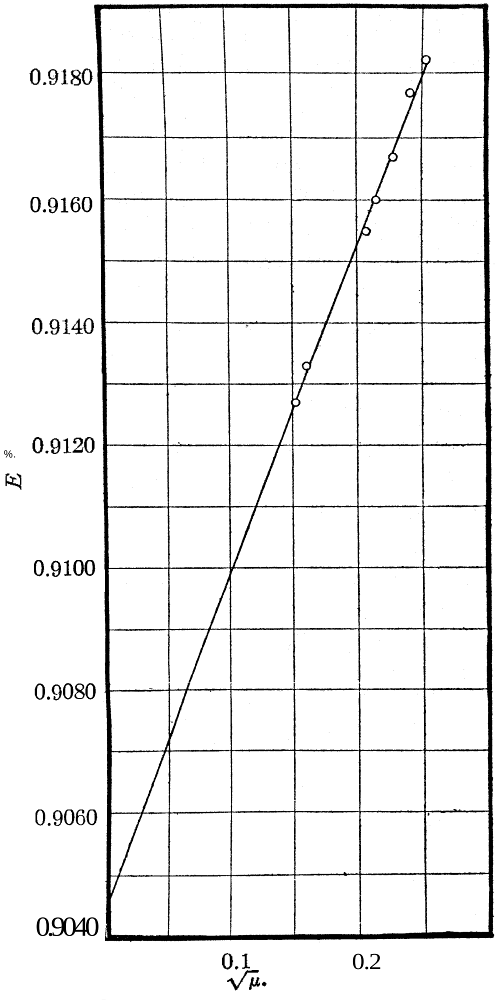

Fig. 4.—The standard oxidation–reduction potential from ionic strength.

4. Comparison with Other Investigations.— The oxidation–reduction potential of the mercuric–mercurous electrode was determined by Carter and Robinson[1] at 18°, using the perchlorates of mercury. They found a value of 0.913 and a much greater variation in the potential with acid concentration. They employed a calomel electrode as the reference electrode, using a potassium nitrate solution as a salt bridge. The use of the bridge in no way eliminates the liquid junction potentials. In all of their calculations they employed the same correction factor, –0.0044 volt, for the activity coefficient regardless of changes in the concentrations of mercury salts. Latimer and Hildebrand[20] give a

---

[20] Latimer and Hildebrand, "Reference Book of Inorganic Chemistry," Macmillan Co., New York, 1929, p. 368.

value of -0.92 volt, which was calculated from values given by Abegg, Auerbach and Luther.[21]

5. The Standard Potential.—Since practically the same oxidation–reduction potential for the mercuric–mercurous electrode was obtained from either total concentration or ionic strength, one may justify the final value of 0.9050 volt. For analytical purposes the values in various acid concentrations given in Table VI are of special importance.

Conclusions

1. The standard oxidation–reduction potential of the mercuric–mercurous electrode was determined using the perchlorates of mercury.

2. Using suitable mathematical and graphical treatments as well as the activity coefficients of divalent ions from the limiting case of Bronsted and La Mer's equation, the standard oxidation–reduction potential was found to be 0.9050 v.

3. The mean activity coefficients of perchloric acid solutions were found to be practically of the same order as those for hydrochloric acid solutions up to 0.4 *m*.

4. Methods of analysis involving mercuric and mercurous salts, and acidity in the presence of mercury salts are given.

5. From an analytical standpoint and for all practical purposes, the potentials at various acidities are of greater importance than the standard one and are herein given. The potential goes through a minimum at about 0.2 m perchloric acid.

THE MEASUREMENT OF THE CONDUCTANCE OF ELECTROLYTES.

IV. THE VALIDITY OF OHM'S LAW FOR ELECTROLYTES[1]

BY GRINNELL JONES AND GILES M. BOLLINGER

RECEIVED OCTOBER 7, 1930 PUBLISHED APRIL 6, 1931

Introduction

Recently M. Wien[2] has published a paper entitled "On a Deviation from Ohm's Law for Electrolytes" in which he has recorded measurements of the conductance of electrolytes in very strong fields from about 30,000 volts per centimeter up to about 300,000 volts per centimeter. He reached the conclusion that a real increase in conductance with increase in field strength occurs at very high voltages. An increase in conductance of more than 50% above the conductance with low voltages was found in one case and smaller increases in many other cases. The feature most clearly established by his experiments is the great influence of the valences of the ions on the Wien effect. He made measurements on twenty-three different salts of varied valence types and concluded that the effect is proportional to the square of the product of the valences of the ions. The effect is greater for concentrated solutions than for dilute. For dilute solutions and for the lower range of voltages for which the effect was measurable he found that the increase in equivalent conductance appears to be proportional to the field strength, but at very high field strengths the conductance appears to approach a definite maximum. He says: "The observation of the limit of the effect as well as its theoretical interpretation is . . . extremely uncertain, and for the present it can only be inferred from the experiments that the limit of the effect agrees at least in rough order of magnitude with the decrease in equivalent conductance from the conductance at infinite dilution. . . . It is probable that the great velocity which the high field imparts to the ions completely or partially abolishes the cause for the change of equivalent conductance with the concentration."

This experimental paper of Wien stimulated the theoretical analysis of the problem by Joos and Blumentritt,[3] based on the interionic attraction

theory of Debye and Hiickel. According to this theory the electric forces between the ions tend to maintain the ions in a space lattice distribution and oppose any displacement of the ions from their position in the lattice by an outside field. Since this braking effect of the interionic electric forces increases with the concentration it accounts for the decrease in mobility of the ions and hence of the equivalent conductance with increasing concentration. But when the solution is subjected to an outside electric field, the resulting motion of the ions tends to destroy the space lattice distribution and give a more random distribution, with the result that the mobility tends to rise until with sufficiently high field strengths it becomes the same as the mobility at infinite dilution.

Joos derived the expression

$$\Delta\Lambda = AX3 - BX^4$$

where M is the increase in equivalent conductance in a field, X (volts/cm.) and A and B are independent of the field strength but vary in a complicated but explicit manner with the temperature, and with the dielectric constant and viscosity of the solution, and with the valences, mobilities and concentrations of all of the ions.

These theoretical papers in turn stimulated Wien[4] to a renewed experimental study of the problem with an improved technique which permitted the effect to be measured with field strengths as low as 3000 volts per centimeter. Although the precision attained in these difficult experiments is not great, they appear to support the theoretical deductions of Joos.

If, as seems probable, Wien's experiments are reliable, it means that Ohm's Law is not strictly valid for electrolytes over the entire range of voltages.[5] The Wien effect must therefore be of interest and importance in the theory of solutions but it is not necessarily significant for the measurement of conductance by the Kohlrausch method, because the field strengths used by Wien were at least 1000 to 100,000 times as great as those commonly used in the Kohlrausch method. It may be inferred from Wien's data that the effect will be entirely negligible in the weak fields suitable for the Kohlrausch method. This is encouraging but not entirely conclusive because the form of the function as given by Joos is not well established nor can the value of the coefficients be precisely determined from Wien's experiments. A direct experimental test at low voltages is

---

[4] M. Wien, *Ann. Physik,* [4] 85, 795 (1928); [5] 1, 400 (1929).

[5] Incidentally it is of interest to point out that P. W. Bridgeman [*Proc. Am. Acad.,* 57, 131 (1922)] has made experiments on the electric conduction of thin strips of gold and of silver at high current densities which he interprets as showing that Ohm's Law is not strictly valid for metallic conductors. "The maximum current densities were about 5×10^6 amp./cm.^{2}, and the deviations from Ohm's Law were of the order of one per cent." This interpretation of these experiments has, however, been challenged by H. M. Barlow, *Phil. Mag.,* [7] 9, 1053 (1930).

therefore desirable—especially since there are also reports in the literature of an apparent variation in the resistance of electrolytes with variation of applied voltage as determined by the Kohlrausch method.

Comparatively few of the earlier experimenters on the conductances of electrolytes by the Kohlrausch method have purposely varied the voltage which they used and observed the effect, if any, on the apparent resistance. An apparent change of resistance with voltage (or with the current density, which amounts to the same thing) and which may be ascribed to polarization, has been observed by several experimenters, including Wien, Haworth, and Percy;[6] but experiments in which the disturbing effect of polarization are avoided are more pertinent for our present purpose.

Early in his work on conductance, Kohlrausch,[7] having first devised a technique which minimized polarization, tested the validity of Ohm's Law for electrolytes and found no variation of resistance with the voltage applied to the bridge greater than the errors in his measurements, although the precision attained in this early work was much below more modern standards.

More recently several experimenters have found a change in apparent resistance with change in voltage even when using conditions favorable for the elimination of polarization.

Taylor and Acree[8] report variations in apparent resistance as large as 0.08% in unclean cells when the voltage was changed from 0.25 to 2 volts, but they state that no such effect was observed with clean cells.

Kraus and Parker[9] do not accept the suggestion that lack of cleanliness is the sole reason for a variation in resistance with the voltage applied. They report that in their experiments a change in voltage from 0.2 to 7.0 volts caused a decrease of 0.02% in the apparent resistance when using iodic acid solutions and an increase of about the same magnitude with potassium chloride solutions. "It was not found possible to locate the cause of this effect in the limited time available. . . ."

This question has been further studied by Parker,[10] who gives a curve showing the apparent percentage increase in resistance caused by varying the voltage applied to the bridge from 0.2 volt to 10 volts with numerous different solutions of potassium chloride covering the range from very low resistances up to nearly 10,000 ohms. He found that the higher voltage gave the higher resistance throughout the range so that the effect cannot be ascribed to heating. At low resistances variations up to 0.13% were

shown. Within the range from 1000 to 6000 ohms, the difference was about 0.02% and rose to nearly 0.04% at about 10,000 ohms. Parker concluded that there are two different causes for the variation, superimposed on each other. He ascribes the controlling influence at low resistances to polarization. With increasing resistance the polarization dwindles and yet the influence of change in voltage on the resistance passes through a minimum and then rises. This clearly indicates that there is some effect other than polarization influencing the results. Parker does not express an opinion as to the nature of the effect.which predominates at the higher resistances, nor as to whether the results obtained with the high or the low voltage are more nearly correct. Morgan and Lammert, after referring to the papers of Taylor and Acree and of Kraus and Parker cited above, say: "In the present research no change in resistance with the change in impressed voltage has been observed when the electrodes were properly cleaned." The range used is not stated.[11]

Experimental Part

Since we had available a new and improved bridge,' it became of interest to determine whether or not the deviations from Ohm's Law detected by Wien are detectable at voltages suitable for use in the Kohlrausch method and to endeavor to decide whether the apparent failure of Ohm's Law reported by Taylor and Acree, Kraus and Parker, and Parker is real or due to experimental error. With very low resistance (under 100 ohms) and a high voltage (4 volts or more) we have observed small changes in apparent resistance with change in voltage, but under these conditions the heating effect of the current on the cell is sufficient to make precise measurements difficult and polarization occurs, so that the apparent changes in resistance are not believed to be significant. In some of our earlier work, small voltage effects were detected which could not be ascribed to polarization or to heating and were traced to mutual inductance between the oscillator and the bridge[1b] and the detector. It was shown that the results with the higher voltage were more nearly correct since the effect of mutual inductance had a relatively greater influence when the voltage impressed on the bridge was low. After the oscillator was moved to a safe distance, the influence of variation in voltage applied on the measured resistance disappeared entirely when measuring 300 ohms or more as is demonstrated by the data in Table I.

The cells designated by A, D and G are of the pipet type. Cells K, L, M and N are of our new type designed to minimize the effects of capacitance between parts of the cell and have been described and illustrated in the third paper of this series.[1c] Cell Z is also of the new type. It has a capillary tube 70 cm. long and with a bore of about 0.9 mm., giving an

exceptionally high cell constant. With some of these cells an appreciable variation of apparent resistance with frequency may be observed, whereas others are free from this fault The electrolyte used was potassium chloride in all cases except the experiments with cell Z, which was filled with a solution of sulfuric acid having approximately the maximum specific conductance. The variations in measured resistance shown in the table might all be caused by a variation of 0.001°C. in the temperature and are regarded as insignificant. These data, selected from many others of like import in our notebooks, show that when suitable experimental precautions are taken to avoid heating and polarization, and when using a bridge properly designed to avoid complications inherent in working with alternating current, the voltage used is without effect on the measured resistance, over a wide range of frequencies and of resistances and with cells of widely varying design, throughout the range of voltages which are useful for the practical measurement of the conductance of electrolytes by the Kohlrausch method.

Grateful acknowledgment is made for an appropriation from the Milton Fund of Harvard University for the expenses of this investigation.

Summary

Wien has shown experimentally that deviations from Ohm's Law amounting to more than 50% in some cases occur in electrolytes at very high field strengths (3000 to 300,000 volts per centimeter). It is demonstrated in this paper that if adequate experimental precautions are taken to avoid errors due to heating, to polarization, and to the secondary effects of inductance and capacitance, there is no measurable variation of the real resistance of electrolytes with variation of the applied voltage throughout the range of voltages and frequencies suitable for use in the Kohlrausch method of measuring electrolytic conductance. Ohm's law may, therefore, be regarded as valid for electrolytes under these conditions.

THE STRUCTURE OF FERRIC THIOCYANATE AND THE THIOCYANATE TEST FOR IRON

BY H. I. SCHLESINGER AND H. B. VAN VALKENBURGH[1]

RECEIVED DECEMBER 15, 1930 PUBLISHED APRIL 6, 1931

The usual explanation of the thiocyanate test for ferric ions assumes that the red color is due to the formation of un-ionized ferric thiocyanate, but there is no convincing evidence that dilute aqueous solutions of ferric thiocyanate are only very slightly ionized. Even if they were, it seems unlikely that the union of slightly colored ferric ion with colorless thiocyanate ion should produce a highly colored molecule, since simple ionic dissociation is usually not accompanied by marked color changes. On the other hand, it has been known for a long time that the action of an excess of ammonium or alkali thiocyanate on ferric salts leads to the formation of highly colored substances of the type $Me_3[Fe(CNS)_6]$.[2] That the formation of the complex ion $[Fe(CNS)_6]^{\equiv}$ has not been generally accepted as an explanation of the reaction is due to two causes. In the first place, the solid salts do not appear to have a color exactly identical with that of the solutions in question. In the second place, these salts are not soluble in dry ether, which, as is well known, extracts the colored substance from

---

[1] This article is taken from a thesis presented by H. B. Van Valkenburgh to the Ogden Graduate School of Sciences in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] Krüss and Moraht, *Ann.*, 260, 193 (1890); Rosenheim and Cohn, *Z. anorg. Chem.*, 27, 280 (1901).

aqueous solutions. The ethereal solutions thus obtained do not contain either ammonium or alkali salts.

Both of these objections to the hypothesis that the color of the solutions is due to the complex ferric thiocyanate ion $[Fe(CNS)_6]^{\equiv}$ can be easily met. Solid salts frequently exhibit shades of color which differ from those of their solutions. Furthermore, the absorption spectra[3] of aqueous solutions of salts of the type $Me_3Fe(CNS)_6$ of ethereal extracts of these solutions, of aqueous solutions of ferric thiocyanate and of solutions of anhydrous ferric thiocyanate in anhydrous ether exhibit practically identical absorption spectra,[4] as shown in Figs. 1 and 2. These facts indicate that the light-absorbing substances are the same in these three types of solutions, and

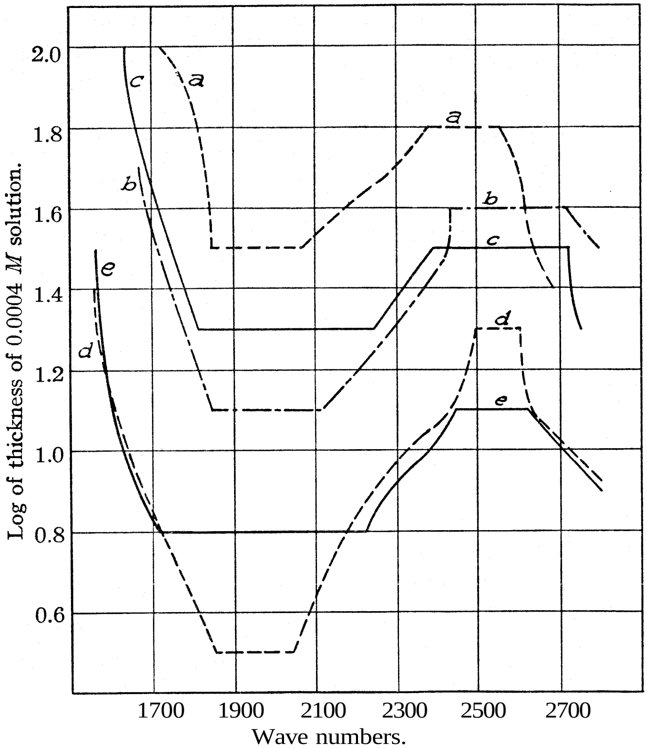

Fig. 1.—Absorption spectrum of $Fe(CNS)_3$: a, 0.0004 *M*, c, 0.0008 *M*, in water; d, 0.0002 *M*, e, 0.0004 *M*, in ether; of $Na_3Fe(CNS)_6$: b, 0.0004 *M* in wafer.

---

[3] The absorption spectra were photographed with a Hilger quartz spectrograph. A description of the apparatus and experimental procedure will be found in an article by Schlesinger and Salathe, This journal, 45, 1871 (1923).

[4] The slight differences in the absorption spectra are due to the addition of thiocyanic acid to the aqueous solutions of ferric thiocyanate to prevent hydrolysis, and to unavoidable differences in the unknown concentration of the actual absorbing substance.

therefore exclude the possibility that the red color is due, as might be otherwise imagined, to an ether-soluble, non-ionizable aquo compound, $\left[Fe^{(CNS)_3}_{(H_2O)_3}\right]$. The latter conclusion is corroborated by the finding that electrolysis of aqueous solutions of ferric thiocyanate causes the red color to migrate toward the anode, while ferric ions pass toward the cathode.

The identity of the absorption spectra of solutions of hexathiocyanate salts and of ferric thiocyanate, as well as the ionic migration experiment, suggest that solutions of the supposedly simple salt also contain the complex ion. If that is the case the formula $Fe[Fe(CNS)_6]$ should be assigned to ferric thiocyanate. That this assumption is correct is borne out by the fact that in anhydrous ethereal solutions, as well as in benzene, its molecular weight is practically twice that corresponding to the simple salt. In aqueous solutions, unless a large excess of thiocyanate ion is present, the complex ion is more or less dissociated; thus are explained the slight differences in absorption spectra noted above.[4] Furthermore, if a large excess of thiocyanate ions is added to the aqueous solutions, all of the ferric ion is converted into the complex ion and ether can no longer extract $Fe[Fe(CNS)_6]$ from the solutions. These conclusions are in agreement with the facts.

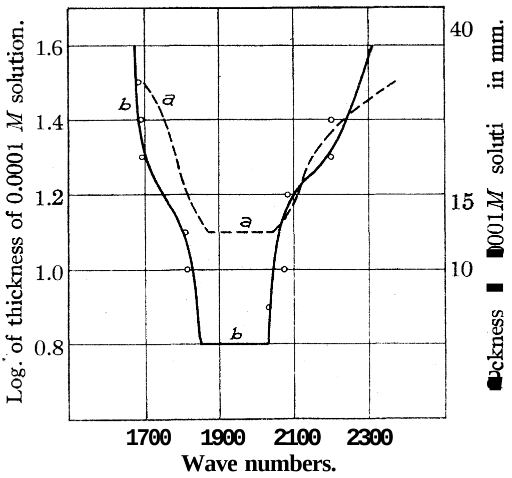

Fig. 2.—Absorption spectra of ethereal extracts: a, 0.0004 M $Na_3Fe(CNS)_6$; b, 0.0001 M $(NH_4)_3Fe(CNS)_6$.

Only one point remains to be discussed. The effect of ammonium chloride in decreasing the color of ferric thiocyanate solutions was formerly explained as being due to the reaction: $3NH_4Cl + Fe(CNS)_6 \rightleftharpoons 3NH_4CNS + FeCl_3$. A more logical explanation is the reaction represented by the equation: $[Fe(CNS)_6]^{\equiv} + 6Cl^- \quad [FeCl_6]^{\equiv} + 6CNS^-$. The existence of a hexachloroferric ion is not unwarranted in view of the well-established existence of the corresponding fluoro ferric ion; furthermore, addition of chloride ions to ferric salt solutions alters the absorption spectra of the latter, indicating complex ion formation, as is described below.

Experimental

Preparation of Ferric Thiocyanate.—**The preparation of anhydrous ferric thiocyanate proved very troublesome until it was discovered that the products of decompo-**

sition of the substance in solution could be excluded from the crystals only if crystallization was carried out very slowly. Equivalent quantities of solutions of barium thiocyanate and ferric sulfate were mixed, and the solution, after standing for some time, was filtered to remove barium sulfate, and placed over sulfuric acid in a brown desiccator until a small crop of crystals had formed. The crystals were removed by decantation of the solution, which was again allowed to evaporate. This process was repeated several times until crystals of constant composition were obtained. Various samples of such material gave an iron content of 24.49 ± 0.02%; calculated for $Fe(CNS)_3$, 24.29%.

Preparation of Sodium Ferric **Hexathiocyanate.**—This salt was obtained according to the directions of Rosenheim and Cohn.[2] It was found that the compound $Na_3Fe(CNS)_6 \cdot 12H_2O$, described by them, loses water over sulfuric acid, yielding a trihydrate.

The absorption spectra of the various thiocyanates in aqueous and ethereal solutions have already been adequately described. Figure 3 shows the effect of the addition of ammonium chloride to 0.02 and 0.002 *M* solutions of ferric chloride, acidified with a small amount of hydrochloric acid to prevent hydrolysis. It is seen that the addition of the chloride shifts the end absorption markedly toward the longer wave lengths.[5] Such changes indicate the formation of a new compound, presumably a complex ion.

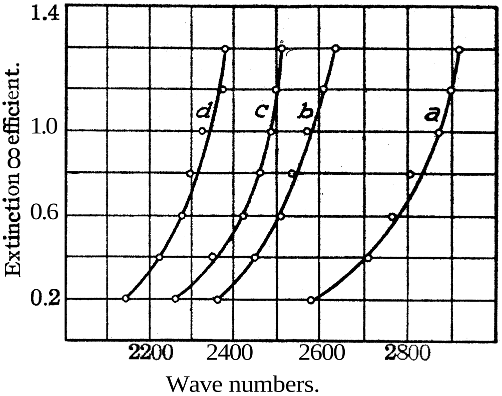

Fig. 3.—Absorption spectrum of aqueous solutions of $FeCl_3$: a, 0.002 *M;* b, 0.002 *M* $FeCl_3$ + 2.0 *M* NH_4Cl; c, 0.02 *M;* d, 0.02 *M* $FeCl_3$ + 1.0 M NH_4Cl.

Determinations of the molecular weight of ferric thiocyanate in benzene were made by the freezing point method and in ether by the boiling point method. The apparatus of Menzies, as well as that of Washburn–Cottrell, was used in the latter. The benzene was carefully distilled twice and showed a constant freezing point. The ether was purified in the usual manner and finally distilled twice from sodium. It had a constant boiling point. The results of the molecular weight determinations are shown in Table I. Both in benzene and in ethereal solutions ferric thiocyanate undergoes moderately rapid spontaneous decomposition as already described by Rosenheim and Cohn.[2] Among the products of decomposition are polymerized derivatives of thiocyanic acid. It is therefore not surprising that the results are on the whole somewhat higher than values corresponding to twice the molecular weight of $Fe(CNS)_3$. The agreement of individual values is as good as is to be expected in view of the instability of the solutions.

---

[5] The measurements were made with the Hilger spectrograph and sector photometer.

This research is one of a series of investigations carried out with the aid of a grant from the Bache Fund of the National Academy of Sciences.

Summary

1. In aqueous solutions of ferric thiocyanate the red color migrates to the anode during electrolysis.

2. The red color of these solutions is shown by their absorption spectra to be identical with that of aqueous solutions of salts containing the complex ion $[Fe(CNS)_6]^{\equiv}$ and with ethereal solutions of anhydrous ferric thiocyanate.

3. In the latter as well as in benzene, ferric thiocyanate has a molecular weight approximately twice that corresponding to the formula of the simple salt. On the basis of these results it is concluded that the red color observed in the thiocyanate test for iron is due to the ion $[Fe(CNS)_6]^{\equiv}$, and that ether extracts the compound $Fe[Fe(CNS)_6]$, from aqueous solutions. The diminution in color caused by ammonium chloride is ascribed to the formation of a hexachloro ferric ion.

THE SOLUBILITIES OF LANTHANUM OXALATE AND OF LANTHANUM HYDROXIDE IN WATER. THE MOBILITY OF THE LANTHANUM ION AT 25°

BY I. M. KOLTHOFF AND RUTH ELMQUIST[1]

RECEIVED DECEMBER 22, 1930 PUBLISHED APRIL 6, 1931

In a study of the quantitative determination of lanthanum by precipitation as lanthanum oxalate and as hydrous lanthanum oxide—the results of which will be discussed in a later paper—it was of interest to know the solubilities of the two slightly soluble compounds in water. Since the saturation values are extremely small, the electrical conductance method can be applied advantageously. As will be shown later, the results of the latter method have to be accepted with caution and, therefore, the data have been verified by volumetric and sometimes by colorimetric procedures.

Materials Used.—The lanthanum compounds were prepared from lanthanum ammonium nitrate procured through the courtesy of Dr. H. S. Miner of the Welsbach Company, Gloucester, New Jersey. The arc spectrum of this material photographed with a quartz spectrograph showed entire freedom from any other rare earth elements. It was treated with ammonium hydroxide and hydrogen peroxide to insure absence of any cerium, using sufficient excess of ammonia to precipitate a small amount of lanthanum with any cerium that might be present. Following this, the lanthanum was precipitated with oxalic acid a number of times with thorough washing each time. The air-dry oxalate was converted into the oxide by ignition in an electric furnace at 800° to constant weight. An excess of this oxide was added to hydrochloric acid which had been prepared by bubbling hydrogen chloride into redistilled water. After the excess had been filtered off, the lanthanum chloride was crystallized from the solution and then twice recrystallized from conductivity water. The crystals containing seven molecules of water were kept in a desiccator over deliquescent calcium chloride. Lanthanum and chloride were determined quantitatively; the results agreed within 0.1%. The PH of the 0.1 molar solution, determined colorimetrically with adjusted brom thymol blue as an indicator in carbon dioxide-free water as a solvent was 6.2.[2]

---

[1] From a thesis submitted by Ruth Elmquist to the Graduate School of the University of Minnesota in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

[2] The data reported by J. H. Kleinheksel and H. C. Kremers [THIS JOURNAL, 50, 959 (1928)] are not in agreement with our results. Their figures on the hydrolysis of salts of rare earth elements cannot be accepted as being reliable since they prepared the anhydrous salts in a stream of hydrochloric acid and did not give any proof that no free acid was adsorbed or occluded by the crystals. From their experimental figures (p. 965) it is quite evident that the acidity of lanthanum chloride reported was due to the presence of free hydrochloric acid.

Lanthanum **Oxalate.**—This was prepared by precipitating a solution of pure lanthanum chloride with pure oxalic acid. The precipitated lanthanum oxalate was washed with distilled water until the P_H of the wash water remained unchanged (methyl red as indicator) and then repeatedly washed with conductivity water. The air-dried crystals contained ten molecules of water.

Lanthanum Oxide and Hydrous Lanthanum Oxide.—Three samples of lanthanum oxide were used, one prepared from lanthanum hydroxide, the second from lanthanum oxalate and the third from lanthanum nitrate. All three had been ignited to constant weight in an electric furnace at 800°. Also freshly precipitated hydrous lanthanum oxide was used. It was prepared by slowly adding a solution of pure lanthanum chloride to an excess of ammonium hydroxide. An attempt was made to wash the hydrous oxide free from electrolytes in the filtering apparatus of Bachmeyer and thus protect it from carbon dioxide of the air. On account of the gelatinous character of the precipitate this purification method had to be given up. Good results were obtained by centrifuging the precipitate several times with carbon dioxide-free water until the conductance of the saturated solution remained unchanged upon further washing. The wet precipitate was quickly transferred to the conductance cell. The various oxides and the hydrous oxide absorb carbon dioxide from the air very readily; the order of the solubility is changed entirely even by traces of this impurity.

Conductivity Water.—Conductivity water was distilled over sulfuric acid, then over barium hydroxide and finally without any addition to remove traces of acid and alkaline impurities. It was collected in aged Pyrex flasks with precautions against contamination from the air. In equilibrium with the air it had a conductivity of 0.80 to 0.85 × 10^{-6} rec. ohms. It could be kept for a week in the Pyrex flasks without change in conductance.

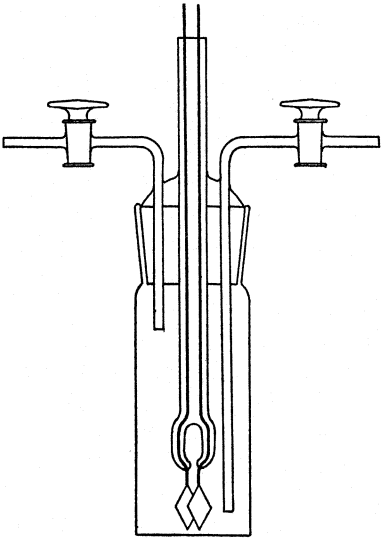

Fig. 1.

Arrangement for the Measurement of the Conductance.—A Leeds and Northrup Wheatstone bridge (rheostat with ratio arms, accuracy 0.1%) was used in this work. Although a condenser was used to balance most of the interference by capacitance, some error was introduced by the latter and by induction. These errors, however, are small compared with other experimental errors in measuring extremely dilute electrolyte solutions.

Conductivity cells of the Washburn type were used for the measurement of solutions with a concentration greater than 0.001. Special cells were constructed for the measurement of the conductance of extremely dilute solutions. The type of cell is given in Fig. 1. The platinum electrodes, which had a diameter of about 25 mm., were placed at a small distance from each other, making the constants of all the cells of the order of 0.01. The electrodes were kept in position by four glass beads at the corner.

Air could be passed through the cell to make the water or solution carbon dioxide free or to put it in equilibrium with the normal air. When equilibrium water was prepared the air from the air pressure in the laboratory was bubbled through a train of two wash bottles containing dilute permanganate, two bottles containing 0.01 *N* sulfuric acid and three with pure water, the last one being mounted in the thermostat. A similar arrangement was used when the water had to be made carbon dioxide free, but three large towers filled with soda lime were then placed between the permanganate and sulfuric acid bottles and a fourth tower after the last flask in the thermostat, The thermostat was kept at 25 ± 0.05°.

For solutions with a concentration smaller than 0.0001 *N*, bright platinum electrodes have to be used, with slightly platinized electrodes irregularities and deviations of the order of 1% are observed. The effect is much smaller than L. de Broeckère[3] noted. With dilute hydrochloric acid solutions the effect is slightly greater than with neutral salts. When using even slightly platinized electrodes, dilute alkaline solutions cannot be measured with any degree of accuracy on account of the relatively strong adsorbent power of the platinum black.[4] In working with extremely dilute alkaline solutions the Pyrex vessels must be paraffined or coated with some other inert material to prevent the attack of the glass by alkali. After the coat has been thoroughly cleaned, constant and reproducible results are obtained even with sodium hydroxide solutions more dilute than 0.0001 N. Some measurements were made in the following way. A measured volume of water (about 200 cc.) was placed in the cell and made carbon dioxide free by passing through purified air. A 0.01 *N* sodium hydroxide solution was added from a microburet with the air still bubbling through. The inlet and outlet tubes were closed by the glass stopcocks and the readings made. After subtracting the conductivity of the carbon dioxide-free water (0.12×10^{-6} rec. ohms) an equivalent conductance of 250 was found for 0.0001 N sodium hydroxide and of 249.2 for 0.00005 N base at 25°.

In determining the conductivity of a saturated solution of lanthanum hydroxide, the water was made carbon dioxide free and the pure oxide or hydrous oxide was added quickly with the air still bubbling through. Readings were taken until the resistance was constant.

The Water Correction.—An excellent review on the "water correction"

has been written by J. Kendall.[5] He prefers to work with pure water which is a saturated solution of carbon dioxide under atmospheric conditions (equilibrium water). E. W. Washburn[6] showed, however, that it is impracticable to extend conductivity measurements in equilibrium water as long as the slightest uncertainty exists as to the exact purity of the water to such high dilutions. Therefore, he worked under those conditions with ultra pure water having a conductivity of 0.06 X 10^{-6} rec. ohms at 18°. From Kendall's work different authors[7] improperly concluded that carbon dioxide is the only contaminant of good conductivity water, and that the carbonic acid content can be computed from the conductance by means of Kendall's table. Hence they use this water even if not in equilibrium with the air. There are various objections to such a procedure. Even if the equilibrium water at 25° has a conductance of 0.8 X 10^{-6} rec. ohms (which is the theoretical value if carbon dioxide is the only impurity of electrolytic nature), there is no guarantee that carbon dioxide is the only contamination. In our experiments equilibrium water with a conductance of 0.80 to 0.85 X 10^{-6} at 25° had a residual conductance of 0.11 to 0.14 X 10^{-6} after removing all the carbon dioxide. In working with extremely dilute solutions of neutral salts there is no objection to the use of equilibrium water if the water is brought *into equilibrium with air at the temperature at which the measurements are made.* This point is often overlooked, and if the above condition is not fulfilled the water correction will become uncertain, for the conductance of the water will change when exposed to the air. As an illustration some values of the cell constant determined with extremely dilute solutions of potassium chloride in equilibrium water (conductance 0.85 × 10^{-6}) and in the same water when carbon dioxide free (cond. 0.12 × 10^{-6}) will be given. The conductance of the water is subtracted as a correction. The agreement is satisfactory.

Concentration of KC1	Cell constant using equilibrium water	Cell constant using carbon dioxide-free water
0.0005 N	0.01242	0.01240
.00025 N	.01240	.01239
.0001 *N*	.01241	,01239
.00005 N	.01238	.01241

In the measurements of the conductance of extremely dilute lanthanum chloride solutions and in the determination of the solubility of lanthanum oxalate, both equilibrium water and the latter freed from carbon dioxide have been used. The conductivity of the water was subtracted as a correction and the results of both sets of measurements as a rule agree to

within 0.3%. In order to get reliable results from the conductance measurements of a saturated solution of the slightly soluble lanthanum hydroxide, carbon dioxide-free water has to be used as a solvent. Its conductivity was subtracted from the figure, which may cause a slight uncertainty in the result.

The Conductance of Lanthanum Chloride Solutions and the Mobility of the Lanthanum Ion.—The conductance of lanthanum chloride solutions was measured at different dilutions in various cells. The duplicates agreed within 0.1%.

Conductance of Lanthanum Chloride at 25°.—**Conductivity** of equilibrium water, 0.8×10^{-6}; of carbon dioxide-free water, 0.15×10^{-6} rec. ohms. These figures have been subtracted from the conductances of the solution.

At concentrations between 0.001 and 0.01 N the following relation holds

$$\Lambda = 152.8 - 146\sqrt[3]{c}$$

Using the value 75.8 for the mobility of the chloride ion at infinite dilution[10] a value of 77 is found for the equivalent conductance of the lanthanum ion at an ionic strength of zero. This value is higher than those reported in the literature. H. Ley[11] found 67.3, A. A. Noyes and J. Johnston[12] 72.0, and Rimbach and Schubert,[13] 67.3. The measurements described in this paper have been extended to extremely high dilutions and the extrapolated figure of Λ, therefore is more certain than that of previous authors.

The Solubility of Lanthanum Oxalate in Water at 25°

(a) Conductivity Method.—The conductance of a saturated solution of lanthanum oxalate (three different products) in equilibrium water and carbon dioxide-free water was determined at 25°. After subtracting the conductivity of the solvent, a specific conductance of $9.97\ (\pm 0.1) \times 10^{-6}$ rec ohms was found. Assuming complete ionization and a value of 77 for the mobility of the lanthanum ion and of 72.7 of the oxalate ion,[14] this conductance corresponds to a solubility of 0.60 mg. of the anhydrous salt per liter or a molarity of 3.35×10^{-6}.

(b) Volumetric Method.—Saturated solutions of three different products of lanthanum oxalate were prepared in conductivity water by shaking an excess of the solid with 2.5 liters of water for a week in a thermostat at 25 ± 0.05°. After settling in the thermostat, large samples were removed by means of a pressure pipet and each sample examined in a strong light to make sure of the absence of any suspended solid. Two

liters were evaporated to a small volume (about 25 cc.) and the oxalate titrated with 0.01 *N* permanganate. A solubility of 2 0X ± 0.03 mg. of anhydrous oxalate per liter was found in this way.

(c) Colorimetric Method.—As there was a large discrepancy between the conductimetric and volumetric methods, the solubility was approximated in a colorimetric way. It was found that a dilute solution of sodium alizarinate gives a bright violet color to a solution of lanthanum containing as little as 1 mg. of the latter in a liter. This test can be applied successfully to the colorimetric estimation of lanthanum in extremely small concentrations down to 0.1 mg. of lanthanum per liter. At a definite lanthanum content the sensitivity and the color observed are dependent upon the hydrogen-ion concentration. In order to get comparable conditions, 1 cc. of an acetate buffer containing *2 N* ammonium acetate and *2 N* acetic acid is added to 10 cc. of the nearly neutral solution to be tested. Then 0.4 cc. of a 0.1% sodium alizarinate solution is added and comparison made with lanthanum solutions of known content. The method gives good results for concentrations between 0.1 and 2 mg. of lanthanum per liter. The solutions for comparison cannot be kept for a long time as the lanthanum alizarinate compound flocculates as a purple precipitate after standing for ten to twenty hours. Oxalate interferes somewhat with this color test; therefore, in the determination of the solubility of lanthanum oxalate the anion was replaced by sulfate. Five, 10 and 20 cc. samples of the saturated solution were evaporated to dryness. A little sulfuric acid was added to the residue, which was then heated until no more fumes were given off. After cooling, 1 cc. of the acetate buffer was added and the colorimetric measurement made as described before. In this way a solubility was found corresponding to 1.95 mg. of anhydrous lanthanum oxalate per liter. This figure is about 6% smaller than that found by the volumetric method, which is a satisfactory agreement considering the approximate character of the colorimetric reading. The following table gives a summary of the data on the solubility of lanthanum oxalate described in the literature.

SOLUBILITY OF LANTHANUM OXALATE

Mg. of Anhydrous Oxalate per Liter

Investigator	Conductivity method	Gravimetric method	Volumetric method	Colorimetric method
Rimbach and Schubert[13]	0.62			
Hauser and Herzfeld[15]	0.70	0.96	1.21	
Sarver and Brinton[16]	2.07	2.14		
Kolthoff and Elmquist	0.60		2.08	1.95

The agreement between Sarver and Brinton's gravimetric figure and our volumetric one is very satisfactory. The conductivity method undoubtedly gives much too low results, which is not surprising considering the tendency of various earth alkali oxalates to form complex ions in the solution.[17]

The Solubility of Lanthanum Oxide and Hydrous Lanthanum Oxide

Conductivity Method.—At the beginning of this paper, it was mentioned that the hydrolysis of lanthanum chloride is negligibly small. Therefore, lanthanum hydroxide

[16] L. A. Sarver and P. H. M.-P. Brinton, THIS JOURNAL, 49, 943 (1927).

[17] Cf. R. Scholder, E. Gadenne and H. Niemann, *Ber.*, 60, 1510 (1927). Recently Mr. Sandell found in this Laboratory a much lower value for the solubility of magnesium oxalate by the conductivity method than by direct determinations and even in the case of calcium oxalate there was a small but distinct difference.

must be a strong base and the saturated, extremely dilute solution can be considered as being completely ionized.

Various products of lanthanum oxide (cf. under materials used) were added to the water which had been made carbon dioxide free in the conductivity cell. The passage of carbon dioxide-free air was continued until the conductance was constant, As a rule this was the case after one-half to three hours and then it remained constant for at least a day. If some more oxide was added to the saturated solution, the conductance did not change, which is a good proof of the absence of foreign electrolytes. As lanthanum oxide absorbs carbon dioxide very readily, the products were ignited in an electric furnace at 800" and while still hot introduced into the cell. The saturated solution of the various products had the same conductivity; after subtracting the conductivity of the carbon dioxide-free water, a value of 3.34×10^{-6} rec. ohms was found, corresponding to a solubility of 0.67 mg. of La_2O_3 per liter. For the conductance of the saturated solution of precipitated and washed hydrous lanthanum oxide a lower value was found, probably on account of a slight contamination by carbon dioxide. A solubility of 0.3 mg. of La_2O_3 per liter was derived from the conductivity figures.

Volumetric Method.—The solubilities of the three oxides and the hydrous oxides were also determined in a volumetric way. Water was made carbon dioxide free in 2.5-liter paraffin-lined bottles (the paraffin coat was washed with a solution of ammonia in 50% alcohol to remove traces of acids), the oxide or hydrous oxide was added quickly and the bottles rotated in a thermostat for ten days. After the settling of the precipitate in the thermostat, large samples were collected with a pressure pipet. One liter of each solution and the same volume of a blank were evaporated to a small volume, a known excess of 0.01 N hydrochloric acid was added, and after removing all carbon dioxide, back titrated with 0.01 N base, using brom cresol green as an indicator. The titration error was corrected for in an empirical way. In all cases it was found that 1 liter of solution required 1.29 to 1.36 cc. of 0.01 N acid for its neutralization, corresponding to a solubility of 0.73 mg. of La_2O_3 per liter. This is in satisfactory agreement with the conductimetric data considering the extremely slight solubility. W. Busch[18] found by the volumetric method a solubility of 4 mg of La_2O_3 per liter at 25°. However. he mentions that the accuracy of his method is dependent upon the rapidity and the thoroughness of the filtration. E. Sadolin[19] calculated from potentiometric determinations of PH in mixtures of lanthanum chloride and hydrous lanthanum oxide at 18° a solubility product $[La^{+++}][OH^-]^3 = 10^{-20.98}$, corresponding to a solubility of 0.405 mg. of lanthanum oxide per liter. From our figures a solubility product of aged lanthanum hydroxide of $10^{-20.04}$ is derived.

Summary

1. The mobility of the lanthanum ion at infinite dilution and at 25° is 77.
2. A colorimetric method with sodium alizarinate as reagent has been developed for the determination of traces of lanthanum.
3. At 25° the solubility of lanthanum oxalate is equal to 2.08 mg. of the anhydrous salt per liter. The conductivity method gives much too low results on account of a complex dissociation of the dissolved lanthanum oxalate.
4. The solubility of lanthanum oxide and aged hydrous lanthanum

oxide is found to be 0.7 mg. of La_2O_3 per liter at 25°. The data from the conductivity and volumetric methods agree within 10%.

THE QUANTITATIVE DETERMINATION OF LANTHANUM BY PRECIPITATION AS OXALATE OR AS HYDROXIDE AND THE HIGHER OXIDE FORMATION OF LANTHANUM

BY I. M. KOLTHOFF AND RUTH ELMQUIST[1]

RECEIVED DECEMBER 22, 1930 PUBLISHED APRIL 6, 1931

The Determination of Lanthanum by Precipitation as Oxalate.—As lanthanum oxalate carries down alkali oxalates[2] oxalic acid must be used as a precipitating agent. The determination can be made volumetrically or gravimetrically. All experiments have been carried out with lanthanum chloride solutions. Pure[3] lanthanum chloride ($LaCl_3 \cdot 6H_2O$) was prepared and a standard solution of this product made up in a known weight of water. The latter was standardized by gravimetric chloride and lanthanum determinations according to precision methods, and contained 0.2946 equivalent of $LaCl_3$ per 1000 g. of solution (chloride analysis). In all further experiments a known volume was pipetted out and weighed. All reagents used were purified and tested for purity according to precision methods.

Volumetric Determination.—(a) The excess of oxalic acid is titrated in an aliquot part of the filtrate. (b) After washing out with water the precipitate is dissolved in warm dilute sulfuric acid and titrated according to the standard procedure with permanganate.

Ten-cc. portions of the stock solution of lanthanum chloride were pipetted into iodine flasks of known weight. Afterward the flasks were reweighed, varying amounts of a pure 0.05 molal oxalic acid solution were added and the flasks and contents again weighed. After standing overnight, weighed portions of the filtrates were titrated with a standard permanganate solution added from a weight buret. In all cases the titration error was determined by experiment. The precipitated lanthanum oxalate was collected on a filter and washed with cold water until the filtrate turned methyl orange the same shade as the water. The precipitate was

[2] Th. Sheerer, Ann. *phys. chim.*, [II]56,479 (1842); G. P. Baxter and R. C. Griffin, THIS JOURNAL, 28, 1684 (1906); G. P. Baxter and H. W. Daudt, *ibid.*, 30, 563 (1908); compare next paper in this series, where an interpretation of this so-called coprecipitation has been given.

[3] *Cf.* I. M. Kolthoff and Ruth Elmquist, THIS JOURNAL, 53, 1217 (1931).

then dissolved in dilute sulfuric acid and titrated with permanganate. The results are given in Table I. From Expts. 1–4 it is evident that a relatively large excess of oxalic acid must be added in order to get a quantitative precipitation of lanthanum oxalate. Moreover, the high values in Expts. 2, 3 and 4 obtained by titrating the filtrates (Columns 4 and 5) show that oxalic acid is carried down by lanthanum oxalate, the amount increasing with the quantity of precipitant. This occlusion, however, is much less than with alkali oxalates.

In order to get good results a large excess of oxalic acid must be used in the precipitation, and the precipitate washed for a long time with water in order to remove the adsorbed oxalic acid. Even after the filtrate gives an intermediate color with methyl orange, the precipitate still contains oxalic acid and about 175 cc. more wash liquid is required to remove the last traces of oxalic acid.

Precise results are obtained according to the following procedure (Expt. 5, Table I): 50 cc. of normal oxalic acid is added to 10 cc. of the lanthanum chloride solution. The precipitate is collected and washed until the filtrate turns methyl orange the same shade as that of the wash water. The lanthanum oxalate is dissolved and titrated. The results are accurate to 0.1%.

Experiments 5 (Table I) have been carried out according to the above procedure; 275 cc. of water was used to wash out all the oxalic acid. As the solubility of lanthanum oxalate in water amounts to 0.033 milliequivalent per liter,[3] the error due to solubility in our case cannot be greater than 0.2%, and in reality it was much smaller, since the filtration was rapid and permitted only momentary contact between liquor and precipitate.

TABLE I

VOLUMETRIC DETERMINATION OF LANTHANUM BY PRECIPITATION AS OXALATE

Expt.	M. equiv. La taken	M. equiv. oxalic acid added	M. equiv. La found from titration of filtrate	Deviation from calcd. value, %	M. equiv. La found from titratiou of ppt.	Deviation from calcd. value, %
1	2.990	4.332	2.960	−1.00	2.951	−1.30
2	2.996	5.005	3.002	+0.20	2.990	−0.20
3	2.999	7.508	3.016	+ .57	3.012	+ .43
4	2.989	10.201	3.133	+4.81	2.984	− .17
5a	2.993	50			2.991	− .07
5b	2.994	50			2.995	+ .03
5c	2.992	50			2.988	− .13

In the literature[4] it is reported that the volumetric determination of lanthanum by titration of the lanthanum oxalate gives high results. This must be attributed to an incomplete removal of oxalic acid from the precipitate.

[4] G. Krüss and A. Loose, *Z. anorg. Chem.*, 4, 161 (1893); W. A. Drushel, *Am. J. Sci.*, [IV] 24,197 (1907).

Since sodium oxalate (and other alkali oxalates) are carried down to a considerable extent by lanthanum oxalate and cannot be removed by washing the precipitate, the experiments described in Table I have been repeated in the presence of 2 and 3 g. of sodium chloride added as a 1 *N* solution. The results showed a slight coprecipitation of sodium oxalate or bioxalate. According to the precise procedure (Expt. 5) the results were accurate to within 0.2%.

The Gravimetric Determination of Lanthanum by Precipitation as Oxalate.—Twenty-five to 100 cc. of a 1 *N* oxalic acid solution was added to 10 or 40 cc. of the standard lanthanum solution (weighed portion) with constant stirring. After standing overnight the precipitate was filtered, washed and dried at temperatures between 50 and 300°. No temperature was found at which any hydrate of lanthanum oxalate reached constant weight. The oxalate decomposes before the last portion of the water has been removed.[5] Therefore the filter and precipitate were ignited in an electric furnace, in which the oxalate was transformed into oxide. It was found that the lanthanum oxide absorbs water from the atmosphere very readily. When the relative humidity of the air is low (about 20%), the oxide does not increase in weight during the weighing, but when it is high (60% or more) its weight increases rapidly when the oxide is exposed to the air. Therefore for accurate work it is recommended that the crucible containing the oxide, after being cooled in a desiccator, be weighed in a weighing bottle with well-fitted cover. At 700° the oxide is slow in coming to constant weight; after heating for twenty-four hours at this temperature the weight was 6% too high. This result is not in harmony with the statement of Racker and Klaassens,[5] who find that on heating lanthanum oxalate the formation of the oxide is quantitative at 600°. It was found that after heating the oxalate for five to eight hours at temperatures between 800 and 900°, a quantitative formation of the oxide takes place; the weight does not change upon prolonged heating at these temperatures. It is recommended that the ignition temperatures should not exceed 850°; at 1000°, the oxide, after having reached a minimum weight, increases its weight upon further heating. A similar phenomenon has been noted by P. H. M.-P. Brinton and L. A. Sarver,[6] though they did not investigate the influence of the temperature upon this effect. It is possible to obtain perfectly constant results if the ignition temperature is kept between 800 and 850°.

---

[5] After this work was finished, a paper was published by H. J. Backer and K. H. Klaassens, *Z. anal. Chem.*. 81, 104 (1930). These authors state that at 250" lanthanum oxalate is obtained in the anhydrous form and that the weight is constant. At temperatures above 300" they noticed a decomposition of the oxalate under evolution of carbon monoxide and carbon dioxide. Between 400 and 500° again a constant weight was found, corresponding to the composition La_2CO_5 (basic carbonate), and it is recommended that this compound be used as a weighing form of lanthanum oxalate.

[6] Sarver and Brinton, THIS JOURNAL, 49, 943 (1927).

The results given in Table II were obtained by weighing the crucible containing the oxide in a closed weighing bottle after constant weight had been attained at 800°.

TABLE II

GRAVIMETRIC DETERMINATION OF LANTHANUM BY PRECIPITATION AS OXALATE AND WEIGHING AS OXIDE

M. equiv. La taken	M. equiv. $H_2C_2O_4$ added	M. equiv. La found	Deviation from theoretical value, %
10.425	100	10.453	+0.25
11.684	100	11.698	+ .15
11.691	100	11.713	+ .19
11.639	100	11.658	+ .16
11.609	100	11.625	+ .14

The results are consistently 0.15% high. Comparing the results with those reported in Table I (5a, 5b and 5c) it may be inferred that the volumetric method gives more precise results. As the latter is much easier to perform, and gives results in a much shorter time it is preferable to the gravimetric method.

The Determination of Lanthanum by Precipitation as Hydrous Oxide

Volumetric Determination.—Though lanthanum hydroxide behaves like a strong base, its solubility in water is so small that the saturated solution does not react alkaline to thymolphthalein as indicator. Therefore the direct titration of lanthanum chloride with sodium hydroxide (or with an excess of the latter and back titration) was tried using thymolphthalein as an indicator. The end-points were indistinct and the results very unsatisfactory. Later the interesting fact was found that a suspension of lanthanum oxide in water assumes a dark blue-violet color upon addition of thymolphthalein, though the clear saturated solution remains colorless. The indicator is hydrolytically adsorbed by the solid strong base.

In the following experiments a weighed portion of a standard 0.05 N sodium hydroxide solution (carbonate free, kept in paraffin-coated flasks) was added to a weighed amount of the stock solution of lanthanum chloride. The next day weighed portions of the filtrate (the first few cc. were discarded) were titrated with 0.05 N hydrochloric acid, using methyl orange as an indicator. The acid and base were standardized according to precision methods, and the titration error was corrected for in an experimental way. In all experiments weight burets were used. The precipitates were washed with a mixture of 50% alcohol and water until the wash liquid was free from alkali when tested with phenol red. They were then dissolved in a weighed excess of standard acid and the excess titrated back.

As shown by Expts. 1 and 2 in Table III, the results are low. The deviation is due to basic chloride formation, which was proved by quantitative chloride determinations in the filtrate and in the precipitate. Better results might be expected if the lanthanum chloride were added slowly to an excess of sodium hydroxide. Experiments **3, 4, 5** and **6** in Table III were carried out in this way. The last two experiments show that good results are obtained if the lanthanum solution is added slowly to a large excess of sodium hydroxide (about five times the theoretical amount) and the precipitate is titrated after having been washed with a mixture of 50% alcohol and water. No basic chloride is formed. The chloride in the filtrates and wash liquids of Expts. 5 and 6 was determined gravimetrically; the results were 0.10 and 0.15% higher than the theoretical figures.

TABLE III

VOLUMETRIC DETERMINATION OF LANTHANUM BY PRECIPITATION AS HYDROXIDE

Expt.	M. equiv. La taken	M. equiv. NaOH added	M. equiv. La found from filtrate	Deviation from calcd. value, %	M. equiv. La found from titration of ppt.	Deviation from calcd. value, %
1	2.985	3.179	2.897	−2.95	2.891	−3.15
2	2.999	4.974	2.941	−1.93	2.950	−1.63
3	3.001	3.185	2.957	−1.47	2.978	−0.77
4	2.989	4.287	2.951	−1.27	2.973	− .54
5	2.984	15	...	....	2.986	+ .13
6	3.001	15	...	....	3.007	+ .20

Precipitation **of** the Hydrous Oxide by an Excess **of Ammonia.**—Carbonate-free ammonia was prepared by distillation over calcium oxide and the solution was kept in a paraffin-coated flask. An excess of ammonia was added to the lanthanum chloride solution and the precipitate after having been washed was titrated in the way described. In all cases the results were low on account of basic chloride formation, the deviation being larger when the ammonia was added to a hot solution of lanthanum chloride than at room temperature. The speed of addition of ammonia has also an influence; the results are better when it is added quickly (deviation in the various cases between **1.5** and 3.8% from the theoretical value). By gravimetric chloride determinations it was found that no basic chloride is formed when lanthanum chloride is added slowly to an excess of ammonium hydroxide. A series of experiments was next run in which **10** cc. (weighed portion) of the approximately **0.3** *N* lanthanum chloride was added slowly to about **30** to **40** cc. of **1** N ammonia. The precipitate was collected the next day and washed with a mixture of **50%** alcohol and water until free from ammonia. The results obtained agreed within 0.1% with the theoretical figures.

Gravimetric Determination.—Since it was found that the last procedure gives a quantitative precipitation of hydrous lanthanum oxide free from chloride, 40-cc. weighed portions of the approximately **0.3** *N* lanthanum chloride stock solution were added with constant stirring to about 80 to 100 cc. of N ammonia. The next day the precipitates were filtered and washed with a dilute solution of ammonium hydroxide to decrease the solubility. After ignition to constant weight in an electric furnace at 800°, the precipitate was weighed in a closed weighing bottle.

The results are accurate within 0.3% as indicated by the figures in Table IV.

TABLE IV

GRAVIMETRIC DETERMINATION OF LANTHANUM BY PRECIPITATION AS HYDROUS OXIDE BY AMMONIA

M. equiv. La taken	M. equiv. La found	Dev. from calcd. value, %
11.666	11.674	+0.07
11.633	11.657	+ .21
11.574	11.610	+ .30
11.619	11.656	+ .3
11.648	11.673	+ .22

T. O. Smith and C. James[7] found higher results when they precipitated lanthanum chloride with sodium hydroxide and ignited to oxide than when they used the oxalic acid method. With ammonium hydroxide the results were found to lie between the two. This can be easily explained by the formation of a basic chloride in the direct precipitation with base.

Higher Oxide Formation of Lanthanum.—In the discussion of the gravimetric determination of lanthanum reference has been made to an increase in weight obtained upon the ignition of lanthanum oxide at high temperature. This phenomenon was first noted by R. Hermann,[8] who reported a gain of 0.24%. H. Tschiesche[9] however, found no variation in weight upon heating lanthanum oxide and decided that Hermann's results were erroneous. Neither investigator reported the temperature at which the ignitions were made. Sarver and Brinton[6] next observed that lanthanum oxide shows a well-defined tendency to descend to a minimum in weight and then to register small gains of approximately 0.1 to 0.2 mg. upon subsequent ignitions. After heating lanthanum oxide for three hours at 500° under a pressure of 300 pounds, H. A. Pagel and P. H. M.-P. Brinton[10] found an increase in weight of only 0.02%. They concluded that no higher oxide of lanthanum exists. On the other hand, P. Melikoff and L. Pissarjewsky[11] report having obtained a peroxide to which they assigned the formula $La_2O_5 \cdot xH_2O$ by adding hydrogen peroxide and potassium hydroxide to solutions of lanthanum nitrate.

Since the work described in the present paper indicated the existence of a higher oxide, an extensive study of its formation at high temperatures has been made. Though it has not been possible to find the exact con-

---

ditions (temperature) at which it is formed, there is hardly any doubt that peroxides are formed when lanthanum oxide is ignited at very high temperatures in the air.[12]

The results described in Table V have been obtained by heating lanthanum oxide at various temperatures in an electric muffle furnace (gas burners should be avoided, as the oxide will be contaminated by sulfur trioxide upon long heating). The oxide was obtained from hydrous lanthanum oxide, the latter being prepared by slowly adding a solution of lanthanum chloride to an excess of ammonia. The precipitate was ignited at 800° to constant weight.

The experiments have been carried out with five different samples of lanthanum oxide. In all cases an increase in weight amounting to 10.2 to 10.8% was noticed upon prolonged ignition at white heat. Identical results were obtained with lanthanum oxide obtained from the oxalate.

If the sesquioxide were converted into the higher oxide, La_2O_5, an increase in weight of 9.81% would result.

TABLE V

INCREASE IN WEIGHT OF LANTHANUM OXIDE UPON HEATING AT HIGH TEMPERATURES

Time, hours	Condition	Increase in weight of 0.1655 La_2O_3 in %	Increase in weight of 0.2585 g. of La_2O_3 in %
10	Red heat	0.0	0.0
5	Light red heat	.0	.0
14	Light red heat	1.03	1.21
14	White heat	1.94	7.34
14	White heat	9.45	8.85
18	White heat	10.06	9.88
12	White heat	10.48	10.25
15	White heat	10.48	10.26

In other experiments three different types of oxide were used: one from hydrous oxide, one from oxalate and one from pure lanthanum nitrate. Another muffle furnace was used, as the former was burned out. After a long period of heating at white heat the increase in weight was 18.5 to 19.7%. These values closely check the theoretical gain in weight (19.63%) which would result if the higher oxide La_2O_7 were formed.

Four other sets of experiments were run in which the temperature was measured by means of an electric pyrometer. The results were irregular; after an increase in weight of 5.65% had been noticed, the increase in weight dropped again to about 2% on longer heating. It seems that the formation of higher oxide is slow at temperatures of 1100". Other furnaces were built; the addition of a trace of a cerium salt[13] and of platinum salt

---

[12] For a detailed discussion of all experiments, see thesis of Ruth Elmquist, pp. 73-88.

[13] R. Marc, *Ber.*, 35, 2370 (1902), stated that the presence of a trace of cerium catalyzes the higher oxide formation of praseodymium.

as a catalyst was tried,[14] but at present no definite information on the conditions of formation of the higher oxide has been obtained.

The results so far, however, show definitely that lanthanum oxide heated for long periods of time at very high temperature in an electric furnace and exposed to the air can be transformed into the higher oxides La_2O_5 and La_2O_7.

Summary

1. A precise volumetric procedure has been described for the determination of lanthanum as lanthanum oxalate. The oxalate can be estimated gravimetrically as oxide if ignited to constant weight in an electric furnace at 800 to 900° and weighed in a well-closed weighing bottle.
2. In the precipitation of lanthanum chloride with sodium hydroxide or ammonia basic chloride is formed. This is avoided by adding the lanthanum solution slowly to an excess of the base. Use of this fact is made in the volumetric and gravimetric determinations of lanthanum by precipitation as hydrous oxide.
3. Lanthanum oxide heated for long periods of time at white heat in an electric muffle furnace in air can be transformed into higher oxides La_2O_5 and La_2O_7.

LANTHANUM ALKALI OXALATES[1]

BY I. M. KOLTHOFF AND RUTH ELMQUIST

RECEIVED DECEMBER 22, 1930 PUBLISHED APRIL 6, 1931

The fact that alkali oxalates are carried down by lanthanum oxalate was first observed by Th. Sheerer.[2] G. P. Baxter and R. C. Griffin[3] stated that ammonium oxalate, but not oxalic acid, was carried down in considerable quantities by rare earth oxalates and that occlusion of ammonium oxalate was made negligible by acidifying the solution with twice the equivalent amount of nitric acid. G. P. Baxter and H. W. Daudt[4] reported that potassium oxalate was occluded to the same extent as ammonium oxalate (5–18%) but that sodium oxalate was occluded only slightly even in neutral solution. Since the occluded oxalate was determined after washing the lanthanum oxalate, part of the occluded salt may be removed from the precipitate. For this reason a series of experi-

ments was carried out in which an excess of alkali oxalate was added to a lanthanum chloride solution. The excess of oxalate was determined in an aliquot part of the filtrate by titration with potassium permanganate. The precipitates obtained with ammonium oxalate were washed out with distilled water containing a trace of potassium sulfate in order to prevent them from going into colloidal solution, and after dissolving in warm sulfuric acid titrated with permanganate. The procedure was the same as that described in a previous paper[5] for the experiments with oxalic acid. As may be seen from the results in Table I, the greater part of the alkali oxalate carried down by lanthanum oxalate is removed by washing out. The low results obtained with sodium and potassium oxalate which are given in the last column are explained by the fact that at the end of the washing a trace of the precipitate ran through the filter in a colloidal state.

TABLE I

COPRECIPITATION OF ALKALI OXALATES BY LANTHANUM OXALATE

Preciuitant oxalate	M. equiv. of $LaCl_3$ taken	M. equiv. of oxalate added	Equiv. of alkali oxalate carried down by 100 equivs. of lanthanum oxalate	Equiv. of alkali oxalate in 100 equivs. of the ppt. after washing out
Sodium	2.999	4.024	5.53	(−1.10)
Sodium	2.990	7.555	15.15	(−0.27)
Potassium	2.993	3.993	13.1	(− .90)
Potassium	2.991	7.487	48.2	(− .50)
Potassium	2.986	9.983	66.5	(−1.2)
Ammonium	2.993	3.982	18.5	+2.2
Ammonium	2.992	9.954	33.0	+3.6

The order of the coprecipitation found is potassium oxalate > sodium oxalate > ammonium oxalate.

This carrying down of alkali oxalates can be explained as due to the ordinary causes of coprecipitation or by the formation of definite double salts of lanthanum oxalate with alkali oxalate. The large extent to which the alkali oxalates are carried down indicates double salt formation. No double oxalates of the[4]cerium group of rare earth elements have been described in the literature;[6] the following study, however, shows that even at relatively low concentrations of alkali oxalates in the solution lanthanum oxalate is transformed into a double salt. In the present investigation weighed amounts of lanthanum oxalate were shaken in paraffined oil bottles in a thermostat at 25° with 75 to 100 cc. portions of solution of ammonium oxalate, sodium oxalate and potassium oxalate of various but known concentrations. After shaking for a definite time the bottles were clamped in

---

[5] Kolthoff and Elmquist, THIS JOURNAL, 53, 1225 (1931).

[6] Double alkali oxalates of the yttrium group of rare earth elements are known; see P. T. Cleve and O. Hoeglund, Bull. *soc. chim.*, *18*, 289 (1872); C. A. von Welsbach, *Monatsh.*, 27,935 (1906); L. A. Pratt and C. James, THIS JOURNAL, **34,488** (1911).

an upright position in the thermostat. Although a few samples settled quickly, considerable difficulty was usually experienced in removing the suspended solid from the solution. Filtration through various materials gave opalescent filtrates. The best method for obtaining a clear solution was to place the oil bottles in which the experiments were made in a centrifuge. They were rotated for several minutes and the clear solution removed by cautious pipetting with slow mechanical suction. Every sample was examined for suspended solid and discarded if any was found. Aliquot portions of both samples and blanks were titrated with permanganate. From the difference in concentration the number of moles of alkali oxalate removed by one mole of lanthanum oxalate was calculated.

The lanthanum oxalate used was prepared by precipitating a pure lanthanum chloride solution with an excess of oxalic acid. The precipitate was washed with distilled water until methyl orange gave the wash liquid the same color that it gives to the water. The lanthanum oxalate was air-dried and analyzed by titrating with a standard solution of potassium permanganate (weight buret) just before the shaking experiments were started. The results are given in the tables. The formation of the double salts is very slow, especially at low concentrations of alkali oxalate; in some cases equilibrium had not been attained even after four weeks of shaking.

Discussion of the Results.—Even at low concentrations of alkali oxalates, lanthanum oxalate is slowly transformed into a double salt of the general composition $1La_2Ox_3 \cdot 1Alk_2Ox \cdot xH_2O$ (1:1 compound). At concentrations of ammonium oxalate smaller than 0.012 *N*, lanthanum oxalate is the stable solid body; at higher concentrations it is transformed into the double salt 1:1 (Table II, Expts. 3 and 4). At a concentration of

about 0.01 N potassium oxalate both lanthanum oxalate and the double salt 1:1 can exist as solid bodies, whereas the former seems to be stable in sodium oxalate solutions up to a concentration of about 0.02 N Na_2Ox.

It is desirable to determine the equilibrium concentration of alkali oxalate at which lanthanum oxalate and the double compound 1:1 can exist as solid bodies from the other side by starting with the double salt. As the formation of the double salt, especially at relatively low oxalate concentrations, is slow, it is not quite certain whether in all cases equilibrium had been attained even after shaking for seven weeks.

Sodium and potassium oxalate can form two kinds of double salts, $La_2Ox_3 \cdot 1K_2(Na_2)Ox \cdot xH_2O$ and $La_2Ox_3 \cdot 2K_2(Na_2)Ox \cdot yH_2O$. Both solid phases are in equilibrium with the solution at a potassium oxalate concentration of 0.125 N (Table III, Expts. 8 and 9) or a sodium oxalate concentration of 0.225 *N* (Table IV, Expts. 9 and 10). No indication has been obtained that a similar compound 1:2 of ammonium oxalate exists.

Lanthanum oxalate was also shaken with solutions of oxalic acid of concentrations varying between 0.01 and 1.01 N. After shaking for a few weeks the filtrates were analyzed by titration with sodium hydroxide and with permanganate. Under no conditions was there a double compound formation. At higher oxalic acid concentrations (0.1 *N)* a slight adsorption of the acid by the lanthanum oxalate of the order of one equivalent per cent. was found.

The above results explain why oxalic acid and not alkali oxalates must be used as a precipitant in the determination of lanthanum.

Summary

The so-called coprecipitation of alkali oxalate with lanthanum oxalate is to be attributed to a double salt formation. Lanthanum oxalate is in equilibrium with the double salt $La_2Ox_3 \cdot (Alk)_2Ox \cdot xH_2O$ at a concentration of about 0.012 N ammonium oxalate, 0.01 *N* potassium oxalate or 0.02 N sodium oxalate.

Potassium and sodium oxalate also form double salts of the composition $La_2Ox_3 \cdot 2K_2(Na_2)Ox \cdot yH_2O$ at a concentration of 0.125 N potassium oxalate and 0.225 N sodium oxalate, respectively. No double compounds of lanthanum oxalate and oxalic acid are formed.

THE DECOMPOSITION OF HYDROCARBONS IN THE POSITIVE RAY TUBE

BY H. R. STEWART AND A. R. OLSON

RECEIVED DECEMBER 27, 1930 PUBLISHED APRIL 6, 1931

Some time ago, Olson and Meyers[1] investigated the reactions produced by excited mercury atoms in mixtures of hydrogen and ethylene. The products were analyzed by Dr. H. M. Kvalnes using the positive ray apparatus which Dr. Hogness and his students had constructed. By making some assumptions which were stated in the above paper, Olson and Meyers were able to postulate a reaction mechanism which accounted for the results of the analysis. The desirability of determining the trustworthiness of such an analysis was discussed privately at that time, but the actual investigation had to be postponed until a new apparatus could be built.

---

[1] Olson and Meyers, THIS JOURNAL, 49, 3131 (1927).

The apparatus which was constructed was quite similar to that used by Hogness and Lunn.[2] Known mixtures of methane and ethane, which had not been exposed to light from the mercury arc, were analyzed. The results seemed to justify the assumptions made by Olson and Meyers.

Benzene and hydrogen were then exposed to the arc in the usual way. Benzene was selected so that there would no longer be a ratio of unity between the number of moles of hydrogen and the number of moles of product formed by hydrogenation. On analysis of the product in the positive ray apparatus, a complex set of peaks was obtained which indicated that benzene was broken up in the photochemical reaction. However, when pure benzene was used for analysis, lower molecular weight peaks corresponding to some of those found with the reaction product were present. This result, coupled with the results of the analysis of methane-ethane mixtures mentioned above, raised two questions: how complex can a molecule be and not be decomposed in the positive ray analysis, and what is the cause of the disruption?

Pure hydrocarbons up to and including hexane were then prepared. These substances were distilled repeatedly and the first and last fractions rejected. Positive ray analyses were then made of each hydrocarbon. Peaks due to ions of carbon chains shorter than the original were found in every case except that of methane. These peaks were too high for them to be ascribed to impurities. (Additional evidence for the purity of the original hydrocarbons is offered later.) The peak due to methane as a decomposition product is always small, accounting for the satisfactory analyses of the methane–ethane mixtures.

Hexane, at a pressure of about 10 cm., was then exposed to a hot filament of the type used in the positive ray tube (Western Electric low temperature filament) for some hours, and analyzed. The low molecular weight peaks were higher than for untreated hexane, showing that thermal decomposition by the filament was at least in part responsible for the presence of foreign substances with shorter chains.

A new tube was then constructed in such a way as to minimize thermal decomposition. In this tube (see Fig. 1) the top of the copper-plated iron ionization chamber was closed over with a copper disk soldered in place, and provided with a slot and sliding jaws. These jaws were adjusted to form a narrow slit (0.08 × 4 mm.) just below the filament and opening into the ionization chamber. The base of the chamber was closed off from the filament space by a glass sleeve fastened to the metal with cement. Two very high capacity mercury vapor pumps, each backed by an ordinary mercury vapor pump and an oil pump in turn, were connected, one to the filament chamber and the other to the magnetic deflection chamber, through large diameter tubing. The gas under analysis was introduced

---

[2] Hogness and Lunn, *Phys. Rev.*, **26**, 44 (1925).

into the ionization chamber by a glass tube entering through the base. The diagram in Fig. 2 will make clear the pressure relationships.

Preliminary runs showed that the pressure in the filament chamber and deflection chamber could be maintained at 10^{-5} mm. when the pressure in the ionization chamber was 10^{-2} mm Since the field between the filament and the first slit is accelerating for electrons, any positive ions formed between the filament and the slit will be thrown back toward the filament. No negative ions have ever been detected in the ionization chamber with this tube. Due to the pressure gradient, it does not seem likely that any decomposition products formed by the filament can be present in the ionization chamber at a pressure high enough to be important. *Yet runs with the pure hydrocarbons (to hexane) showed in every case a peak for every hydrocarbon up to and including the one introduced.* The peaks were just as well marked as those obtained with the original tube, in which the bare filament was in direct contact with the gas to be ionized, and no pumping took place except through the bottom slit. Methane, which in the old apparatus gave peaks for ions of masses 12, **13,** 14, **15** and 16, showed peaks only for **15** and 16 in the new tube, in agreement with the results obtained by Hogness and Kvalnes[3] after they had succeeded in minimizing thermal decomposition.

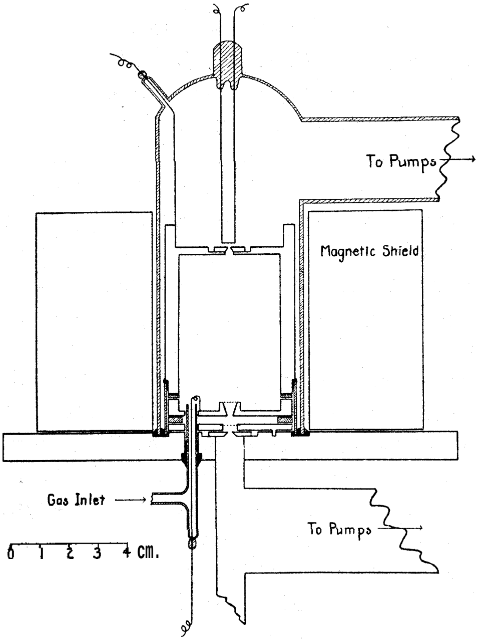

Fig. 1.—Positive ray tube. Base plate and deflection chamber are of brass. Metal parts within tube are of soft iron, copper plated. Tube proper and insulating rings (shaded) are of glass.

As will be seen later, the relative heights of the peaks vary with pressure in such a way in the range investigated (1×10^{-3} mm. to 100×10^{-3} mm.) that it is difficult to account for them as being due to secondary reactions between ions and molecules in the ionization chamber. Calculation readily shows that multiple ionization cannot account for the appearance of peaks at all of the positions of ions of the lower molecular weight hydrocarbons. For example, propane should give ions of apparent masses 44,

---

[3] **Hogness and Kvalnes,** *Phys. Rev.*, **32,** 942 **(1928).**

22, 15, corresponding to $C_3H_8^+$, $C_3H_8^{++}$, $C_3H_8^{+++}$, but 22 does not appear on the curves, thus making it very unlikely that any of the ions ascribed to CH_3^+ are due to $C_3H_8^{+++}$.

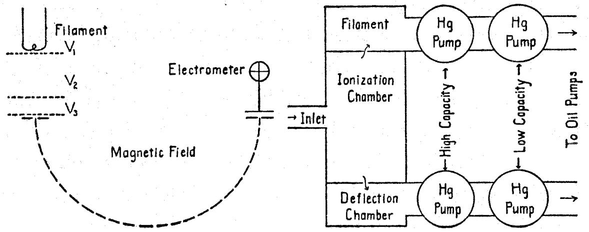

Fig. 2.—Pressure and field diagrams.

Another possibility is that ions of the original hydrocarbon are being disrupted by collision near the bottom slit, after having been accelerated in the high voltage field, and that the separate (charged) portions are being deflected in the magnetic field, thus appearing at false m/e positions. It can be shown that if an ion of mass m_1 and charge c_1 becomes an ion of mass m_2 and charge c_2, after having acquired nearly its final velocity, then the resulting ion will appear at a position given by the equation

$$\left(\frac{m}{e}\right)_2 = \left(\frac{c_1}{c_2} \times \frac{m_2}{m_1}\right)^2 \left(\frac{m}{e}\right)_1$$

Calculation again shows that the positions of the observed peaks cannot be accounted for in this way. In addition, even if positions corresponded, it would be very difficult to account for the relative intensities by such a process, for it is necessary that the ions be broken up by collision without being deviated appreciably from their original path. Peaks of this type have been reported only once, by Smyth[4] in the case of hydrogen.

There seems to be only one alternative, that the ionizing electrons decompose the hydrocarbons on impact, and this will be studied in the remainder of this paper.

Positive Ray Analysis of Propane and Butane

Series of runs were made with pure propane and with pure butane, over a range of pressures. The results of typical runs are shown in Fig. 3. In this figure, the ordinates represent electrometer deflections, and the abscissas are proportional to the current through the magnet, but for convenience each peak is labeled with the calculated m/e value of the corresponding singly charged ion. Due to the great range of mass which it was necessary to cover in a single run, it was found convenient to fix the accelerating voltage V at a suitable value (in these runs, 1200 volts) and vary the magnetic field.

---

[4] Smyth, *Phys. Rev.*, *25*, 452 (1925).

There is no question of the purity of the gases employed. As was mentioned previously, they were dried and distilled repeatedly, with rejection of the first and last portions. As a final test, the positions of the peaks in separate runs on methane, ethane, propane and butane were compared. Note, in Fig. **3**, that in the case of butane, CH_4^+, $C_2H_6^+$ and $C_3H_8^+$ are missing; that in the case of propane, while $C_3H_8^+$ is present, $C_2H_6^+$ and CH_4^+ are missing. In ethane one finds $C_2H_6^+$ but not CH_4^+. The peak corresponding to mass 16 (CH_4^+) never appeared except when methane had been intentionally introduced. If the peaks for the hydrocarbons lower in molecular weight than the one introduced were due to their presence as impurities, a peak for the corresponding saturated ion would be present, and this is found not to be the case.

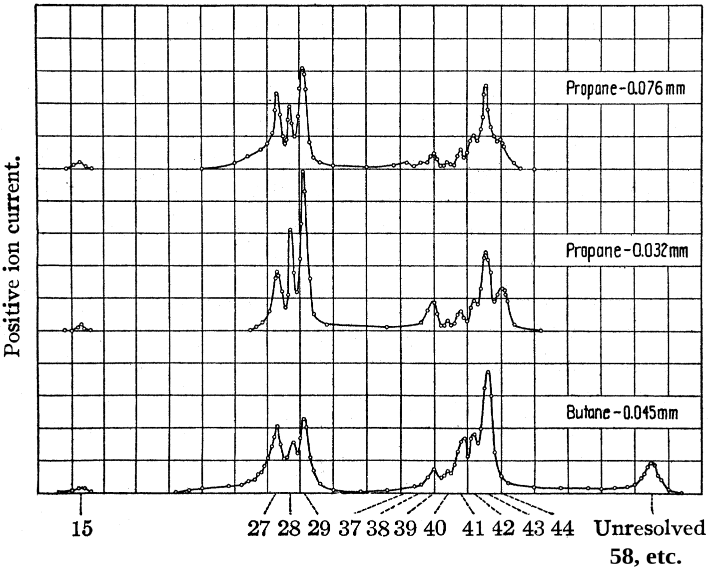

Fig. 3.—Typical runs with propane and butane. Ordinates represent electrometer deflections; abscissas, current through the magnet. Numbers given are calculated masses of corresponding singly charged ions.

The results for propane and butane are given in the accompanying tables, which summarize the peak heights (in one case the areas under the peaks) for various pressures. The policy of measuring the total areas under the curves for ions having the same number of carbon atoms but varying amounts of hydrogen, was adopted for butane on account of the lack of resolution at higher pressures and molecular weights. It can be shown that the geometrical resolving power of the apparatus is ample, and that the lack of complete resolution is due to other causes.

The tables also include a tabulation of the relative proportions of the several types of carbon chains present as ions, calculated from the previous data, and plotted in Figs. 4 and 5. In order to restrict attention to **the** features of the data which it is desired to discuss, and to avoid complicating

the diagrams, all ions containing the same number of carbon atoms are plotted as a single species, and designated by the symbols C_1, C_2, C_3, C_4.

Discussion

It has been customary in the past to ascribe progressive variations of the percentage of a given ion species with pressure to secondary reactions involving that ion. However, since the simple ion of the hydrocarbon introduced does not approach 100% as the pressure is decreased, it is apparent that in addition to ionization, other primary processes must be operative. Thermal decomposition cannot be responsible for these reactions, not only because of the evidence we have already presented, but also because the percentage of higher molecular weight ions increases with increasing pressure. We therefore conclude that the primary process involves the splitting of carbon bonds in a large fraction of ionizations. On this assumption, the curves of Figs. 4 and 5 should be horizontal straight lines. However, it has lately been pointed out by Kallman and Rosen[6] that insufficient attention has been given to selective absorption of ions in the ionization and magnetic deflection chambers of the positive ray tube. By experiments in which the pressures in the chambers were controlled separately, they were

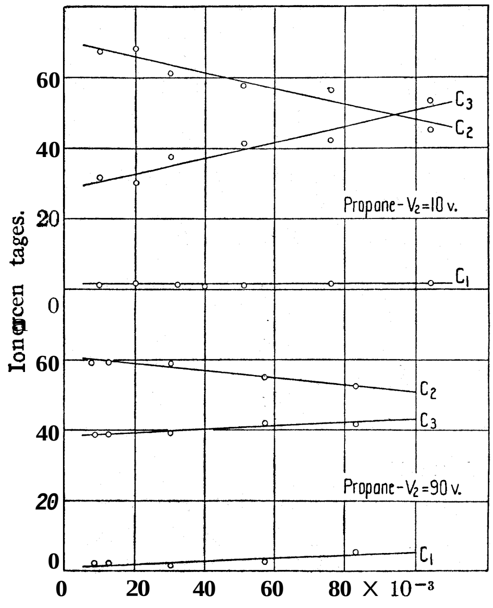

Fig. 4.—Ion percentage–pressure curves for propane. Ordinates represent percentages of total number of ions per second in a run in which the pressure in the ionization chamber is that given by the abscissa.

---

[6] Kallman and Rosen, *Z. Physik*, 58, 52 (1929).

able to show in the case of nitrogen, previously an outstanding example of dissociation by secondary reaction alone, that all of the dissociation took place by primary electron impact, and that the observed variation in the percentages of N_2^+ and N^+ with pressure was due to strong selective absorption. It would be strange indeed if there were no similar effects for the hydrocarbons at the pressures employed. Thus the slopes of the ion percentage–pressure curves do not necessarily indicate secondary processes. This information, coupled with the fact that the percentage of the ion of the original hydrocarbon increases with pressure, and does not approach 100% as the pressure is reduced, definitely precludes any mechanism involving secondary reactions, at least for the principal effect.

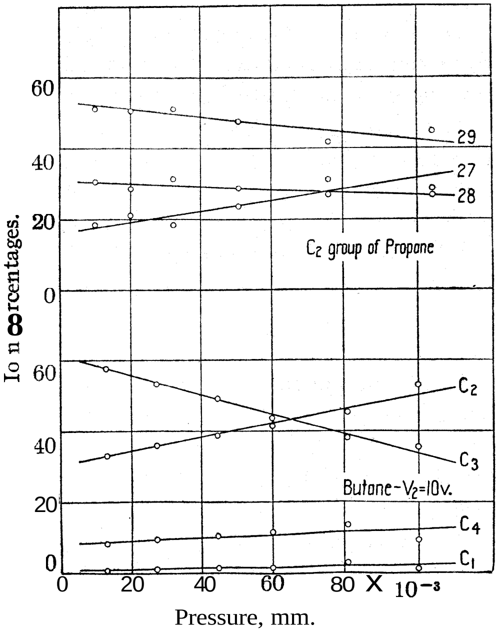

Fig. 5.—Ion percentage–pressure curves for butane and for the ions $C_2H_3^+$, $C_2H_4^+$ and $C_2H_5^+$ of the C_2 group in propane. Ordinates and abscissas are the same as in Fig. 4.

Simultaneous ionization and dissociation by electron impact can be explained satisfactorily by the same reasoning as was employed by Franck[6] for light absorption, and has been discussed in this light by Birge and Sponer[7] and others. As a result of electron impact, one electron may be removed from the hydrocarbon molecule, forming a positive molecule ion. It is also possible not only to remove an electron, but simultaneously to displace another electron to an excited level in which the binding force in a C–C or a C–H bond is weakened, and the equilibrium positions of the nuclei are more widely separated. If, then, as the result of an electron ejection, the equilibrium positions of the nuclei are suddenly at a greater distance apart than before, the two nuclei may, at the moment of ejection, be within the limiting distance of approach, and dissociation will follow.

Using propane as an example, the corresponding equations are

$$C_3H_8 \longrightarrow C_3H_8^+ + E^-$$
$$C_3H_8 \longrightarrow C_2H_5^+ + CH_3 + E^-$$
$$C_3H_8 \longrightarrow C_2H_5^+ + CH_3^+ + E^-$$
$$C_3H_8 \longrightarrow C_3H_7^+ + H + E^-$$

---

[6] Franck, *Trans. Faraday Soc.*, *21,* 536 (1925).

[7] Birge and Sponer, *Phys. Rev.,* 28, 279 (1926).

The last equation also represents the fact that hydrogen ions were not observed in this work, and is similar to the one which Hogness and Kvalnes[3] found it necessary to assume in their study of methane.

To explain the multiple sub-peaks of propane and butane it seems necessary to assume that a single electron can eject a number of hydrogen atoms. This assumption is in accord with the work of Bleakney,[8] who has shown that a single electron can eject simultaneously as many as five electrons from mercury.

It may now be readily seen that the propane which Olson and Meyers reported had been formed from ethylene and hydrogen, may have been produced in the positive ray tube from the butane.

It is harder, as Taylor and Hill[9] point out, to understand why the positive ray analysis did not show the presence of methane in the ethane which had been exposed to ultraviolet light. The only explanation which we can offer is that the polymerization product of ethane deposited on the quartz window soon after beginning illumination and made the window opaque. Olson and Meyers[10] found that this was the case with ethylene.

Summary

1. By experiments with a specially designed tube, it is shown that the decomposition of the hydrocarbons in positive ray analysis is due to dissociation by the ionizing electrons, rather than to thermal decomposition by the hot cathode, or to secondary reaction between ions and neutral molecules.

2. It is shown that a previous determination of the saturated products of the hydrogen–ethylene reaction by positive ray methods gave ambiguous results, since part of the products reported have been found to decompose in the process of analysis.

3. Selective absorption of hydrocarbon ions by propane and butane is observed.

THE DETERMINATION OF TRACES OF IODINE.
V. FURTHER REFINEMENTS IN TECHNIQUE

BY ROE E. REMINGTON, J. F. MCCLENDON AND HARRY VON KOLNITZ

RECEIVED DECEMBER 29, 1930 PUBLISHED APRIL 6, 1931

In previous papers of this series[1] there has been developed a technique for the micro-estimation of iodine in organic materials. Although the methods as described have been employed in a number of laboratories, further improvement seemed possible at certain points in the operation. It has been found practically impossible to avoid the formation of some tar or soot if organic matter is burned in the silica tube by the method described in the second and third papers, where the sources of heat were the heat of combustion of the material itself and a bank of Méker burners placed under the tube. The production of tar and soot necessitates a second burning, in a similar or smaller tube. Low temperature ignition in a muffle as previously described possesses the advantage of brevity, so essential in survey work where a large number of samples must be analyzed, and gives fairly accurate results on plant materials (except grain). Reith reports losses as high as 60% by this method when applied to flour or milk, but our results on milk powder have been quite as good as by any other method. It cannot be applied to nuts, cheese or other oily substances, which must be burned in the tube. Careful temperature control by automatic pyrometers is extremely necessary. In the fourth paper a small oxygen–gas torch was described, which insures sufficient heat to incinerate the sample thoroughly, and at the same time an excess of oxygen. Since this torch worked well on the small samples used in the determination of iodine in thyroid tissue, it seemed desirable to attempt to adapt it to reinforcing the heat of combustion of the larger samples necessary when foods or excreta are burned. Heat outside the silica tube as by Méker burners cannot be relied upon to maintain the stream of gases above the ignition point of organic combustion products, even though an excess of oxygen is always present. This external heat has therefore been replaced by a "hot spot" inside the tube over which the gases must pass, the hot spot consisting either of an electrically heated platinum spiral placed in a narrow part of the tube, or a roughly coiled piece of chromel wire placed a short distance in advance of the oxygen–gas torch. The platinum spiral has been found particularly adapted to the burning of such substances as urine and feces, which must be placed in combustion boats, while the flame-heated chromel wire has been found quite as satisfactory, and much simpler

---

[1] McClendon and co-workers, THIS JOURNAL, 50, 1093 (1928); 51, 394 (1929); 52,541 (1930); 52,980 (1930).

in operation, for those substances which can be fed continuously, such as powdered dried vegetables by a screw feed device, or oils by an atomizer.

The flame-heated spiral inside the tube becomes very hot.[2] We have frequently been troubled with the appearance of nitrite in our absorbers, even when substances low or lacking in nitrogen, such as starch, were burned. This we have attributed to the fixation of atmospheric nitrogen, and have avoided by partially closing the opening around the screw feed device at the end of the tube, and so adjusting suction and oxygen supply that very little air is drawn in. Any appreciable amount of nitrite ruins the determination, since iodine is set free when the solution is acidified. The use of sodium sulfite instead of or in addition to hydroxide in the absorbers has been found desirable. Even so, it is a question whether all iodate is reduced by sulfite in alkaline solution, so that in some cases we have found it desirable to adopt the suggestion of Reith[3] to acidify and add sulfurous acid, and then make alkaline again before evaporation to complete dryness. Iodates are not extracted by alcohol. Reith also holds that alcohol will not make a complete extraction of iodides from a semi-crystalline mass, due to inclusion in the crystals. By making extraction in a ball mill, however, (which he did not do) and so adjusting our concentration of alcohol that a two-phase liquid system is formed, we are able to obtain satisfactory recoveries.

For burning any substances which can be continuously fed, such as oils by an atomizer or powdered substances by a screw-feed device, the set-up is essentially as previously described[4] except that the Méker burners are omitted, and the platinum spirals replaced by about 75 cm. of 20 gage chromel wire roughly coiled into a conical spiral and placed inside the silica tube about 5 cm. in advance of the point of delivery of the sample. To heat the spiral, two small copper tubes (1.5 mm. bore) are attached to the outside of the feed device, to deliver oxygen and gas. The ends of these tubes are brought together to form a torch immediately in front of the delivery point of the sample. The joint between the feed device and the silica tube is covered with a wad of wet asbestos, to exclude air as far as possible. The supply of oxygen is so adjusted as to furnish practically all the gas that is drawn through the absorbers. Burning is complete and extremely rapid, requiring only twenty minutes for 100 g. of material. A curved piece of 22 gage sheet nickel large enough to catch the ash, if inserted inside the silica tube, will facilitate removal of ash and lengthen the life of the tube. After the combustion, adhering particles of ash are

---

[2] Platinum wire was tried for the spiral, but fused completely (m. p. 1755°). Tungsten wire (m. p. 3400°) was tried but ignited. The chromel wire becomes oxidized, but holds its form. Its life, however, is only one burning.

[4] McClendon, Remington, von Kolnitz and Rufe, THIS JOURNAL, 52, 542, 544 (1930).

removed from the wire, which is preferably not placed in the solution, the tube and piece of nickel washed, washings combined with the solutions from the absorbers and the determination carried out as directed in previous papers. In burning oils, it is not practicable to feed both torch and atomizer from the same cylinder of oxygen. To check recovery when fats are burned by this method, we analyzed a sample of cod-liver oil, finding 10,400 parts of iodine per billion, and a sample of butter fat, finding 40 parts. The two were then mixed in proportions varying from 1 to 25 to 1 to 10, and burned. Percentage recoveries were, respectively, 80, 90, 80, 100, 91, 87, 84, 83, 82; average 86.

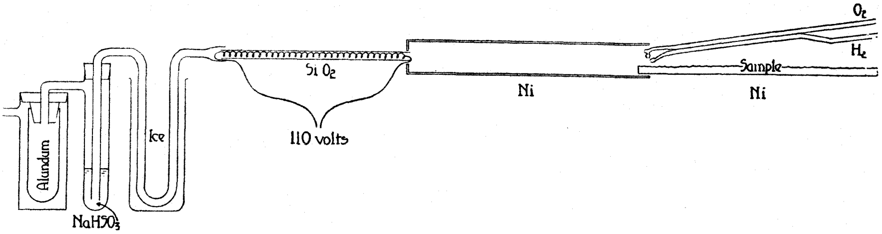

Fig. 1.

To burn urine residues and other pasty materials which cannot be packed into sausage casings nor sprayed, a different set-up has been devised (Fig. 1) This consists of a nickel tube of convenient diameter, into which a long nickel boat containing the sample is introduced. Nickel is used to reduce breakage when substances containing considerable amounts of fusible alkali, such as urine, are burned. The end of the nickel tube is constricted so as to fit over a silica tube of about 5 mm. bore, which contains a platinum spiral. This spiral is heated to a cherry red electrically by means of a 110-volt alternating current through an adjustable transformer. The joint between the nickel and silica tubes need not be perfectly tight but should be fitted fairly snugly. It is not necessary that the platinum wire be insulated from the nickel, but the whole apparatus can be placed on a dry wood or alberene table and the operator protected from accidental contact by wrapping the torch with tape. One end of the silica tube is introduced into the end of the U-shaped Pyrex tube, the joint being packed with wet asbestos. This tube is immersed in *a* beaker of cracked ice, and is connected with one or more Milligan wash bottles filled with sodium bisulfite solution. Finally the gases are drawn through an alundum capsule or Jena fritted glass filter to catch the white smoke which sometimes appears and is not absorbed by the wash solution. The nickel boat containing the sample is introduced gradually, the sample being burned by the small oxygen-gas torch shown in the drawing, which has a small opening in the oxygen supply tube, so placed as to allow a part of the oxygen to escape into the combustion tube above the sample. After the sample has all been introduced and burned, the torch is removed, the opening at the end is partly closed, oxygen being introduced continually, and the whole of the nickel tube is heated by means of a burner, so as to burn or volatilize any matter which may have been deposited in it during the earlier stage of the combustion. The washings from the apparatus and the liquid from the absorption vessels are combined and treated as previously described.

Pfeiffer[6] has developed an acid distillation method involving oxidation by perhydrol in sulfuric acid. We have tried the modification of this method proposed by Glimm and Isenbruch[6] but the operation is extremely time-consuming, is not adapted to large samples (in the tube furnace we have burned as high as 1 kg. of wheat or corn continuously), the oxidation is never complete, and the results are low in our hands. Out of more than twenty trials we were able to recover measurable quantities of iodine in only three. A sample of dried whey, which was the only one to give results comparable to the tube method, was carbonized in a dish before the acid digestion. A few typical results by these different methods are given in Table I.

TABLE I

SOME COMPARATIVE IODINE ESTIMATIONS BY DIFFERENT METHODS

Results are in parts per billion, dry basis

Turner[7] has recently described a method for estimating iodine in blood, in which he employs ashing in a current of oxygen in an open crucible, oxidation with bromine, the use of the iodide–iodate reaction, and colorimetric measurement of the blue color developed with starch. Although we have not worked on blood, we have repeatedly found that losses occur if ashing is done in open dishes at uncontrolled temperatures, even when an

[6] E. Glimm and J. Isenbruch, *ibid.*, 207, 368 (1929).

[7] R. G. Turner, *J. Biol. Chem.*, 88,497 (1930); THIS JOURNAL, 52, 2768 (1930).

excess of alkali is used. Neither can we confirm his observations as to the reliability and stability of the color developed. If the blue solution is read against a blue glass instead of a starch–iodine solution, it will be found that the color is quite sensitive to temperature changes, and varies with time. Furthermore, in our hands, the depth of color produced by a given amount of iodine was not uniform. Four solutions, each prepared as described by Turner for his standard solutions, and each containing 0.001 mg. of I_2, read 22 5, 12.8, 9 24 and 26.0 mm. in the colorimeter, against our blue glass. Apparently there is some uncontrolled factor.

Other workers have made use of the iodide–iodate reaction to increase the iodine available for estimation. We have always felt that due to the uncertainty as to the presence of oxidizing substances other than iodate in extracts of the ash of plant and animal matter, and the effect of atmospheric oxygen on free hydriodic acid, this is a very dangerous procedure. It would be very desirable to increase the sensitivity of our present methods for substances such as blood or tissue, of which small amounts only are available, and for cereals or diets extremely low in iodine. Atmospheric effects can perhaps be eliminated by promptly removing the liberated iodine from the excess of potassium iodide by shaking out with carbon tetrachloride. This would move the lower limit of estimation down to about one-sixth its present value. When this was tried with pure solutions prepared by oxidation of known quantities of sodium iodide, the results were quite constant, and tended to approach the theoretical value, usually somewhat less. When, however, it was applied to extracts prepared from the ash of plant or animal matter, results were found to be extremely variable, and often many times the amount we had found to be present by other methods. Alcohol cannot be supposed to be an absolutely selective solvent for iodides to the exclusion of all other oxidizable substances.

Summary

1. An improvement in the destruction of organic matter in the micro-estimation of iodine by the tube furnace method, consists in a "hot spot" within the tube over which gaseous products must pass. This makes a second combustion unnecessary.

2. The perhydrol–sulfuric acid distillation method of Glimm and Isenbruch was found to be inapplicable to large samples of plant or animal matter, giving incomplete oxidation and low results.

3. The starch–iodide reaction is unreliable as a quantitative colorimetric method for estimation of iodine.

THE DISSOCIATION CONSTANTS OF NITROGEN TETROXIDE AND OF NITROGEN TRIOXIDE

BY FRANK H. VERHOEK AND FARRINGTON DANIELS

RECEIVED JANUARY 8, 1931 PUBLISHED APRIL 6, 1931

It was found necessary to redetermine the dissociation constants of nitrogen tetroxide and nitrogen trioxide accurately as part of a larger program dealing with the kinetics of the decomposition of nitrogen pentoxide.

Although the dissociation of nitrogen tetroxide is used as a classical example of an equilibrium, the data are unsatisfactory and no attempts have been made to correct for deviations from the simple gas laws. In fact there has not been a sufficiently large number of independent measurements at any single temperature to determine quantitatively how these deviations affect the value of the dissociation constant and how it changes with pressure. Some of the earlier work was rendered inaccurate by the use of stopcock grease, rubber or mercury, but Bodenstein[1] in 1922 described accurate measurements using an all-glass apparatus at different temperatures. He gave two values of the equilibrium constant, one for high pressures and another for low pressures.

The dissociation constant of nitrogen trioxide had not been known with any accuracy and in fact the very existence of nitrogen trioxide in the gas phase was disputed. The earlier work was inaccurate because the apparatus was not chemically inert. Evidence that some nitrogen trioxide exists in a gaseous mixture of nitric oxide and nitrogen tetroxide is offered by the fact that when such a mixture is bubbled through alkali the oxides are absorbed in equivalent amounts to form almost pure nitrite; nitric oxide alone does not react and nitrogen dioxide gives equal quantities of nitrite and nitrate. Wourtzel[2] obtained two good measurements of the equilibrium constant by allowing nitric oxide to mix with an insufficient supply of oxygen. After the work described in this communication was well started a preliminary article on nitrogen trioxide was published by Abel and Proisl.[3] Although the apparatus and technique was similar to that of the present authors, the work was not discontinued because it seemed desirable to have measurements of such an uncertain quantity from two different laboratories.

Furthermore, it seemed likely that accurate measurements on these two equilibria might reveal the possible existence of oxides of nitrogen other than the four in question. Such oxides would be of interest in connection with studies on kinetics. To determine the effect of inert gases

on the equilibrium and the rate of dissociation, measurements were made in the presence of such gases.

Experimental Procedure

The apparatus is shown in Fig. 1. It is so constructed that the reacting gases come in contact with no material other than glass. Each gas is sealed off in a one-liter Pyrex flask and its pressure is measured by means of the glass manometer developed in this Laboratory.[4] A measured air pressure is balanced against the pressure in the flask through a glass diaphragm which is provided with an electrical contact. The air can be evacuated rapidly through K or slowly through the capillary J or the pressure may be allowed to increase rapidly through H or slowly through G, thus facilitating the rapid and exact adjustment of the balancing pressure. Calcium chloride tubes are used to keep the manometer system dry. A trap L and an automatic check valve N, consisting of a glass bead seated on a small rubber tube inside a glass tube, were used to prevent water running back from the aspirator.

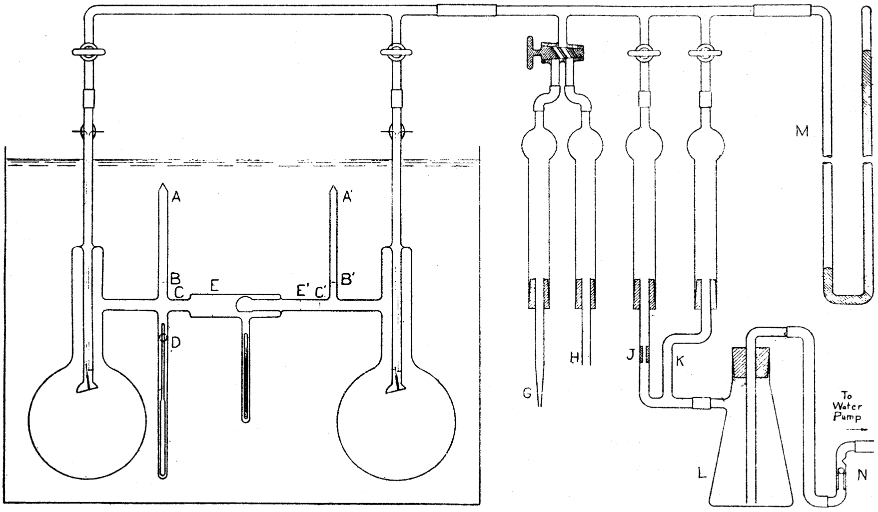

Fig. 1.

The device for keeping the gases separate and later allowing them to mix consists of a glass bulb blown from 12-mm. tubing and flattened on one side; this is sealed into 20-mm. tubing, and a side tube attached opposite the flat place. This central piece is now sealed onto the side arms of the two flasks at E and E', and the flasks clamped in position on the ring stand which is later to be set into the thermostat. An iron nail enclosed in glass tubing of such a size that it moves easily inside the side tube is now inserted in the latter and the tube sealed off so as to leave about two centimeters in which the hammer may move. When it is desired to break the bulb, a solenoid is placed around the side tube and the hammer driven up into the bulb when a current is sent through the solenoid. It is imperative that the bulb be flattened; the keystone effect of a spherical bulb is so marked that the glass of the hammer breaks instead of the bulb. The most durable hammers are those made of soft glass padded with asbestos at each end of the nail. The asbestos serves to keep the iron from scratching the glass and to equalize the pres-

---

[4] Daniels, THIS JOURNAL, 50,1115 (1928)

sure of the nail on the end of the tube as it is bumped against the bulb. The glass must be worked quickly in the flame and at some distance from the nail, to prevent the temperature strains which would result if the metal were allowed to become heated. In these experiments, small finishing nails ground round on the ends and sealed inside four millimeter tubing moving in seven millimeter tubing, were used as hammers.

The solenoid was made by winding 400 ft. of No. 24 double cotton covered copper wire on a brass tube about **6** cm. long. It was connected in series with a rheostat to a **55** v. direct current circuit and operated at a current of five amperes or less.

A similar device was used at D for breaking the file-scratched capillary of a bulb containing nitrogen tetroxide.

The volumes of the flasks were obtained by filling with distilled water to marks at B, C and B', C' and weighing. After the center piece was inserted, the volumes on each side of the bulb were obtained by tipping to one side or the other and running in water from a standardized buret through A and A' to C and C'.

The outside volume of the filled nitrogen tetroxide bulb was found from the volume of water displaced by it and the inner volume of the broken bulb was determined after the completion of an experiment by running in water from a buret. The difference between the two gives the volume of glass in the bulb. The volumes of the side arms A and A' were obtained at the end of the run by inverting the flasks and filling the arms to the marks B and B' from a buret.

A second apparatus using 500-cc. flasks connected by 20-mm. tubing was also used. No difference could be detected in the results obtained with the different apparatus. The larger connecting tube decreased the time necessary for complete diffusion of the two gases.

The gas for the right-hand flask was prepared and stored over concentrated sulfuric acid in a two-liter flask with a three-way stopcock. When the gas was needed, the stopcock was sealed to the filling tube A'. The inorganic stopcock lubricant described by Stephens[6] was used. It was prepared by heating a mixture of 85% phosphoric acid and metaphosphoric acid to 300°.

The two flasks of known volume are sealed to the center piece and the whole clamped in position. After setting in the hammer, the flasks are dried and evacuated thoroughly and the zero points of the diaphragms are determined. A bulb of known volume containing a weighed amount of nitrogen tetroxide is dropped in through A and the left-hand flask evacuated thoroughly while being heated with a luminous flame to drive out adsorbed water. It is then sealed off at A and the side arm A' is sealed to the gas holder and evacuated through the three-way stopcock, while the flask is heated. Some gas is allowed to enter the flask and then it is re-evacuated; finally it is filled with gas to approximately the desired pressure and sealed off. The nitrogen tetroxide bulb is broken, the apparatus immersed in the thermostat, and the pressure in the two flasks determined. The separating bulb is then broken and the pressures determined at intervals until there is no further change, showing that diffusion has been complete and equilibrium has been reached. The flasks are next opened to the atmosphere and the zero points re-determined. The broken center piece is cut off at E and E' and the volumes of the arms A and A' and of the nitrogen tetroxide bulb determined. After sealing in a new central piece the apparatus is ready for a second determination.

The apparatus was completely immersed in a large water thermostat the temperature of which was kept constant to within 0.05" and measured with a calibrated thermometer. The closed-end manometer agreed with a standard barometer within 0.2 mm. and the glass diaphragm gave readings reproducible to within 1 mm. All manometer readings were corrected to 0°.

---

[6] Stephens, THIS JOURNAL, 57,635 (1930).

The nitrogen tetroxide was prepared by heating lead nitrate and condensing the gas in a flask containing phosphorus pentoxide, from which it was redistilled after several days into weighed bulbs, in the manner described by Daniels, Mathews and Williams.[6]

There was some possibility that this method of procedure might allow the nitrogen tetroxide to become contaminated with moisture, due to diffusion of air down the tube while being filled. To eliminate this uncertainty, several experiments were made with nitrogen tetroxide sealed off in the following manner. A tube of the shape shown in Fig. 2 was weighed, and the bulb *Q* filled with phosphorus pentoxide. Nitrogen tetroxide was now distilled into the bulb and the tube sealed off at R. The nitrogen tetroxide was allowed to dry for a few days and then distilled over into the right-hand arm, which was then sealed off at S. All the glass was then thoroughly cleaned and dried, and reweighed; the difference between the original and final weights gave the weight of nitrogen tetroxide sealed in the bulb. Experiments using this technique gave results in agreement with those of the simpler technique described in the reference, whence the conclusion was drawn that the simpler procedure was satisfactory.

Nitric oxide was prepared from sodium nitrite and sulfuric acid according to Noyes,[7] bubbled through sulfuric acid and stored over concentrated sulfuric acid in the gas holder.

Measurements of $N_2O_4 \rightleftarrows 2NO_2$.—In every experiment of this investigation liquid nitrogen tetroxide was weighed out and the pressure and volume of the gas were measured in the left-hand flask. In several experiments the right-hand flask was evacuated and a second determination of the dissociation constant was made at a lower pressure after breaking the connecting bulb.

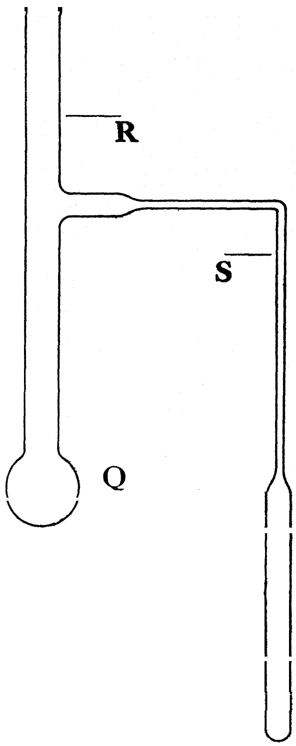

Fig. 2.

In all cases the dissociation constant, $K_{N_2O_4}$, was calculated from the formula

$$K_{N_2O_4} = \frac{4\alpha^2 P}{1 - \alpha^2}$$

where P is the measured pressure in atmospheres and α is the degree of dissociation as defined by the expression

$$\alpha = \frac{P - p^0_{N_2O_4}}{p^0_{N_2O_4}}$$

$p^0_{N_2O_4}$ is the pressure which would be exerted by undissociated nitrogen tetroxide, *i. e.*

$$p^0_{N_2O_4} = \frac{g}{M}\frac{RT}{V}$$

---

[6] Daniels, Mathews and Williams, "Experimental Physical Chemistry," McGraw-Hill Book Co., New York, 1929, p. 115.

[7] W. A. Noyes, This Journal, 47, 2170 (1925).

in which g is the weight of nitrogen tetroxide, *M* is the molecular weight, and R, T and V have their usual significance.

In these and all subsequent calculations a lower case *p* with subscript referring to the gas in question indicates the partial pressure of that gas; a superscript zero indicates the idealized pressure which the gas would exert if it did not dissociate nor react with other gases; and a capital P represents the total, measured pressure.

29.68	.9470	.2792	14520	1.0474	.5934	14700

The experimental results are summarized in Tables I and II and in Fig. **3.** In each case the ideal concentration, $C^0_{N_2O_4}$, is given assuming no dissociation. In Table I the values marked (*) were determined with the special drying precautions described above. The two marked (†) were obtained in the presence of 0.2608 and 0.2689 atmosphere of oxygen and the experiment marked ($) was made in the presence of 0.3643 atmosphere of carbon dioxide. These determinations are designated with triangles in Fig. **3.** In these experiments the right-hand flask was filled with the foreign gas before breaking the connecting bulb.

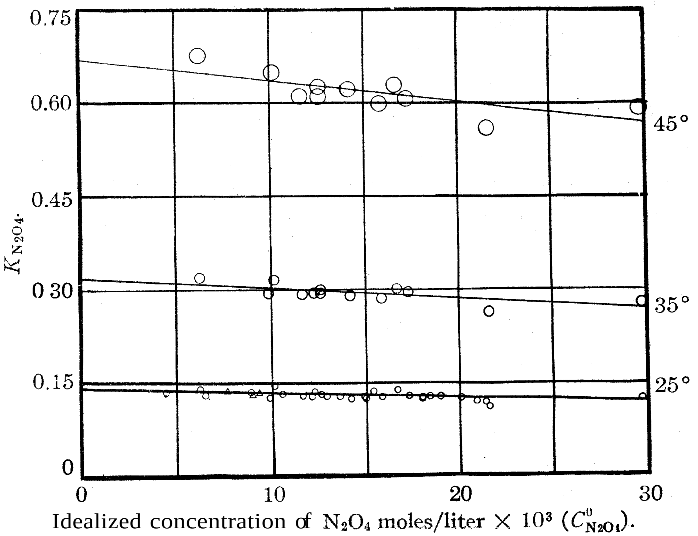

Fig. 3.

The calculation of the dissociation constant is such that an error of 1 mm. in the pressure measurements introduces a larger error in the value of the equilibrium constant at 45° than at 25° and the circles have been drawn larger. In each case the radius is a measure of the experimental accuracy.

The heat of dissociation, ΔH, as calculated from the van't Hoff equation

$$\log \frac{K_2}{K_1} = \frac{\Delta H\ (T_2 - T_1)}{2.303\ R\ T_2T_1}$$

is included for each experiment in Table II. Although the equilibrium constant is markedly affected at the higher pressures by the deviations from the perfect gas laws, the heat of dissociation remains nearly constant.

Measurements of $N_2O_3 \rightleftarrows NO_2 + NO$.—When nitrogen tetroxide expands into an evacuated space the resulting pressure is greater than that calculated by the ideal gas laws on account of the greater dissociation into nitrogen dioxide at the lower pressures. When it expands into an inert gas the partial pressures of nitrogen tetroxide and nitrogen dioxide are still the same as when expanding into an evacuated space, but when it expands into nitric oxide the pressures are smaller on account of the reaction

$$NO_2 + NO \rightleftharpoons N_2O_3$$

The calculation of the equilibrium constant for this reaction is complicated by the fact that as soon as nitrogen dioxide is used up more nitrogen tetroxide dissociates. However, the following relations between the partial pressures of the gases present must hold under any conditions

$$\begin{aligned} K_{N_2O_4} &= p_{NO_2}{}^2/p_{N_2O_4} \\ p^0_{NO} &= p_{NO} + p_{N_2O_3} \\ 2p^0_{N_2O_4} &= 2p_{N_2O_4} + p_{NO_2} + p_{N_2O_3} \\ P &= p_{N_2O_4} + p_{NO_2} + p_{NO} + p_{N_2O_3} \end{aligned}$$

At equilibrium, these four equations must be simultaneously satisfied. The four values on the left are experimentally measured quantities. $K_{N_2O_4}$ is the value of the equilibrium constant for the reaction

$$N_2O_4 \rightleftharpoons 2NO_2$$

obtained from the curves in Fig. **3** for the particular concentration of nitrogen tetroxide existing in the final volume, as calculated from the original weight of nitrogen tetroxide. **A** very slight approximation is being made here, because the concentration of nitrogen tetroxide will decrease on account of the formation of some nitrogen trioxide; the resulting change in K, however, will cause no change in the results within the experimental error. p^0_{NO} is the pressure which would be exerted by the original quantity of nitric oxide if present alone in the final volume. $p^0_{N_2O_4}$ is the pressure exerted by the original weight of nitrogen tetroxide if present alone and undissociated in the final volume. **P** is the total pressure as measured at the end of the experiment.

Solving these four equations simultaneously

$$\begin{aligned} p_{NO_2} &= \frac{-K_{N_2O_4} + \sqrt{K^2_{N_2O_4} + 4K_{N_2O_4}(P - p^0_{NO})}}{2} \\ p_{NO} &= 2P - p^0_{N_2O_4} - p^0_{NO} - p_{NO_2} \\ p_{N_2O_3} &= p^0_{NO} - p_{NO} \end{aligned}$$

whence $K_{N_2O_3}$ can be calculated from

$$K_{N_2O_3} = \frac{p_{NO} \times p_{NO_2}}{p_{N_2O_3}}$$

The results are shown in Tables III, IV and V and in Fig. 4, in which the values of $K_{N_2O_3}$ are plotted against the concentration of nitrogen trioxide assuming no dissociation; that is against $C^0_{N_2O_3}$ where

$$C^0_{N_2O_3} = 1/2(p_{NO_2} + p_{NO} + 2p_{N_2O_3})\,\frac{1}{RT}$$

In the determination of $K_{N_2O_3}$ there is a large accumulation of errors such that the experimental error amounts to about 10%. The curves for the three different temperatures are plotted on different scales, such that the radius of the circles drawn around the points represents in each case the experimental error.

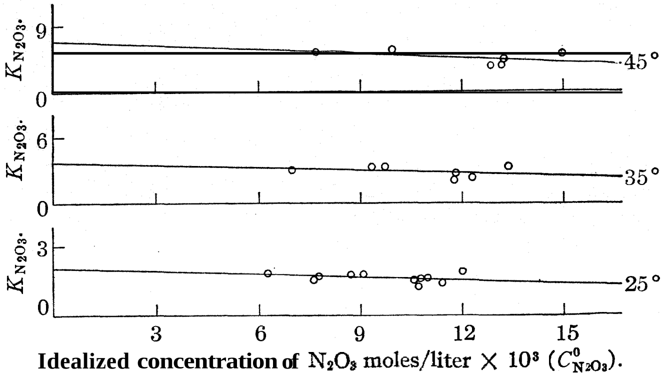

Fig. 4.

The data and calculations for the first experiment in Table III are given to illustrate the details of the method. Here the weight of nitrogen

tetroxide introduced into the left-hand flask was 1.2798 g., the volume of the flask was 1.1042 liters, the pressure, P, at 25°, 299.6 mm. From these data, $K_{N_2O_4}$ is calculated.

$$p^0_{N_2O_4} = \frac{1.2798 \times 0.08206 \times 298}{92.02 \times 1.1042} = 0.3080$$

$$\alpha^2 = \left(\frac{P - p^0_{N_2O_4}}{p^0_{N_2O_4}}\right)^2 = \left(\frac{\frac{299.6}{760} - 0.3080}{0.3080}\right)^2 = 0.0783$$

$$K_{N_2O_4} = \frac{4\alpha^2}{1 - \alpha^2}P = \frac{4 \times 0.0783}{0.9217} \times 0.3942 = 0.1340$$

$$C^0_{N_2O_4} = \frac{1.2798}{92.02 \times 1.1042} = 12.59 \times 10^{-3}$$

The volume of the right-hand flask was 1.1254 liters and the pressure of nitric oxide in it was 276.2 mm. The final pressure measured at equilibrium after breaking the connection was 294.0 mm. From these data and those above, $K_{N_2O_3}$ is calculated as follows.

$$p^0_{NO} = \frac{276.2}{760} \times \frac{1.1254}{(1.1254 + 1.1042)} = 0.1834$$

$$C^0_{N_2O_4} = \frac{1.2798}{92.02 \times 2.2296} = 6.236 \times 10^{-3}$$

From an equation given below for the curve in Fig. 3

$$K_{N_2O_4} = 0.1426 - 0.7588 \times 6.236 \times 10^{-3} = 0.1379$$

$$p^0_{N_2O_4} = \frac{1.2798}{92.02} \times \frac{0.08206 \times 298}{2.2296} = 0.1525$$

$$P = \frac{294.0}{760} = 0.3868$$

These values for $p^0_{N_2O_4}$, p^0_{NO}, P, and $K_{N_2O_4}$ are to be substituted in the solutions of the simultaneous equations already given, to give

$$p_{NO_2} = \frac{-0.1379 + \sqrt{(0.1379)^2 + 4 \times 0.1379(0.3868 - 0.1834)}}{2} = 0.1122$$

$$p_{NO} = 2 \times 0.3868 - (2 \times 0.1525 + 0.1834 + 0.1122) = 0.1730$$

$$p_{N_2O_3} = 0.1834 - 0.1730 = 0.0104$$

$$K_{N_2O_3} = \frac{0.1122 \times 0.1730}{0.0104} = 1.87$$

$$C^0_{N_2O_3} = 1/2(0.1122 + 0.1730 + 2 \times 0.0104)\frac{1}{0.08206 \times 298} = 6.27 \times 10^{-3}$$

Discussion

The number of independent measurements at a single temperature is sufficiently great to permit reliable calculations of the influence of pressure on the equilibrium constants. The three curves of Fig. 3 are reproduced by the following equations obtained by the method of least squares.

TABLE VI

$N_2O_4 \rightleftharpoons 2NO_2$

Temp, °C.	Equilibrium constants ($C^0_{N_2O_4}$ = total weight/92 02 X volume in liters)
25	$K_p = 0.1426 - 0.7588 \times C^0_{N_2O_4}$
35	$K_p = .3183 - 1.591 \times C^0_{N_2O_4}$
45	$K_p = .6706 - 3.382 \times C^0_{N_2O_4}$

The idealized equilibrium constants extrapolated to zero pressure are 0.1426 at 25°, 0.3183 at 35° and 0.6706 at 45°. These values are important for they give the equilibrium constants for perfect gases and the laws of thermodynamics may be applied with exactness. They correspond to values obtained with fugacities or activities rather than pressures. Then

$$-\mathrm{AF}^{\circ} = RT \ln K_p$$

and $\Delta F^{\circ}_{298} = 1154$ calories, $\Delta F^{\circ}_{308} = 700$ calories and $\Delta F^{\circ}_{318} = 252$ calories. AF° is the increase in free energy necessary to convert one mole of nitrogen tetroxide at a fugacity of 1 atmosphere into 2 moles of nitrogen dioxide at a fugacity of 1 atmosphere. From the free energy of formation of nitrogen dioxide[8] the free energy of formation of 1 mole of nitrogen tetroxide from nitrogen and oxygen at 25° and 1 atmosphere is 23,836 calories.

The heat of dissociation, *AH*, calculated from the values of the equilibrium constant extrapolated to zero pressure gives from 25–35° 14,670 cal., from 35–45" 14,530 cal. The entropy change, *AS*, may be calculated from the equation

$$AF = \mathrm{AH} - T\Delta S$$

using the average value of the heat of dissociation AH = 14,600. *AS* is constant over this range of temperature and equal to 45.1 entropy units.

The values of the equilibrium constant are somewhat lower than those calculated for corresponding pressures from the equations of Bodenstein.[1]

By weighing out the samples of nitrogen tetroxide, a more direct evaluation of the amount of material present is obtained than by the method of Bodenstein, who determined the concentration of nitrogen dioxide from the pressures existing at temperatures in the neighborhood of 150°, making corrections for the nitrogen tetroxide and nitric oxide and oxygen present at those temperatures. Further, this communication reports a large number of separate determinations made on different samples of

[8] "International Critical Tables" ("revised" data of Randall and White), McGraw-Hill Book Co., Inc., New York, Vol. VII, 1930, p. 239.

tetroxide, whereas Bodenstein used one original sample and obtained results at lower pressures by progressively removing portions of this original material from the reaction flask. On the other hand, Bodenstein's manometer was more sensitive and the temperature range studied was considerably greater.

The decrease in the equilibrium constant with increase in pressure is due to the deviation of the gases from the ideal gas laws. Although the critical data for the gases are inaccessible to experimental measurement, it is reasonable to assume that they are similar to those of sulfur dioxide, which has a structure somewhat like that of nitrogen dioxide and a boiling point near that of nitrogen tetroxide. Assuming that the mixture of gases in the reaction vessel acts like sulfur dioxide, as far as its non-ideal properties are concerned, it is possible to idealize the total pressure and recalculate α and $K_{N_2O_4}$. Using Berthelot's equation of state and the critical data of sulfur dioxide ($T_c = 430°K.$ and $P_c = 78$ atm.), the values of $K_{N_2O_4}$ calculated from the idealized pressures agree with those obtained by extrapolating to zero pressure.[9]

In spite of the fact that the change of K with pressure seems to be explained by the deviation of nitrogen tetroxide and nitrogen dioxide from the gas laws, there was a further possibility that it might be due to increased adsorption of the gases on the glass walls at higher pressures, complicated by a preferential adsorption of the nitrogen tetroxide over the nitrogen dioxide. From the start it seemed unlikely that the decrease of K could be explained in this way, because calculation showed that at a concentration of 0.030 mole/liter, the unlikely amount of 0.037 g. of material would have to be adsorbed in the liter flask at 25° in order to account for the drop from K = 0.1426 at zero concentration to K = 0.1198 at a concentration of 0.030 mole/liter. To investigate this point, scales of Pyrex glass made by breaking up thin bulbs, with a total surface at least twice as great as the inner surface of a flask, were put into a U-tube, covered with water overnight in order partially to etch the surface, dried by heating in a stream of dry air, and then weighed. Liquid nitrogen tetroxide was poured into the tube, the liquid allowed to evaporate and the U-tube re-weighed. An increase in weight of only 0.0013 g. was observed. In another experiment, gaseous nitrogen tetroxide was passed through the weighed U-tube; no increase in weight could be detected.

---

[9] The fact that one constituent of the gas mixture may show a deviation from the gas laws different in degree from that of the other does not alter this result. Any idealization whatsoever must increase the total pressure and, consequently, the degree of dissociation; the equilibrium constant is thus increased in every case, in spite of the fact that, as is probably true, a greater correction is to be applied to nitrogen tetroxide than to nitrogen dioxide. The assumption made above is that the combined effect of the deviations of the two gases is such as to give a resultant non-ideality, over the temperature range in consideration, like that of sulfur dioxide.

Finally, glass scales having an area over twenty times as great as that of the inner surface of a liter flask, were treated overnight with chromic acid, washed and dried. A regular determination of the equilibrium constant with this extra glass in the apparatus showed that any adsorption of nitrogen tetroxide or nitrogen dioxide is entirely negligible.

The fact that inert gases such as oxygen and carbon dioxide do not affect the equilibrium constant is of interest in kinetics. The decomposition of nitrogen tetroxide is probably unimolecular and its formation is a bimolecular reaction. If a large increase in the number of collisions affects either reaction more than the other, the equilibrium constant should be shifted. However, no influence of this kind was found.

An interesting observation regarding diffusion was made during the course of the experiments. When the nitrogen tetroxide'in the left-hand flask was allowed to expand into a vacuum the equilibrium was reached quickly. When the right-hand flask was filled with a gas, such as oxygen, carbon dioxide or nitric oxide, twenty hours or more were necessary to insure complete mixing of the gases. The rate of diffusion was determined qualitatively by observing the decrease in red color in the left-hand flask and its increase in the right-hand flask. It was measured more quantitatively by observing the pressure increase on standing. As the nitrogen tetroxide diffuses to regions of lower concentrations it dissociates to a greater extent and increases the total pressure. In many experiments involving the mixing of gases there is no simple indicator to tell when the mixing is complete. With a smaller connecting tube or with a stopcock in the tube, the rate of mixing would be very much lower.

The curves of Fig. 4 are reproduced by the following equations obtained by the method of least squares.

TABLE VII

$N_2O_3 \rightleftharpoons NO_2 + NO$

Temp., °C.	Equilibrium constants
25	$K_p = 2.105 - 45.63\ C^0_{N_2O_3}$
35	$K_p = 3.673 - 78.11\ C^0_{N_2O_3}$
45	$K_p = 6.880 - 196.4\ C^0_{N_2O_3}$

The heat of dissociation calculated from the van't Hoff equation between 25 and 35" is 10,160 at zero concentration (from extrapolated values of K) and 10,310 at a concentration of 15 X 10^{-3} moles per liter. Calculating between 35 and 45" the heat of dissociation is 12,210 at zero concentration and 8820 at a concentration of 15 × 10^{-3}. From the constancy of the value of $\Delta H_{(25-35°)}$ as the pressure changes and from analogy with the results on nitrogen tetroxide, it seems likely that the variation of $\Delta H_{(35-45°)}$ is due to experimental error. At 45° the errors are considerably magnified and the number of determinations is rather small.

The curve is probably slightly too steep. An average of the four values gives A H = 10,300.

The free energies changes are as follows:

$$\Delta F^\circ_{298} = -441 \qquad \Delta F^\circ_{308} = -796 \qquad \Delta F^\circ_{218} = -1218$$

and using the data of "International Critical Tables," Vol. VII, p. 238, for the free energy of formation of nitric oxide and nitrogen dioxide, the free energy of formation of nitrogen trioxide from its elements is 33,805 calories.

The values of the equilibrium constant check only fairly well with those of Abel and Proisl.[3] For example, at 25° the value of K extrapolated to zero concentration from their curve and translated into the notation used in this communication gives 1.43 as against the value of 2.10 given here.

The straight line relation between $C_{N_2O_3}$ and $K_{N_2O_3}$ seems definitely to indicate that this reaction is actually

$$NO + NO_2 \rightleftarrows N_2O_3$$

No other reaction gives a smooth straight line. If the equilibrium constant is calculated from

$$2NO + 2NO_2 \rightleftarrows N_4O_6$$

the "constant" varies greatly with pressure, even though fairly regularly. If the reaction is considered to be

$$N_2O_4 + 2NO \rightleftarrows 2N_2O_3$$

the equilibrium "constant" shows wide and irregular variations. If the calculations are made from

$$N_2O_4 + 2NO \qquad N_4O_6$$

the "constant" is very irregular.

It is believed that the results of the present investigation show that the dissociation of nitrogen tetroxide is correctly represented by the equation $N_2O_4 \rightleftarrows 2NO_2$ and that the dissociation of nitrogen trioxide is correctly represented by the equation $N_2O_3 \qquad NO + NO_2$. Within the limits of experimental accuracy recorded here it may be concluded that no other oxides of nitrogen are present in appreciable amounts in the partially dissociated gases.

Summary

1. The dissociation constant for gaseous nitrogen tetroxide has been measured at 25, 35 and 45° with special reference to the influence of pressure. The dissociation constant is directly proportional to the pressure and is about 13% greater at 0.1 atmosphere than at 1 atmosphere.

2. The presence of inert gases such as oxygen and carbon dioxide has no effect upon the dissociation constant in the above reaction.

3. The dissociation constant for gaseous nitrogen trioxide has been measured with an all-glass apparatus at 25, 35 and 45° at different pressures.

4. The value of the equilibrium constant is not affected by any adsorption on the glass walls.

5. The influence of pressure on the equilibrium constants can be attributed to deviations from the simple gas laws.

6. The true equilibrium constants for thermodynamical calculations have been determined by extrapolation to zero pressure. Calculations are given for ΔF, ΔH and ΔS.

7. The measurements indicate that the dissociations proceed according to the reactions $N_2O_4 \rightleftharpoons 2NO_2$ and $N_2O_3 \rightleftharpoons NO + NO_2$.

THE DIELECTRIC PROPERTIES OF ANTIMONY PENTACHLORIDE AND PHOSPHORUS PENTACHLORIDE[1]

BY J. H. SIMONS AND GILBERT JESSOP

RECEIVED JANUARY 14, 1931 PUBLISHED APRIL 6, 1931

The dielectric properties of antimony pentachloride and phosphorus pentachloride were studied in the hope of adding some information on which to consider the structure of these compounds.

The apparatus used has been described by Lowry and Jessop.[2] The materials used were carefully purified. The carbon tetrachloride was treated with chlorine and allowed to stand in sunlight for several days. It was dried with freshly fused calcium chloride and distilled. The antimony pentachloride was distilled three times in a vacuum and kept sealed in glass. It had a very light color and a sharp melting point. The phosphorus pentachloride used to make the solutions was contained in a small sealed glass vessel into which it had been distilled in vacuum.

In order to test out the apparatus, the dielectric constant of pure dry carbon tetrachloride was determined in it over a range of temperatures. These values and also the molar polarizations calculated from them are given in Table I. These agree very well with published data.[3] Pure benzene and chloroform were used to calibrate the cell. The densities

were determined with calibrated quartz floats by the method described by Lowry and Jessop.[4]

The Molar Polarization of Antimony Pentachloride and Phosphorus Pentachloride in Solution in Carbon Tetrachloride.—The density and capacity of these solutions were determined over a range of temperatures. The results are given in Tables II and III together with the molar polarizations calculated from them by means of the modified Clausius and Mosotti eauation[6]

$$P_{12} = \frac{\epsilon - 1}{\epsilon + 2}\,\frac{M_1f_1 + M_2f_2}{\rho} = P_1f_1 + P_2f_2$$

As the molar polarizations of both antimony pentachloride and phosphorus pentachloride show no appreciable deviation with temperature, it can be assumed that if these molecules have a dipole moment, it must be very small. Only a very dilute solution of phosphorus pentachloride could be made, as the solubility is low. The precision of the molar polarization calculated from the capacity of the solution is, therefore, not very high.

TABLE II

MOLAR POLARIZATION OF ANTIMONY PENTACHLORIDE IN SOLUTION IN CARBON TETRACHLORIDE

The Dielectric Constant of Antimony Pentachloride.—This was determined over a range of temperature, the values being given in Table IV. The molar polarization was calculated from these measurements by means of the Clausius and Mosotti equation. This equation has been used previously for pure non-polar liquids, and so its use in this case is probably justified. These values agree well with those obtained from the capacity measurements of the carbon tetrachloride solution.

[5] Debye, "Polar Molecules," The Chemical Catalog Co., Mew York, 1929, p. 45.

TABLE IV

DIELECTRIC CONSTANT AND MOLAR POLARIZATION OF ANTIMONY PENTACHLORIDE

Temp., °C.	Dielectric constant	Density, g./cc.	Molar polarization, cc.
0.0 crystal	3.3		
2.6 liquid	3.307	2.387	54.1
17.6	3.220	2.356	53.7
19.8	3.222	2.352	53.8
20.9	3.212	2.349	53.7
30.0	3.173	2.331	53.5
38.4	3.136	2.314	53.5
47.2	3.103	2.296	53.4

The Dielectric Constant and Conductivity of Phosphorus Pentachloride.—The dielectric constant of phosphorus pentachloride was found to be as follows: crystal material at 135°, 4.2, and the liquid under pressure at 165°, 2.7. The conductivity of this compound was also measured with the following results

	Specific conductivity
Liquid at the melting point	6×10^{-9} reciprocal ohms
Crystal at 100°	3×10^{-8} reciprocal ohms
Crystal at 20°	3.3×10^{-7} reciprocal ohms

Discussion

The dielectric constant of the crystalline phosphorus pentachloride being greater than for the liquid is a result that is both interesting and unusual. If we apply the method of Errera,[6] which uses the dielectric constant of the solid to determine P_0, in order to calculate the electric moment, we shall have negative values, for $P - P_0$ will be negative. This makes the use of the method of Errera doubtful, for if it is certain that it cannot be used in this case, then its use in any other case is questionable.

A possible explanation for this result is that the crystal forces distort the molecule and increase the polarization, the molecule being symmetrical and without dipole moment in the liquid state. The conductivity measurements also indicate this, for the liquid has a lower conductivity than the crystalline material. The doubt that this casts upon the method of Errera is that molecules of other compounds may be more or less distorted when crystallized.

The zero or very small dipole moment of these compounds suggests a symmetrical structure. This is definitely in favor of a ten electron shell for the central atom with the five chlorine atoms attached by the five electron pairs. The polar formula, $SbCl_4^+Cl^-$, is definitely ruled out and grave doubts are cast on the structure advanced by Prideaux[7] in which three of the chlorine atoms arc held by electron pairs and two held by single

---

[6] Debye, "Polar Molecules," p. 53.

[7] Prideaux, *Chem. & Ind.*, 42, 672 (1923).

electrons. Only one structure on this basis could give zero dipole moment and that one would have the three electron pairs in a plane with the two single electron bonds at right angles to this plane. Doubt is cast on this structure from three directions. The substance is diamagnetic, and it is difficult to see how two unpaired electrons on opposite sides of the central atom could neutralize each other's magnetic fields. The molecules dissociate readily to give the trichloride and chlorine, which may indicate that, if there are two chlorine atoms held differently than the other three, they should be adjacent. Chemical reactions such as the hydrolysis with water to form the oxychloride also indicate the same. The double molecule formula, $SbCl_3 \cdot Cl_2$, is ruled out by the vapor density measurements, which show $SbCl_5$ to exist in the gas phase.

Summary

The molar polarizations of antimony pentachloride and phosphorus pentachloride have been measured in carbon tetrachloride solutions and the dipole moments concluded to be either zero or very small.

The dielectric constants of antimony pentachloride and phosphorus pentachloride have been measured for both liquid and crystalline states.

The specific conductivity of phosphorus pentachloride has been measured.

Antimony pentachloride and phosphorus pentachloride are assumed to have a symmetrical structure with a ten electron shell for the central atom.

THE ENTROPY AND FREE ENERGY OF METHANE[1]

BY H. H. STORCH[2]

RECEIVED JANUARY 15, 1931 PUBLISHED APRIL 6, 1931

Introduction

In a recent publication[3] C. G. Maier reported a discrepancy of about five entropy units between the entropy of methane as calculated by way of low temperature specific heat data and the third law of thermodynamics, and that obtained from Randall and Gerard's[4] and Randall and Mohammad's[5] work on equilibria in the reactions

$$CO_2 + 4H_2 = CH_4 + 2H_2O \qquad (I)$$

$$C + 2H_2 = CH_4 \qquad (II)$$

[5] Randall and Mohammad, *ibid.*, 21, 1048 (1929).

In view of the numerous reactions involving methane in which the U. S. Bureau of Mines Experiment Stations are interested, it was considered desirable to recalculate the entropy of methane using the recent measurements of Clusius[6] on the specific heat of methane in the temperature range 10.33–105.3°K.; and to revise the calculations of Randall and his collaborators, using a recent experimental value of the heat of combustion of methane, the specific heat equations given by Eastman[7] for hydrogen, carbon dioxide and water, and for methane the data given by Eucken and Lüde[8] for the temperature range 297.7–481.2°K. ,

Entropy of Methane from Specific Heat Data.—The entropy data given in Table I were obtained by using the data of Clusius,[6] the approximate Debye equation for the range 10.33–0.00°K., the heat of vaporization of liquid methane as calculated from the vapor pressure measurements of Keyes, Taylor and Smith,[9] and finally the equation $C_p = 5.90 + 9.60 \text{ X } 10^{-3}T$ given by Eastman[7] in the range 111.8–298.1°K.

In employing the approximate Debye equation, $C_v = 12\pi^4 N \text{ kT}^3/50^3$, the value of Θ used was that given by Clusius. In the range 10.33–111.8°K. the specific heat curve was extrapolated to cover the region under the cusp in the vicinity of 20.4°K., the entropy of transition at the latter temperature being calculated from the value for the heat of transition as given by Clusius.

Recalculation of Entropy and Free Energy of Methane from Equilibrium Measurements.—The specific heat equations given in Table II were used in recalculating the entropy and free energy of methane, using Randall and co-workers'[4,5] data. The equations are all of the form $C_p = a + bT + CT^2$.

[6] Clusius, Z. *physik. Chem.*, [Abt. *B*] 3, 41 (1929).

[7] Eastman, U. S. Bureau of Mines Technical Paper 445 (1929).

[8] Eucken and Liide, *Z. physik. Chem.*, [Abt. *B*] 5, 436 (1929).

[9] Keyes, Taylor and Smith, J. *Math. Phys., Mass. Inst. Tech.*, 1, 191–212 (1922). determined the vapor pressure of methane and the densities of the coexisting phases, whence by. use of the Clapeyron equation they calculate the heat of vaporization to be 123 cal./g. or 1968 cal./mole at the boiling point (given by them as 111.52° K.), and 2104 cal./mole at the triple point (89.98° K.). The latter figure is in excellent agreement with a calculation based on the vapor pressure of solid methane in the range 76.89–87.25°K. as obtained by Karwat, *Z. physik. Chem.*, 112, 486 (1924)] and by Freeth and Verschoyle [*Proc. Roy. Soc.* (London), A130, 453 (1931)] in the range 64.78–90.66°K.; and on the heat of fusion as given by Clusius.[6] The heat of vaporization of solid methane calculated from Karwat's measurements is 2326 cal./mole, and combining this with 224 cal./mole for the heat of fusion (at 90.6°K.) given by Clusius, the value 2102 cal./mole is obtained for the heat of vaporization of liquid methane in the vicinity of the melting point. This figure checks that of Keyes, Taylor and Smith within 0.1%. It appears therefore that the datum 1968 cal./mole calculated by the latter authors for the heat of vaporization at the boiling point is to be preferred to 2075 cal./mole calculated from the data of Stock, Henning and Kuss [*Ber.*, 54, 1119 (1921)]. However, it would be very desirable to obtain an accurate redetermination of the heat of vaporization.

TABLE I

ENTROPY OF METHANE FROM SPECIFIC HEAT DATA

Temp. range, °K.	Transition points, and form of methane	Entropy units	Authors of specific heat data
0-10.33	Solid	0.36	Debye equation
10-111.8	Solid A–Solid B at 20.4°K. AH = 18.1 cal./mole	0.89	Clusius
	Heat of fusion at 90.6°K. = 224.0 cal./mole	2.47	Clusius
	Specific heat 10.33–111.8°K.	14.55	Clusius
111.8	Heat of vaporization = 1968 cal./mole	17.60	Keyes, Taylor and Smith
111.8–298.1	Gas	7.52	Eastman
Total		43.39	

TABLE II

C_p EQUATIONS

Substance	a	$b \times 10^3$	$c \times 10^6$	Reference to authors
Graphite	1.22	4.89	−1.11	Eastman[10]
H_2	6.85	0.28	0.22	Eastman[7]
H_2O	8.22	0.15	1.34	Eastman[7]
CO_2	7.70	5.30	−0.83	Eastman[7]
CH_4	4.38	14.17	0.00	Euken and Lüde[8]

A recent determination[11] of the heat of combustion of methane yielded the value 212,728 cal, at 25°, which is in good agreement with the figure chosen by Lewis and Randall.[12] This value combined with 94,250 cal. for the heat of combustion of graphite at 25°, and 68,270 cal. for the heat of formation of liquid water at 25°, yields 18,062 cal. for the heat of formation of methane. Using this figure and the equilibrium constants determined by Randall and Gerard,[4] the following free energy equation for reaction I was obtained

$$AF = -35578 + 14.28T \ln T - 4.03 \times 10^{-3}T^2 - 0.44 \times 10^{-6}T^3 - 51.0T \quad \text{(III)}$$

This equation yields $\Delta F_{298.1} = -26912$ cal/mole. Combining this datum with the free energies of carbon dioxide and of water,[10] *viz.*, $\Delta F_{298.1,\ CO_2} = -93{,}647$ and $\Delta F_{298.1,\ H_2O_{(g)}} = -54{,}467$, the free energy of methane is found to be $\Delta F_{298.1,\ CH_4} = -11{,}625$. Hence, substituting in the equation AF = AH − TAS, −11,625 for AF and −18,062 for ΔH, the entropy change (AS) at 25° is found to be −21.60 entropy units. Using the figures 1.3 and 31.23 for the entropies of graphite[12] and of hydrogen gas,[13] respectively, the entropy of methane is calculated to be 42.16 units at 25°.

[13] W. F. Giuque, THIS JOURNAL, 52, 4816 (1930).

There is no scarcity of data on direct measurements of equilibrium in reaction II. These data are thoroughly reviewed by Randall and Mohammad[5] and by Egloff, Schaad and Lowry.[14] Despite the number of experimenters and the relatively large amount of data available, in no case is a sufficiently complete analysis of the equilibrium mixture described which would indicate with certainty the presence or absence of hydrocarbons other than methane, . For this reason, the accuracy of the equilibrium constants reported for reaction (II) is not readily determinable. In fact, it is probable that the entropy and free energy of methane as calculated from direct equilibrium measurements are not as reliable as the figures obtained by way of low temperature specific heat measurements. Recalculating the data given by Randall and Mohammad[5] for reaction (11), using the specific heat data of Table II, and the value of $\Delta H_{298.1,\ \mathrm{CH_4}} = -18{,}062$ cal./mole, the free energy of methane is found to be $\Delta F_{298.1,\ \mathrm{CH_4}} = -12{,}542$ cal./mole; whence, using the values of the entropies of carbon and hydrogen previously cited, the entropy of methane at 298.1°K. is 45.26 units. This value is 1.87 entropy units higher than that obtained from Clusius[6] specific heat data, and 3.10 units higher than that yielded by Randall and Gerard's[4] data on reaction (I).

Using the value 43.39 units for the entropy of methane, the specific heat data of Table II, and —18,062 cal./mole for AH,,,,,, $\mathrm{CH_4}$, the following free energy equation for methane is obtained

$$AF = -15{,}313 - 10.54T \ln T - 4.36 \times 10^{-3}T^2 - 0.11 \times 10^{-6}T^3 - 47.6T \qquad \text{(IV)}$$

Summary

The entropy of methane at 25° as calculated from Clusius' recent low temperature specific heat measurements is 43.39 units. By calculation from equilibrium measurements for the reactions $CO_2 + 4H_2 = CH_4 + 2H_2O$ and $C + 2H_2 = CH_4$, using Eastman's revision of the specific heat equations of carbon, hydrogen, water and carbon dioxide, the measurements of Eucken and Lüde of the specific heat of methane in the range 297.7–481.2°K., and a recently determined (by the U. S. Bureau of Standards) experimental value of the heat of combustion of methane, the figures 42.16 and 45.24 entropy units, respectively, were obtained. The value 43.39 entropy units as calculated from specific heat measurements is close to the average of the two data calculated from equilibrium measurements and is considered to be the most reliable estimate available at present. A free energy equation for methane based on this entropy figure is presented.

CALCIUM OXALATE FROM CALCIUM CYANAMIDE

BY GEORGE BARSKY AND G. H. BUCHANAN

RECEIVED JANUARY 16, 1931 PUBLISHED APRIL 6, 1931

The hydrolysis of calcium cyanamide to ammonia and calcium carbonate is a well-known industrial chemical reaction. The hydrolysis of alkali and alkaline earth cyanides to ammonia and salts of formic acid is also familiar. The reactions, expressed in their simplest form, are shown in the equations

$$CaCN_2 + 3H_2O = 2NH_3 + CaCO_3 \qquad (1)$$
$$Ca(CN)_2 + 4H_2O = 2NH_3 + Ca(COOH)_2 \qquad (2)$$

The present paper describes a new reaction, namely, that when a mixture of cyanamide and cyanide is subjected to alkaline hydrolysis there is formed in addition to carbonate and formate, a substantial amount of oxalate, the reaction being expressed by the equation

$$2CaCN_2 + Ca(CN)_2 + 10H_2O = 6NH_3 + 2CaC_2O_4 + Ca(OH)_2 \qquad (3)$$

In a previous communication[1] the present authors discussed the reaction in which cyanamide is converted to dicyandiamide. It was there shown that, confirming the conclusions of Grube and Krüger,[2] this polymerization is a reaction between cyanamide ions and cyanamide molecules and that, consequently, the rate of the reaction is a function of the hydrogen-ion concentration. It was shown that theoretical considerations require that this rate be at a maximum at P_H 9.6, and this calculated value for the optimum hydrogen-ion concentration was confirmed by experiment. The dicyandiamide-forming reaction is represented by the equation

$$NHCN^- + NH_2CN = NHCNHNHCN^-$$

Turning to the behavior of the second component of the reaction mixture, namely, hydrocyanic acid, we have another compound whose polymerization is known to be influenced by hydrogen-ion concentration. Although no quantitative data on the subject are available, it is known that solutions of hydrocyanic acid which have been slightly acidified are stable almost indefinitely. Solutions made strongly alkaline, *i. e.*, solutions of sodium cyanide containing no free hydrogen cyanide, are also stable. On the other hand, solutions of hydrocyanic acid made faintly alkaline polymerize rapidly, depositing brown flocks of the so-called azulmic compounds. We have at present under way an investigation of the polymerization of hydrocyanic acid in aqueous solution which is expected to show that this polymerization, like the polymerization of cyanamide, is also essentially a reaction between ion and molecule.

---

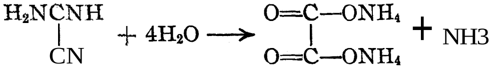
[1] Buchanan and Barsky, THIS JOURNAL., 52,195 (1930).

[2] Grube and Krüger, *Z. physik.* Chem., 85, 65 (1913).

That a reaction of the same type takes place between cyanamide and cyanide is shown in the present paper. This reaction may perhaps be represented by the equation

$$H_2NCN + HCN \longrightarrow H_2NCNH{-}CN$$

This hypothetical intermediate was not isolated; it hydrolyzes readily to form ammonium oxalate according to the equation



$$\begin{matrix} H_2NCNH \\ | \\ CN \end{matrix} + 4H_2O \longrightarrow \begin{matrix} O{=}C{-}ONH_4 \\ | \\ O{=}C{-}ONH_4 \end{matrix} + NH3$$

The existence of the intermediate is shown by the fact that mixtures of cyanamide and cyanide allowed to react at 50° in the absence of lime salts must be boiled with hydrochloric acid before precipitating the oxalate if concordant results are to be obtained. When the boiling is omitted, irregular, low results are obtained.

The reaction described may be considered to be a sort of mixed polymerization. Just as cyanamide, given the proper conditions of hydrogen-ion concentration, reacts with itself to give dicyandiamide, and hydrocyanic acid reacts to give the brown azulmic bodies, so can cyanamide and hydrocyanic acid react with each other, this reaction also being influenced by the hydrogen-ion concentration of the solution in which it takes place.

Experimental Part

During the course of experimental work on the autoclaving of the crude calcium cyanide made by fusion of crude calcium cyanamide and salt, it was observed that, in addition to calcium formate, traces of calcium oxalate were always produced. When pure cyanides were autoclaved, no oxalate was obtained, During the attempt to run down the source of this oxalate it was recalled that the crude calcium cyanide contained small amounts of cyanamide; it was then discovered that the autoclaving of mixtures of calcium cyanide and calcium cyanamide greatly increased the production of oxalate. No oxalate is produced when calcium cyanamide is autoclaved alone.

TABLE 1

RESULTS OF EXPERIMENTS

Mixture, run no.		Weight used in grams	Grams $Ca(COOH)_2 \cdot H_2O$ in cake
1	Crude calcium cyanide	25.0	0.025
2	Calcium cyanamide	31.5	None
3	Crude calcium cyanide	25.0	9.12
	Calcium cyanamide	31.5	
4	Crude calcium cyanide	25.0	3.91
	Dicyandiamide	10.4	
5	Sodium cyanide (97%)	12.6	3.66
	Dicyandiamide	10.4	

In the first experiments the solids were stirred up in 150 g. of water and the mixture was autoclaved for two hours at 75 pounds' steam pressure. The mixture was then filtered and the cakes analyzed for oxalate. In the case of mixture No. 5 where no lime was present, calcium chloride was added to precipitate the oxalate.

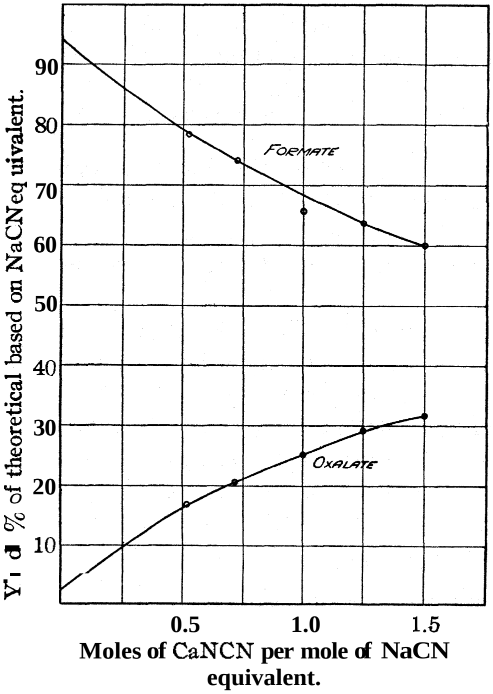


Fig. 1.—Effect of mole ratio on yield.

It is seen that dicyandiamide as well as cyanamide yields oxalate when autoclaved with a cyanide.

Continuing the experiments with crude calcium cyanide and calcium cyanamide, various mixtures of the reactants were autoclaved. The experimental procedure consisted in mixing the solids with water and autoclaving for two hours at 75 pounds' steam pressure. Upon removal from the autoclave the mixtures were filtered and calcium oxalate was determined in the filter cakes.

The results are given in Table II, where the amounts of oxalate found are reported and the yields of oxalate from cyanide are calculated on the assumption of reaction according to Equation 3. The data are also shown graphically in Fig. 1.

The crude calcium cyanide used contained approximately 48.5% $Ca(CN)_2$; the calcium cyanamide, 59.6% $CaCN_2$.

The total yield of oxalate and formate is less than 100% in all cases,

Table II

Experimental Data

Crude $Ca(CN)_2$, g.	Calcium cyanamide, g.	H_2O, cc.	Molar ratio CaNCN/NaCN[a]	$CaC_2O_4 \cdot H_2O$ formed G.	$CaC_2O_4 \cdot H_2O$ formed Yield on NaCN, %	$Ca(COOH)_2$ formed G.	$Ca(COOH)_2$ formed Yield on NaCN, %	Yield, total, %
25.0	15.8	150	0.52	6.08	16.8	12.7	78.5	95.3

25.0	39.4	150	1.25	10.55	29.2	10.3	63.7	92.9
25.0	47.3	150	1.48	11.33	31.3	9.7	60.1	91.4

[a] For convenience we use % NaCN equivalent instead of % $Ca(CN)_2$.

partly if not entirely because of loss of hydrocyanic acid by volatilization and by azulmic formation. The oxalate yield cannot be accounted for if we assume it is derived from cyanide alone or from formate alone. The increasing yield of oxalate with increasing amounts of cyanamide added is additional proof that cyanamide takes part in the reaction.

Effect of Hydrogen-Ion Concentration.—The data show that the oxalate yield based on cyanide increases as the amount of calcium cyanamide used is increased. The reasons for this are apparent if the previous work on the polymerization of cyanamide is recalled. The *P*H of a filtered solution of the reaction mixture is 9.8, which is very near the optimum *P*H for dicyandiamide formation. In other words, we are dealing with competing reactions, one involving dicyandiamide formation and the other the formation of the complex which eventually decomposes to form oxalate. The experiments given in Table I show that the oxalate yields from cyanide and dicyandiamide are low,

This suggested that the reaction be conducted at a *P*H less favorable to dicyanadiamide formation and led to an attempt to investigate the effect of hydrogen-ion concentration upon the oxalate forming reaction by following its course in buffered solutions. The technique of these experiments was the same as that employed in our study of the polymerization of cyanamide.[1]

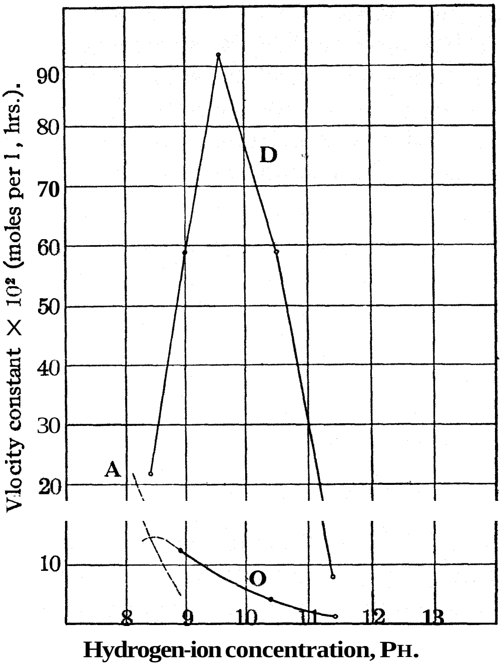

Fig. 2.—Effect of hydrogen-ion concentration. A, azulmic; D, dicyandiamide; O, oxalate; temp., 50° C.

The study proved very difficult, particularly in solutions of lower alkalinity than *P*H 9. The solutions discolored badly due to azulmic formation and there were large losses of hydrocyanic acid by vaporization. The data obtained are therefore only approximate and are presented with this qualification. The results are shown in Fig. 2. The curve for dicyandiamide is taken from our work on cyanamide.[1] The heavy portions of the oxalate curve represent out best experimental data; the broken portions present the less accurate values.

It is apparent from these data that little can be done toward increasing the yield by conducting the experiments at higher or at lower *P*H's than the normal PH of the reaction mixtures. At higher *P*H's cyanide is stable but dicyandiamide formation is rapid. At lower *P*H's cyanide is lost by azulmic formation. At *P*H's at which oxalate formation is most rapid it is accompanied both by dicyandiamide formation and by azulmic decomposition. The reason is, of course, that the ionization constants of hydrocyanic acid and of cyanamide are so nearly alike that it is impossible to have cyanide ions in the presence of cyanamide molecules without having hydrocyanic acid molecules and cyanamide ions present as well.

That reduction of the PH is right in theory was also shown by a few experiments in which calcium chloride was added to the reaction mixture. The purpose was to reduce the PH to a more favorable value by reducing the solubility of calcium hydroxide to which the alkalinity of the solution is due. The results are given in Table III.

TABLE III

25 *g*. of crude calcium cyanide; 31.5 g. of calcium cyanamide; 150 cc. of water; 2 hours at 75 pounds' pressure

[a]	0	...	...	..	25.0
1	11.7	48.24	21.33	10.3	28.5
2	35.0	55.13	21.78	12.0	33.1

[a] From Table II.

The practical significance of this moderate increase of oxalate yield by the addition of calcium salts is derived from the fact that the solutions obtained by the autoclaving of mixtures of cyanamide and cyanide contain large amounts of formate which is formed from that part of the cyanide which does not react with cyanamide. The return of this solution to a succeeding autoclave charge is practical and was adopted as regular procedure.

Stage Addition of Cyanamide.—The results of some preliminary experiments indicated that small concentrations of cyanamide were more effectively employed in the reaction with cyanide, presumably because less of other products were formed from the cyanamide. That is, the reaction of cyanamide to form dicyandiamide is accelerated by increased concentration to a greater extent than is the formation of oxalate. By keeping the concentration of cyanamide low, that is, by continuous addition of calcium cyanamide, we should expect a higher oxalate yield from a given amount of cyanamide than if the cyanamide were all added at once. This method of adding the cyanamide was followed in experiments described below.

Mixtures were digested for six hours at 60 and 80° in a constant temperature bath. The mixtures were stirred continuously during the digestion. Four samples were run at each temperature.

Twenty-five grams of crude calcium cyanide was added in each case to 150 cc. of water heated to the temperature at which the digestion was to be carried out. They were then placed in the water-bath and the stirrers started. To one pair of the mixtures 31.5 g. of calcium cyanamide was added immediately. To the second pair the 31.5 g. of calcium cyanamide was added in twelve equal portions at half-hour intervals.

At the end of six hours' digestion, one of each pair of mixtures was analyzed directly. The two remaining samples were autoclaved for two hours at 75 pounds' pressure.

During the preliminary digestion some cyanide was lost due to volatilization of hydrogen cyanide formed by hydrolysis.

Table IV

25.0 g of crude calcium cyanide; 31.5 g. of calcium cyanamide; 150.0 cc. of water

Digestion			Subsequent to six hours' digestion	Cake, g.	% in cake	Calcium oxalate	
Time, hours	Temp., °C.	Addition of calrium cyanamide				Grams total	% yield on NaCN
6	60	All at start	Not autoclaved	45.04	13.16	5.92	16.3
6	60	Continuous[a]	Not autoclaved	42.99	14.56	6.25	17.3
6	60	All at start	Autoclaved	46.45	18.42	8.57	23.7
6	60	Continuous	Autoclaved	49.40	20.67	10.22	26.3
6	70	All at start	Not autoclaved	46.50	13.50	6.28	17.4
6	70	Continuous	Not autoclaved	44.86	17.88	8.01	22.2
6	70	All at start	Autoclaved	47.07	19.90	9.36	25.9
6	70	Continuous	Autoclaved	46.80	24.26	11.38	31.4
6	80	All at start	Not autoclaved	44.23	16.20	7.29	20.1
6	80	Continuous	Not autoclaved	46.19	22.30	10.30	29.2
6	80	All at start	Autoclaved	47.53	19.46	9.25	26.3
6	80	Continuous	Autoclaved	48.04	24.12	11.80	32.9

[a] The continuous addition of cyanamide refers to the addition of small portions of calcium cyanamide at half-hour intervals.

Application.—Although the percentage yield of oxalate from cyanide by this process is low, it does not follow that the process is without commercial value. Where cyanamide is being autoclaved for ammonia production the addition to the autoclave of small amounts of cyanide, itself produced from cyanamide in a previous operation, is not impractical. All of the nitrogen of both compounds is liberated as ammonia and recovered, and a part of the carbon of both compounds is converted into valuable by-products. The autoclave solids ordinarily thrown away may be treated by a comparatively simple process and the valuable calcium oxalate separated from the excess of calcium carbonate with which it is associated. Return of the autoclave solution to a subsequent operation provides the excess of soluble calcium salts which has been shown to have a favorable influence on the reaction.

The process above described is protected by U. S. Patent No. 1,717,353, assigned to the American Cyanamid Company. The thanks of the authors

are due to this company for permission to publish these results, and to Mr. K. D. Ashley for his cooperation in the work.

Summary

A reaction not previously reported has been found to take place between cyanamide and cyanide, resulting in the formation of an intermediate compound which can be hydrolyzed to oxalate. The velocity of this reaction is dependent' on hydrogen-ion concentration.

Autoclaving calcium cyanide and calcium cyanamide with water produces calcium carbonate, calcium oxalate and a solution of calcium formate. Replacing the water with calcium formate solution results in increased yields of oxalate.

ZIRCONIUM. II. ZIRCONIUM OXALATE AND DIPHENYLDINITROGEN ZIRCONIUM

BY HOWARD S. GABLE

RECEIVED JANUARY 19, 1931 PUBLISHED APRIL 6, 1931

Zirconium Oxalate

The fact that an insoluble precipitate was obtained upon the addition of oxalic acid or ammonium oxalate to solutions of zirconyl salts has been known since 1820. Since that time a number of investigations have been made concerning various compounds containing zirconium and the oxalate group, but so far as can be determined there seems to have been no success when efforts were made to obtain the normal zirconium oxalate $Zr(C_2O_4)_2$. The marked success with which the author has prepared other normal zirconium compounds in methyl alcoholic solutions suggested that the oxalate might be prepared in a similar manner.

A methyl alcoholic solution of zirconium tetrachloride was treated with a methyl alcoholic solution of oxalic acid. A reaction took place at once with the formation of a white gelatinous precipitate. This was filtered off, washed, dried and analyzed.

Anal. **Calcd. for $Zr(C_2O_4)_2$: Zr, 34.80. Found: Zr, 35.08.**

The two figures are close enough together to establish the identity of the compound.

The effects of a number of common solvents were observed. They are given below in table form. It is worthy of note that the normal zirconium oxalate is quite soluble in water, quite contrary to what might be expected from the literature, since the basic salts investigated by other workers are noted for their insolubility.

Diphenyldinitrogen Zirconium

The formation of a precipitate upon the addition of aniline to a solution of a zirconium salt has been reported by Alice M. Jefferson.[1] She states that the addition of aniline is accompanied almost immediately by a separation of a beautiful white gelatinous precipitate. The results indicated that the reaction was quantitative. No analytical results as to the composition were given.

Mathews[2] had reported a few years earlier on the formation of an addition compound between aniline and zirconium tetrachloride when aniline was added to an ethereal solution of the zirconium compound. This was a gray precipitate corresponding to the formula $ZrCl_4 \cdot 4C_6H_5NH_2$.

The object of this investigation was to repeat the work by Jefferson, to determine the composition of the precipitate, and to carry out the reaction in methyl alcoholic solution.

An investigation proved that the precipitates obtained in alcoholic and water solutions were identical. The work carried out in methyl alcoholic solution is given below.

An excess of aniline was added to a dilute solution of zirconium tetrachloride in methyl alcohol, and the mixture allowed to stand for several days. On examination a voluminous precipitate was found which was filtered off and washed with methyl alcohol. The filtrate contained an excess of hydrochloric acid, showing that a replacement and not addition reaction had taken place. After drying the precipitate for some time it was analyzed.

Anal. Calcd. for $(C_6H_5N)_2Zr$: Zr, 33.37; N, 10.25. Found: Zr, 33.34; N, 10.40.

These figures indicate that the reaction took place according to

$$2C_6H_5NH_2 + ZrCl_4 \longrightarrow C_6H_5N{=}Zr{=}NC_6H_5 + 4HCl$$

The solubility of the diphenyldinitrogenzirconium was observed in a number of solvents. These are given below with the solubilities of the oxalate.

Solvent	$Zr(C_2O_4)_2$	$(C_6H_5N)_2Zr$
CCl_4	Insoluble	Insoluble
CS_2	Insoluble	Insoluble
C_2H_5OH	Insoluble	Insoluble
CH_3OH	Insoluble	Insoluble
NH_4OH	Insoluble	Insoluble
HCl	Insoluble	Insoluble
$C_6H_5NH_2$	Slightly soluble	Insoluble
HCOH	Reaction	Reaction
H_2O	Very soluble	Insoluble
CH_3COOH	Slightly soluble	Insoluble
$(CH_3)_2CO$	Slightly soluble	Insoluble
HNO_3	Insoluble	Soluble

The reaction was quantitative.

Summary

1. The use of methyl alcoholic solutions allows compounds of zirconium to be prepared without danger of hydrolysis.

2. The normal zirconium oxalate, $Zr(C_2O_4)_2$, was prepared and described.

3. Diphenyldinitrogen zirconium, $(C_6H_5N)_2Zr$, was prepared and described.

THE DIELECTRIC CONSTANT OF HYDROGEN CHLORIDE FROM 85 TO 165°K.

BY RICHARD M. CONE, GEORGE H. DENISON AND JACOB D. KEMP

RECEIVED JANUARY 23, 1931 PUBLISHED APRIL 6, 1931

A consideration of the motions of molecules in crystals has led Pauling[1] to conclude that in certain cases there is complete rotation of the molecules at temperatures below the melting point. He also points out that the transition from a condition in which most of the molecules undergo small oscillations about equilibrium orientations, to one in which they rotate completely, may take place over a very small increase of the oscillational quantum number.

Transitions in the solid hydrogen halides involving the absorption of considerable amounts of heat have been reported by Eucken and Karwat[2] and measured accurately by Giauque and Wiebe.[3] The transition in hydrogen chloride[3a] is perfectly isothermal at 98.36°K., and requires 284.3 calories per mole. Pauling associates such transitions with the taking up of rotational energy.

Whenever the molecules of highly polar substances, such as the hydrogen halides, are free to rotate, those substances must have a high dielectric constant. If the transition in hydrogen chloride at 98.36°K. has produced free rotation of the molecules, then the dielectric constant of the solid should increase considerably at that temperature, in accordance with Pauling's prediction. The purpose of this work was to determine whether or not such an increase occurs.

Apparatus and Experimental Procedure

Hydrogen chloride, prepared by allowing C. P. concentrated sulfuric acid to drop on C. P. sodium chloride, was condensed by liquid air. After

boiling off the product at atmospheric pressure and warming the container to room temperature, there was no evidence of moisture. From this result we concluded that the hydrogen chloride was sufficiently dry for our purpose.

The method of measuring the dielectric constants was similar to that employed by Zahn.[4] A Hartley oscillator, kept at a constant frequency of about 3000 kilocycles, was coupled capacitatively from the plate coil to the grid of a single circuit radio receiver which used two stages of audio frequency amplification. A second Hartley oscillator, tuned by a "Precision" standard condenser of the General Radio Company in parallel with the dielectric cell, was loosely coupled to the first; it was sufficient to have the oscillators a meter distant from one another without electrical connection. UX 201-A tubes were used throughout.

The dielectric cell consisted of two concentric copper cylinders, about 18 mm. in diameter and 90 mm. long, with a capacity in air of 42$\mu\mu$f. The construction is apparent from Fig. 1, which is drawn to scale. At the conclusion of our experiments the cell showed no evidence of corrosion.

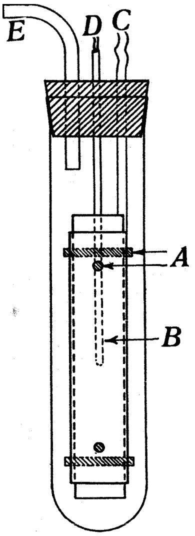

Fig. 1.—A, glass spacers; B, thermocouple tube; C, condenser leads; D, thermocouple leads; E, filling tube.

The solid hydrogen chloride obtained by condensation in liquid air was allowed to melt, and the dielectric cell was immersed in the liquid. The container was closed and the liquid frozen around the condenser. Since freezing began at the outside and at the bottom, and since there was a considerable depth of liquid above the condenser, any cracks formed in the process were probably filled by liquid flowing in from above.

A copper–constantan thermocouple made of wire calibrated in this Laboratory[5] was given us by Professor W. F. Giauque, and was used with a Leeds and Northrup Type K potentiometer for all temperature measurements.

The apparatus shown in Fig. 1 was suspended within a cylindrical lead block of 10 kg. mass, and the whole placed in a Pyrex Dewar flask containing liquid air. A tight cover was fitted to the Dewar flask, and the temperature was lowered to 83°K. by boiling the air at reduced pressure. The liquid air was then sucked out and the apparatus allowed to warm slowly. As a consequence of the large heat capacity of the lead, the temperature rose only about three degrees an-hour at 85°K.; accordingly, except from 95 to 107°K., dry air was blown in to warm the apparatus at the rate of about ten degrees an hour.

[4] Zahn, *Phys. Rev.*, 24, 400 (1924).

[5] Giauque, Buffington and Schulze, THIS JOURNAL, 49, 2343 (1927).

With one oscillator at constant frequency, the other, without the dielectric condenser, was tuned by the standard condenser until the beat note came to zero frequency. The dielectric cell was then switched in parallel with the standard condenser and the latter retuned until the beat note again became inaudible. The difference between the two settings of the standard gives the capacity of the dielectric cell; the ratio of the capacity of the dielectric cell in hydrogen chloride to its capacity in air is recorded as the dielectric constant of hydrogen chloride. Simultaneous readings were taken of temperature and capacity.

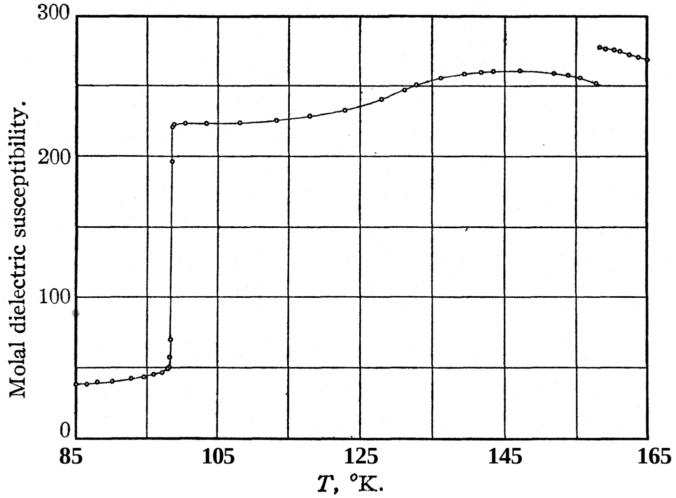

Fig. 2.—Molal dielectric susceptibility of hydrogen chloride.

The accuracy of the temperatures is ±0.1°K., except above 150°K., where an accident to the thermocouple made the accuracy no greater than ±0.4°K. The absolute accuracy of the dielectric constants is probably no better than ±2%, as a consequence of the small capacity of the dielectric cell in air, but variations in the dielectric constant could be followed much more accurately. Of the 135 measurements made, the 40 given in Table I serve to establish the curve of Fig. 2; the deviation of the others from the curve is no greater than that of those shown in the figure.

Results

In Table I are listed for each value of the temperature: D, the dielectric constant; D − 1, which we may call the dielectric susceptibility; $(D-1)M/d$, the molal dielectric susceptibility, where M is the molecular weight and d the density; and P, the polarizability, equal to $(D-1)M/(D+2)d$. In Fig. 2, molal dielectric susceptibility is plotted against T. Values for the density of the liquid are given by the formula d = 1.270 −

0.00276 T, according to Baumé and Perrot.[6] The density of the solid is given by Simon and Simson[7] as 1.469 g./cc. at 107°K. Though the use

of this value for the density at the freezing point is questionable, it is the only reliable one above the transition. A better value may alter the break in the curve at the melting point. This value was also used below the transition, as it is unlikely that the contraction of the solid drew more hydrogen chloride between the plates.

Discussion of Results

The isothermal nature of the change in dielectric constant at 98.4°K. (Table I shows that the change is practically complete over 0.2°K.) was to be expected from the isothermal nature of the transition reported by Giauque and Wiebe[3a] at the same temperature. The suggestion was made by Giauque and Wiebe in reference to hydrogen iodide[3'] that the excitation of only a few molecules may render the low temperature crystal lattice unstable, and that energy is absorbed at the transition to effect a change to a new crystalline form in which another degree of freedom is permitted. If the rotational energy in this new form is sufficiently small, a large fraction of the molecules may take up rotation during the transition. That the higher specific heat above the transition may be due in part to the taking up of this rotational degree of freedom is borne out by the gradual rise in the dielectric constant of the solid between 105 and 150°K. We may conclude from the small change in D on melting that in the solid near the melting point the molecules are rotating almost as freely as in the liquid.

The dielectric constant of the liquid decreases regularly with rising temperature; extrapolation of our curve to 183°K. confirms the value 8.85 found for that temperature by Schaefer and Schlundt.[8] Although our values for the liquid cover too short a range of temperatures to permit the application of Debye's equation, they seem to be in general accord with his theory of dipoles.[9]

We wish to acknowledge our indebtedness to Professor W. F. Giauque for his helpful suggestions in regard to this work.

Summary

The dielectric constant of solid hydrogen chloride has been measured from 85°K. to the melting point, and that of the liquid from the melting point to 165°K. The molal dielectric susceptibility and polarizability have been computed. At 98.4°K., the transition temperature, the dielectric constant changes isothermally from 3 to 10, a behavior which is in accord with Pauling's theory of the rotation of molecules in crystals.

APPLICATIONS OF CERIC SULFATE IN VOLUMETRIC ANALYSIS. IX. THE STANDARDIZATION OF THIOSULFATE SOLUTIONS. DETERMINATION OF THIOSULFATE

BY N. HOWELL FURMAN AND JOHN H. WALLACE, JR.

RECEIVED JANUARY 24, 1931 PUBLISHED APRIL 6, 1931

Introduction

It has been demonstrated that ceric sulfate solutions **0.5–3** N in sulfuric acid are stable for long periods of time (at least a year) if prepared from rare earth oxide mixture of suitable grade.[1] Having a standardized ceric sulfate solution available it is desirable to know whether such a solution may be used for checking the normality of a standard thiosulfate solution in the same manner that bichromate or permanganate solution may be used.[2] Ceric ion is reduced readily and completely by iodide ion, and the equivalent quantity of iodine that is liberated may be titrated with thiosulfate in the usual manner. Several investigators[3] have shown that such a process is tedious to carry out experimentally, apparently because the oxidation of hydriodic acid by air is catalyzed by cerous salts. This error may be minimized or eliminated by working with solutions freed from air, in an inert atmosphere (Martin[3]). We have studied this method of standardization of thiosulfate and have found that the presence of a small quantity of ferric ion in the ceric solution causes an additional error which may be minimized by adding a small quantity of phosphoric acid in order to render the ferric ions inactive. In view of all of these complications, we have studied an alternative method which has proved to be excellent.

This alternative method consists in the titration of a measured volume of the thiosulfate solution with ceric sulfate. Direct titration in the absence of iodide is far from stoichiometric, because of the effect of the acid which must be present in the ceric solution, and probably because of the nature of the reaction between ceric and thiosulfate ions as well.[4] If a suitable

[4] Benrath and Ruland found that the direct reaction proceeded approximately according to the equation: $2Na_2S_2O_3 + 2Ce(SO_4)_2 = Ce_2(SO_4)_3 + Na_2SO_4 + Na_2S_4O_6$

amount of iodide is added to the thiosulfate solution, and *if the initial volume is made sufficiently large, disturbing effects are eliminated,* and the titration may be made rapidly and simply to the starch–iodine end-point. The same method of titration may of course be applied to the determination of thiosulfate.

At the start of the titration there is visible liberation of iodine about the entering drops of ceric sulfate, but the iodine is consumed rapidly by the thiosulfate and the blue starch–iodine color does not appear even temporarily if the solution is well stirred until the concentration of thiosulfate is greatly diminished near the end-point.

The reaction $2Ce^{++++} + 2I^- = 2Ce^{+++} + I_2$ proceeds almost instantaneously so that the oxidation of the thiosulfate is effected by the normal reaction: $I_2 + 2S_2O_3^= = 2I^- + S_4O_6^=$. Under these conditions direct interaction of ceric and thiosulfate ions plays a negligible role.

Experimental

The ceric solutions were prepared by dissolving commercial rare earth oxides in sulfuric acid, filtering and diluting to 0.1 N oxidizing power and 1–2 N sulfuric acid concentration.[5] The solutions were standardized against Bureau of Standards sodium oxalate, either potentiometrically or by the iodine monochloride catalytic method of Willard and Young.[5,6]

0.1 N Iodine and thiosulfate solutions were prepared in the usual manner and standardized against Bureau of Standards arsenious oxide, and resublimed iodine, respectively, using starch indicator.[7]

Use of Standard Ceric Sulfate to Determine the Normality of Thiosulfate

Method 1.—The ceric solution was pipetted into a solution containing an excess of potassium iodide; the iodine was titrated with thiosulfate. When air was not excluded, errors of the following magnitudes were found: cc. of approx. 0.1 *N* thiosulfate calcd.. 28.39; cc. found, 28.61–28.81. The end-point was not permanent, nor even moderately stable. If the air is displaced with carbon dioxide, and if no phosphate is present, the error is smaller, but not negligible. For example, we found 28.61, 28.49, 28.51 cc. of thiosulfate; calcd., 28.39 cc. Much better results are obtained if phosphoric acid is added to combine with the iron, the air of course being excluded by carbon dioxide. The solutions were prepared by mixing 60 cc. of potassium iodide solution (20 g. per liter), 25 cc. of sulfuric–phosphoric acid mixture (150 cc. of each of the concentrated acids per liter), and 25 cc. of ceric sulfate, after air had been expelled from the solution: calcd., 23.87 cc.; found, 23.90, 23.92 cc. Under these conditions no ceric phosphate is

---

[*Z. anorg. allgem. Chem.*, 114, 267 (1920)]. Our experiments indicate a larger consumption of ceric sulfate per mole of thiosulfate.

[5] Procedure of Willard and Young, THIS JOURNAL, 50, 1322 (1928); 51, 149 (1929). and Furman and Evans, *ibid.*, 51, 1128 (1929).

[6] Furman, *ibid.*, 50, 755 (1928).

[7] The details given by Kolthoff, "Volumetric Analysis," Vol. II, Chap. XII, were followed carefully.

precipitated. Previous experience of one of us (F.) had shown that with pure ceric solutions no phosphoric acid is necessary: calcd., 16.58 cc.; found, 16.60, 16.60 cc.

Our experience is, therefore, in agreement with that of others in finding the method to be accurate if proper precautions are observed. We believe that it is much more tedious and no more accurate than the following one.

Method 2.—Measured volumes of thiosulfate solution are added to a suitable mixture of potassium iodide, starch solution and water and are titrated directly to the starch–iodine end-point with standard ceric sulfate. If the initial volume of the solution is large enough, the acid and the iron which are present in the ceric sulfate solution do not interfere.

There is a lower limit of iodide concentration for any given set of conditions. For example, with an initial volume of 125 cc., containing 25 cc. of approximately 0.1 *N* thiosulfate and 20 cc. of starch (2 g. starch per liter), the following values were found

KI present, g..	0.8	0.4	0.16	0.128	0.08	0.08	0.08
$Ce(SO_4)_2$ soln., cc..	23.42	23.40	23.41	23.43	23.56	23.50	23.55

Correct values (23.41 cc.) were found down to 0.128 g. of potassium iodide. We therefore recommend that at least 0.15 g. of the iodide be present per 125 cc. of initial volume.

Erratic results are obtained if the initial volume of the solution is too small. The summary of results and conditions that is given in Table I will show the magnitude of the errors when the volume is too small.

NOTE: Determinations 13–17 were made with different ceric and thiosulfate solutions from the others.

A series of determinations with 25 cc. of thiosulfate and initial volumes of 200–300 cc. gave results of 22.01, 22.00, for the 0.0956 *N* solution, and 25.44, 25.46, 25.47 for another solution for which the calculated value was 25.45 cc. If 25 cc. of thiosulfate is used, accurate results are found with initial volumes of 100–300 cc. Note, however, the large errors that result when the volume is 50 cc. (Nos. 4 and 5, Table I). When 50 cc. of thiosulfate is used, the initial volume must be about 500 cc. in order to avoid erratic results (Nos. 15–17, Table I). The error disappears somewhere between an initial volume of 400 and one of 500 cc. If the initial volume is as low as 100 cc. with 50 cc. of thiosulfate taken, errors as large as 0.7 to 1.7 cc. may result. We attribute the erratic values to decomposition of thiosulfate by the acid from the ceric solution, followed by oxidation of the sulfurous acid by either iodine or ceric sulfate. It is possible that the ferric iron (about 1 mg. per 25 cc.) which is present in the ceric solution may cause error when the acidity is high (small initial volume), but we have invariably observed the error to be in the opposite direction to that which would be caused by the iron, and in extreme cases to be three or four times as great as the maximum possible effect of the iron. In general, it appears to be wise to make the initial volume at least 10 times the volume of the thiosulfate used.

The correctness of the method was tested in a preliminary fashion by standardizing both iodine and ceric solutions directly against 25-cc. portions of 0.1000 N arsenious oxide solution prepared from Bureau of Standards arsenious oxide. The normality of the thiosulfate was then determined by titration with the iodine and ceric solutions, respectively.

Standardization of *Ceric* Solution.—Twenty-five cc. portions of arsenite required: 22.67, 22.75, 22.75, 22.68, 22.75, 22.73, 22.77 cc.; average 22.73 cc. equivalent to normality of 0.1100.

Iodine Solution.—Twenty-five cc. of arsenite required: 25.57, 25.58, 25.53, 25.52 cc., average 25.55 cc. Normality 0.0978 (4). Normality of thiosulfate, assuming ceric to be correct: 0.0957, 0.0954, 0.0958, 0.0957, average 0.0957. Normality of thiosulfate assuming iodine to be correct: 0.0958, 0.0959, 0.0960, 0.0959, average 0.0959.

The standardization of ceric sulfate against arsenious oxide was made by Willard and Young's procedure.[8] They found that this procedure gives results about 3 parts per 1000 lower than those found with electrolytic iron or sodium oxalate as a primary standard. Our work was done before the appearance of Swift's paper in which he states that correct results may be obtained in 4 N hydrochloric acid solution with iodine monochloride catalyst: We applied no correction to our results, but if such correction were applied the ceric normality would be 0.1103 and hence the two methods would agree to about 1 part per 1000. Unfortunately, no oxalate standardization of the ceric sulfate solution which we used for this work was made.

A more rigorous check on the fundamental correctness of our-method of standardizing thiosulfate was made with weight buret technique. The Friedman and La Mer type of buret was used and found to be eminently satisfactory.[10]

STANDARDIZATION OF CERIC SULFATE AGAINST BUREAU OF STANDARDS SODIUM OXALATE

	1	2	3	4	5
$Na_2C_2O_4$, g.	0.2047	0.2471	0.2457	0.2116	0.2744
Ceric soln., g.	31.655	38.189	37.977	32.650	42.409
Weight normality	0.09659	0.09657	0.09657	0.096'74	0.09657
				Average,	0 09661 N

Nos. 1, 2, 4 and 5 were made by the iodine monochloride method of Willard and Young;[5] No. *3* was titrated in hot solution containing 20 cc. of concd. hydrochloric acid per 100 cc. Nos. 1–3 were separately weighed samples of oxalate, and Nos. 4 and 5 were weighed aliquot portions of a weighed solution of 1.1270 g. of oxalate.

STANDARDIZATION OF THIOSULFATE AGAINST RESUBLIMED IODINE[11]

	1	2	3	4
Iodine, g.	0.3741	0.6186	0.3379	0.5248
Thiosulfate soln., *g*.	29.787	49.236	26.879	41.736
Weight normality	0.09895	0.09899	0.9905	0.09907
			Average	0.09901 N

TITRATION OF THIOSULFATE WITH CERIC SULFATE

	1	2	3	4	5
Initial vol., cc.	300	300	300	300	500
(1) Thiosulfate soln., g.	20.172	21.924	19.455	18.747	40.252
(2) Ceric soln., g.	20.650	22.452	19.903	19.201	41.184
Ratio [(2)/(1)]	1.0237	1.0241	1.0231	1.0242	1.0231
				Average	1.0236

In Nos. 1–4, 2 g. of potassium iodide, and in No. 5, 4 g. of potassium iodide were present. In each case 20 cc. of 0.2% starch solution was present.

Hence the normality of the thiosulfate found indirectly is 0.09961 X 1,0236 = 0.09889 as contrasted with the directly determined value of 0.09901. The method, therefore, appears to be quantitative to better than 2 parts per 1000 (1.2 parts); the discrepancy between the direct and indirect values is of the same order of magnitude as that of the uncertainty regarding the purity of the sodium oxalate (one part per thousand according to the Bureau of Standards).

Potentiometric Method.—A number of experiments were made potentiometrically; these will not be described in detail. It was found that in the presence of iodide a very small jump in potential, Pt vs. N calomel electrode (about 0.01 volt per 0.05 cc. of 0.1 N ceric sulfate), occurred at the end-point of the reaction. The iodine–starch end-point is much superior in this case.

In the absence of iodide there is no definite potentiometric end-point; no fairly stable high e. m. f. (0.8–0.9 volt, Pt vs. N calomel electrode) is

---

[11] The iodine was kept until needed in a stoppered vessel in a desiccator over anhydrous barium perchlorate ("desicchlora"). The lid of the desiccator was not greased.

developed until about a 25% excess of ceric sulfate has been added; the potential is not constant, indicating further reaction. The direct interaction of ceric and thiosulfate ions appears to be rather slow, and the thiosulfate is in part decomposed (by acid) with formation of sulfurous acid (odor of sulfur dioxide).

Determination of **Thiosulfate.**—It is possible to determine thiosulfate in solutions or in salts by titration with standard ceric solution, if potassium iodide is present.

Recommended Procedure.—If approximately 0.1 N ceric solution is used: dissolve 0.5–0.7 g. of crystalline sodium thiosulfate (or an equivalent quantity of any other thiosulfate) in water, add 0.3 to 0.4 g. of potassium iodide, and starch solution (20 cc. of 0.2% solution), dilute to 250 cc. and titrate with ceric sulfate to the starch–iodine end-point.

Eleven students followed a procedure approximately as given in the preceding paragraph, although the importance of the initial volume–concentration relations was not fully realized at the time when this work was done. Working on clear crystals of uneffloresced sodium thiosulfate pentahydrate (Kahlbaum preparation), the following values were found: 63.69, 63.82, 63.90, 63.72, 63.53, 63.82, 63.30, 63.60, 63.61, 63.38, 63.52% $Na_2S_2O_3$ (calcd., 63.71%). In each case the value given is an average of two or more concordant determinations. The majority of the determinations (9 out of 11) are satisfactory.

A number of other possible applications of the use of iodide as a sort of "catalyst with known mechanism" in ceric sulfate oxidations are being studied in this Laboratory. In effect this method makes use of the iodide–iodine system not only as a catalyst but as an oxidation–reduction indicator (with the addition of starch) as well.

Summary

A standard ceric sulfate solution may be used to determine the normality of thiosulfate: (a) by liberating iodine from an iodide and titrating the former with thiosulfate. Air must be excluded, and ferric iron, if present in the ceric solution, must be rendered inactive by means of phosphate, (b) by titration of a mixture of thiosulfate, iodide and starch indicator with ceric sulfate. The initial volume should be ten times that of the thiosulfate used; 0.15 g. of potassium iodide should be present per 125 cc. of initial solution.

The reaction between ceric sulfate and thiosulfate, with intermediate action of iodide, has been shown to be stoichiometric at least to 1.2 part per thousand.

The reaction may be applied to the determination of thiosulfate.

REACTIONS OF HYDROGEN AND OXYGEN ON PLATINUM WIRES AT LOW TEMPERATURES AND PRESSURES

BY HERBERT G. TANNER AND GUY B. TAYLOR

RECEIVED JANUARY 24, 1931 PUBLISHED APRIL 6, 1931

Introduction

In an attempt to make a study of a well-defined surface for a simple catalytic reaction, pure platinum wire was chosen as the catalyst, and for the reaction, the combination of hydrogen and oxygen to form water vapor. Wire drawn through a series of agate dies is cryptocrystalline. If annealed at dull red heat, strain is removed, but the crystals are still very small. By heating to a temperature near the melting point crystals readily visible to the unaided eye are formed in the wire. A pure platinum wire 0.1 mm. in diameter and 2 meters long was heated by direct current in the air to dazzling white heat for ten minutes. Many single crystals, extending clear across the wire, were about one millimeter long. However, because of the variability in catalytic behavior of every specimen of wire used, it was not possible to establish any relationship between the activity of cryptocrystalline and macrocrystalline wires. Both kinds of wire behaved much alike. In studying these wires some unexpected observations were made and are here presented.

Apparatus

The apparatus was designed to work at a few microns' pressure and is sketched in Fig. 1. It was constructed of 15-mm. Pyrex tubing, except that in some experiments tube C was made of transparent silica attached to the train by a graded seal. The catalyst wire was mounted in tube C and supported by heavy tungsten wires sealed through the glass. These supports were glass-coated except at the tips, where the platinum was spot-welded to the tungsten. The platinum wire, 58 cm. long by 0.10 mm. in diameter (area 1.8 sq. cm.), was used either in the form of a spiral, or of hairpin loops similar in arrangement to the filament in a vacuum Mazda lamp. The distance from the

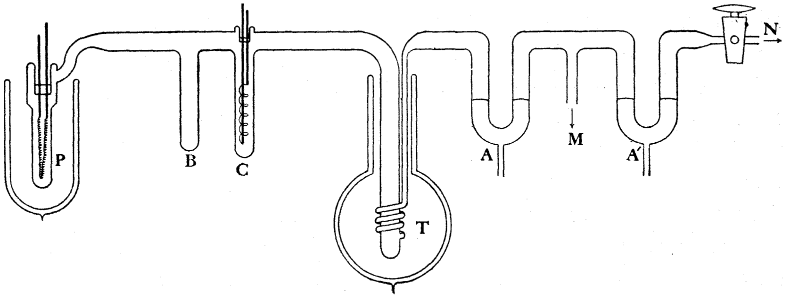

Fig. 1.—Apparatus: M, to McLeod gage; N, to pump and gas reservoirs.

wire to the wall of C was 3 to 4 mm., which is less than the mean free path of the molecules of the common gases at 10 microns' pressure.

The special form of Pirani gage[1] at P was capable of detecting the disappearance of 0.001 cu. mm. of gas, N. T. P., a quantity considerably less than that calculated to form a monomolecular layer of hydrogen on a surface area of one square centimeter. The trap at T was cooled with liquid air or solid carbon dioxide in methanol as occasion required. Mercury cut-offs, **A-A'**, were used instead of stopcocks, and between them was attached a McLeod gage, range 0.01 to 100 microns. The total volume A to P, was about 75 cc.

Prior to a series of experiments and sometimes prior to each experiment, the apparatus was thoroughly baked out by flaming until a vacuum was obtained so low as to be unreadable on the McLeod gage. A small Tesla discharge brushed over the glass parts was found to be very effective in hastening the release of gases from the walls.[2]

The catalyst wire in C was heated electrically by making it one arm of a Wheatstone bridge, and its temperature was calculated from its resistance. The Pirani gage was calibrated against the McLeod gage with pure oxygen, pure hydrogen and electrolytic gas ($2H_2:O_2$). All gases used were carefully purified and stored in glass bulbs sealed to the line beyond the stopcock shown in Fig. 1. The electrolytic gas was generated from potassium–barium hydroxide solution with nickel electrodes. No gas was collected until the generator was evolving a gas mixture in equilibrium with electrodes and solution. The sample collected, 20 cc. N. T. P., furnished all the aliquots used in several hundred experiments.

The usual procedure for determining catalytic activity was to exhaust the apparatus thoroughly, introduce the gas, close A' and read the pressure on both the Pirani and McLeod gages. Then **A** was closed, the wire heated and the pressure change followed with the Pirani gage.

Experimental Results

Nature **of** the Reaction.—In the earlier experiments the platinum wires were never at any time heated above 500°. With electrolytic gas complete clean-up was seldom obtained, pure hydrogen being left when the reaction stopped. Figure 2 shows a typical rate curve with the wire at 90° and the tube wall at room temperature. In common with curves for many other experiments, there is an induction period at the start. This is followed by a section of curve which bends more and more pronouncedly in the opposite direction, not reaching zero pressure as demanded by theory if electrolytic gas reacted quantitatively to form water. The general shape of the curve shows that the catalytic formation of water on platinum is not a simple process.

When an equimolar mixture of hydrogen and oxygen was used, the clean-up was frequently as high as 90% instead of the 75% demanded by theory if water formation were the only reaction concerned. The gas left in this case was pure oxygen. The nature of the residue was easily ascertained by exhausting the McLeod gage, closing **A'**, opening A and then comparing pressures read on the McLeod and Pirani gages. For example, if the actual pressure determined by the McLeod gage fell on the hydrogen calibration

---

[2] The Tesla coil was found much more effective when locating pinhole leaks if the apparatus contained a low pressure of hydrogen rather than air.

curve of the Pirani gage, introduction of oxygen always caused further reaction. A few typical results are given in Table I.

TABLE I

REACTION OF HYDROGEN–OXYGEN MIXTURES

Gas	Pressures, microns Initial	Pressures, microns Final	Residue
$2H_2 + O_2$	14.4	7.2	H_2
$2H_2 + O_2$	42.3	12.0	H_2
$2H_2 + O_2$	123.0	6.0	H_2
$H_2 + O_2$	19.7	2.2	O_2
$H_2 + O_2$	25.0	2.7	O_2

These results show that considerably more oxygen disappears than corresponds to water formation. This effect has been also noted by Langmuir,[3] who attributed it first to oxidation of gases dissolved in the platinum, but later to evaporation of atoms from the surface and their subsequent combination with oxygen to form ozone, or with water vapor on the bulb walls to form hydrogen peroxide. The hypothesis of reaction with dissolved oxygen does not explain our results because the effect was observed after repeated heating and cooling in pure oxygen. If the atomic oxygen explanation is correct, there should have been a clean-up of oxygen after the reaction with hydrogen ceased, but this was never observed at any temperature used for the catalysis experiments, *i. e.*, up to 380°. Hydrogen peroxide can be formed directly from its elements since its free energy of formation is half that of water,[4] and it seems probable that it is formed directly on the catalyst surface.

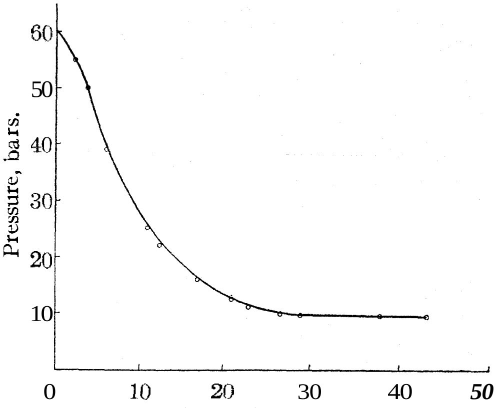

Fig. 2.—Rate of reaction of electrolytic gas on platinum.

The reaction at low pressures of hydrogen and oxygen on platinum has been widely quoted as a conspicuous example of a reaction retarded by one of the reactants.[5] In one series of our experiments, the initial partial pressure of oxygen was kept constant and the hydrogen pressure varied fourfold. The results with the wire at 100° and the wall at liquid-air

temperature are shown in Table II. Experiment 1 shows that oxygen in excess of electrolytic gas ratio has an accelerating effect on the reaction.

TABLE II

EFFECT OF VARIATION OF HYDROGEN CONCENTRATION

Initial pressures, bars		Ratio	Final pressure,	Minutes for re-
H_2	O_2	$H_2:O_2$	bars	action to stop
12.5	12.5	1:1	6.5	9
25	12.5	2:1	2.5	45
50	12.5	4:1	24.0	5

Experiment 3 shows that an excess of hydrogen over the amount present in electrolytic gas likewise accelerates the reaction. The composite nature of the reaction is still evident.

At much higher pressures Donnelly and Hinshelwood[6] found the reaction rate to be independent of the hydrogen pressure.

After a wire had been seasoned by use for some time, the abnormal consumption of oxygen tended to disappear. Perhaps a fresh surface is composite, part of it promoting hydrogen peroxide formation and part water formation.

Wall-Temperature Effect.—When the tube containing the catalyst was surrounded by liquid air, the rate of the reaction was surprisingly accelerated. Some acceleration would be anticipated because of the increased concentration[7] of the reactants produced by cooling the tube. From Charles' Law, the increase in concentration by cooling from 298 to 90 Å., would be 3.3 to 1. At pressures where the mean free path is comparable with the diameter of the tube, the increase in concentration is the ratio of the square roots of the temperature—in this case 1.8 to 1. This latter condition was approximately realized in the experiments, so that roughly the increase in concentration was 2 to 1 instead of 3 to 1. The increase in rate due to cooling the catalyst tube, although variable, was frequently as high as sixfold. The rate during the middle part of any one experiment with all temperatures constant changed comparatively little over small pressure differences. The effect is illustrated in Fig. 3. The curve from A to B shows the rate of reaction when the catalyst was at 200° and the wall at room temperature.

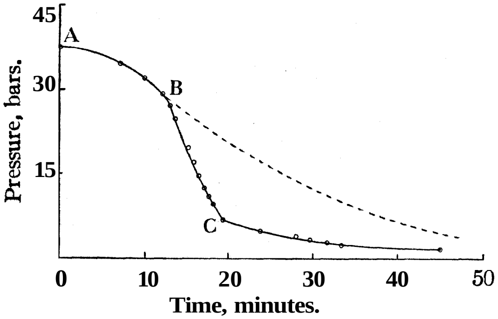

Fig. 3.—Effect of wall temperature on reaction rate of electrolytic gas.

---

[6] Donnelly and Hinshelwood, *J. Chem. Soc.*, 1727 (1929).

[7] S. Dushman, *High Vacuum*, 135–36 (1922).

The steep slope of the curve from B to C shows the effect of placing liquid air around the catalyst tube, during which time the catalyst was maintained at 200°. Had no liquid air been used, the rate would have been more nearly described by the dashed line.

Unless the catalyst was specially activated (see below) no reaction occurred upon introducing electrolytic gas into the reaction tube when the catalyst and the tube wall were both at room temperature. If the wire only was heated, usually to 150°, a reaction started, increased in rate quite rapidly for the first few minutes, then settled down to nearly a straight line rate until the end was approached. If, however, the gas was introduced at room temperature and then both the mire and wall were heated simultaneously, no reaction occurred even by the time a temperature of 200° had been reached. If the wire was heated beyond this point and the wall held at 200°, reaction occurred when the wire attained a temperature of 300°.

Again, starting with a fresh sample of gas, with wire and wall at room temperature no reaction occurred. Placing liquid air around the wall did not start the reaction, but when the wire was heated for a few seconds to 100°, the reaction started. Lowering the temperature of the wire to room temperature retarded the reaction but did not stop it until the wall was brought to room temperature by removing the liquid air. When wire and wall were again at room temperature, no reaction occurred. In a qualitative way these effects, with but occasional unexplainable exceptions, could be reproduced.

Other reactions than that between hydrogen and oxygen were investigated, *e. g.*, the hydrogenation of ethylene, the oxidation of carbon monoxide, and the decomposition of nitrous oxide. Changes in the slope of the rate curve upon cooling the catalyst tube were found, but these changes were comparatively small. The wall-temperature effect is masked if the rate of a reaction varies with pressure. Since the rates of the above-mentioned reactions change with pressure, the small accelerations observed when the catalyst tube was cooled are difficult to interpret. All that can be safely concluded is that the wall effect, if shown at all by these reactions, is comparatively small.

The wall-temperature effect shown by electrolytic gas reacting on platinum is independent of the geometrical position of the wire with respect to the wall. In many experiments the catalyst was wound in a short helix and located axially within the tube. In other experiments it was arranged in long hairpin loops.

No difference in the effect was observed with fused silica or Pyrex glass walls.

Gold was substituted for platinum. The higher temperature to which the gold had to be heated to cause electrolytic gas to react, and the added complication of the reaction rate changing rapidly with pressure masked the wall effect. So far as these few experiments apply, the conclusion is reached that any wall effect which gold may show is so small as to be obscured by other complications.

Super-activity.—Along with the study of the wall-temperature effect, experiments were performed in the hope of finding the most potent causes of variability in the activity of the catalyst. The rate curves (for the electrolytic gas reaction) showed high variation from one experiment to the next, and they were not always consistent with each other as to form. Some of the curves were straight lines, others were hyperbolas, and others were S-shaped. The latter were the most frequent. At the start of a reaction the rate would become accelerated, reach a steady state and then decrease. Some of this curvature may be due to the reaction not proceeding to the formation of water only. The induction period portion of the curve may be due to variation in the composite nature of the catalyst surface.

In order to find out whether or not outgassing the wire and apparatus had any important influence on activity, the wire and walls were baked out at about 400° for several hours, during which time the pumps were running. No unusual variation in results was observed. A silica tube was substituted for the glass tube, and the wire catalyst was suspended on silica supports. This was baked out at 700° with pumps running for five hours, but no unusual results were obtained. Next, the catalyst was heated to 900° while the walls were gently heated by a flame for one-half hour during exhaustion. This procedure activated the catalyst so highly that a sample of electrolytic gas reacted while being introduced even though both catalyst and wall were at room temperature. The reaction was nearly complete in two minutes. The rate was so surprisingly rapid in spite of the fact that no temperature difference existed between the wire and wall that measurement of the rate could not be made. It was necessary to cool the wall and catalyst with liquid air before introducing the sample in order to control the reaction. Careful heating of the wire from -180 to $-120°$ initiated a reaction which went from an initial pressure of 10.6 microns to completion in three hours and ten minutes. The pressure was followed to the gage limit of 0.01 micron. As far as we are aware, this is the lowest temperature at which a catalytic reaction has been observed.

Later it was found that this super-active state of the wire could be induced merely by heating the wire for a few seconds (in *vacuo*) to 900°. Another platinum wire catalyst surrounded by a Pyrex wall behaved similarly. This shows that the effect was not peculiar to a particular wire, and that the silica tube was of no consequence.

The super-active state was not permanent. Even when the catalyst tube was kept surrounded by liquid air so that no condensable gas could contaminate the wire, the super-activity had largely disappeared after five hours.

Bone and Wheeler[8] found that platinum was made more active if heated to 165° in pure hydrogen prior to the addition of electrolytic gas. They found that many other catalysts, metallic and otherwise, behaved similarly. Some of these catalysts were given a preliminary heating in oxygen. One sample of porcelain used as catalyst had its activity increased whether heated in hydrogen or oxygen. Another sample was activated only by hydrogen. Oxygen reduced the activity of silver, which fact has been confirmed by Chapman and Hall.[9]

Since platinum could be made super-active by heating *in vacuo* to 900°, in view of the Bone and Wheeler experiments one might expect an even greater degree of activation if platinum was heated to this temperature in hydrogen. The temperature at which reaction began was taken as the criterion for estimating super-activity. No substantial difference was found in this temperature whether the wire was heated *in vacuo,* or in hydrogen at 0.1 mm. pressure, or in oxygen at this pressure. The super-active state could be produced in a cryptocrystalline wire as well as in a macrocrystalline wire. The temperatures at which the reaction of electrolytic gas was initiated varied even in check experiments from −75 to −120°.

In one experiment the wire had to be heated to +60° to start the reaction which would have gone to completion in several minutes had the temperature not been reduced to −35°. During this same experiment if the walls and catalyst were made 0° the reaction stopped. With walls at 0° the catalyst had to be heated to 110° to cause a reaction which stopped if the catalyst was allowed to cool to the same temperature as the wall. If the catalyst was heated to 60°, the reaction would start when the walls were cooled with liquid air. Removal of the liquid air stopped the reaction.

This experiment shows that the wall effect persists when the wire is intermediate between ordinary and superactivity, and indicates that the effect is not dependent primarily upon the degree of activity. At the highest degree of activation the wall-temperature effect has not yet been investigated.

A possible explanation of the temporarily increased activity of the wire by high temperature treatment is the evaporation of surface contaminations caused by diffusion of gases from the interior of the wire. It is well known that nearly all metals contain dissolved gases, principally carbon monoxide and hydrogen, which are difficultly eliminated by any treatment short of melting the metal *in vacuo.* Experiments with platinum completely outgassed by melting are projected.

In any case, the effect of high temperature treatment observed here is

---

[8] Bone and Wheeler, *Phil. Trans. Roy. Soc.*, **206A,** 1 (1906).

[9] Chapman and Hall, *Proc. Roy. Soc.* (London), **124A,** 478 (1929).

quite the opposite of that which would be expected from current theories of sintering active metal areas by heat treatment. In the case of finely divided catalysts sintering must effect a reduction of surface and hence lessened activity. In the case of wires,. the macrocrystalline one, whose sintered surface was obvious, was quite equal in activity to a cryptocrystalline one. This fact taken in conjunction with the remarkable activity at −120° of the heat-treated wire shows that sintering is of no consequence, at least in the case of platinum wires.

Summary

1. A study of the hydrogen-oxygen reaction at low pressures on platinum wires has been made.

2. The reaction is not as simple as is commonly supposed. An excess of oxygen may react. This fact is here attributed to hydrogen peroxide formation from the elements.

3. The activity of platinum is variable even under carefully controlled conditions.

4. The rate of this reaction varies with the temperature difference between the wire and the wall of the containing vessel.

5. Flashing the wire at 900° in vacuum, hydrogen or oxygen induces super-activation which decays after some hours. A wire in the superactive condition causes an easily measurable rate of reaction at as low a temperature as −120°.

ELECTRIC MOMENT AND MOLECULAR STRUCTURE. III. DOUBLE AND TRIPLE BONDS AND POLARITY IN AROMATIC HYDROCARBONS

BY C. P. SMYTH AND R. W. DORNTE

RECEIVED JANUARY 26, 1931 PUBLISHED APRIL 6, 1931

The electric moments of simple molecules containing double and triple bonds have been investigated with the object of determining the polarities of these bonds and their relations to structure[1] and these results, together with those of Errera for acetylene dihalides,[2] have been examined in the light of electronic theories of valence.[3] The need of further accurate measurements upon molecules in which ethylene and acetylene hydrogens are replaced by hydrocarbon groups has been evident for some time. An unusual opportunity for such measurements arose through the kindness of Professor Donald H. Andrews of the Johns Hopkins University, who

loaned us pure samples of the phenyl substituted ethylenes and acetylenes prepared in his laboratory by Dr. R. H. Smith. 1,1,1-Triphenylethane also from the Johns Hopkins laboratories has been measured in order to compare the effect of phenyl substitution in a saturated hydrocarbon **with** the effects in the unsaturated.

Method of Determination

The dielectric constants, ϵ, and densities, d, were measured with the apparatus used in previous work,' the former being determined at a wave length of 600 meters. All the determinations were made in solution in benzene, which appeared to be the best non-polar solvent for these substances, with the exception of those upon phenylacetylene, which was more soluble in heptane. The polarizations, P_2, of the polar components of the solutions were calculated by means of the equations

$$P_{12} = \frac{\epsilon - 1}{\epsilon + 2}\,\frac{c_1M_1 + c_2M_2}{d} \text{ and } P_2 = \frac{P_{12} - P_1}{c_2} + P_1$$

in which P_{12} is the polarization of the mixture, and c_1 and c_2, M_1 and M_2 and P_1 and P_2 are, respectively, the mole fractions, molecular weights and polarizations of the individual components. The values of P_2 have been plotted against those of c_2 and extrapolated to $c_2 = 0$ to obtain the values of P designated as P,. The values of P_∞ when plotted against $1/T$ should give a straight line, as required by the Debye equation, $P = a + b/T$, in which $a = P_E + P_A$, the sum of the electronic polarization, P_E, and the atomic, P_A, and $b = 4aNp^2/9k$, N being the Avogadro number, 6.061×10^{23}, μ, the electric moment, and k, the molecular gas constant, 1.372×10^{-16}. Unfortunately, the short temperature range within which benzene is liquid renders the location of the $P_\infty - 1/T$ curves inaccurate for these solutions. It has seemed best, therefore, to disregard P_A for these substances and use for P_E the molar refraction for the sodium D line, MR_D, which is slightly higher than P_E, a fact which partially compensates for the neglect of P_A. The pronounced variation of the polarizations of the substituted acetylenes with temperature made it possible to locate the $P_\infty - 1/T$ curves with seeming accuracy but with surprising values for a and b. However, instead of using the constant $(P_\infty - a)T = b$, it is safer to use the quantity (P, $- MR_D)T$ at each temperature and calculate the moment from the relation, $\mu = 0.0127 \times 10^{-18}\sqrt{(P_\infty - MR_D)T}$, which follows from the preceding equation. The values of MR_D were determined experimentally—in the case of the solids, from measurements upon the solutions—and are listed in Table III in the "Obs." column. In the "Calcd." column are given the refractions calculated as the sum of the atomic refractions and those for the

---

[4] Smyth, Morgan and Boyce, THIS **JOURNAL**, 50,1536 (1928); Smyth and Morgan, *ibid., 50,1547 (1928);* Dornte and Smyth, *ibid., 52,3546* (1930).

unsaturated bonds. The differences between the observed and the calculated values are given in the column under E. The refractive indices and densities of the two substances which could be measured pure in the liquid state are given in Table I. The values used for the polarizations, P_1, of benzene and heptane were those determined in previous measurement~.~

When $P_\infty - MR_D$ is small, a small variation in P, causes a large variation in μ. It has been pointed out[6] that, in such cases, neglect of P_A may lead to apparent values of μ as large as 0.4 or 0.5 X 10^{-18} when they are really zero. However, the values of P_A found for saturated hydrocarbons[5,7] are so small that their neglect is approximately compensated for by the failure to extrapolate MR to infinite wave length. The values found for ethylene, acetylene and benzene,[6] though small, are sufficient to suggest the possibility that considerable error may arise from the neglect of P_A in the substituted ethylenes and acetylenes, but the closeness of MR_D to P in the cases of phenylethylene and 1,1-diphenylethylene seems to indicate that the effect of P_A is slight. The values for the acetylenes lead to the impossible result, large negative values for P_A, which will be discussed later. The most serious error is that of P_∞, which is magnified by the necessity of working in dilute solution. It is greatest for the difficultly soluble tetraphenylethylene, which, in the one solution deemed worth measuring, gave an apparent value of P_2 lower than MR_D, the probable error being about equal to the difference. The accuracy of the moments is not sufficient to distinguish between a value of zero and one of 0.2×10^{-18}, but it is significant that two of the three substances for which an approximately zero moment is found have molecules which should be symmetrical, while the third, phenylethylene, has not a very unsymmetrical molecule. It seems probable that this latter substance may have a small moment.

Discussion of Results

It is interesting to compare the small moment 0.4 X 10^{-18} found for 1,1,1-triphenylethane with those of other phenyl substituted ethanes and also methanes. The moments of methane[S] and ethane[1] have been found to be zero. When one methane hydrogen is replaced by phenyl to form toluene,[9] a moment of 0.4 X 10^{-18} results. This moment is presumably the resultant, in part, at least, of small displacements of charges in the benzene ring. Because of the symmetry of the ring,[10] it probably acts in the direction of the line joining the ring to the methyl carbon, which lies in the plane of the ring. When a second methane hydrogen is replaced by a phenyl group to form diphenylmethane, a second doublet is introduced which, if the tetrahedral valence angles of the methane carbon are maintained, should give a slightly larger moment to the molecule. Estermann's[11] value 0.37 X 10^{-18} for diphenylmethane is not sufficiently accurate to show whether the moment is really larger or smaller than that of phenylmethane or toluene. This is shown by the fact that his measurements on diphenyl, which should have zero moment,[12] merely indicate the moment to be less than 0.4 × 10^{-18}. The application of the same arguments concerning structure to triphenylmethane leads to the conclusion that it should have the same moment as toluene, 0.4 X 10^{-18}, which has been found to be the case.[13] Actually, the well-known abnormal behavior of the triphenylmethyl radical would lead one to expect a displacement of the charges between the methane carbon and its one remaining hydrogen with resulting alteration of the moment. However, no such alteration is evidenced in the value for triphenylmethane, which is consistent with the absence of any regular differences in the moments of triphenylmethyl chloride and alcohol as compared to-those of the normal and the tertiary butyl compounds.[5] As it has been shown[3,14] that a hydrogen attached to an aliphatic carbon in a hydrocarbon may be replaced by a methyl group without alteration of moment, the moment of 1,1,1-triphenylethane should be the same as that of triphenylmethane as actually observed.

Although all of these values for the substituted methanes and ethanes are inaccurate from the same causes as those to which the probably smaller uncertainties of the results in Table III are due, they show that electrical dissymmetry arises when an aliphatic hydrocarbon group is attached to a

benzene ring, but give no evidence of a resultant displacement of charges in the bonds of these groups. This latter is in marked contrast to the considerable differences in chemical behavior observed.

Smyth and Zahn[1] have found zero moment for the ethylene molecule, but a moment of 0.37×10^{-18} for ethylethylene. This is in contrast to the absence of moment when the carbon chain of a paraffin is lengthened,[4] and is indistinguishable experimentally from the moment produced when a methyl or ethyl group is substituted for a hydrogen on a benzene ring. One would look for a moment in phenylethylene, but the experimental results indicate a zero value, although, as previously pointed out, their accuracy is not such as to preclude the possibility of a moment somewhat smaller than 0.4×10^{-18}. The dissymmetry in 1,1-diphenylethylene is sufficient to give rise to a moment of 0.5×10^{-18}, while, in the *trans*-1,2-diphenylethylene, the moment is zero as in the trans-acetylene dihalides investigated by Errera.[2] It is curious that the value found for triphenylethylene should be higher than that for the more unsymmetrical 1,1-diphenylethylene, but the difference is probably not significant. The value for the symmetrical tetraphenylethylene is apparently zero, as would be expected from its symmetry.

It was hoped at the beginning of this investigation that the substitution of a phenyl group for a hydrogen on a doubly-bonded carbon might have a marked effect upon the moment. However, although the exaltation of refraction usually found in conjugated systems given in the column under E in Table III shows a loosening of the electron binding,[15] no abnormal dissymmetry in the arrangement of the charges is apparent. In fact, there is no evidence of a measurable polarity inherent in the double bond itself apd the attachment of hydrocarbon groups to it appears to have about the same effect upon the moment as a similar attachment to a benzene ring. The Kekulé formula for benzene has been indicated to be correct in so far as it places the carbons at the corners of a regular hexagon and the immediately attached atoms in the same plane.[10,16] In view of the mobile double bonds which this formula contains and of the fact that the benzene ring may take part in the formation of-a conjugated system, it is suggestive that the substitution of a hydrocarbon group for a hydrogen on a doubly-bonded carbon gives rise to a moment of the same magnitude as that resulting from a similar substitution on a benzene carbon.

Judging from these results and the fact that acetylene has been found to have zero moment,' one would expect a small moment for phenylacetylene and a zero value for the seemingly symmetrical diphenylacetylene,

[15] Smyth, *Phil. Mag.,* 50,361 (1925).

[16] Williams, *Chem.* ***Rev., 6,*** *589* (1929); Lonsdale, *Proc. Roy. Soc.* (London), **123A,** 494 (1929); Hendricks, *Chem. Rev.,* 7,431 (1929).

instead of which Table III shows a considerable moment for phenylacetylene and a larger one for diphenylacetylene. In Table II, the values of $(P_\infty - MR_D)T$ and the values of the moment calculated from them, instead of being constant as they should be, have a tendency to fall off with rising temperature. With all the substances except the substituted acetylenes, the change in polarization is so small that the change in (P, $-MR_D)T$ and μ, although relatively large, cannot be regarded as definitely significant. However, the polarizations of the acetylenes vary more with temperature. If P, is plotted against $1/T$, a straight line results from which are obtained the values of a, b and μ shown at the bottom of the data for each of the two substances in Table II. The constancy of the values for (P, $- a)T$ = b testifies to the linearity of the curves and the seeming consistency of the results. It must be remembered, however, that a = $P_E + P_A$. The values found for a are much lower than those in Table III for MR_D, which is approximately equal to P_E, and, accordingly, lead to large negative values for P_A, which are impossible. It seems best, therefore, to disregard the value of μ calculated from b and use the mean of the values calculated from (P, $-MR_D)T$ as an approximate indication of the moment.

Evidence of a tautomerism for acetylene and its derivatives, $HC{\equiv}CH \rightleftarrows H_2C{=}C$, was obtained by Nef[17] and later investigators,[18] but Biltz has criticized this evidence and argued against the supposition of the acetylidene form.[19] It is evident that the second structure containing bivalent carbon is unsymmetrical and should possess a considerable moment. The zero moment found for acetylene does not preclude the possibility of the existence of a small fraction of the molecules in the unsymmetrical form, the number of these molecules being too small to have a detectable effect upon the dielectric constant. It would appear that the replacement of a hydrogen by a phenyl group increases the tendency to give the unsymmetrical form, which is still further increased in diphenylacetylene, the behavior being analogous to that of the halogen-substituted acetylenes. The observed moment would thus be the effective mean of those of the two forms. As change in temperature would shift the tautomeric equilibrium, the apparent falling off of moment with rising temperature could be explained by increase in the proportion of the symmetrical form. The uncertainty connected with the temperature variation of the moments weakens it as evidence of the tautomeric equilibrium, but the considerable size of the moments found definitely requires the existence of an unsymmetrical molecule in mono- and diphenylacetylene.

Summary

The dielectric constants and densities of dilute solutions of the phenyl substituted ethylenes and acetylenes have been measured between 10 and 70°, the molar refractions of the substances have been determined and the data used to calculate the electric moments of the molecules.

The phenyl substituted ethylenes have small or zero moments according to the symmetry of their arrangement about the double bond, showing that there is no measurable polarity inherent in the bond itself. The replacement of a hydrogen on a doubly-bonded carbon by a hydrocarbon group gives rise to a moment of the same magnitude as that which results from a similar replacement in benzene.

The considerable moment found for phenylacetylene and the still larger value for diphenylacetylene, acetylene itself having no moment, give evidence of unsymmetrical molecules and may be explained in terms of a tautomeric equilibrium between a symmetrical form and an unsymmetrical containing bivalent carbon as proposed by Nef, the shift of equilibrium with temperature perhaps causing the temperature variation of the moment observed.

THE EFFECT OF AN ELECTRIC FIELD ON FLAMES AND THEIR PROPAGATION[1]

BY BERNARD LEWIS[2]

RECEIVED JANUARY 27, 1931 PUBLISHED APRIL 6, 1931

The knowledge that flames conduct electricity goes back many years. As early as 1801, Volta showed that the leaves of a gold-leaf electroscope diverge when burning charcoal is brought in contact with the knob. Many researches followed for the purpose of measuring the electrical conductivity of flames. It was found that the gases which emerge from the flame are conductive for some time afterward and furthermore, that this property of conduction can be lessened or removed by passing the gases through an electric field of appropriate strength. Complete accounts of these early researches are to be found in Wiedermann's "Elektricität,"[3] in a paper by de Hemptinne,[4] and in the "Handbuch der Experimentalphysik."[5]

[5] "Die Elektrischen Eigenschaften der Flamme," by H. Becker, Vol. 13, 1929.

For some time attention was directed to the question whether ionization in the flame is of a chemical or thermal origin.[6] The earlier investigations recognized that ionization could not result from chemical action alone, while Garner[6] ascribes the ionization mainly to thermal origin on the basis of calculations using the Saha equation,[7] which postulates a thermal equilibrium between atoms, ions and electrons. Haber,[8] on the other hand, believes that the heat energy of an explosive reaction is not sufficient to account for the observed ionization currents. He suggests that ionization is brought about by collisions of the second kind between energy-rich products of the reaction and molecules possessing low ionization potentials. Although Haber's suggestion finds support in the spectroscopic detection of such groups as OH, CC and CH in flames, the origin of ionization in flames still remains open to further experimental investigation.

A number of attempts were made[9] without success to arrest the propagation of a flame by means of an electric field. About the same time, Malinowski[10] announced that he had arrested a 2.8% benzine (C_6H_{14})–air mixture in a transverse electric field. Later, Bernackyj and Retaniw[11] and Malinowski and Lawrow[12] found that not only the flame of a benzine–air mixture but also that of an acetylene–air mixture could be extinguished before it could pass through the condenser. In agreement with the experiments of Lind, no positive results were obtained with hydrogen–air mixtures. It is unfortunate that in the foregoing investigations no direct visual observations of the flame could be made while it was under the influence of the field. The gases were passed through the annular space between two metal cylinders between which a potential could be applied. The cooling effect of the wall must have been considerable in view of the small space (1.5 to 4 mm.) between the cylinders.

For some time we have been engaged in an investigation of the effects of an electric field on flames, and it is the purpose of this paper to explain briefly the method used and to make known some of the results obtained. In view of the fact that new equipment is being obtained for the production of steady high voltage, and for measuring voltage and ionization currents accurately, these results are preliminary in character.

Method

There are two ways in which an electric field may be applied: (1) longitudinally—that is, in the direction of the flow of gas; and (2) transversely — that is, across the gas stream. The longitudinal field method possesses certain advantages—namely, that the flame is not in contact with the electrodes and that possibly more information may be obtained concerning the role of ionized species by reversing the direction of the field. The first method was employed in these experiments.

Apparatus

To obtain a source of direct current, a transformer, synchronous rectifier, condensers and choke coil were arranged as in Fig. 1. The amount of ripple in the delivered potential was estimated to be about 5 to 8%. A synchronous rectifier is not entirely satisfactory because marked variations in potential sometimes occur; it served well, however, for these experiments. The potentials were measured by means of an electrostatic voltmeter. After considerable time had been spent on cell construction, a cell was finally adopted which was both durable and simple to construct. It consists (see Fig. 2) of a Pyrex glass tube of 1 cm. inside diameter into which two electrodes were placed 1 cm. apart. The electrodes consist of 80-mesh nichrome wire gauze bent by means of a special die into shape to fit the glass tube snugly. The outer edge of the electrodes was cemented to the glass tube by means of a porcelain cement, Insalute. The leads were attached firmly and brought out through side arms, in which they were sealed with wax. Ignition of the gas–air mixtures was accomplished by sparking (with a spark coil) across the electrodes.

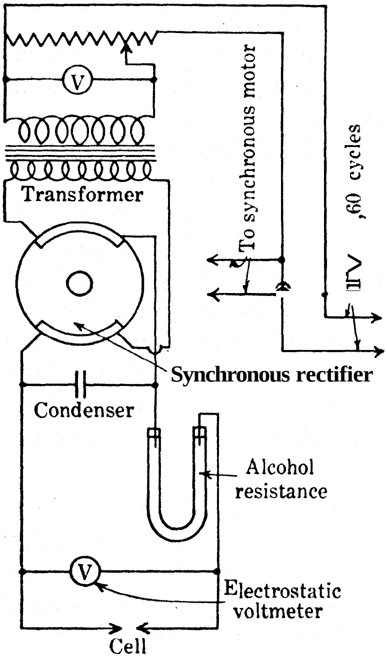

Fig. 1.—Apparatus used in experiments to determine the effect of electric field on flames.

Of the gases used, methane, ethane, ethylene, propane, propylene, butane, isobutane and butylene were obtained reasonably pure in tanks. Pittsburgh natural gas was taken from the pipe line and carbon monoxide was prepared from sulfuric acid and formic acid.

Procedure

Air and the flammable gas were led separately through calibrated flowmeters in amounts to give the desired mixture. They were passed into a mixing chamber and thence through the cell. Samples of the mixture were withdrawn and analyzed as a check on the flowmeters. The rate of flow of the mixture was adjusted to just balance the velocity of propagation of the flame in the opposite direction. Under these conditions a steady, stationary conical flame could be made to burn midway between the electrodes. The potential was then applied and increased and the effects were noted. Experiments were performed with the downstream electrode both positive and negative. A blast of air was used to prevent the glass cell from melting. The products of combustion were led to the open through a wide tube.

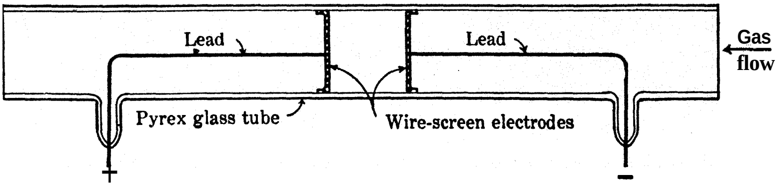

Fig. 2.—Diagram of cell used for confining a flame and applying an electric field.

Observations

The phenomenon observed, which is quite general for all the mixtures investigated, is that on application of the electric field the flame is invariably pulled toward that electrode which is negatively charged. Figure **3** shows this photographically. The upper picture is illustrative of a steady stationary flame of isobutane and air. The center picture shows the effect on the same flame on applying a field with the right-hand (upstream) electrode negatively charged. The lower picture shows the effect when the left-hand (downstream) electrode is negatively charged. This indicates that *the flame moves in the direction of positive ion flow.* It follows that the propagation of flame is *speeded up* if the upstream electrode is negatively charged and *slowed down* if the downstream electrode is negatively charged. Upon removing the electric field the flame returns to its original position in the tube.

If the potential applied is increased to a certain value, depending on the gas mixture, the flame may be extinguished. Depending on the direction of the field the phenomena observed are different. With the downstream electrode negatively charged, the flame is pulled toward this electrode as a body without much spreading. It undergoes intense oscillatory motions. Sometimes, when the potential is high enough, an occasional spark passes between the upstream (positive) electrode and the flame front. As the flame nears the negative electrode (with increasing potential) it becomes decidedly weak and unstable and then disappears. It is not possible to decide whether the flame is pulled through the wire-gauze electrode through which it is unable to propagate, or whether it is extinguished near the electrode accompanying the removal of charged species. With the upstream electrode negatively charged, the flame having been drawn toward this electrode spreads out somewhat, undergoes vibrations and takes on a weak-like, fading-out appearance prior to its disappearance. Here there is no question that the extinguishing of the flame is in some way connected with the removal of charged species. For the sake of convenience we shall arbitrarily denote the field as negative when the downstream electrode is negatively charged, and as positive when the upstream electrode is negatively charged.

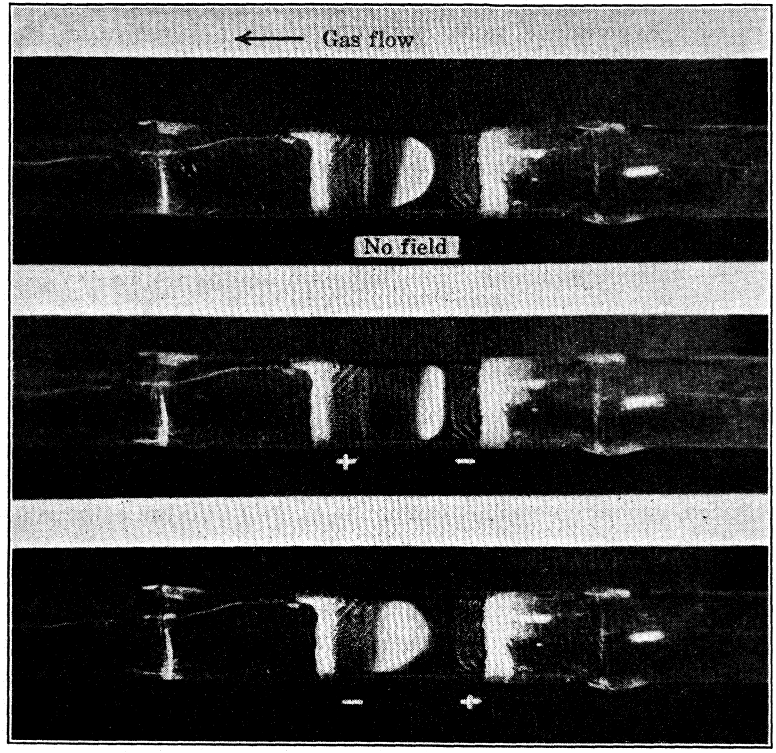

Fig. 3.—Photographs showing the effect of electric field on flames (natural size).

Table I summarizes the observations. Column 1 contains the flammable gas; column 2 the percentage of this gas mixed with air; column 3 the type of mixture—that is, whether it is richer or leaner in combustible gas than corresponds to a mixture in which gas and air are present in combining proportions. It should be noted that only in one or two cases was it

TABLE I

[a] The potentials for negative fields are usually considerably higher than those for positive fields. This is due to the fact that with a negative field the upstream portion of the cell which is free of flame is also practically free of ions and therefore highly resistant. With a positive field the downstream portion of the cell is free of flame but contains ions carried along by the moving gases, rendering this space conductive.

[b] Close to combining proportion mixture.

[c] Very unsteady flame prior to application of voltage

[d] Flows too high to be measured.

[e] Difficult to obtain steady flame with other mixtures.

possible to maintain a steady stationary flame between the electrodes with a mixture whose constituents were present in combining proportions. The flame of the latter mixture, which is close to one for which a maximum temperature and maximum flame speed are found, is usually extremely unsteady and very sensitive to small variations in composition.

Column 4 gives the velocity of flow of gases. These speeds may not correspond exactly to the horizontal speed of propagation of a flame in a 1-cm. tube measured in the usual way—namely, with stationary gases. Under the conditions of these experiments, turbulence is set up as a result of passage of the gases through the wire gauze. It becomes more pronounced with greater gas flows. Thus, it is possible to maintain stationary flames with quite different flows for the same percentage of combustible in the mixture.

Column 5 gives the potential at which the flame is extinguished with a negative field, and column 6 the potential at which the flame is extinguished with a positive field. Where dashes are indicated under positive field the flame was not extinguished with the highest voltage attainable (about **10,000** volts), although it was drawn toward the negative electrode, often violently, and set into intense vibration. At a somewhat lower voltage than this, sparks pass across the gap between one electrode and the flame. In a number of cases the flames were extinguished at voltages at which sparking occurred. However, this sparking was only intermittent (arising from gapping across the brushes of the synchronous rectifier). It was possible to observe that the flame was extinguished in a moment when the sparking ceased, in other words, when the applied potential was greatest. The voltages recorded were read just after the flame was extinguished.

Discussion of Observations

In many of the mixtures given in Table I the flame could be extinguished at practically every trial. In a few, the number of successful trials was from 7 to 8 out of 10. Where dashes are given under negative fields the flame could be extinguished only rarely, once or twice out of 10 trials. Dashes under positive fields, however, indicate no success in extinguishing the flame. Indeed, the phenomena are so easily reproducible that the experiment may be utilized for lecture demonstration with reasonable surety of success.

The results obtained by the longitudinal electric field method show:

1 The flames of rich mixtures of Pittsburgh natural gas (which is mainly CH_4 and C_2H_6), CH_4 and C_2H_6 are extinguished with positive fields; the flames of lean mixtures of these gases cannot be extinguished with positive fields.

2. The flames of lean mixtures of C_3H_8, C_4H_{10}, iso-C_4H_{10}, C_3H_6 and C_4H_8 are extinguished with positive fields; the flames of rich mixtures of these gases cannot be extinguished with positive fields.

3. The flames of rich or lean mixtures of all these hydrocarbon gases and in addition CO and C_2H_2, can be extinguished with negative fields. (It was found impossible to maintain a steady flame with rich mixtures of CO and C_2H_2 under these experimental conditions.)

The observed increase and decrease in the speed of propagation of flame may be linked with a greater or smaller concentration of ions. With a positive field in which an increase in velocity of flame propagation occurs, the ion concentration is greater than with a negative field in which a decrease in velocity is observed, because the field draws back into the flame ions which otherwise would have been carried downstream by the moving gases. An experiment by Malinowski[10] lends support to this view. He found that the ionic current was greater in the faster than in the slower moving portions of an oscillating non-stationary flame. If ion concentration governs flame speed, then, because the latter is directly related to the temperature of a flame, it follows that the temperature of a flame should be markedly affected by an electric field.

Several important questions arise. (1) Is the function of the ions and electrons to activate unburned molecules in the fresh gases and so raise them to the reaction threshold? (2) Is the formation of ions and electrons a result of collisions of the second kind between highly energized products of the reaction and molecules possessing low-ionizing potentials in the Haber sense? *(3)* Is the removal of positive ions the only requisite for extinguishing a flame, or are active molecules clustered around them and also drawn away from the reaction zone? At the present time these questions cannot be answered satisfactorily. It is evident, however, in the light of these experiments, that the positive ion plays an important part in the maintenance of flames.

Knowledge of the current–voltage characteristics would throw much light on the nature of flame processes. This we hope to determine with new equipment which we are designing.

Mention should be made of some results by Thornton.[13] He observed that while the flame of a 7% methane–air mixture (lean mixture) was speeded up in a transverse field, there was no effect on a 9.5% mixture (combining proportions). On the other hand, Malinowski and Lawrow[12] observed a marked slowing up of a 15% methane–air mixture (rich mixture). It has been shown above by the longitudinal field method that the flame can be speeded up or slowed down in a rich or lean mixture, depending merely on the direction of the field.

Some further experiments employing a tranverse field may be mentioned. Using a duplicate of Thornton's cell it was found, in agreement with him, that with a 7% methane–air mixture the propagation of flame could be speeded up very much (2 to 3 times) if the flame was moving originally in

---

[13] Thornton, *Phil.* Mag., 9, 260 (1930).

the direction of oncoming unburned gases. If the velocity of the same mixture was adjusted so as to produce a stationary flame, the propagation was slowed down—that is, the flame moved in the direction of flow of gases. The strength of the field was below that which would extinguish the flame.

Likewise in rich mixtures, such as Malinowski used, propagation could be speeded up or slowed down under the same conditions mentioned above. Rich or lean butane–air mixtures showed the same effects. Acceleration of the flame was never observed, however, in a long rectangular cell two sides of which were of metal and two sides of transparent mica. In this cell, whatever the conditions, the speed of propagation was decreased by the transverse field.

These results clear up the apparent differences between the results of Thornton and Malinowski. The former worked with a flame in motion and the latter with an almost stationary flame or one moving slowly in the same direction as the gases. It is believed that these totally different effects are due to a difference in the shape of the flame fronts when the flame is in movement and when it is stationary,[14] which probably results in the positive ions being drawn on the one hand more to the upstream side and on the other hand the downstream side of the flame' front.

As the proof of this paper was being read, attention was drawn to a recent publication by Guénault and Wheeler.[15] These authors show pictures of the distortion of flames under the influence of an electric field and reach the same conclusion as the writer—namely, that the flame moves in the direction of the positive ion flow.

Acknowledgment. The writer takes pleasure in acknowledging the assistance of Harold J. Muendel, coöperative research fellow, Carnegie Institute of Technology.

Summary

The effects of an electric field on the flames of ten hydrocarbon–air and carbon monoxide–air mixtures were investigated. The field was applied in the same direction as the moving gas between fine wire-gauze electrodes placed on either side of a stationary flame confined in a Pyrex glass tube. It is found that the flame is invariably pulled toward that electrode which is negatively charged. Photographs of this effect are shown. These indicate that the flame moves in the direction of positive ion flow, and it follows that the propagation of flame is speeded up or slowed down depending on the direction of the electric field. With appropriate field direction and strength, the flames of all the mixtures could be extinguished. The results show that:

---

[14] See Mason and Wheeler, *J. Chem. Soc.*, 1227 (1920), and Thornton, Ref. 13.

[15] Guénault and Wheeler, *J. Chem. Soc.*, 195 (1931).

1. The flames of rich mixtures of Pittsburgh natural gas, CH_4 and C_2H_6, are extinguished when the upstream electrode is negatively charged; the flames of lean mixtures of these gases cannot be extinguished with this direction of the field.
2. The flames of lean mixtures of C_3H_8, C_4H_{10}, iso-C_4H_{10}, C_3H_6 and C_4H_8 are extinguished when the upstream electrode is negatively charged; the flames of rich mixtures of these gases cannot be extinguished with this direction of the field.
3. The flames of rich or lean mixtures of all the above hydrocarbon gases and in addition lean mixtures of C_2H_2 and CO are extinguished when the downstream electrode is negatively charged.
4. Certain effects with a tranverse field are cleared up.

A brief discussion of the results is given. It is concluded that the positive ion plays an important role in the maintenance of flames.

SONIC STUDIES OF THE PHYSICAL PROPERTIES OF LIQUIDS. II. THE VELOCITY OF SOUND IN SOLUTIONS OF CERTAIN ALKALI HALIDES AND THEIR COMPRESSIBILITIES

BY EGBERT B. FREYER[1]

RECEIVED JANUARY 29, 1931 PUBLISHED APRIL 6, 1931

In a previous paper[2] the velocities of sound in a number of organic liquids were reported. The measurements were made according to the method of Hubbard and Loomis,[3] and from the data so obtained, with the aid of other data, the adiabatic compressibilities, and in some cases also the isothermal compressibilities, were calculated. For the details of the method reference must be made to the earlier papers. It shall suffice here to mention that the high frequency or supersonic waves were generated by the piezo action of a quartz disk. For producing the high frequency alternating field a common type of vacuum tube oscillator was employed, and the positions and separation of nodes were indicated by abrupt changes of frequency. A secondary quartz controlled oscillator served to fix the frequency at resonance, and using a double heterodyne method the position of nodes as read from a micrometer screw could be determined to within

---

[1] From the dissertation submitted by Egbert B. Freyer in partial fulfilment of the requirements for the degree of Doctor of Philosophy at the Johns Hopkins University.

0.002 mm. The following equation relates the velocity of sound V in a liquid to its adiabatic compressibility β_ϕ, and density ρ

$$\beta_\phi = \frac{1}{V^2\rho}$$

The isothermal compressibility β_T may be calculated from β_ϕ by means of the thermodynamic relation

$$\beta_T = \beta_\phi + \frac{\alpha^2 T}{JC_p\rho}$$

where α is the coefficient of thermal expansion, C_p the specific heat at constant pressure at absolute temperature T, and J is the mechanical equivalent of heat. These equations were used to calculate the data presented in this paper.

Solutions of Alkali Halides

Since Hubbard and Loomis[3] had observed an apparently anomalous behavior of sodium iodide solutions (compared to those of potassium chloride and sodium chloride) in respect to the course of their curves of velocity of sound against temperature, it was considered desirable to study rather closely the velocity of sound in the chlorides, iodides and bromides of sodium and potassium.

The samples of the salts used were of the "Baker's C. P. Analyzed" grade, the purity of these being sufficiently high for the precision of this investigation. Considering, for example, that the most likely impurity in a given halide of potassium would be the same halide of sodium, it is evident from Fig. 2 that a trace of one salt in the other would have only a very slight effect on the velocity of sound. As much as a tenth of a per cent. of potassium chloride in sodium chloride would lower the velocity of sound in a solution only 0.05 m./sec., and the effect diminishes in the order Cl > Br > I. A precision greater than 1.0 m./sec. is not claimed for these measurements.

Results

In Table I are recorded the same quantities calculated from the velocity of sound as were reported for the organic liquids, except that here the compressibilities, etc., are given as a function of the weight per cent. of salt in solution. The data are for 20°. The density values are from the "International Critical Tables." The coefficients of expansion were calculated from density tables. The specific heat data were taken from the Landolt–Bornstein "Tabellen."

Table II shows (a) the velocity of sound and adiabatic compressibility as a function of temperature for concentrated solutions of the salts, and (b) the velocity of sound alone as a function of both temperature and concentration in the case of the iodides. All these data were taken from smooth curves drawn through the experimental points found by the author

locity of sound in solutions of sodium chloride, potassium chloride, sodium bromide and potassium bromide. In the case of potassium iodide the velocity decreases and passes through a minimum at about 37%, at 25, 35 and 45°, whereas at 15° the minimum occurs at 20% salt concentration. Considering sodium iodide, the minimum shifts to lower concentration as the temperature is lowered. An explanation of the general course of these curves will be given presently. In Fig. 2 is shown the change in the velocity of sound in solutions of varying concentration as the temperature changes. A characteristic of all the curves is the decrease in slope at a given temperature and a general flattening as the concentration increases. This tendency is least in the case of potassium chloride. The slope of the curve is zero for 45% sodium iodide and becomes negative at higher concentration. Figure 3 shows the lowering of the adiabatic compressibility produced by adding the various salts to water as a function of the quantity of salt added.

Discussion

Since the velocity of sound in a liquid is related to its density and adiabatic compressibility, we should be able to predict changes in the first quantity if we know how the other two vary. The general trend of the velocity of sound-concentration curves is accounted for as follows: the decreasing compressibility tends to increase the velocity, while the increasing density tends to lower it. The predominating effect obviously determines whether addition of salt shall increase or decrease the velocity of sound in the solution. These relations are clearly illustrated by the figures of the first two columns of Table III, where the fractional changes

in the compressibility and percentage density change due to adding 10% of each salt are recorded. In the case of sodium chloride the compressibility change greatly predominates and the velocity of sound increases relatively quite rapidly. · This predominance decreases in the order NaCl>KCl>NaBr>KBr. The density change has the greater influence in the case of sodium iodide and potassium iodide, and the velocity of sound in solutions of these salts accordingly decreases with concentration. The same reasoning evidently applies also to the curves of Fig. 1, except that here the velocity of sound change is determined by the effect of temperature on the compressibility and density.

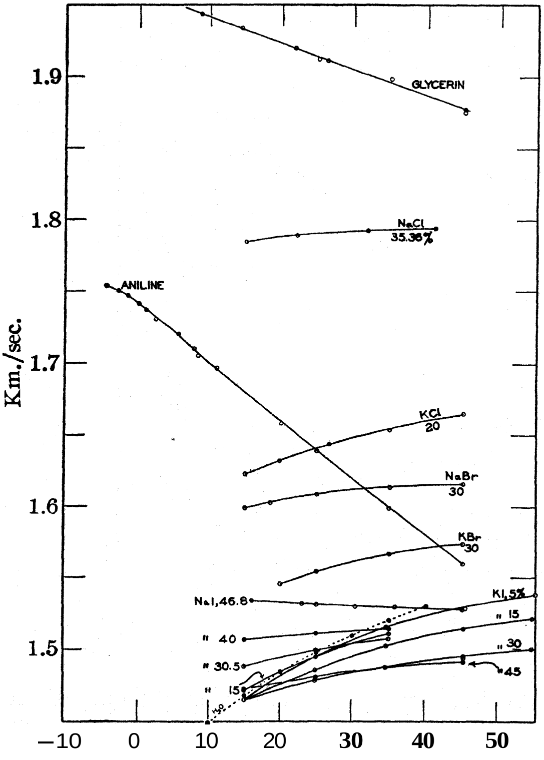

Fig. 2.

Figure 3 shows that a solution of each of the several salts has a lower compressibility than has the pure solvent, and that the lowering produced is greater the larger the amount of salt added. It seemed of interest to examine rather closely the specific effect of each salt at one concentration.

To this end a number of properties of the salts and of their ions were sought in the literature, in the hope that a qualitative relation, at least, might be found between some of these properties and the effect of the ions on the compressibility of their solution. The following question presents itself: what factors may be operative when a salt is added to water that might produce a compressibility change? First, it is conceivable that the presence of ions may change the condition of aggregation of the solvent molecules, *i. e.*, may shift the trihydrol–dihydrol–monohydrol equilibria. Second, it is known that ions concentrate solvent molecules in their immediate vicinity, this hydration being, in effect, a compression, and related to a volume change observed when the components are mixed. It seems a fairly remote possibility that the compressibility of a salt as measured for the solid should have an appreciable effect on that of its solution. The first two possibilities become one when we consider that any effect of the ions on the equilibria between the various hydrols would actually be brought about as a result of hydration. Now the compressibility of a substance decreases with increasing pressure or, simply, the more a substance is compressed the less it can be compressed. It should accordingly be expected that for a given concentration those solutions will have the lower compressibility whose ions are most hydrated, or, expressed in another way, the lowering of the compressibility produced when different salts are added to water should vary in the same order as the relative degrees of hydration of their ions. Thus Webb[4] has calculated the contraction of the solvent produced by ions of various radii.

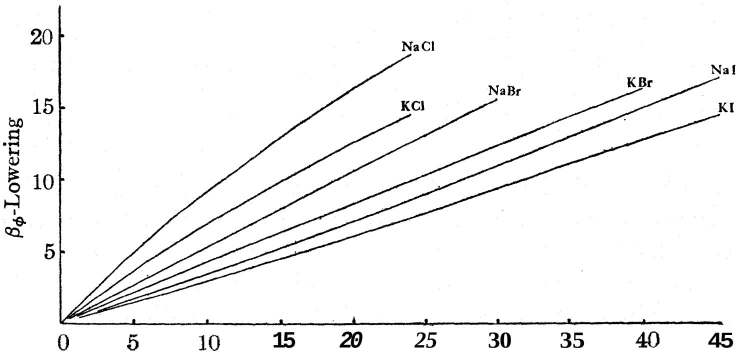

Fig. 3.

The figures in column two of Table IV represent the mean contraction produced by the two ions composing the salts which affect the fractional compressibility lowerings given in the first column. The assumption is made that this contraction effect is a measure of the relative mean degree

---

[4] Webb, This Journal, **48**, 2598 (1926).

of hydration of the ions. The third column shows how nearly the compressibility change is proportional to the contraction. The mean ionic radii of the salts as calculated by Webb are given in the fourth column. It is to be noted that in the range considered, the contraction of the solvent is almost inversely proportional to the mean radii of the ions producing it. This is due to the greater intensity of the electric field about the ions of the low atomic number and small radii, resulting in a greater attraction of the water dipoles for the ions. This is the so-called electrostriction.

TABLE IV

DATA FOR 3 MOLAL SALT SOLUTIONS

	(a) $\frac{\beta\phi_0 - 84}{\beta\phi_0}$	(b) Mean relative contraction	$\frac{(b)}{(a)}$	Mean r, Å.
NaCl	0.129	10.7	83	1.87
NaBr	.124	10.2	83	1.95
NaI	.113	9.5	84	2.05
KCl	.116	9.5	82	2.05
KBr	.108	9.0	83	2.12
KI	.105	8.4	80	2.23

It would seem desirable, before concluding, to direct attention to one further observation. It is the approximate proportionality between the activity coefficients and percentage density changes due to equal weight percentages of the six salts in solution. This is shown in the last column of Table III. The data are for 10% solutions. The relation is seen to be not even approximate in the case of lithium chloride and hydrochloric acid. This is not surprising in view of the differences in properties usually observed between the elements of the first series of the periodic table and those of the other series. It was found also not to hold for salts of other valence types.

Summary

The velocity of sound in solutions of iodides, chlorides and bromides of sodium and potassium has been measured, using high frequencies and a resonance method of detecting nodes. The data cover nearly the entire concentration range for the various salts, and the temperature range 15 to 45°.

The adiabatic and isothermal compressibilities have been calculated for various concentrations at 20°. The adiabatic compressibilities have been calculated as a function of temperature for certain concentrated solutions of the salts.

It is shown that addition of salt lowers the adiabatic compressibility of the solutions, the lowering being quite different for equal percentages of the different salts, and much more nearly equal for equal molalities. In the latter case, the lowering is shown to be related to the contraction of the solvents and hence, presumably, to the hydration produced by the ions.

THE COLORIMETRIC DETERMINATION OF MINUTE AMOUNTS OF CADMIUM

BY LAWRENCE T. FAIRHALL AND LEON PRODAN

RECEIVED JANUARY 30, 1931 PUBLISHED APRIL 6, 1931

Cadmium is becoming increasingly an industrial hazard both in the primary smelting of ore and in such secondary uses as cadmium plating. The need for an accurate method for the determination of minute amounts of the metal is apparent both in the analysis of ores and in toxicological investigation of the substance. Although many methods for the micro scopical detection of cadmium have been developed, none of these is particularly applicable to quantitative use. The blue color which is developed when resorcinol is added to solutions of cadmium salts[1] is far less intense than that developed by zinc, is subject to vagaries and is seriously affected by other metals which yield the same color. Breyer[2] determined small amounts of cadmium in the dry way by volatilizing cadmium and measuring the depth of yellow color of the sulfide deposited on a glass tube. The most promising method is that of Hessel,[3] who employed the yellow color of the sulfide in solutions as a means of determining cadmium quantitatively in amounts of 2 to 10 milligrams in organic material. These various methods and several of the microscopic methods were investigated in an attempt to develop a method for cadmium analysis, accurate for small quantities and particularly in organic material.

Experimental

In the initial experiments it was found that extremely dilute solutions of cadmium salts, which under ordinary light develop only a faintly yellow coloration with hydrogen sulfide water, give a pronounced bright yellow appearance under a quartz mercury vapor lamp. In concentrations of less than 0.1 mg./50 cc. of cadmium, differences in the yellow color of the sulfide become indistinguishable in ordinary light, while under the mercury arc the yellow color is perceptible in concentrations as low as 0.01 mg./50 cc., so that differentiation may be made with experience between solutions of this volume varying but 0.01 mg. of cadmium in amount. If we assume a lower limit of twice this value, however, that is, of 0.02 mg./50 cc., this represents a delicacy of 1:2,500,000, whereas Hessel found with his method a delicacy of but 1:70,000.

Since cadmium and its salts are so volatile, ashing in the ordinary way is out of the question. Nitric acid ashing with the addition of a small

amount of sulfuric acid gives good results and in the case of animal tissues is most conveniently effected by slow oxidation in conical beakers at a low heat on an electric hot-plate. As cadmium sulfide is much more insoluble in acid than zinc sulfide, it is possible to separate the two readily when the zinc is not present in greater amount than that found in animal tissues. In order to insure complete separation of the cadmium as sulfide, copper may be added as an entraining medium. Copper was chosen because it is normally present in animal tissues and because the coloration of cadmium sulfide may be produced in the presence of copper without interference merely by the addition of potassium cyanide. The disagreeable tendency of cadmium sulfide to pass into the colloidal condition when it is washed is readily overcome by the addition of a drop of 5% aluminum chloride solution in the initial stage of separation.

Using the method outlined below, various analyses were made of organic material to which known amounts of cadmium had been added. Cadmium in amounts varying from 0.40 to 1.00 mg. was added in each case to 100 g. of muscle and the material oxidized. The cadmium was separated and read as the sulfide, comparison being made with cadmium standards prepared in an exactly similar manner. Readings were made by two observers on separate aliquot portions of the separated cadmium chloride obtained in the course of analysis. The results are shown in the following table. The error in these analyses ranged from zero to 0.09 mg. and averaged 0.04 mg.

					Average	0.04

Method of Analysis

Add sufficient concentrated nitric acid to the organic material to cover it and heat it very gently at first. After the solid material has dissolved, add 10 cc. of concentrated sulfuric acid and occasionally add small amounts of nitric acid until oxidation is complete and then heat until fumes of sulfur trioxide are freely given off. Dilute to 75 cc. and add the equivalent of 0.5 mg. of copper and 2 g. of sodium citrate. Neutralize the acid solution for the first precipitation with ammonia (rather than potassium hydroxide, as this avoids precipitation of potassium sulfate from the cooling solution) and adjust the concentration of hydrogen ion to approximately 10^{-3} by means of the indicators thymol blue and brom chlor phenol blue. Pass hydrogen sulfide into the resulting solution for five to ten minutes, add one drop of 5% aluminum chloride solution and allow the solution to stand for six to twelve hours. Filter, dissolve the precipitate in nitric acid and hydrochloric acid and carefully evaporate to dryness. Repeat the precipitation as sulfide twice more, omitting the addition of sodium citrate the last time and adjusting the hydrogen-ion concentration to 10^{-2} by means of dilute potassium hydroxide. Carefully evaporate the final solution of chloride to dryness, dissolve it in water and make up to a convenient exact volume in a volumetric flask. An aliquot portion of this solution is used in a Nessler tube for the final reading. To each tube add five drops of 10% potassium cyanide, distilled water and finally 5 cc. of hydrogen sulfide water. Mix thoroughly and compare under a flood of ultraviolet light with standards similarly prepared. The solution should exhibit a bright, clear yellow color under the mercury arc. Dark or turbid solutions usually indicate incomplete removal of iron. Traces of lead although not usually present in animal tissues are usually found in the reagents and must be removed.[4] The reagents are usually free from cadmium. The comparison tubes and the standard tubes should be prepared at the same time, as there is a notable deepening in tone when they are allowed to stand overnight. In doubtful cases, however, it is sometimes advantageous to allow the tubes to stand for a few hours before reading.

Conclusion

A colorimetric method for the determination of minute amounts of cadmium is described in which advantage is taken of the intensification of color of the sulfide under ultraviolet rays. A sensitivity of 1:2,500,000 is thus obtained and an accuracy attained of 4% in the analysis of material containing from 0.40 to 1.00 mg. of cadmium in 100 g. of organic material.

THE ROLE PLAYED BY ADSORBED GASES IN INITIATING REACTION CHAINS: THE COMBINATION OF HYDROGEN AND OXYGEN

By Hubert N. Alyea

Received February 4, 1931 Published April 6, 1931

Reaction chains initiated in the gas phase, and being broken upon collision with the walls of the containing vessels, have received considerable attention during the past few years. This paper presents a new type of chain mechanism: one in which chains are initiated on a catalytic wall surface, enter into the gas phase, and may eventually return to be broken at the walls.

An equivalent oxygen–hydrogen mixture at about 550° has been found by Thompson and Hinshelwood[1] to exhibit an extremely interesting phenomenon. Between the limits 10 to 100 mm. mercury pressure it explodes; outside these limits it does not. The variation of these limits with temperature is represented by the unbroken line in Fig. 1. At pressures greater than the upper explosion limit B–C a slow measurable reaction occurs, which we shall designate as "the non-explosive reaction." It will be our purpose to develop the evidence which shows that the non-explosive and the explosive reactions differ strikingly from each other, and that factors which accelerate the former retard the latter. A change of a few millimeters' pressure, and the one type of reaction is replaced by its opposing type. For this phenomenon a mechanism will be proposed which involves selective adsorption of gases on the walls of the containing vessel, initiation of chains from these adsorbed gases, and subsequent extension of reaction chains out into the gas phase. Finally it will be shown that such a mechanism can explain other reactions as well, such as the oxidation of carbon disulfide, carbon monoxide and the hydrocarbons.

Explosion Starts from the Walls.—We have been able to demonstrate this by a method described in detail elsewhere.[2] Two heated porcelain tubes 2 mm. in diameter, at right angles to each other, conducted streams of oxygen and of hydrogen, respectively, into a large iron chamber filled with nitrogen. The gases were pumped off continuously. Suitable devices permitted adjusting the streams so that they exactly crossed each other in an atmosphere of nitrogen, determining their maximum temperature at the point of coincidence within 1° with a thermocouple, and regulating the pressure of the streams by altering the total pressure in the chamber. Under these conditions oxygen and hydrogen were brought together in the absence of walls. An approximately isothermal run was

---

[1] Thompson and Hinshelwood, Proc. Roy. *Soc.* (London), [A] 122, 610 (1929).

[2] Alyea and Haber, *Z. physik.* Chem., [B] 10, 193 (1930).

made by crossing the oxygen and hydrogen initially at 50 to 200 mm. pressure, and following visually through a window in the chamber, or thermally with a thermocouple poisoned to prevent catalytic action, any change which occurred upon lowering the pressure to 10 mm. of mercury. At all pressures the temperature of the crossed streams remained about 20° higher than that of each single stream. The broken-line curves, Fig. 1, represent the thermal observations of seventeen such runs. In none of them is there a sudden increase in temperature when the pressure of the gases has fallen to the region where explosion should be occurring. Moreover, there were never any visual indications that explosion had taken place. This means that in the absence of walls no explosion occurs.

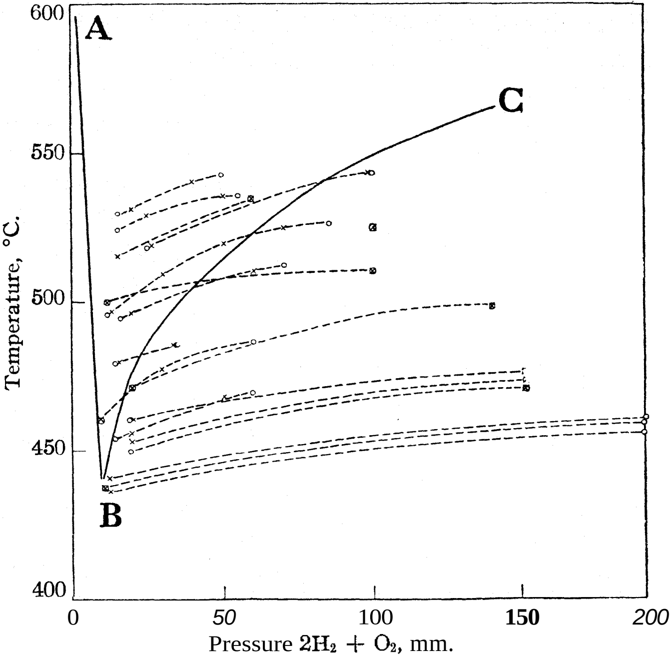

Fig. 1.

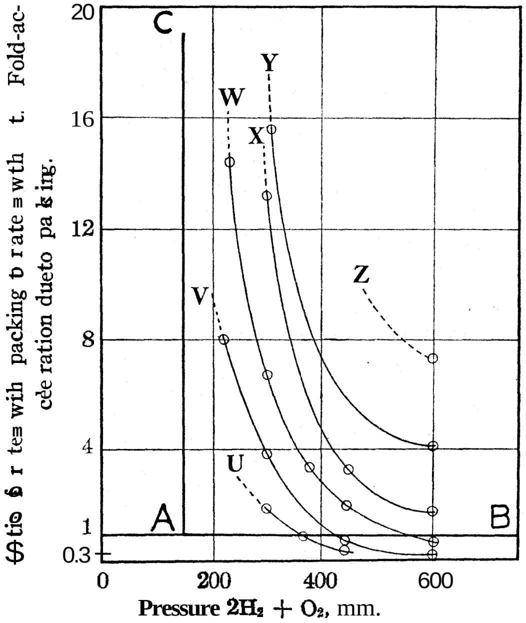
An artificial wall was then supplied: a quartz tube heated from within so that its surface was less than 520° was pushed into the gas stream at 530° and 35 mm., conditions where explosion should have occurred. As if lighted by a match, the gas exploded, and a visible sodium flame immediately appeared, extending from the quartz out into the gas in the direction in which the gas was flowing. The explosion continued until the quartz tube was removed from the gas stream. This could be repeated at will.

These facts clearly indicate that the explosion originates on the walls, and does not take place in their absence.

Unfortunately our experimental method does not give an equivalent oxygen–hydrogen mixture, but instead a portion of the crossed streams contains oxygen-rich mixtures which will explode even at pressures much above the upper explosion limit. This makes it impossible to identify the upper explosion pressure by the use of the quartz rod.

Effect of Different Surfaces.—Rods of glass, porcelain, copper, or iron, initiated explosion just as does quartz. **A** rod of aluminum, however, **was** without effect.

Effect of Packing.—The explosion limit is the same in quartz or porcelain vessels, unpacked or filled with crushed quartz or porcelain. This fact naturally led Hinshelwood,[1] and Semenoff and co-workers,[3] to believe the reaction to be homogeneous. The experiments described above, and the pretreatment experiments given below, at once disprove the homogeneous mechanisms, which they have postulated, for sudden explosion of oxygen–hydrogen mixtures, and warn against presenting such data as absolute proofs of homogeneity of reaction henceforth.



U, 576°; V, 569°; W, 559°; X, 549°; Y, 529°; Z, 506°.

Fig. 2.—The explosive region lies at pressures below AC. Values below AB indicate that packing retards reaction.

The non-explosive reaction, on the other hand, is extremely sensitive to the amount of surface present. Hinshelwood and co-workers early data[4] show that at pressures immediately above the upper explosion limit, the non-explosive reaction is accelerated by filling the vessel with bits of porcelain or silica. It must be pointed out that the retardation due to packing claimed by these authors applies only to their high pressure data; at pressures immediately above the explosion limit, packing accelerated, not retarded. This becomes obvious when their results are plotted as in Fig. 2, showing the packing

[4] **Hinshelwood and Thompson,** *Proc.* **Roy.** *Soc.* **(London), [A]** 118, **170** (1928); **Gibson and Hinshelwood,** *ibid.*, **[A]** 119, 591 (1928).

effect at different temperatures. In a second paper,' however, they present data where, under comparable extent and particle size of packing material, it appears that packing tremendously retards reaction (Table I).

TABLE I

REACTION RATE DATA

Oxygen–hydrogen pressure, 555°, mm.	Ratio of rates with packing to rates without Early publications		Later publication
600	0.7	0.9	0.08
300	6.7	8.5	.056

The reason for this discrepancy between their early and later results no doubt lies in differences in the washing process or previous history of their packing material. Pease[5] found that a slight change in the nature of the glass walls, such as is obtained by washing the walls with a solution of potassium chloride, slows down the reaction several thousand fold. This is because the number of chains started is fewer, and the chain-breaking efficiency is increased, on the coated wall, as the work of Taylor and Lavin[6] on combination of hydroxyl radicals and hydrogen atoms on various surfaces amply confirms.

Effect of the Hydrogen–Oxygen Ratio.—Increasing the ratio accelerates the non-explosive, but is unfavorable to the explosive, reaction. The latter is demonstrated in Thompson and Hinshelwood's results in the first two columns of Table II, where in hydrogen-rich mixtures one must exhaust to lower total pressures before explosion will occur.

TABLE II

REACTION RATE DATA

H_2–O_2 ratio	Mixture explodes below (mm. Hg) Pressure $2H_2 + O_2$	Pressure H_2
0.5	129	43
0.67	115	46
1.0	97	49
2.0	99	66
3.0	83	62
4.0	68	56

Attention is directed especially to our calculation in the last column, where it is evident that the hydrogen pressure at which explosion sets in is fairly constant, irrespective of the hydrogen-oxygen ratio.

Pretreatment of the Walls.—Bone and Wheeler[7] showed that porcelain walls around 500° adsorbed large quantities of hydrogen, but no oxygen. Analogously, when walls were preexposed to hydrogen for some hours, subsequently admitted oxy-hydrogen gas reacted much faster. The surface activity was proportional to the length of pretreatment. Preëxpo-

sure to oxygen had no effect. It is striking that the increased activity of the surface due to hydrogen pretreatment was still manifest after the walls had been exposed continuously to the oxy-hydrogen mixtures for two hours, i. e., their reaction rate continued to be greater than normal.

For the explosive reaction we have found the reverse is true.[2] Ten liters per hour, measured at N. T. P., of oxy-hydrogen gas were passed through a porcelain reaction tubing 30 cm. long and 2 mm. in diameter heated at 550° and leading into the large partially evacuated chamber described above. Regulating the pressure in the chamber controls the pressure in the porcelain tube. Normally, if the gas is below 60 mm. pressure it explodes and burns at the mouth of the porcelain tubing; above this it ceases to burn, thus identifying itself with the upper explosion limit discovered by Thompson and Hinshelwood. Procedure was then varied: hydrogen was first passed through the heated tubing at 40 mm. pressure; this was followed by oxy-hydrogen gas at 200 mm., upon lowering the pressure of which, no explosion occurred. Conversely, pretreatment with oxygen seems to favor explosion. A series of consecutive runs carried out in one tubing, Table III, confirm this. Here is evidence that three minutes

TABLE III

DATA OF CONSECUTIVE RUNS

Consecutive pretreatments at 40 mm. with	Time of pretreatment in minutes	On withdrawing $2H_2 + O_2$ gas from 200 to 40 mm. it explodes at
$H_2 + O_2$	2	60 mm.
	2	50
	2	55
	2	70
H_2	5	No explosion
H_2	2	No explosion
O_2	2	70
O_2	3	65
O_2	1	90
O_2	1	60
$H_2 + O_2$	1	50
$H_2 + O_2$	2	50
H_2	3	No explosion
H_2	2	No explosion
H_2	1	No explosion
O_2	5	145
O_2	2	120

H_2	6	No explosion
H_2	1	No explosion
O_2	0.5	No explosion
O_2	1.0	110

or longer of hydrogen pretreatment prevents explosion, and that this is counteracted by longer than thirty seconds oxygen pretreatment. We might add that oxy-hydrogen gas may be passed over the hydrogen pretreated surface for several minutes without normal explosion occurring. Four other tubes yielded the same qualitative results, although they required varying lengths of hydrogen pretreatment, up to fifteen minutes, to prevent the explosion. It can be seen in Table III that not even the normal explosion limit could be evaluated accurately.

The results on pretreatment, and the retarding influence of excess hydrogen, make it clear why Thompson and Hinshelwood found that at 550° hydrogen exploded upon streaming into oxygen at 135 mm. or less while oxygen did not explode upon admission to hydrogen unless the pressure of the latter was lower than 84 mm.

Effect of Steam.—Gibson and Hinshelwood[4] found that the addition of 40% of steam to the oxy-hydrogen mixture speeded up the non-explosive reaction six-fold. That explosion, on the other hand, is completely prevented under these conditions is seen in Table IV. Here our calculations on a few typical measurements by Hinshelwood and co-workers show that the oxy-hydrogen pressure during the course of many of their non-explosive reactions fell into that low pressure region where explosion should have occurred. The steam formed has prevented explosion.

TABLE IV

EXPERIMENTS WITH STEAM

Bulb	Temp., °C.	Initial pressures H_2	O_2	P_{steam} preventing explosian at P_E	Should explode below P_E	Non-explosive reaction measd. down to P_{final}
Packed silica	648	200	129	120	150	86
Packed porcelain	582	150	75	46	155	112.5
Empty silica	567	80	51.5	4	126	71.5
Empty silica	549	403	212	356	82	46

P_E and P_{final} are pressures in millimeters from data by Hinshelwood and co-workers.

Effect of Inert Gases.—Nitrogen and argon act in the same way as steam, accelerating the non-explosive reaction, but preventing explosion,[3,8] since in the absence of inert gases the oxy-hydrogen mixture will explode at higher pressures than in their presence.

Discussion

It is quite certain that we are dealing with chain reactions in both the explosive and the slow reaction,[9] probably involving the mechanism suggested by Bonhoeffer and Haber

$$OH + H_2 = H_2O + H$$
$$H + O_2 + H_2 = H_2O + OH$$

---

[8] Thompson, *Z. physik.* Chem., [B] 10, 280 (1930).

[9] See Farkas, Haber and Harteck, *Naturwiss.*, 18, 266 (1930).

It is clear that the wall breaks the chains by catalyzing the recombination or interaction of H and of OH.

The Non-Explosive Reaction.—But how does the wall initiate chains? The answer was suggested in our introduction: gases adsorbed on its surface release into the gas phase a supply of hydrogen atoms. Bone and Wheeler's results on adsorbed hydrogen were so important as to warrant repetition. Their results are confirmed in Table V and Fig. 3. A 500-cc. Pyrex vessel was filled with coarsely powdered new Pyrex tubing, and placed in an oven. Between each run the vessel was exhausted at 500° for about twenty hours with a Cenco oil pump. The greater part of the gas

adsorbed could be pumped off and collected again at low pressures, although a small amount was consumed in reducing the Pyrex, which became darkened during the measurements. It is apparent that while no hydrogen was adsorbed at room temperatures, tremendous amounts were taken up at 500°. Oxygen under these conditions was not absorbed at either temperature.

Benton[10] observed the identical phenomenon for hydrogen on nickel. Such a type of curve can only be interpreted as meaning that *at the higher temperature hydrogen is adsorbed in an activated form which it is not at room temperature.* This is also substantiated in the pretreatment phenomena discussed above, where hydrogen being desorbed so slowly indicated a large heat of activation for the removal of the hydrogen. The silica surface  has now become possibly  $\overset{OH}{Si}-O-\overset{OH}{Si}-O$.

But we shall go one step further to state *that hydrogen in this form on glass is capable of performing reactions which it is unable to effect at room temperature.*[11] One possible reaction is

$$Si-OH + H_2 \longrightarrow Si-OH_2 + H$$

and by such a mechanism our chain reaction is initiated, the hydrogen atom being liberated into the gas phase.

Such a mechanism for the initiation of chains in the non-explosive reaction explains the phenomena discussed previously. Excess of hydrogen, pretreatment with hydrogen, increasing wall surface, would all accelerate the non-explosive reaction and such is found to be the case. The action of inert gases is possibly connected solely with the gas chains, not the initiating of them at the walls. Steam may act by changing the nature of the adsorbed gas layer[12] and breaking the gaseous reaction chains less easily than a dry surface.

In addition to giving us a satisfactory explanation for the hydrogen–oxygen reaction, this idea clarifies numerous other reactions. Polyakov,[13] passing hydrogen over palladium at 400° obtained an active form of hydrogen which could react with oxygen or recombine further down the tube at a considerable distance from the catalyst. While it is thermodynamically impossible for the palladium to act by shifting the $H_2 \rightleftarrows 2H$ equilibrium and thereby manufacture atomic hydrogen in excess of its exceedingly small equilibrium concentration, the mechanism

$$PdO + H_2 \longrightarrow PdOH + H\uparrow \text{ and } PdOH + H_2 \longrightarrow PdOH_2 + H\uparrow$$

is entirely orthodox and made exceedingly likely in this case where a film of oxygen is known to adhere firmly to a palladium surface.

[12] Elgin and Benton, *ibid.*, 51, 7 (1929).

[13] Polyakov, *Naturwiss.*, 16, 131 (1928); see also Chem. *Abstracts*, 24, *4434* (1930).

Professor H. S. Taylor has pointed out to me an even more illuminating example: a paper where Mitchell and Marshall[14] demonstrated that hydrogen passed over a platinum catalyst yielded what was undoubtedly monatomic hydrogen only if the gas contained a small amount of oxygen. The hydrogen atoms could reduce copper oxide at 5.5 cm. distance from the catalyst.

Additional applications of this type of reaction, the oxidation of carbon disulfide, of carbon monoxide and of the hydrocarbons are discussed subsequently.

Once the reaction chains have been initiated, what is their course? Thompson and Hinshelwood's data can be best interpreted by assuming that the chains which are set up are both straight and branching, the latter predominating at higher pressures and temperatures. This may be due to a reaction slightly endothermic such as

$$\mathrm{H} + \mathrm{H_2} + \mathrm{O_2} \longrightarrow \mathrm{H} + \mathrm{OH} + \mathrm{OH} - 14\mathrm{K.\ cal.}$$

In an unpacked bulb the rate of reaction, therefore, increases very rapidly with temperature until the chains become so branching that explosion occurs.

Halving the pressure will cut down the reaction rate many-fold; this effect will be most pronounced at high temperatures, where branching predominates. This is confirmed in Gibson and Hinshelwood's results where the ratio of reaction rate, time for half change, at 600 mm. to the rate at 300 mm. of $2\mathrm{H_2} + \mathrm{O_2}$ gas mixture is 3.7 at 529° but 18.9 at 569°. In fact this result seems to indicate that there is little if any branching at 529°, so that one must distinguish between the branching-chain, high-temperature explosion at $>570°$, and the low-pressure explosion at 500°, which as pointed out subsequently may consist only of a very large number of straight chains.

In the packed bulb, chains are broken too soon to permit much branching. The reaction increases less slowly with temperature. Explosion is delayed until much higher temperatures, representing maximum branching. Halving the pressure hardly affects the reaction rate until very high temperatures are reached. Gibson and Hinshelwood found that in a packed vessel the rate at 600 mm. was the same as that at 300 mm. at 529°, and 1.8 faster at 569°.

The retarding effect of packing should be greater under those conditions favoring branching chains, *i. e.*, high temperature and pressure. Actually it becomes so great as to counterbalance the catalytic effect of walls initiating chains; the reaction is less in the packed vessel.

[14] Mitchell and Marshall. *J. Chem. Soc.*, 123, 2448 (1923).

Change of Adsorbed Gas **Layer** at the upper Explosion Pressure.—At the beginning of the paper we mentioned the curious abruptness with which the explosive reaction replaces the non-explosive, as one passes the upper explosion limit. Why does the latter, which is becoming slower and slower as the pressure is lowered, suddenly become explosive?

The answer is that there is a sudden change in the adsorbed gas layer responsible for the initiation of the reaction chains.

At this point we wish to draw an analogy with experiments by Langmuir.[15] Hydrogen and oxygen do not react on a tungsten filament at 1500°K. There is, instead, a unimolecular film of oxygen which shields the tungsten surface and prevents it from dissociating the hydrogen as it normally does in the absence of oxygen. The oxygen forces are directed inward toward the tungsten, WO_3 forms and distils off, and the oxygen is gradually consumed. At the point where less than a unimolecular film of oxygen remains, it can no longer ward off the hydrogen, the hydrogen gets in and "making a flank attack on the oxygen" rapidly reacts with it to form steam, and almost instantaneously sweeps the surface bare of oxygen. Thereafter, the normal dissociation of hydrogen into atoms on the tungsten surface sets in.

In our case, with a silica vessel, at 500° and pressures of several hundred millimeters, the gas layer is reversed and the walls are covered with hydrogen, to the exclusion of oxygen. When the pressure is lowered some of the hydrogen is desorbed. This, as well as the branching effects discussed above, slows down the non-explosive reaction. We know this from adsorption measurements such as those presented in Table V, and by analogy with desorption of hydrogen on nickel. However, there is still enough hydrogen to prevent the oxygen from entering the surface layer, just as the oxygen layer on tungsten warded off the hydrogen.

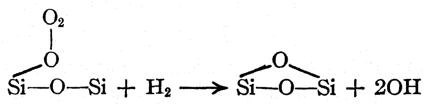
The upper explosion pressure limit is reached. Further reduction in pressure results in the hydrogen sheath losing its power to exclude oxygen from the surface. This may be caused either by a small desorption of hydrogen, or a large stepwise desorption similar to that found by Benton and White,[10] where a small reduction of hydrogen pressure resulted in the sudden desorption from nickel of a third of all the adsorbed hydrogen. In this way the hydrogen sheath is broken open to a flank attack by the oxygen, excess hydrogen swept from the surface and the surface exposed to equal bombardment by oxygen as well as hydrogen.

The original hydrogen-covered surface released hydrogen atoms into the gas phase at a slow rate such that the ensuing reaction was non-explosive. We cannot predict the new type of surface reaction which will be suddenly produced below the explosure pressure. The nature of the adsorbed gas has been radically altered, and there is no objection to assuming that it

---

[15] Langmuir, THIS JOURNAL, **38,** 2271 (1916).

might initiate chains much faster than the hydrogen-covered surface, in fact so fast that explosion occurs. **A** possible reaction is



where the energy necessary to produce 2OH from $H_2 + O_2$ (only 14 cal.) is supplied by the formation of the Si–O bond. This cannot happen of course if the Si–O is covered with hydrogen, *i. e.*, Si–OH, at higher pressures.

The Lower Explosion Limit.—Professor Haber[2] has already suggested as the cause of the lower explosion limit, AB, Fig. 1, an insufficiency of triple collisions at low pressure to carry on the chain step $H + O_2 + H_2 \longrightarrow H_2O + OH$, which explains why, below the identical lower pressure limit, neither the thermal explosion[1,3] nor the spark explosion[16] occurs.

Explanation of Factors Influencing Explosion.—In addition to what has already been said explaining phenomena connected with the non-explosive reaction, such a mechanism satisfies explosive characteristics as well. The upper explosion limit is independent of packing in such similar surfaces as quartz, glass and silica, because it marks the pressure at which oxygen first gains admission to the surface, independent of the amount of surface present. Surfaces of iron and copper give the same qualitative results. Aluminum was expected to be ineffective in causing the explosion, and indeed such was found to be the case. Professor Taylor has called my attention to the similarity between an alumina surface and Langmuir's oxygen-coated tungsten filament.[15] In both instances the covering of oxygen atoms is so tightly bound, chemically, to the metal surface that activity in catalyzing the combination of hydrogen and oxygen is completely paralyzed. No explosion results,

Pretreatment with hydrogen saturates the walls and thereby delays explosion. Of course, the hydrogen may also prevent explosion by poisoning the surface with excess steam.

Excess of hydrogen naturally means one must exhaust to lower total pressures of oxy-hydrogen gas before the hydrogen sheath is broken. The significance of the last column in Table II now becomes apparent: it is the hydrogen pressure below which oxygen gains access to the silica surface.

Other Reactions.—There is every reason to expect that a great many other chain reactions may be initiated at the walls and extend into the gas phase by such a mechanism as we have proposed above. Moreover, in addition to the normal non-explosive reaction, there is always a possibility in each of these cases of sudden change in the nature of the adsorbed gas layer, and a corresponding sudden alteration in reaction velocity upon lowering the pressure. The explosion characteristics of the hydrogen–

---

[16] Kowalsky, *Z. physik. Chem.*, [B] 11, 56 (1930).

oxygen reaction are probably to be met with in numerous reactions. Several such reactions in the field of oxidations are given.

Oxidation of Carbon Disulfide.—It has already been confirmed by H. W. Thompson[8,17] that this reaction simulates the hydrogen-oxygen reaction. Reaction chains are initiated at above 150° at a wall doubtless covered with carbon disulfide, which by a mechanism analogous to that postulated above for the generation of hydrogen atoms liberates oxygen atoms into the gas phase. These will react with carbon disulfide in the gas phase, as Kopsch and Harteck[18] have shown, and the reaction chain be propagated as usual. As the pressure is lowered explosion sets in at 200 mm. This would be interpreted to mean that the carbon disulfide is sufficiently desorbed from the glass surface at this point to permit oxygen to gain access to the surface layer, giving rise to a new explosive surface reaction. Carbon disulfide and oxygen flowing from two concentric tubes explode at a much lower temperature[19] (107°) than under the usual static[8] measurements (140°). This is to be expected because the surface of the oxygen tube should undoubtedly be relatively free from adsorbed carbon disulfide, and, therefore, favorable to initiate explosion at much lower than the normal temperatures.

Oxidation of Carbon Monoxide.—This proceeds at about 650°, presumably initiated on the walls by reaction with adsorbed carbon monoxide. Even at these high temperatures oxygen is still not appreciably adsorbed in an active state.' However, if the chains are initiated by the release of oxygen atoms into the gas phase, the oxidation reaction would proceed by subsequent interaction with water, and not by direct reaction with gaseous carbon monoxide.[20] As the pressure of the gases at 650° is lowered to 100 mm., the same phenomenon appears as in the hydrogen-oxygen reaction: due to the possible desorption of carbon monoxide the surface is suddenly bared to attack by oxygen and explosion results.[3]

Oxidation of Hydrocarbons.—Pease[21] has demonstrated that the oxidation rate of propane decreases several-fold as the temperature is raised from 300 to 425°, but that above this temperature it explodes. The presence of hydrogen has no effect at the lower temperatures, but above 425° it completely inhibits explosion. It is possible that at 300° the surface is covered with propane. As the temperature is raised, propane is desorbed, and the measurable reaction between oxygen and adsorbed propane decreases. At 425° the propane sheath becomes permeable to oxygen and with the new type of adsorbed gas layer explosion occurs.

The hydrogen inhibits only above 425° because below this temperature it is not appreciably adsorbed. Our measurements, Table V, Fig. 3, make it probable that above 425°, however, it would effectively poison the surface and prevent propane explosion.

Post-Explosion.—Farkas, Haber and Harteck[22] observed that if, within two minutes after an oxygen–hydrogen mixture has been exploded by a spark, a fresh supply of gas is admitted to the reaction vessel, explosion occurs even at 420, 20° lower than the lowest normal explosion temperature. It is possible that the spark explosion removes adsorbed hydrogen from the walls, leaving them accessible to oxygen and in a still highly activated state sufficient to catalyze the explosion of the newly admitted gas.

The author wishes to thank Professor H. S. Taylor for his sympathetic interest in, and criticisms of, this paper.

Summary

1. The adsorption of hydrogen on glass increases tremendously above 450°. It is, therefore, adsorbed in a highly activated form not possible at lower temperatures.

2. This gas layer initiates reaction chains which extend out into the gas phase in the combination of hydrogen and oxygen at 500°.

3. Analogously, other chain reactions may be initiated from a layer of gas adsorbed on glass or metallic surfaces, as in the oxidations of carbon disulfide, carbon monoxide and the hydrocarbons.

4. The reaction rate of a hydrogen–oxygen mixture diminishes as the pressure is lowered. Below a certain pressure, however, it explodes. It is shown that the non-explosive and the explosive reactions differ strikingly from each other. The former is extremely sensitive to increase of reaction surface; the latter, not. Pretreatment of the walls with hydrogen, excess hydrogen in the gas mixture, steam and inert gases all accelerate the non-explosive reaction but prevent explosion.

5. These characteristics can be attributed to the controlling influence of the adsorbed layer of hydrogen gas. Explosion occurs at that pressure below which the surface ceases to be completely protected by the hydrogen

6. Desorption of carbon disulfide or carbon monoxide may similarly account for the sudden explosion of these gases in oxygen below a critical pressure, or for phenomena in the oxidation of the hydrocarbons.

A STUDY OF THE ELECTROLYTIC DETERMINATION OF COPPER IN THE PRESENCE OF PLATINIC ION[1]

BY T. LEONARD KELLY AND JOSEPH J. MOLLOY

RECEIVED FEBRUARY 5, 1931 PUBLISHED APRIL 6, 1931

In the procedure for the electrolytic determination of copper, as outlined by Fales,[2] it is recommended that the cathode should not be weighed until the electrolysis is completed, after which the copper is dissolved off by means of 6 molar nitric acid and then the cathode itself is weighed, the difference in weight being that of deposited copper. Such a procedure is deemed necessary in view of the fact that during electrolysis the anode may dissolve to the extent of several tenths of a milligram with subsequent plating out on the cathode.[3] Strange as it may seem this is the only reference to this phenomenon that may be found. According to Popoff,[3] since the platinum is plated over the copper, both the platinum and copper deposited are removed by the nitric acid and consequently there is no need of Fales' precaution.

The object of the present investigation was to determine whether the deposited platinum remained on or was removed from the cathode upon dissolving the copper deposit.

Experimental Procedure

The copper sulfate used was Baker's C. P., which had been recrystallized several times. The electrolyte was made by dissolving this copper sulfate in distilled water and making up to the proper concentration by dilution. These solutions were standardized by electrolysis, using a rotating platinum wire anode and platinum gauze cathode as electrodes. A current of 1.5 amperes was used, this being increased to 2.0 amperes during the last ten minutes of the electrolysis. Electrolysis was carried out in a tall form 300-cc. beaker, covered with split watch glasses, which was placed within a wide-mouthed one-liter beaker.

Fifty cc. of standard copper sulfate is placed in the 300-cc. beaker and 2 cc. of 16 molar nitric acid and 2 cc. of 18 molar sulfuric acid are added and the whole diluted to 200 cc. The same current density was used as in the standardization. After electrolysis had proceeded for about thirty minutes and the cathode was well covered with deposited copper, 1 cc. of the electrolyte was pipetted off and 1 cc. of a standardized platinic chloride solution was added. In this way no fresh surface of the electrode was

---

[1] This paper is constructed from a thesis submitted by Joseph J. Molloy to the Faculty of Holy Cross College in partial fulfilment of the requirements for the degree of Master of Science.

Vales, "Inorganic Quantitative Analysis," Century Book Co., New York, 1925, p. 386.

[3] Although C. W. Easley, THIS JOURNAL, 32, 1123 (1910), has reported only a slight solvent effect of chlorine on a platinum anode, it is a well-known fact that fairly high concentrations of nitric and sulfuric acids do have an appreciable effect. This is reported by Popoff, *ibid.*, 51, 1304 (1929), and has also been experienced by us in this Laboratory.

exposed. In every instance it was observed that the platinum was plated over the copper, this being evident from the darkening of the cathode deposit.

The electrolysis was made to proceed until no positive test for copper was obtained with sodium diethyl dithiocarbamate. A discussion of the method employed in using the indicator and the effect of interfering elements will be found below. The time required for complete deposition varied with the concentration of the copper sulfate used, ranging from fifty minutes for a 64-mg. deposit to ninety minutes for a 315-mg. deposit.

When deposition was complete the cathode was removed in a manner which was partly the method of Beans and Stillman[4] and partly the siphon method as described by Popoff.[5] At the end of the electrolysis, distilled water was run into the electrolyte until the outside beaker was two-thirds full. Then the whole was gradually lowered, distilled water being played upon the cathode as the copper deposit was exposed, the current being shut off only when the electrodes were completely out of the electrolyte. The method resulted in practically no loss of cathode deposit, is efficient, requires but little time and obviates the use of a siphon.

After the cathode was removed it was washed with distilled water, then 95% alcohol, dried and weighed. The copper was now dissolved in 6 molar nitric acid, the cathode washed in distilled water, then in 95% alcohol, dried and weighed. Thus any increase in weight of the cathode over the original weight would be due to the platinum which had plated out on it and had not been dissolved off during the solution of the copper. *In every case the cathode gained in weight.*

The electrolyses were run using various concentrations of the copper sulfate solution and adding 1 cc. of platinic chloride solution, which was also varied in concentration. In this manner we studied the effect of the weight of the copper deposit and also the

effect of the concentration of platinum on the increase in weight of the cathode. These results are given in Table I.

In order to show that the amount of platinum remaining on the cathode seems to be a function of the amount of platinum present in the electrolyte and not on the amount of copper deposited, the following tables are arranged. Table II shows the result of the experiments with one milligram of platinum present and Table III shows the result of the experiments with two milligrams of platinum added to the electrolyte.

These results show that even though there would not be any platinum in the electrolyte at the beginning of a copper determination, the platinum which might dissolve off the anode will deposit not only over the copper but also ***through*** it, because the platinum was not added in our experiments until a heavy deposit of copper was deposited on the cathode. Also it will be seen that all of the platinum which is deposited on the cathode is not removed by the solution of the copper deposit by the nitric acid. Therefore the procedure outlined by Fales, *viz.,* deposit the copper, weigh, dissolve off the deposit and then weigh the cathode, will take care of any additional weight which might be due to solution of the anode and subsequent deposition on the cathode.

As stated above, the indicator used to determine when deposition was complete was sodium diethyl dithiocarbamate. This indicator was introduced by Callan and Henderson.[6] It is used as follows: 1 cc. of the electrolyte is pipetted into a 100-cc. Nessler cylinder, diluted with distilled water, made ammoniacal, 10 cc. of a 0.1% solution of the indicator added and the whole diluted to 100 cc. and well mixed. If copper is present, a clear brownish-yellow color is obtained. This is then matched against a standard, in a Duboscq colorimeter, the standard containing 0.00001 g. of copper per cc. It was found that a decided test for copper could be obtained with a solution containing 0.001 mg. with this indicator. Callan and Henderson have investigated the effects of iron, lead and zinc on the use of this indicator. Since these are not the only elements which are encountered in copper determinations, we thought it would be well to determine the effects of others which are found in these analyses. They are as follows.

NICKEL.—If present, even to the extent of one milligram per 100 cc., nickel gives a decidedly light green precipitate which interferes with the copper reaction. No method of overcoming this difficulty was found.

CADMIUM.—Cadmium gives a cloudy white turbidity which interferes with the copper reaction. No method of overcoming this difficulty was found.

ARSENIC.—As arsenate ion, even when present in fairly large quantities, arsenic does not interfere; as arsenite, however, unless the solution be made strongly ammoniacal, it will yield a white turbidity if present in excess of one milligram per 100 cc.

BISMUTH.—This element presented many difficulties, chief among them being the fact that even after the ammoniacal solution was filtered the filtrate showed a higher concentration of copper than was added. If the solution is made ammoniacal, boiled and filtered and then treated with the indicator, this difficulty is obviated.

Manganese, aluminum and magnesium, which are now encountered in the new light weight alloys, will not interfere with the copper reaction if the ammoniacal solution is boiled and filtered before adding the indicator.

Summary

1. From a study of the electrodeposition of copper in the presence of platinic ion, it has been found that the platinum deposits not only over the copper but also through it, causing an increase in weight of the cathode. It is therefore recommended that the cathode be weighed after the copper is dissolved off, instead of weighing before the deposition, in order to obtain the true weight of the cathode.

2. It has also been shown that the weight of the copper deposited,

---

[6] Callan and Henderson, *Analyst.* 54, 650 **(1929).**

within limits, does not affect the amount of platinum remaining on the cathode after solution of the copper deposit.

3. The effects of certain elements on the use of diethyl dithiocarbamate as an indicator for copper have been shown.

SOLUTIONS OF SALTS IN PURE ACETIC ACID. IV. CUPRIC ACETATE AND AMMONIUM CUPRIC ACETATE

BY ARTHUR W. DAVIDSON AND ERNEST GRISWOLD

RECEIVED FEBRUARY 6, 1931 PUBLISHED APRIL 6, 1931

Introduction

In the first article of this series,[1] it was mentioned that cupric acetate is but slightly soluble in pure acetic acid, and that its solubility is markedly increased upon the addition of ammonium acetate; it was suggested that in this respect the cupric and ammonium acetates might be regarded as analogous to the corresponding hydroxides, whose interaction in aqueous solution is so familiar a phenomenon. No quantitative solubility data for cupric acetate in anhydrous acetic acid have been reported previously. Sandved,[2] however, determined the isotherm for the ternary system cupric acetate–acetic acid–water at 25°, and a short extrapolation from his data indicates the solubility in the pure acid to be about 0.24 mole per cent. of cupric acetate, the solid phase being the acid salt $Cu(C_2H_3O_2)_2 \cdot HC_2H_3O_2$. In the present investigation the solubility of cupric acetate over a range of temperatures has been measured, both in pure acetic acid and in the presence of ammonium acetate in varying concentration. The effect of potassium acetate, at one concentration, was determined also. Consideration of the results obtained has led to certain new ideas, which will be developed below, with respect to the analogy between these solvent effects and the corresponding phenomena in aqueous solution.

Method

Preparation of Materials.—The acetic acid, ammonium acetate and potassium acetate employed were all prepared as described in the second paper of this series.[3] The anhydrous cupric acetate used was prepared by recrystallizing the hydrate from solution in dilute acetic acid, and dehydrating at 90° until analysis showed no water to be present. Samples of the product, which was dark bluish-green, were analyzed for copper by the electrolytic and by the iodimetric method, and gave closely concordant results, averaging 34.99% of copper (calcd. for $Cu(C_2H_3O_2)_2$, 35.00%).

Binary System.—The solubility of cupric acetate in pure acetic acid was determined

by the freezing point method previously described,' large stoppered test-tubes provided with thermometer and stirrer being used for the freezing point determinations. Short-range calibrated thermometers were employed, and each freezing point was determined at least twice. The equilibrium temperatures reported are believed to be correct to within 0.2".

Ternary System.—In the study of the solvent effect of ammonium acetate, the method described in the preceding paper of this series[4] was employed. Acetic acid solutions were prepared containing 7.9, 11.6, 15.1, 20.7, 22.1 and 23.7 mole per cent., respectively, of ammonium acetate. Known amounts of cupric acetate were dissolved in these solvents, and the equilibrium temperatures were determined just as in the binary systems. In these cases, however, due to the greater viscosity and deeper color of the solutions, the same degree of accuracy could not be attained; most of the temperatures reported, however, are believed to be correct to within 1°. By plotting these temperatures as ordinates against the mole percentages of cupric acetate as abscissas, a series of curves was obtained, each representing the variation with temperature of the solubility of cupric acetate in a solution having a fixed value of the ratio, number of moles of ammonium acetate/number of moles of (ammonium acetate + acetic acid), which ratio will hereafter be referred to as R.

Analysis of Solid Phases.—Samples of the solid phases present at equilibrium were obtained by crystallization from the solution under suitable conditions, followed by filtration and rapid drying between porous tiles. When the compound contained only cupric acetate and acetic acid, determination of copper by the electrolytic or iodimetric method sufficed to fix its composition. When a qualitative test showed ammonia to be present in the solid phase, however, a portion of the sample was analyzed for copper as above, and another portion for ammonia by addition of sodium hydroxide solution, followed by distillation into standard hydrochloric acid.

The data obtained are tabulated below, and are represented also in the accompanying diagrams. The concentration of cupric acetate in the solution is expressed throughout in mole percentage, and the equilibrium temperature is denoted by T.

Results

I. Binary System $Cu(C_2H_3O_2)_2$–$HC_2H_3O_2$.—The solutions were bluish-green, and showed no change in color on heating.

somewhat smaller than that obtained by extrapolation from the data of Sandved.[2]

The solid phase (b) was light blue-green in color, and was quite unstable, rapidly losing acetic acid vapor on exposure to the atmosphere. Because of this instability, a high degree of accuracy was not to be expected in its analysis; the percentage of $Cu(C_2H_3O_2)_2$ would tend to be too high. Five analyses for copper, in which the samples were handled as rapidly as possible before weighing, gave the following results (calculated to mole per cent. of $Cu(C_2H_3O_2)_2$): 51.14, 54.41, 56.02, 52.73, 50.28; average 52.93%. It is believed that these figures establish satisfactorily that the compound is the solvate $Cu(C_2H_3O_2)_2 \cdot HC_2H_3O_2$, previously reported by Sandved. In the neighborhood of 50° this compound undergoes transition to a dark bluish-green substance *(c)* which could not be obtained in sufficient quantity for analysis, but which appears to be unsolvated $Cu(C_2H_3O_2)_2$.

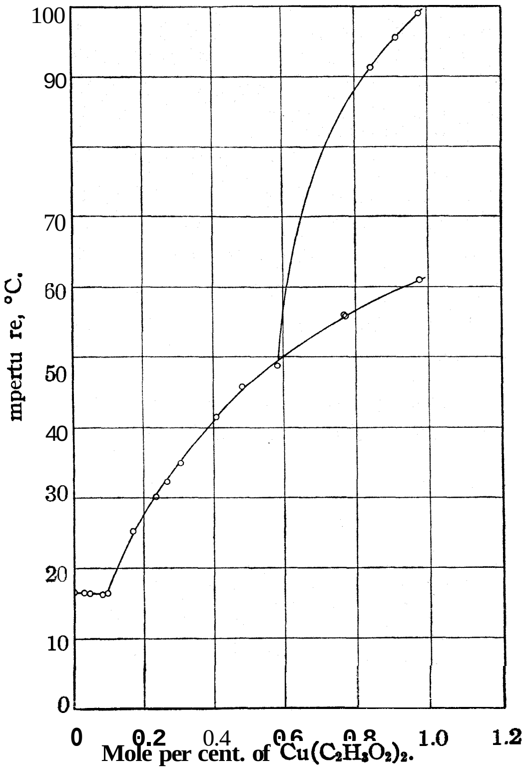

Fig. 1.—Solubility curve of $Cu(C_2H_3O_2)_2$ in pure $HC_2H_3O_2$.

II. Ternary System $NH_4C_2H_3O_2$–$Cu(C_2H_3O_2)_2$–$HC_2H_3O_2$.—These solutions were greenish-blue at ordinary temperatures. On heating, a marked deepening in color took place, together with a change toward the violet. At temperatures in the neighborhood of 120° for small values of R, or lower for the larger values, they attained a deep violet-blue color strongly reminiscent of aqueous cupric ammonia solutions; on cooling, they resumed their original greenish-blue color. This color change will be discussed later.

The curves for this system are given in Fig. 2; for purposes of comparison, part of the curve for the binary system is reproduced here also. In series **A**, B, C and D (b), the solid phase was light blue-green in color, as in **(b)** of the binary system; qualitative tests showed it to contain no am-

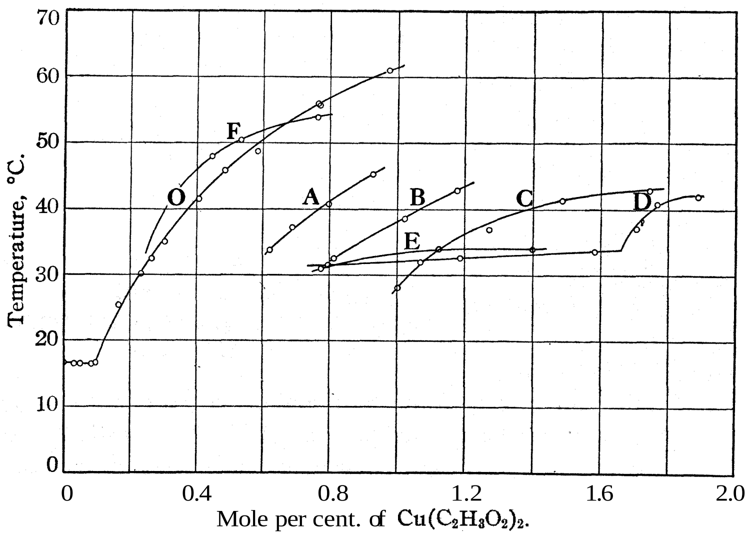

Fig. 2.—Solubility curves of $Cu(C_2H_3O_2)_2$ in $HC_2H_3O_2$ containing various concentrations of $NH_4C_2H_3O_2$: O, $R = 0$ (pure $HC_2H_3O_2$); A, R = 0.079; B, R = 0.116; C, R = 0.151; D, R = 0.207; E, R = 0.221; F, R = 0.237.

monia. No quantitative analysis of this compound was made, since its close resemblance in appearance and behavior to the solid phase which had been isolated, under similar conditions, from the binary system, was deemed sufficient to identify it as the same substance, namely, the solvated cupric acetate $Cu(C_2H_3O_2)_2 \cdot HC_2H_3O_2$. Further evidence of the correctness of this conclusion is to be found in the solubility isotherm of Fig. **3** (to be discussed in detail later); it will be seen that the solubility values for cupric acetate in pure acetic acid and at the lower concentrations of ammonium acetate fall upon a perfectly smooth curve, which could hardly be the case unless they referred to the same solid phase throughout this range.

In series D(a), E and F, the solid phase was quite evidently a different compound from that just discussed. It was deep blue in color, fairly stable on exposure to the atmosphere, and evolved ammonia on treatment with sodium hydroxide. In this case, the high viscosity of the mother liquor made its complete removal difficult; three quantitative analyses, however, gave the following results

	Mole, % $Cu(C_2H_3O_2)_2$	Mote, % $NH_4C_2H_3O_2$	Mole, % $HC_2H_3O_2$ (by difference)
	10.85	46.18	42.97
	9.49	43.49	47.02
	10.17	44.16	45.67
Average	10.17	44.61	45.22
Calcd. for $Cu(C_2H_3O_2)_2 \cdot 4NH_4C_2H_3O_2 \cdot 4HC_2H_3O_2$	11.11	44.44	44.44

These figures leave little room for doubt that the deep blue substance is a ternary compound, or solvated ammonium cupric acetate, of the composition given. No such compound has been reported previously, although an ammoniated cupric acetate of the formula $Cu(C_2H_3O_2)_2 \cdot 4NH_3$ is well known;[5] a hydrated ammonium cupric acetate, $2Cu(C_2H_3O_2)_2 \cdot NH_4C_2H_3O_2 \cdot H_2O$, is to be found in the literature,[6] and there is also some evidence for the existence of a hydrate of $Cu(C_2H_3O_2)_2 \cdot 4NH_4C_2H_3O_2$, although this compound has not been isolated in a pure state.[7]

It appears from these data that the solubility of cupric acetate in acetic acid at any fixed temperature between 30 and 45° increases with increasing concentration of ammonium acetate, so long as solvated cupric acetate is the stable solid phase. Upon the appearance of the ternary compound, however, the mole percentage of cupric acetate in the saturated solution begins to decrease with increasing ammonium acetate concentration. This is more clearly brought out in Fig. **3,** which represents an isotherm for 33.7°, plotted from data obtained from Fig. 2. It will be seen that the

[7] Foerster, *Ber.*, **25**, 3416 (1892).

solubility of cupric acetate, which is 0.280 mole per cent. in pure acetic acid at this temperature, increases upon the addition of ammonium acetate until R is 0.207, when the solubility reaches a maximum of 1.66 mole per cent., and a new solid phase appears. Beyond this point the concentration of cupric acetate in the saturated solution diminishes very rapidly with further addition of ammonium acetate, falling to a value of no more than 0.25 mole per cent. (somewhat less than the solubility in acetic acid alone) at the highest concentration of ammonium acetate investigated (R = 0.237). Shortly beyond this point, when R = 0.258, the compound $NH_4C_2H_3O_2 \cdot HC_2H_3O_2$ appears as solid phase.

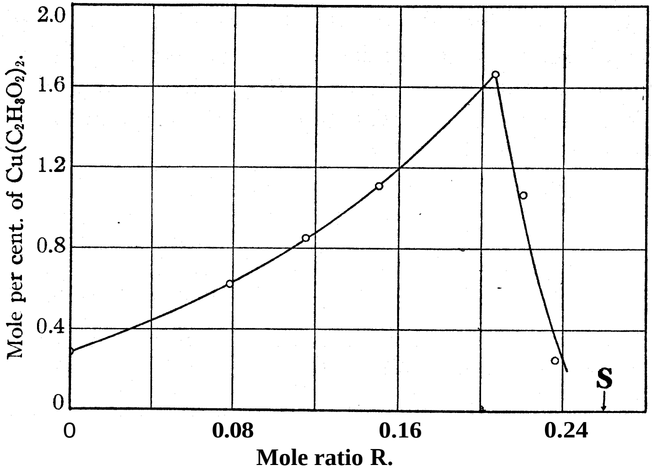

Fig. 3.—Effect of varying concentration of $NH_4C_2H_3O_2$ upon the solubility of $Cu(C_2H_3O_2)_2$ in $HC_2H_3O_2$ at a fixed temperature: isotherm at 33.7°. *S* indicates saturated solution of $NH_4C_2H_3O_2$.

In order to determine whether or not the solvent action upon cupric acetate, which has just been discussed, is due solely to the presence of ammonia, one further experiment was carried out, in which *potassium* acetate was employed as solvent. An acetic acid solution of the latter salt, in which R was 0.083, was found to dissolve 0.476 mole per cent. of cupric acetate at 33.7°. This is evidently of the same order as the solubility of the cupric salt in ammonium acetate solution under similar conditions One marked difference between the two cases, however, is worthy of mention. Although the potassium acetate-cupric acetate solution was very similar in color, at ordinary temperatures, to a corresponding solution containing the ammonium salt, yet in the former case no perceptible color change took place on heating; at 100° the colors of the two solutions were quite unlike. The possible significance of this fact will be considered in the following section.

Discussion

As was stated in the introduction to this article, when it was first discovered that cupric acetate readily dissolved in an acetic acid solution of ammonium acetate, we were disposed to regard this phenomenon as quite analogous to the solubility of cupric hydroxide in aqueous ammonium hydroxide. Superficially, indeed, besides the purely formal resemblance, there is a fairly close parallel between the observed facts in the two cases The solubility of cupric hydroxide increases with increasing concentration of ammonium hydroxide,[8] and although there is no satisfactory evidence as to the solid phase in equilibrium with concentrated solutions, the compound $Cu(OH)_2 \cdot 4NH_3$ is commonly supposed to be present in the solution.[8b,9] The ternary compound obtained in the present investigation might, correspondingly, be regarded as a solvated $Cu(C_2H_3O_2)_2 \cdot 4NH_3$. Further, as stated above, the violet-blue color which appears at high temperatures in the ternary solutions herein described, is strikingly similar to that of the aqueous solutions under discussion. But there are a number of considerations which tend to cast doubt upon the validity of this analogy. Foremost among these is the fact that solutions of ammonium acetate in acetic acid, unlike ammonium hydroxide in water, have no appreciable vapor pressure of ammonia at ordinary temperatures; the ammonium acetate is quite stable and gives every indication of being as strong a base as the corresponding potassium compound, which, indeed, it closely resembles. Not only are the freezing-point curves of potassium and of ammonium acetates in acetic acid very similar,[10] but it has been found that the two bases behave in exactly the same manner upon electrometric titration with strong acids.[11] It has just been shown, too, that the solvent action upon cupric acetate is not peculiar to the ammonium salt but is exhibited by potassium acetate to a similar degree. Furthermore, the isotherm obtained in this investigation is quite similar to that previously found[4] for the system sodium acetate–zinc acetate–acetic acid, and the ternary addition compounds obtained in the two cases are of the same nature, as may be seen by comparing the two formulas

$$Zn(C_2H_3O_2)_2 \cdot 2NaC_2H_3O_2 \cdot 4HC_2H_3O_2$$
$$Cu(C_2H_3O_2)_2 \cdot 4NH_4C_2H_3O_2 \cdot 4HC_2H_3O_2$$

All of these facts point toward the conclusion that the solvent effect of ammonium acetate upon cupric acetate, at least at low temperatures, is due to the strongly basic nature of the ammonium compound, rather than to any specific effect of the ammonia which it contains, and that the analogous

[11] Hall, private communication.

phenomenon in aqueous solutions should be sought in the effect of strong alkalies, rather than of ammonium hydroxide, upon cupric hydroxide.

It is true that cupric hydroxide is not ordinarily regarded as amphoteric; but, as has frequently been pointed out,[12] the difference among the various metals in this respect must be regarded merely as one of degree. Cupric hydroxide is, indeed, appreciably soluble in concentrated aqueous solutions of sodium or potassium hydroxide, giving a deep blue solution, The most reliable quantitative data that have been obtained on this point appear to be those of Müller[13] for the system sodium hydroxide–cupric hydroxide–water. He found that the solubility of cupric hydroxide[14] in sodium hydroxide solutions at 18° increases, at first, with increasing concentration of alkali, reaching a maximum of about 0.3 mole per liter in approximately 12.5 molar sodium hydroxide solution. Here, however, a new solid phase appears, which is referred to as sodium cuprite, and is apparently of the formula $Na_2CuO_2{\cdot}2H_2O$, or $Cu(OH)_2{\cdot}2NaOH$, and from this point on the concentration of cupric hydroxide in the saturated solution decreases sharply with increasing concentration of alkali. The relationships in the ternary system studied in the present investigation are obviously quite similar to those just discussed, with the ternary addition compound, whose formula might alternatively be written $(NH_4)_4Cu(C_2H_3O_2)_6{\cdot}4HC_2H_3O_2$, playing the same part as the sodium cuprite in the aqueous system.[15] However, as in the case of the sodium zinc acetate discussed previously,[4] we are hardly prepared, as yet, definitely to characterize this compound; further study of its properties will be required before it can be determined whether or not it should be considered as a cuprite.[16]

In supposing the effect of ammonium acetate upon cupric acetate to be of the same nature as that of potassium acetate, and in drawing an analogy between these effects, on the one hand, and that of strong alkalies upon cupric hydroxide in aqueous solution, on the other, we have apparently disregarded the marked reversible deepening of color which occurs in the ammonium acetate–cupric acetate solutions, and in these alone, on heating. We suggest the following hypothesis[17] to account for this color change.

---

[12] See, for instance, Goudriaan, *Rec. trav. chim.*, *39*, 505 (1920); Kraus, *Trans. Am. Electrochem. Soc.*, 45, 175 (1924); Franklin, THIS JOURNAL, 46, 2144 (1924).

[13] Müller, *Z. physik. Chem.*, *105*, 73 (1924).

[14] Cupric hydroxide was found to be metastable with respect to cupric oxide under these conditions; nevertheless its solubility could be determined.

[15] Just as the sodium cuprite is unstable in contact with pure water, and can exist only in the presence of concentrated sodium hydroxide solutions, so the ternary compound of this article is unstable in the presence of pure acetic acid.

[16] In the ammonia system, a compound of a somewhat analogous nature, having the formula $CuNK_2{\cdot}3NH_3$, or $CuNH_2{\cdot}2KNH_2{\cdot}NH_3$, was described by Franklin, THIS JOURNAL, 34, 1501 (1912), and was called by him potassium ammonocuprite. In this compound, however, the copper is in the cuprous, not the cupric, state.

[17] *Cf.* Ref. 1, p. 1894.

An ammonium acetate solution in acetic acid may, of course, be regarded, with equal validity, as a solution of *ammonia* in this solvent. At ordinary temperatures, as has been mentioned above, there is every reason to believe that the ammonia is completely combined with the solvent. As the temperature is raised, however, an increasing dissociation into ammonia and solvent doubtless occurs, just as in the case of aqueous ammonium hydroxide. It has, in fact, been shown[18] that the vapor pressure of ammonia from a concentrated solution of ammonium acetate in acetic acid at the boiling point must be appreciable, since the distillate from such a solution contains a perceptible quantity of ammonia. It therefore seems reasonable to suppose that while ammonium acetate in acetic acid at room temperature is comparable to potassium hydroxide rather than to ammonium hydroxide in aqueous solution, yet at temperatures above 100° it begins to exhibit properties analogous to those of aqueous ammonia at ordinary temperatures. The ammonia, then, being but loosely held by the solvent under these conditions, may be available for the formation of other ammonia complexes. If this hypothesis is correct, the violet-blue color which appears in the cupric acetate–ammonium acetate solutions at elevated temperatures may be due to a complexion, $Cu(NH_3)_n^{++}$, of the same nature as that which gives rise to a similar color in the aqueous cupric ammonia solutions.

Summary

1. The solubility of cupric acetate in pure acetic acid and in the presence of ammonium acetate in concentrations up to 23.7 mole per cent. has been determined at various temperatures.

2. The concentration of cupric acetate in the saturated solutions at a fixed temperature has been found to increase with increasing concentration of ammonium acetate as long as a solvated cupric acetate is the stable solid phase, but to decrease with further addition of ammonium acetate after the appearance of a ternary addition compound as solid phase.

3. A solvated ammonium cupric acetate of the formula $Cu(C_2H_3O_2)_2\cdot 4NH_4C_2H_3O_2\cdot 4HC_2H_3O_2$ has been isolated and analyzed.

4. The ternary system here studied has been compared with solutions of cupric hydroxide in concentrated aqueous alkali solutions, and certain resemblances have been pointed out.

5. An hypothesis has been advanced to account for the violet-blue color which appears at elevated temperatures in ammonium acetate–cupric acetateacetic acid solutions.

THE EFFECT OF AMMONIUM FORMATE UPON THE SOLUBILITY OF CUPRIC FORMATE IN FORMIC ACID

BY ARTHUR W. DAVIDSON AND VERNON HOLM

RECEIVED FEBRUARY 6, 1931 PUBLISHED APRIL 6, 1931

Introduction

In a previous article,[1] it was shown that the solubility of cupric acetate in anhydrous acetic acid is markedly increased in the presence of ammonium acetate, and comparisons were drawn between this phenomenon, on the one hand, and the analogous effects of alkalies and of ammonium hydroxide upon cupric hydroxide in aqueous solution, on the other. It seemed desirable to study the corresponding system in another solvent, in order to determine whether acetic acid were unique among non-aqueous media, in this respect, or whether the behavior referred to might be regarded as a more or less general effect of ammonia in systems of the type CuX_2–HX. For this investigation, formic acid was chosen as solvent; this substance is a liquid over a wide temperature range (8.5 to 100.5°), is readily prepared in a pure state, and is known to be a good solvent for numerous salts.

The solubility of cupric formate in anhydrous formic acid was found by Kendall and Adler[2] to be very small, the saturated solution at 140° containing less than 0.1 mole per cent. of solute; no further data are given. In the present work the solubility of cupric formate over a range of temperatures has been measured, both in pure formic acid and in the presence of ammonium formate in varying concentration. The effect of potassium formate, at one concentration, was determined also. The results were similar to, though not identical with, those obtained in acetic acid solution, as will be shown below.

Method

Preparation of Materials.—The formic acid employed was prepared from a good grade of 90% acid by dehydration with boric anhydride, B_2O_3, as suggested by Schlesinger and Martin.[3] The acid was allowed to remain for a week in contact with a slight excess over the theoretical quantity of boric anhydride; it was then distilled off, treated with a small amount of fresh dehydrating agent, and again allowed to stand for several days. Finally the liquid was decanted and distilled under reduced pressure. The product had a freezing point of 8.3 to 8.5°, and was practically 100% formic acid.

Ammonium formate was prepared by passing dry ammonia into 100% formic acid until complete solidification had occurred. The product was desiccated over 99% sulfuric acid, and was then found to have a melting point of 117–118°, agreeing with that reported by Kendall and Adler. Potassium formate was obtained by dissolving pure potassium carbonate in an excess of 90% formic acid, heating to expel carbon dioxide

evaporating off most of the excess acid, and then heating to 150° for several days and finally to 190° for about an hour. The product had a melting point of 168°, agreeing with that reported by Kendall and Adler.

In the preparation of pure anhydrous cupric formate, some difficulty was encountered. An aqueous solution of the salt was readily obtained by dissolving basic cupric carbonate in 50% formic acid and heating to expel carbon dioxide. On cooling to room temperature, crystals of the tetrahydrate separated out, The first attempt to dehydrate this compound by heating to constant weight at 80°, as recommended by Kendall and Adler, was entirely successful, yielding a bright blue product which showed, upon analysis by the electrolytic method, 41.35% of copper (calcd. for $Cu(CHO_2)_2$, 41.39%). Strangely enough, however, several attempts to obtain further quantities of the salt by this method failed, because the cupric formate was partially changed, on heating, to a dark brown substance of unknown chemical nature, before the dehydration was complete. A somewhat different procedure was therefore adopted. Instead of being allowed to cool to room temperature, the solution was maintained at 80°; the crystals separating out under these conditions consisted of the anhydrous salt[4] These crystals were pressed between porous tiles and then dried at 75° for ten hours. The resulting product showed no discoloration, and analysis proved it to be pure anhydrous cupric formate.

Binary System.—The solubility of cupric formate in formic acid was determined by the freezing point method previously described.[5] Large test-tubes, each fitted with a thermometer and a stirrer in such a manner as to exclude moisture, were used for the freezing point determinations. Four calibrated thermometers were employed, and each freezing point was determined at least twice. Because of the very low solubility, in this case, and the very minute amounts of solid phase which could be made to separate, the accurate determination of freezing points was a matter of some difficulty. However. the temperatures reported are believed to be correct to within 0.5°.

Ternary System.—In the study of the solvent effect of ammonium formate, the method described in previous articles[1,6] dealing with similar ternary systems was again employed. Preliminary experiments having shown that the solubility of the copper salt, at any given concentration of ammonium salt, was much smaller in this case than in the acetic acid system, rather high concentrations of ammonium formate were used. Formic acid solutions were prepared containing 1U.00, 19.73, 29.75, 33.54 and 43.75 mole per cent., respectively, of ammonium formate. Known amounts of cupric formate were dissolved in these solvents,[7] and the equilibrium temperatures were determined just as in the binary systems. Thus a series of curves was obtained, each of which represented the solubility of cupric formate, at various temperatures, in a solvent having a fixed value of the ratio, number of moles of ammonium formate/number of moles of (ammonium formate + formic acid); this ratio will subsequently be referred to as R.

Analysis of Solid Phases.—When the solid phase in equilibrium with the solution was obtainable in sufficient quantity to make it possible, samples were prepared for analysis by crystallization from the solution under appropriate conditions, filtration and drying between porous tiles as rapidly as possible, to minimize loss of formic acid. Qualitative tests showed no ammonia to be present in any of the solid phases. Cupric formate and formic acid being the only components, a quantitative determination of copper by the electrolytic method was sufficient to fix the composition of the compound.

[6] Davidson and McAllister, ibid., ***52***, 519 (1930).

[7] The color of the solutions, at room temperature, was a blue resembling that of the cupric ion in aqueous solution; on heating, however, it changed to a deep violet-blue, This color change will be discussed later.

The data obtained are tabulated below, and are also presented graphically in the accompanying diagrams. The concentration of cupric formate in the solution is expressed throughout in mole percentage; T denotes the equilibrium temperature.

Results

I. Binary System $Cu(CHO_2)_2$–$HCHO_2$

$Cu(CHO_2)_2$, %	0.0045	0.0048	0.0066	0.0075
T	35	42	49	52

The curve for this system is given in Fig. 1. It is evident that the solubility of cupric formate at ordinary temperatures is extremely small, far below the maximum value of 0.1% that was given for 140° by Kendall and Adler. It was found impossible to determine equilibrium temperatures below 35°; however, the curvature was so slight as to make it possible to continue the curve to the eutectic point by extrapolation. The solubility at 25° is 0.0040 mole per cent., about one-fortieth of the value obtained for cupric acetate in acetic acid.' The solid phase appeared to be bright blue in color, but could not be obtained in sufficient quantity for analysis.

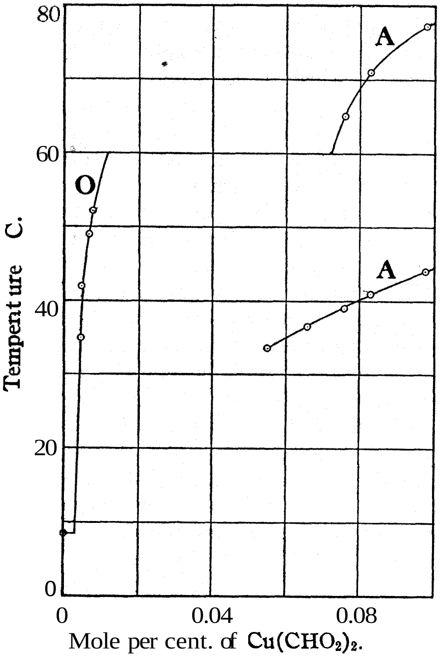

Fig. 1.—Solubility curves of $Cu(CHO_2)_2$ in pure $HCHO_2$ (Curve 0) and in 10% NH_4CHO_2 (Curve A).

II. Ternary System NH_4CHO_2–$Cu(CHO_2)_2$–$HCHO_2$

A. Mole Ratio R = 0.10

Two sets of equilibrium temperatures were obtained in this series, one corresponding to a stable, the other to a metastable equilibrium.

The curves for this system are given in Fig. 2; the one for the lowest concentration of ammonium formate is shown also in Fig. 1, on the same scale as that used in the binary system, for purposes of comparison with the solubility curve of cupric formate in formic acid alone. In series A and B the solid phases were bright blue in color and similar in appearance to that obtained in the binary system; they contained no ammonia, and therefore consisted of cupric formate, presumably solvated. They could not be obtained in sufficient quantity for a reliable quantitative analysis, however.

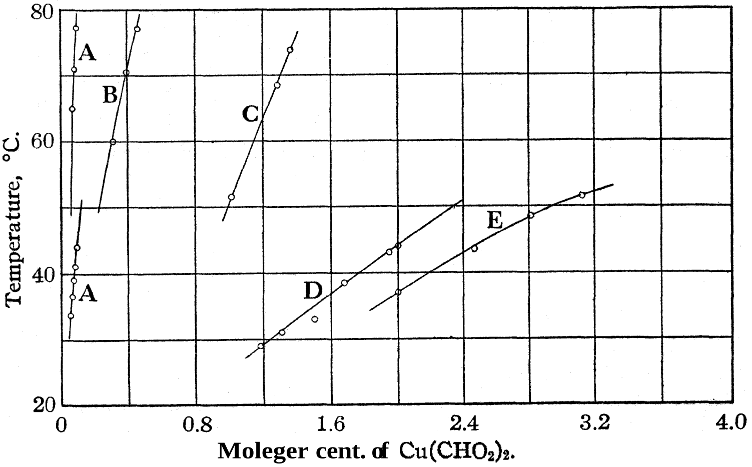

Fig. 2.—Solubility curves of $Cu(CHO_2)_2$ in $HCHO_2$ containing various concentrations of NH_4CHO_2: A, R = 0.10; B, R = 0.1973; C, R = 0.2975; D, R = 0.3354; E, R = 0.4375.

In series C, D and E, the solids isolated were pale blue in color. Qualitative analysis showed them to contain cupric formate and formic acid, but no ammonia. No acid cupric formate has been reported previously. Quantitative analysis gave the following results.

Series	% Cu	Mole % $Cu(CHO_2)_2$
C	28.65	40.26
D	27.78	37.96
E	28.11	38.82
Average	28.18	39.00
Calcd. for $2Cu(CHO_2)_2 \cdot 3HCHO_2$	28.56	40.00

It was impossible to attain a very high degree of accuracy in the analyses of these solid phases, because of the very small amounts of crystals obtainable, the difficulty in freeing them from the rather viscous adhering mother liquor, and their tendency to lose formic acid in vapor form on exposure to the atmosphere. However, it is believed that the figures given satisfactorily establish that the three substances analyzed are identical and that they consist of a solvated cupric formate, probably of the formula $2Cu(CHO_2)_2 \cdot 3HCHO_2$.

It is evident that the solubility of cupric formate in formic acid at a fixed temperature increases with increasing concentration of ammonium formate throughout the concentration range investigated, though not at a uniform rate. This is brought out more clearly in Fig. 3, which is an isotherm for 50°, plotted from the data of Fig. 2. At this temperature the solubility of cupric formate first increases as an almost linear function of R—the solid phase in this range being the bright blue compound of unknown degree of solvation—from 0.0068 mole per cent. in pure formic acid (R = 0) to 0.33 mole per cent. when R is 0.294. There a new solid phase—the pale blue solvate $2Cu(CHO_2)_2 \cdot 3HCHO_2$—appears, and the solubility then increases much more rapidly with increasing R, reaching a value of 2.95 mole per cent. at the highest concentration of ammonium formate investigated (R = 0.4375). A little beyond this point, at R = 0.51, NH_4CHO_2 appears as solid phase.

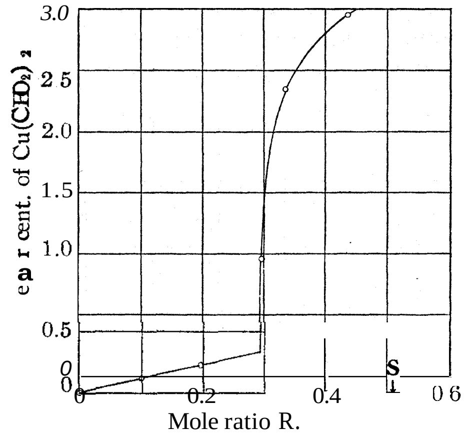

Fig. 3.—Effect of varying concentration of NH_4CHO_2 upon the solubility of $Cu(CHO_2)_2$ in $HCHO_2$ at a fixed temperature: isotherm at 50°. S indicates saturated solution of NH_4CHO_2.

In order to compare the solvent effect of potassium formate with that of ammonium formate, one further experiment, in which the former salt was used, was carried out. A solution in which R was 0.244 was found to dissolve 0.38 mole per cent. of cupric formate below 60°. This, as may be seen from the isotherm, is of the same order as the solubility of the cupric salt in ammonium formate solution under similar conditions.

Discussion

Comparison of Results with Data for the Corresponding Acetic Acid System.—It was shown in the previous article[1] referred to at the beginning of this paper that the solubility of cupric acetate in acetic acid at any fixed temperature between 30 and 45° is at first increased by the addition of ammonium acetate, a solvated cupric acetate being the stable solid phase in contact with these solutions. The data obtained in the present investigation show that this behavior is paralleled in the corresponding ternary system in formic acid, although the solubility of the cupric salt at any given value of R is much smaller in the latter case than in the former.

In the acetic acid system, at higher concentrations of ammonium salt, a ternary compound of the formula $Cu(C_2H_3O_2)_2 \cdot 4NH_4C_2H_3O_2 \cdot 4HC_2H_3O_2$ appears as stable solid phase, and the concentration of cupric acetate in the saturated solution then diminishes with increasing concentration of ammonium acetate. We expected to come upon a similar ternary compound in the formic acid system, but no such substance appeared, and the solubility of cupric formate continued to increase with increasing ammonium formate concentration throughout the range studied. It is, indeed, possible that a ternary compound might have been obtained as solid phase at still higher concentrations of ammonium formate, but this region could not be satisfactorily investigated.[8] It may be of interest to mention here that although no addition compound of cupric formate and ammonium formate appears to be known as yet, a compound of cupric formate and ammonia, having the formula $Cu(CHO_2)_2 \cdot 4NH_3$, has been reported.[9] We confirmed the existence of this compound by passing ammonia over a weighed quantity of cupric formate at 0° until no further increase in weight occurred; the amount of ammonia taken up closely corresponded to the above formula, and the product was blue-violet in color.

One further point of similarity between the two systems remains to be mentioned It was pointed out as a conspicuous property of the cupric acetate–ammonium acetate–acetic acid system that, on heating the solutions, a marked deepening of the blue color, accompanied by a change toward the violet, takes place. An exactly similar change was observed in the present investigation; at temperatures in the neighborhood of 100° for small values of R, or lower for the larger values, the ternary solutions attain a deep violet-blue color closely resembling that of aqueous cupric ammonia solutions; on cooling, they return to their original blue color. On the other hand, although solutions similar in color, at room tempera-

---

[8] An attempt was made to employ as solvent a solution in which R was 0.50—an equimolecular mixture, that is, of ammonium formate and formic acid; but several circumstances made it impossible to obtain satisfactory results in this solvent. In the first place, since such a solution was supersaturated with respect to NH_4CHO_2 at temperatures up to 47°, the latter substance, rather than the copper compound, was likely to separate on cooling. Second, the very high viscosity of the solution promoted supercooling, as well as delayed the escape of air bubbles, and finally, the very deep blue color of the solution united with these other factors to make accurate observation of melting points a practical impossibility.

[9] Ephraim and Bolle, *Ber.*, 48, 1770 (1916).

ture, to those just discussed are readily obtained by the solvent action of potassium acetate and potassium formate upon the corresponding cupric salts in acetic acid and in formic acid, respectively, yet in these cases no color change whatever is observable on heating. The appearance of the violet-blue color in such solutions, therefore, is a phenomenon apparently occurring only in the presence of ammonium salts, is independent of the anion and may be due to the formation of some sort of cupric ammonia complex, as suggested previously.

Conclusions.—It was pointed out by Davidson and Griswold[1] that the water analog of the solubility of cupric acetate in acetic acid solutions of ammonium acetate at low temperatures is to be found in the solvent effect of the strong alkalies, rather than in that of ammonium hydroxide, upon cupric hydroxide, and it was suggested that only at temperatures above 100°, where the bond between the ammonia and the acetic acid may be supposed to be weakened, do the conditions approach those prevailing in an aqueous ammonium hydroxide solution at ordinary temperatures. The facts presented in this article are in complete accord with a similar hypothesis for formic acid solutions. Ammonium formate may obviously be regarded as a base in formic acid; here, it is true, there are no electrometric titration data available for comparing its basic strength with that of the corresponding potassium compound,[10] but the conductivity measurements of Schlesinger and co-workers[3,11] indicate that ammonium formate is highly dissociated, and give evidence of its being at least as strong a base as potassium formate, in this solvent. It is not surprising, therefore, that the solvent effects of the two bases upon cupric formate should be so nearly alike. However, the avidity of cupric formate for ammonia, on the one hand, and the characteristic violet-blue color, suggesting a cupric ammonia complex, that appears in hot cupric formate–ammonium formate solutions, on the other, make it seem probable that at high temperatures the free ammonia formed by dissociation also plays a part in the solvent action of ammonium formate.

Summary

1. The solubility of cupric formate in pure formic acid and in the presence of ammonium formate in concentrations up to 43.75 mole per cent. has been determined at various temperatures.

2. The solubility of cuprie formate at a fixed temperature has been found to increase, throughout this range, with increasing concentration of ammonium formate.

---

[10] Very recently, a study of the potentiometric titration of acids and bases in formic acid solution has been published by Hammett and Dietz, THIS JOURNAL, 52, 4795 (1930). Ammonium formate was not investigated; urea, however, was found to behave as a strong base.

[11] Schlesinger and Calvert, THIS JOURNAL, 33, 1924 (1911).

3. A solvated cupric formate of the formula $2Cu(CHO_2)_2 \cdot 3HCHO_2$ has been isolated and analyzed.

4. The results here obtained have been compared with those previously reported for the corresponding ternary system in acetic acid. Attention has been called to the similarity between these two cases, and certain relationships with analogous aqueous systems have been pointed out.

THE TRANSFERENCE NUMBERS OF POTASSIUM CHLORIDE. NEW DETERMINATIONS BY THE HITTORF METHOD AND A COMPARISON WITH RESULTS OBTAINED BY THE MOVING BOUNDARY METHOD

BY DUNCAN A. MACINNES AND MALCOLM DOLE[1]

RECEIVED FEBRUARY 10, 1931 PUBLISHED APRIL 6, 1931

We have obtained, in this Laboratory, by the moving boundary method a large amount of data, for the most part still unpublished, on the transference numbers of electrolytes. Many of these data differ so widely from the published values for transference numbers obtained by the Hittorf method that the question arose seriously in our minds as to whether the two methods (the Hittorf and moving boundary) obtain measures of the same property of the solutions of electrolytes. With potassium chloride, for instance, the measurements in dilute solutions by Jahn and associates[2] of the cation transference number by the Hittorf method gave values on the average 1% above the determinations by the moving boundary method. On the other hand, Dewey,[3] working at 0.2 N, obtained lower values for this constant by the Hittorf method than those obtained by MacInnes and Brighton[4] and Smith and MacInnes[5] using the moving boundary procedure. We have, however, found it possible to interpret the conductance and transference data, as a whole, for a group of simple electrolytes provided the newer moving boundary results are used. This is far from being true with reference to most of the Hittorf data now published. These new data and their interpretation will be the subject of a series of papers from this Laboratory. It was evidently very important to find out whether the disagreement of the results of the two methods for obtaining transference numbers is due to

experimental error or to a fundamental difference in the quantities measured. Hittorf and moving boundary measurements on solutions of potassium chloride were accordingly carried out, using all possible efforts to attain accuracy in the results. This paper will deal with the experimental details of the Hittorf measurements and their comparison with results obtained by the moving boundary method. The details concerning the latter will appear in another paper from this Laboratory.

The Hittorf Apparatus

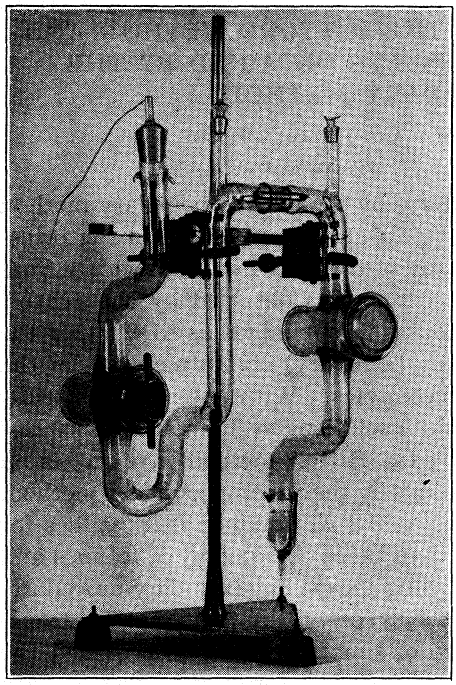

Fig. 1.

The apparatus, shown in Fig. 1, used for the Hittorf measurements was similar to that developed by Washburn[6] but differed from it in several details. It was made of Pyrex glass. A sufficient idea of the dimensions of the apparatus can be obtained from the data that the bore of the tubing used was 2 cm. and the full length of the tubing was 135 cm. The right angled turns of the tubes as shown were included for the purpose of breaking up convection currents due to heating, and were probably effective for the purpose because as soon as they were inserted in the apparatus the results showed a decided improvement. Convection currents were also minimized by the use of small current densities. A source of unequal heating along the tube which can cause convection is the bore of the large stopcocks. Though these were made the same size as the rest of the tube, adequate circulation of the thermostat water around them is not readily obtained. More adequate stirring around the portion of the solution in the bore of the stopcock was obtained by the design of stopcock shown in Fig. 1, and diagrammatically in section in Fig. 2. The usual key or handle for turning the stopcock has been cut away, leaving a hollow shell through which the thermostat water can flow freely. When it is necessary to turn the stopcock a metal key is inserted as is shown on the left-hand side of Fig. 1 and by dotted lines in Fig. 2. As an additional precaution against mixing, the thermostat (a 30 × 30 × 40 cm. glass battery jar) was mounted on the vibration-free support, which has been described in a previous paper.[7] The use of this support was also accompanied by an improvement in the results. The thermostat was stirred by a mechanism mounted independently of the vibration-free support. The stirring rate was regulated to produce no perceptible vibration of the thermostat.

Preparation of Electrodes and Apparatus.—The anode was made from No. 23 B and S gage silver wire coiled into concentric helices to a diameter such that it would fit readily into the apparatus. It was carefully washed by standing it for several hours in distilled water. It was then dried in an oven, after which it was sealed into the glass stopper of the apparatus with de Khotinsky cement. If the silver appeared dark it was heated in a flame, or in an electric furnace to 400°, until the oxide or sulfide was decomposed. If this was not done there was a tendency for the solution in contact with the electrode to become alkaline. Since, during an experiment, the wire becomes coated with silver chloride, it was reduced electrochemically before the next determination. Twenty-five grams of the wire was necessary for the more concentrated solutions, and proportionately smaller amounts for the dilute solutions.

The cathode was also made of No. *23* silver wire coated electrolytically with silver chloride. It was cleaned thoroughly, usually by standing in distilled water overnight. It is very important that a thorough cleaning be carried out as the solution surrounding the electrode in the apparatus may readily become contaminated from occluded electrolyte. The cathode was dried for about an hour at 140°, after which it was sealed into the apparatus with cement.

Between each run the Hittorf apparatus was cleaned by allowing chromic acid to stand in it for some time. After rinsing with distilled water the apparatus was dried by playing a Bunsen flame over the surface while a current of dry air was passed through it. When dried the stoppers carrying the electrodes (previously greased and weighed) were inserted. The stopcocks, after being partly warmed, were greased with a commercial preparation.

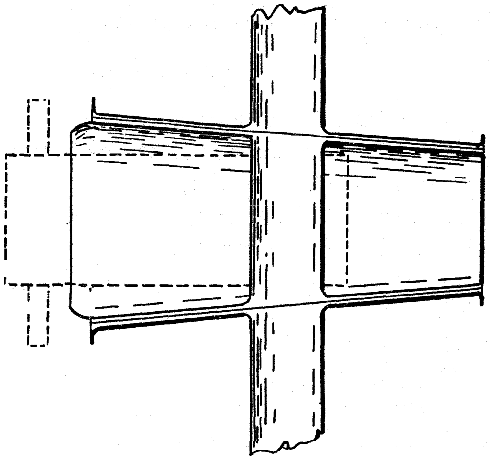

Fig.. 2.

Preparation of Solutions.—The solutions were prepared by weighing out the requisite amounts of potassium chloride and water to yield solutions of the desired normalities in equivalents per liter at 25°. The computation was made using the density data on potassium chloride solutions given in the "Critical Tables." An excellent grade of conductivity water was used in making up solutions. The potassium chloride was a C. P. grade which was further purified by precipitation with hydrogen chloride gas, followed by crystallization from conductivity water and proved to be free from sodium by spectroscopic test.

A difficulty encountered early in this research was that the cathode portion tended to become alkaline even though there was no trace of gas evolution at the electrodes. An investigation disclosed the fact that this alkalinity was due to dissolved oxygen which, presumably, entered into the reaction:

$$O + H_2O + 2e^- = 2OH^-$$

By saturating the solution with purified nitrogen there was no further tendency for the solution to become alkaline. All the work recorded in this paper was carried out using oxygen-free solutions. The proeedure for filling the transference apparatus with such solutions was as follows. The solution was placed in a special Erlenmeyer flask of a design already described.[8] A stream of purified nitrogen was first passed through a saturator containing the same solution as that in the special flask which followed it. The gas bubbled through the solution in that flask and then passed to the transference apparatus, which was furnished with an exit trap to prevent entrance of air. After running the gas for about one hour, which was sufficient to sweep out the oxygen from the solution and apparatus, a half turn of the head of the special flask caused the gas pressure to force the solution into the transference apparatus.

The Coulometers.—Two Richards type porous-cup coulometers were used, one at the anode end and another at the cathode end of the apparatus. Agreement of the weights of these two coulometers is evidence that no current has leaked away in the thermostat. The electrolyte was 10% silver nitrate solution, and No. 8 silver wire was used as anode. Platinum dishes of 75-cc. capacity were used for the more concentrated solutions, and platinum crucibles were used as cathodes for the more dilute solutions. The coulometers were covered with glass bell jars to protect them from dust particles.

The Electrolysis and Analysis

After the Hittorf apparatus was filled as described above, it was placed in the thermostat for at least one-half hour before the current was turned on, after which the electrolysis could be allowed to proceed overnight without attention. The current was supplied from small storage cells yielding about 15 volts. For the 0.02 *N* solution a current of 0.002 ampere was used. This was increased progressively for measurements with higher concentrations until a current of 0.045 ampere for the 3 N solutions was reached.

Following the electrolysis the solution in the apparatus was separated, according to Washburn's scheme, into anode, anode middle, middle, cathode middle and cathode portions. The anode and cathode portions were separated merely by turning the stopcocks. The other samples were drawn from the volume between the two stopcocks. The three middle portions were removed by suction directly into weight burets through clean dry glass tubing. The solutions in the two electrode portions were not removed into weight burets until the two portions into which the apparatus may be separated had been cleaned on the outside, weighed and the solution thoroughly shaken after opening the stopcocks. Portions of the resulting solutions were then transferred into weight burets. Each half of the apparatus, with its electrode, was dried and weighed, and the weight of the solution in each electrode portion could then be computed.

The analyses were carried out using the differential potentiometric method described by MacInnes and Dole.[8] Since the details of the method as applied to the determination of chlorides are given in that paper they will not be repeated here. However, a precision of about 0.003% is obtained in the analyses. With practice the determinations can be carried out quite rapidly, as many as six being possible in one day. The method has the great advantage of requiring no filtering or transfer of solutions, and

---

[8] MacInnes and Dole, THIS JOURNAL, 51, 1119 (1929).

thus corrections for turbidity, etc., necessary with other precision methods for chlorides, are avoided.

Since the most concentrated solutions became turbid on dilution, it was evident that in such cases silver chloride from the electrodes was dissolving in the electrolyte. By allowing the diluted solution to stand, the colloidal material collected and could be filtered off and weighed and an appropriate correction made to the weight of the electrode portions.

The Results

A series of determinations at 0.1 N was made the results of which will not be tabulated, as they did not reach the accuracy of the later work. However, they demonstrated the desirability of the vibration-free support, the bends in the tubing of the Hittorf apparatus, and the air-free solutions, as well as minor experimental improvements. The data concerning the experimental results which attained the desired accuracy are given in Table I. This table is self-explanatory. Two figures for *a* weight or analysis refer to duplicate determinations. These agreements and the agreements of the analyses of the three middle portions give evidence of the accuracy of the work and of the, very essential, lack of mixing of the electrode and middle portions.

Discussion of the Results

The average values of the cation transference numbers at each concentration are given in Table II, and, for comparison, the values by the moving boundary method obtained in this Laboratory by Dr. L. G. Longsworth, to whom we are indebted for permission to quote his results before their formal publication. It will be seen that, at the concentration at which measurements were made by both methods, there is quite extraordinary agreement

TABLE II

CATION. TRANSFERENCE NUMBERS, T_K, OF POTASSIUM CHLORIDE DETERMINED BY THE HITTORF AND MOVING BOUNDARY METHODS

Comparisons could not be made at higher concentrations because it is not yet possible to get accurate data by the moving boundary method at concentrations above about 0.2 *N*. That method is, however, accurate at concentrations so low that the chemical analyses necessary in the Hittorf method become difficult. It is interesting and most gratifying, that the two methods based on phenomena, superficially at least, so dissimilar should yield results that are in such excellent agreement.

As has been said in the introductory paragraph of this paper, these results differ quite widely from the measurements of previous workers in this field. That these early determinations led to values that differed considerably among themselves, and varied widely from later measurements is shown in Fig. 3.[9] Here the determinations, made between 18 and 30°, of the cation transference number of potassium chloride are given as ordinates against the cube root of the corresponding concentrations, the latter function being used only to obtain a convenient plot. Comparisons may be made of data in this temperature range because, within the experimental error, there is no apparent temperature coefficient of the transference number.[10] Washburn's solutions contained 0.1 mol of raffinose in addition to 1.24 mols of potassium chloride. The earlier moving boundary results will be considered in another paper.

It is not possible to assign, with certainty, reasons for the deviations of the earlier work from what we believe to be the correct values, particularly as there are many chances for obtaining inaccurate results with the Hittorf

---

[9] Where determinations by the German workers yielded checks to 0.001 the points have been shifted slightly along the ordinates so as not to overlap. They can still, however, be read from the plot to the accuracy given.

[10] References to values plotted in Fig. 3 and not mentioned elsewhere in this paper are, Richter, *Z. physik. Chem.*, 80, 449 (1912), and Steele and Denison, *J. Chem. Soc.*, **81**, 456 11902).

method. Errors may arise from inaccurate analytical procedures, evaporation of the solvent, mixing of electrode and middle portions, electrical leaks, etc. An important source of error which would, since anion concentrations were determined, tend to give high cation transference numbers, particularly in the dilute solutions, is the fact that in the early work no correction was made for the conductance of the water used. It is difficult to estimate the magnitude of errors arising from this source. Ordinary distilled water would produce deviations of about 0.5% in the most dilute solutions. If the water stood for any time in soft glass containers, it could readily produce errors of several times this magnitude in the direction observed in Jahn's work. In the work described in this paper the best conductivity water was used. It was stored and measurements were made in Pyrex apparatus. No solvent correction was necessary within the experimental error in our Hittorf work. Small corrections have been made, for this effect, to the moving boundary data at the lower concentrations.

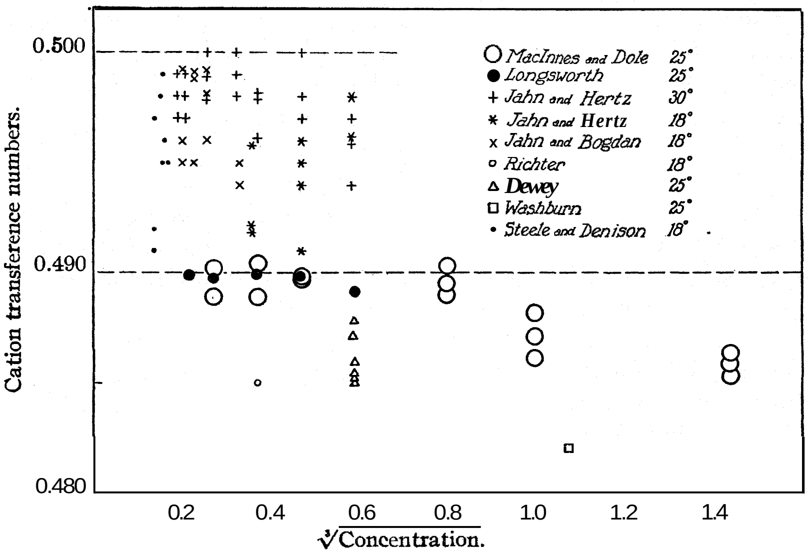

Fig. 3.

It is certainly evident from the discussion of our work and that of the previous investigators that it is difficult to obtain accurate transference numbers by the Hittorf method. Much higher precision can be obtained by the moving boundary method, and with relative ease. The width of the dots representing the moving boundary results in Fig. 3, illustrates roughly, on the scale of ordinates, the limits of error of these results. The value at each concentration represents the mean of at least four determinations, the deviation being 0.05% at most. Furthermore, fifteen figures which are averaged are obtained in each determination, the greatest variation being about 0.1%. Three complete determinations may be carried out in one day. A Hittorf determination which, if successful, gives one figure each for the anode and cathode portions, requires nearly a week.

On the other hand, the theory underlying the Hittorf measurements is simpler than that of the moving boundary method. Since the results of the latter method have been questioned recently,[11] the agreement of the results of these two accurate series of determinations is welcome.

The transference numbers of potassium chloride have been universally used in computing tables of limiting ion mobilities. The results given above indicate that the figures in those tables must be in error. A later paper from this Laboratory will deal with the determination of a new table of those constants based on recent conductance and transference data and on modern theories of solutions of strong electrolytes.

Summary

A series of measurements, by the Hittorf method, of the transference numbers of potassium chloride, at 25°, for the concentration range 0.02 to 3 normal is described. The cation transference numbers are decidedly lower than the generally accepted values for these constants, on which the tables of ionic mobilities are based. The new values are, however, in excellent agreement with a series of values for the same constants obtained by the moving boundary method, the details of the determinations of which will be published later.

Within the experimental error the transference numbers are constant between 0.01 and 0.1 *N* and the cation number decreases slowly above the latter concentration.

[11] Taylor, "A Treatise on Physical Chemistry," D. Van Nostrand Co., 2d ed., 1931, p. 685; also Mukherjee, *Nature*, **122**, 608 (1928); *J. Indian Chem. Soc.*, **5**, 593 (1928). This author considers that there is a large space charge at a moving boundary which appreciably affects its motion. This, he thinks, is caused by the sudden change of the transference number of the common ion at the plane of the boundary. It can readily be shown (though it would lead us too far afield at this point) that this supposed effect is due to a neglect of the fact that the boundary *moves*, the apparent deficiency in the number of the common ions behind the boundary being accounted for by a change of concentration of the ion as the boundary passes a given point.

THE CONSTRUCTION OF DEWAR FLASKS

BY T. E. PHIPPS, M. J. COPLEY AND E. J. SHAW

RECEIVED FEBRUARY 10, 1931 PUBLISHED APRIL 6, 1931

A method of making Pyrex Dewar flasks of considerable capacity has been developed which may be of interest to some who have a limited or intermittent supply of liquid air. The most convenient size, in view of the limited sizes of Pyrex flasks, is probably three liters. The outer wall is made of a 5-liter flask. If 7- or 8-liter flasks were available, 5-liter Dewars could be constructed. However, with a 12-liter outer flask, silvering becomes rather difficult, and the resulting flask is too bulky to be practical.

A heavy-walled 16-mm. tube, E in the figure, is sealed to the base of the neck of a 5-liter round-bottomed flask. The heavy ring at the top of the neck is then cut off as closely as possible and the flask cut in two parts around a great circle perpendicular to the axis of the neck. The crack is shown at B. It is made by scratching a file mark about an inch long on the flask, wrapping one turn of No. 22 chrome1 wire about the flask, and heating with a current of 10–12 amp. until the glass is felt to be warm 6–8 mm. from the wire. A few cc. of water is poured on the file mark. The crack obtained is often so smooth that there is difficulty in determining the relative positions previous to cracking. The inner flask is prepared by cutting off the neck of a 3-liter flask as closely as possible to the base of the neck, A, and sealing on a previously flared 40-mm. heavy-walled tube. This is then cut off so that it extends through the neck of the outer flask a distance about equal to that between the walls of the neck.

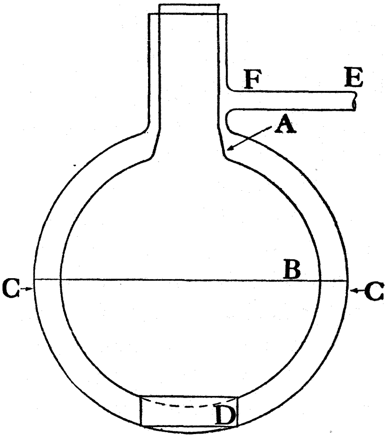

Fig. 1.

The bottom half of the outer flask is placed in an asbestos-covered iron ring. A ring of brass, D, such as a 20-mm. length of a 70-mm. brass tube is then placed in the glass hemisphere, and the inner flask is set on it. The upper half of the outer flask is put in place and clamped down with another asbestos-covered iron ring. The Dewar seal at the top is then made using two hand torches, one with a large air–gas flame, the other with a moderate air-oxygen–gas flame. Obviously this must be done at a rather high temperature, since the inner flask is essentially unstable. Blowing can be done through the evacuating tube, but is usually unnecessary.

Keeping the Dewar seal just below the softening point, the upper iron ring is removed, then the inner flask and top half of the outer lifted and the brass ring removed. The upper half is then replaced, and a large ring burner with holes every 8 mm. is placed around the whole just below the crack, at C. A small gas flame is started first, and the temperature raised slowly. When near the softening point, a small oxyhydrogen torch is used to make the large seal. About four points around the circumference should be sealed initially and then the seal completed rather than attempting to work right around.

As soon as the seal is completed the ring burner is removed and the entire ring stand put in an electric furnace at a temperature of about 600°. The Dewar seal should be at annealing temperature before this transfer is made. The furnace temperature is maintained for about an hour and then the current turned off. After two or three hours the cover is removed and the flask taken out when the furnace is cold.

If new flasks are used it is unnecessary to clean them with cleaning solution, but they should be washed with stannous chloride, rinsed and silvered. Rinsing and silvering should be done with a small quantity of liquid, by shaking and rotating, rather than filling the entire space between the walls. Two or three coats of silver are desirable. The silver is then washed out of the evacuating tube with cotton soaked with very dilute nitric acid, the entire flask rinsed several times with water, and the evacuating tube necked down at F for sealing off. Evacuation is carried out at about 400° in the electric furnace over a period of thirty-six hours, by means of a mercury vapor pump and liquid-air trap. Evacuation for a shorter period of time fails to outgas the silver completely and the flask deteriorates rather rapidly. Sealing off is done as soon after turning off the heat as possible. Our practice is to anneal two of the Dewar flasks at once (this requires the moving of one while hot from one ring stand to another already in the furnace) and later to evacuate them together.

The flask is ordinarily packed in Sil-O-Cel in a 12- or 14-quart pail, and covered over with heavy felt in which a hole is cut for the neck.

One of these Dewars, if filled with liquid air and set aside, will still contain some at the end of thirteen days, whereas the best commercial glass Dewars are empty in four days or less. Also, the soft glass Dewars ordinarily used usually last less than twenty fillings. One of our Pyrex Dewars has been in continuous use for more than three years, and still keeps liquid air as well as it ever did.

THE NATURE OF THE CHEMICAL BOND. APPLICATION OF RESULTS OBTAINED FROM THE QUANTUM MECHANICS AND FROM A THEORY OF PARAMAGNETIC SUSCEPTIBILITY TO THE STRUCTURE OF MOLECULES

By Linus Pauling

Received February 17, 1931 Published April 6, 1931

During the last four years the problem of the nature of the chemical bond has been attacked by theoretical physicists, especially Heitler and London, by the application of the quantum mechanics. This work has led to an approximate theoretical calculation of the energy of formation and of other properties of very simple molecules, such as H_2, and has also provided a formal justification of the rules set up in 1916 by G. N. Lewis for his electron-pair bond. In the following paper it will be shown that many more results of chemical significance can be obtained from the quantum mechanical equations, permitting the formulation of an extensive and powerful set of rules for the electron-pair bond supplementing those of Lewis. These rules provide information regarding the relative strengths of bonds formed by different atoms, the angles between bonds, free rotation or lack of free rotation about bond axes, the relation between the quantum numbers of bonding electrons and the number and spatial arrangement of the bonds, etc. A complete theory of the magnetic moments of molecules and complex ions is also developed, and it is shown that for many compounds involving elements of the transition groups this theory together with the rules for electron-pair bonds leads to a unique assignment of electron structures as well as a definite determination of the type of bonds involved.[1]

I. The Electron-Pair Bond

The Interaction of Simple Atoms.—The discussion of the wave equation for the hydrogen molecule by Heitler and London,[2] Sugiura,[3] and Wang[4] showed that two normal hydrogen atoms can interact in either of two ways, one of which gives rise to repulsion with no molecule formation, the other

---

[1] A preliminary announcement of some of these results was made three years ago [Linus Pauling, *Proc. Nat. Acad. Sci.*, 14, 359 (1928)]. Two of the results (90° bond angles for p eigenfunctions, and the existence, but not the stability, of tetrahedral eigenfunctions) have been independently discovered by Professor J. C. Slater and announced at meetings of the National Academy of Sciences (Washington, April, 1930) and the American Physical Society (Cleveland, December, 1930).

[4] S. C. Wang, *Phys. Rev.*, 31, 579 (1928).

to attraction and the formation of a stable molecule. These two modes of interaction result from the identity of the two electrons. The characteristic resonance phenomenon of the quantum mechanics, which produces the stable bond in the hydrogen molecule, always occurs with two electrons, for even though the nuclei to which they are attached are different, the energy of the unperturbed system with one electron on one nucleus and the other on the other nucleus is the same as with the electrons interchanged. Hence we may expect to find electron-pair bonds turning up often.

But the interaction of atoms with more than one electron does not always lead to molecule formation. A normal helium atom and a normal hydrogen atom interact in only one way,[5] giving repulsion only, and two normal helium atoms repel each other except at large distances, where there is very weak attraction.[5,6] Two lithium atoms, on the other hand, can interact in two ways,' giving a repulsive potential and an attractive potential, the latter corresponding to formation of a stable molecule. In these cases it is seen that only when each of the two atoms initially possesses an unpaired electron is a stable molecule formed. The general conclusion that an electron-pair bond is formed by the interaction of an unpaired electron on each of two atoms has been obtained formally by Heitler[8] and London,[9] with the use of certain assumptions regarding the signs of integrals occurring in the theory. The energy of the bond is largely the resonance or interchange energy of two electrons. This energy depends mainly on electrostatic forces between electrons and nuclei, and is not due to magnetic interactions, although the electron spins determine whether attractive or repulsive potentials, or both, will occur.

Properties of the Electron-Pair Bond.—From the foregoing discussion we infer the following properties of the electron-pair bond.

1. *The electron-pair bond is formed through the interaction of an unpaired electron on each of two atoms.*

2. *The spins of the electrons are opposed when the bond is formed, so that they cannot contribute to the paramagnetic susceptibility of the substance.*

3. *Two electrons which form a shared pair cannot take part in forming additional pairs.*

In addition we postulate the following three rules, which are justified by the qualitative consideration of the factors influencing bond energies. An outline of the derivation of the rules from the wave equation is given below.

---

[9] F. London, *Z. Physik*, 46, 455 (1928); *50*, 24 (1928); "Sommerfeld Festschrift," p. 104; etc.

4. *The main resonance terms for a single electron-pair bond are those involving only one eigenfunction from each atom.*

5. *Of two eigenfunctions with the same dependence on r, the one with the larger value in the bond direction will give rise to the stronger bond, and for a given eigenfunction the bond will tend to be formed in the direction with the largest value of the eigenfunction.*

6. *Of two eigenfunctions with the same dependence on θ and φ, the one with the smaller mean value of r, that is, the one corresponding to the lower energy level for the atom, will give rise to the stronger bond.*

Here the eigenfunctions referred to are those for an electron in an atom, and r, θ and φ are polar coordinates of the electron, the nucleus being at the origin of the coordinate system.

It is not proposed to develop a complete proof of the above rules at this place, for even the formal justification of the electron-pair bond in the simplest cases (diatomic molecule, say) requires a formidable array of symbols and equations. The following sketch outlines the construction of an inclusive proof.

It can be shown[10] that if Ψ is an arbitrary function of the independent variables in a wave equation

$$(H - W)\psi = 0$$

then the integral

$$E = \int \Psi^* H \Psi d\tau$$

called the variation integral, is always larger than W_0, the lowest energy level for the system. A function Ψ containing several parameters provides the best approximation to the eigenfunction ψ_0 for the normal state of the system when the variational integral is minimized with respect to these parameters. Now let us consider two atoms A and B connected by an electron-pair bond, and for simplicity let all the other electrons in the system be paired, the pairs being either lone pairs or pairs shared between A or B and other atoms. Let us assume that there are available for bond formation by atom A several single-electron eigenfunctions of approximately the same energy, and that the change in energy of penetration into the core is negligible compared with bond energy. Then we may take as single-electron eigenfunctions

$$\psi_{\mathrm{A}i} = \Sigma_k\, a_{ik}\, \psi^0_{\mathrm{A}k}$$

in which the a_{ik}'s are numerical coefficients and the $\psi^0_{\mathrm{A}k}$'s are an arbitrary set of single-electron eigenfunctions, such as those obtained on separating the wave equation in polar coordinates. From the $\psi_{\mathrm{A}i}$'s there is built up a group composed of atom A and the atoms to which it is bonded except atom B, such that all electrons are paired except one, corresponding to the eigenfunction $\psi_{\mathrm{A}i}$, say. From atom B a similar group with one unpaired electron is built. The interaction energy of these two groups can then be calculated with the aid of the variational equation through the substitution of an eigenfunction for the molecule built of those for the two groups in such a way that it has the correct symmetry character. The construction of this eingenfunetion and evaluation of the integral would be very laborious; it will be noticed, however, that this problem is formally similar to Born's treatment[11] of the interaction of two atoms in S states, based on Slater's treatment of atomic eigenfunctions, and the value of E is found to be

$$E = W_{\mathrm{A}} + W_{\mathrm{B}} + J_E + J_X - \Sigma_Y J_Y - 2\Sigma_Z J_Z$$

---

[10] A clear discussion is given by C. Eckart, *Phys. Rev.*, 36, 878 (1930).

[11] M. Born, *Z. Physik*, 64, 729 (1930).

Here W_A and W_B are the energies of the separate groups, and J_E represents the Coulomb interaction of A and B, neglecting resonance. The resonance term J_X corresponds to a permutation of the two AB bond electrons; J_Y corresponds to a permutation of the AB bond electron on B with a paired electron with similarly directed spin on A, or *vice verso;* and J_Z corresponds to a permutation of a paired electron on A with one on B (For explicit expressions for these see Born.[11]) The resonance integrals J_X, J_Y and J_Z have been found to have negative signs in the case of simple molecules for which calculations have been made, and it is probable that these signs obtain in most cases. The resonance integrals depend qualitatively on what may be called the *overlapping* of the single-electron eigenfunctions involved; if ψ_A and ψ_B are two single-electron eigenfunctions, the product $\psi_A(1)\,\psi_B(2)\,\psi_A^*(2)\,\psi_B^*(1)$ occurs in the resonance integral corresponding to the permutation involving electrons 1 and 2, and the value of the integral increases as the magnitude of this product in the region between the two nuclei increases.

Now we vary the coefficients a_{ik} in such a way as to minimize E. W_A and W_B are not affected by this variation, and J_E is not changed in case that there is one electron for every eigenfunction in a subgroup on A, and is changed relatively slightly otherwise. The resonance integrals are, however, strongly affected by changing the coefficients. The positive sign preceding J_X requires that the two bond eigenfunctions ψ_A and ψ_B show the maximum overlapping in the region between the two nuclei, while the negative sign preceding J_Y requires the minimum overlapping between ψ_A and the eigenfunctions of B other than ψ_B, and between ψ_B and the eigenfunctions of A other than ψ_A. Hence the correct zeroth-order eigenfunctions for the atom A are such that one, the AB bond eigenfunction ψ_A, extends largely in the direction of atom B, while the other A eigenfunctions avoid overlapping with ψ_B. As a consequence the integral J_X is of large magnitude, while the integrals J_Y, because of the small overlapping of the eigenfunctions involved, are small.

An extension of this argument shows that the phenomenon of *concentration of the bond eigenfunctions* further increases the magnitude of J_X and decreases J_Y. The nonorthogonality of the bond eigenfunctions as well as certain second-order perturbations leads to a shrinkage of the region in which the bond eigenfunctions have appreciable values. This is strikingly shown by a comparison of H_2^+ and H; the volume within which the electron probability function $\psi\psi^*$ for H_2^+ is greater than one-tenth of its maximum value is found from Burrau's calculations to be 0.67 $Å.^3$, less than 10% of its value 8.6 $Å.^3$ for a hydrogen atom.[12] This concentration of the bond eigenfunctions greatly increases their interaction with one another, and decreases their interaction with other eigenfunctions, a fact expressed in Rule 4. For double or triple bonds interactions among all four or six eigenfunctions must be considered.

s and *p* Eigenfunctions. Compounds of Normal Atoms.—As a rule s and *p* eigenfunctions with the same total quantum number in an atom do not differ very much in their mean values of r (the s levels lie lower because of greater penetration of inner shells), so that Rule 6 would not lead us to expect them to differ in bond-forming power. But their dependence on θ and φ is widely different. Putting

$$\begin{aligned} \Psi_{n0}(r,\theta,\varphi) &= R_{n0}(r)\cdot s(\theta,\varphi) && \text{for } s \text{ eigenfunctions} \\ \Psi_{n1}(r,\theta,\varphi) &= R_{n1}(r)\cdot \left.\begin{matrix} p_x(\theta,\varphi) \\ p_y(\theta,\varphi) \\ p_z(\theta,\varphi) \end{matrix}\right\} && \text{for } p \text{ eigenfunctions} \end{aligned} \qquad (1)$$

---

[12] Compare Fig. 6 with Fig. 7, which is drawn to half the scale of Fig. 6, of Linus Pauling, *Chem. Rev.*, 5, 173 (1928).

the parts s, p_x, p_y, p_z of the eigenfunctions depending on θ and φ, normalized to 4π, are

$$\left.\begin{aligned} s &= l \\ p_x &= \sqrt{3}\sin\theta\cos\varphi \\ p_y &= \sqrt{3}\sin\theta\sin\varphi \\ p_z &= \sqrt{3}\cos\theta \end{aligned}\right\} \qquad (2)$$

Absolute values of s and p_x are represented in the xz plane in Figs. 1 and 2. s is spherically symmetrical, with the value 1 in all directions. $|p_x|$ consists of two spheres as shown (the x axis is an infinite symmetry axis), with the maximum value $\sqrt{3}$ along the x axis. $|p_y|$ and $|p_z|$ are similar, with maximum values of $\sqrt{3}$ along the y and z axis, respectively. From Rule 5 we conclude that *p electrons will form stronger bonds than s electrons*, and that *the bonds formed by p electrons in an atom tend to be oriented at right angles to one another.*

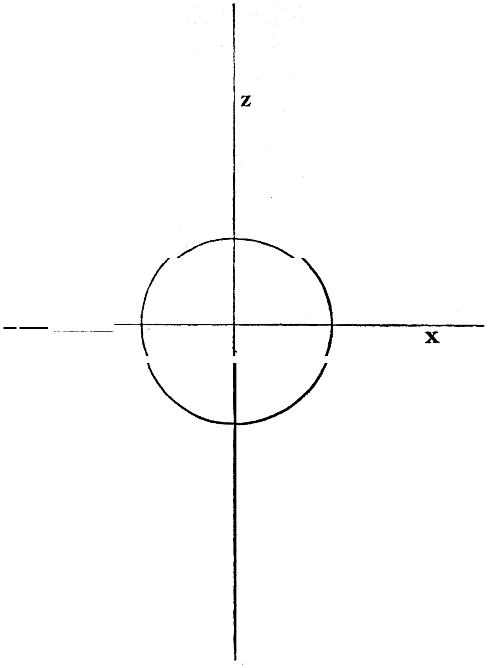

Fig. 1.—Polar graph of 1 in the xz plane, representing an s eigenfunction.

The second conclusion explains several interesting facts. Normal oxygen, in the state $2s^22p^4\ {}^3P$, contains two unpaired p electrons. When an atom of oxygen combines with two of hydrogen, a water molecule will result in which the angle formed by the three atoms is 90°, or somewhat larger because of interaction of the two hydrogen atoms. It has been long known from their large electric moment that water molecules have a kinked rather than a collinear arrangement of their atoms, and attempts have been made to explain this with rather unsatisfactory calculations based on an ionic structure with strong polarization of the oxygen anion in the field of the protons. The above simple explanation results directly from the reasonable assumption of an electron-pair bond structure and the properties of tesseral harmonics.

It can be predicted that H_2O_2, with the structure  $:\ddot{\underset{H}{O}}:\ddot{\underset{H}{O}}:$ involving bonds of p electrons, also consists of kinked rather than collinear molecules.

Nitrogen, with the normal state $2s^22p^S\ {}^4S$, contains three unpaired p electrons, which can form bonds at about 90° from one another with three hydrogen atoms. The ammonia molecule, with the resulting pyramidal structure, also has a large electric moment.

The crystal skutterudite, $Co_4^{3+}(As_4^{4-})_3$, contains As_4^{4-} groups with a square configuration, corresponding to the structure $\left[\begin{matrix}:\ddot{As}:As:\\ :\underset{..}{\ddot{As}}:\underset{..}{\ddot{As}}:\end{matrix}\right]^{4-}$. This complex has bond angles of exactly 90°.

In the above discussion it has been assumed that the type of quantization has not been changed, and that *s* and *p* eigenfunctions retain their identity. This is probably true for H_2O and H_2O_2, and perhaps for NH_3 and As_4^{4-} also. A discussion of the effect of change of quantization on bond angles is given in a later section.

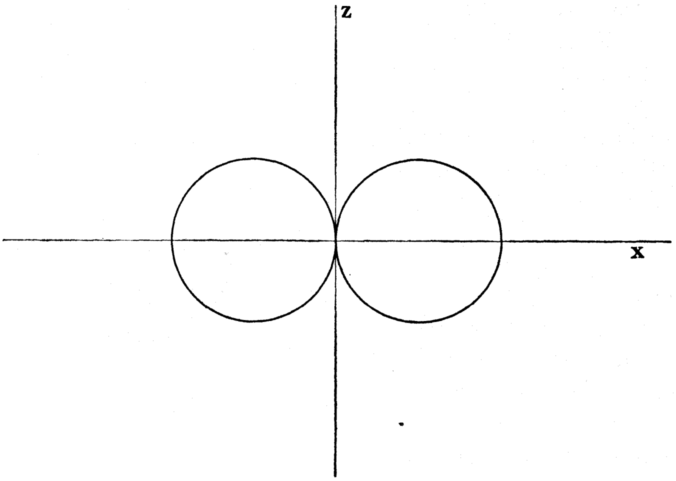

Fig. 2.—Polar graph of $|\sqrt{3}\sin\theta|$ in the xz plane, representing the p_x eigenfunction.

Transition from Electron-Pair to Ionic Bonds. The Hydrogen Bond.—In case that the symmetry character of an electron-pair structure and an ionic structure for a molecule are the same, it may be difficult to decide between the two, for the structure may lie anywhere between these extremes. The zeroth-order eigenfunction for the two bond electrons for a molecule MX (HF, say, or NaCl) with a single electron-pair bond would be

$$\Psi_{MX} = \frac{\psi_M(1)\,\psi_X(2) + \psi_M(2)\,\psi_X(1)}{\sqrt{2+2S^2}} \qquad (3)$$

in which $S = \int \psi_M(1)\,\psi_X^*(1)\,d\tau_1$. The eigenfunction for a pure ionic state would be

$$\Psi_{M^+X^-} = \psi_X(1)\,\psi_X(2) \qquad (4)$$

In certain cases one of these might approximate the correct eigenfunction closely. In other cases, however, it would be necessary to consider combinations of the two, namely

$$\Psi_+ = a\,\Psi_{MX} + \sqrt{1-a^2}\,\Psi_{M^+X^-}$$

and

$$\Psi_- = \sqrt{1-a^2}\,\Psi_{MX} - a\,\Psi_{M^+X^-} \qquad (5)$$

For a given molecule and a given internuclear separation a would have a definite value, such as to make the energy level for Ψ_+ lie as low as possible. If a happens to be nearly 1 for the equilibrium state of the molecule, it would be convenient to say that the bond is an electron-pair bond; if a is nearly zero, it could be called an ionic bond. This definition is somewhat unsatisfactory in that it does not depend on easily observable quantities. For example, a compound which is ionic by the above definition might dissociate adiabatically into neutral atoms, the value of a changing from nearly zero to unity as the nuclei separate, and it would do this in case the electron affinity of X were less than the ionization potential of M. HF is an example of such a compound. There is evidence, given below, that the normal molecule approximates an ionic compound; yet it would dissociate adiabatically into neutral F and H.[13]

But direct evidence regarding the value of a can sometimes be obtained. The hydrogen bond, discovered by Huggins and by Latimer and Rodebush, has been usually considered as produced by a hydrogen atom with two electron-pair bonds, as in $\left[:\overset{..}{\underset{..}{F}}:H:\overset{..}{\underset{..}{F}}:\right]^-$. It was later pointed out[1] that this is not compatible with the quantum mechanical rules, for hydrogen can have only one unpaired 1s electron, and outer orbits are so much less stable that strong bonds would not be formed. With an ionic structure, however, we would expect H^+F^- to polymerize and to add on to F^-, to give H_6F_6 and $[F^-H^+F^-]^-$; moreover, the observed coordination number 2 is just that predicted[14] from the radius ratio 0. Hence the observation that hydrogen bonds are formed with fluorine supports an ionic structure for HF. Hydrogen bonds are not formed with chlorine, bromine, and iodine, so that the bonds in HCl, HBr, and HI are to be considered as approaching the electron-pair type.

Hydrogen bonds are formed to some extent by oxygen ($(H_2O)_x$, ice, etc.) and perhaps also in some cases by nitrogen. The electrostatic structure for the hydrogen bond explains the observation that only these atoms of high electron affinity form such bonds, a fact for which no explanation was given by the older conception. It is of interest that there is considerable

---

[13] There would, however, be a certain probability, dependent on the nature of the eigenfunctions, that actual non-adiabatic dissociation would give ions rather than atoms, and this might be nearly unity, in case the two potential curves come very close to one another at some point. See I. v. Neumann and E. Wigner. *Physik.* Z.. 30, 467 (1929).

[14] Linus Pauling, THIS JOURNAL, 51, 1010 (1929).

evidence from crystal structure data for [OHO]' groups. In many crystals containing H and O, including topaz,[15] $Al_2SiO_4(F,OH)_2$; diaspore,[16] $AlHO_2$; goethite,[16] $FeHO_2$; chondrodite,[17] $Mg_5Si_2O_8(F,OH)_2$; etc., the sum of the strengths of the electrostatic bonds from all cations (except hydrogen) to an anion is either 2 or 1, indicating, according to the electrostatic valence rule,[14] the presence of $O^=$ and of F^- or $(OH)^-$, respectively. But in some crystals, including[18] KH_2PO_4; staurolite,[19] $H_2FeAl_4Si_2O_{12}$; and lepidocrocite,[16] $FeHO_2$, the sum of bond strengths is 2 or $^3/_2$, the latter value occurring twice for each H; the electrostatic valence rule in these cases supports the assumption of $[O^=H^+O^=]^\equiv$ groups, the hydrogen ion contributing a bond of strength $^1/_2$ to each of two oxygen ions.

In other cases, discussed below, the lowest electron-pair-bond structure and the lowest ionic-bond structure do not have the same multiplicity, so that (when the interaction of electron spin and orbital motion is neglected) these two states cannot be combined, and a knowledge of the multiplicity of the normal state of the molecule or complex ion permits a definite statement as to the bond type to be made.

Change in Quantization of Bond Eigenfunctions.—A normal carbon atom, in the state $2s^22p^2$ ^3P, contains only two unpaired electrons, and can hence form no more than two single bonds or one double bond (as in CO, formed from a normal carbon atom and a normal oxygen atom). But only about 1.6 v. e. of energy is needed to excite a carbon atom to the state $2s2p^3$ ^5S, with four unpaired electrons, and in this state the atom can form four bonds. We might then describe the formation of a substituted methane CRR′R″R‴ in the following way. The radicals R, R′, and R″, each with an unpaired electron, form electron-pair bonds with the three *p* electrons of the carbon atom, the bond directions making angles of 90° with one another. The fourth radical R‴ then forms a weaker bond with the *s* electron, probably at an angle of 125° with each of the other bonds. This would give an unsymmetrical structure, with non-equivalent bonds, and considerable discussion has been given by various authors to the difference in the carbon bonds due to *s* and *p* electrons. Actually the foregoing treatment is fallacious, for the phenomenon of change in quantization of the bond eigenfunctions, first discussed in the note referred to before,' leads simply and directly to the conclusion that ***the four bonds formed by a carbon atom are equivalent and are directed toward tetrahedron corners.***

The importance of *s*, *p*, d, and f eigenfunctions for single atoms and ions

[19] St. Naray-Szabo, *ibid.*, 71, 103 (1929).

results from the fact that the interaction of one electron with the nucleus and other electrons can be represented approximately by a non-Coulombian central field, so that the wave equation can be separated in polar coordinates r, θ, and φ, giving rise to eigenfunctions involving tesseral harmonics such as those in Equation 1. The deeper penetration of s electrons within inner shells causes them to be more tightly bound than p electrons with the same total quantum number. If an atom approaches a given atom, forming a bond with it, the interaction between the two can be considered as a perturbation, and the first step in applying the perturbation theory for a degenerate system consists in finding the correct zeroth-order eigenfunctions for the perturbation, one of which is the eigenfunction which will lead to the largest negative perturbation energy. This will be the one with the largest values along the bond direction. The correct zeroth-order eigenfunctions must be certain normalized and mutually orthogonal linear aggregates of the original eigenfunctions. If the perturbation is small, the s eigenfunction cannot be changed, and the only combinations which can be made with the p eigenfunctions are equivalent merely to a rotation of axes. But in case the energy of interaction of the two atoms is greater than the difference in energy of an s electron and a p electron (or, if there are originally two s electrons present, as in a normal carbon atom, of twice this difference), hydrogen-like s and p eigenfunctions must be grouped together to form the original degenerate state, and the interaction of the two atoms together with the deviation of the atomic field from a Coulombian one must be considered as the perturbation, with the former predominating. The correct zeroth-order bond eigenfunctions will then be those orthogonal and normalized linear aggregates of both the s and p eigenfunctions which would give the strongest bonds according to Rule 5.

A rough criterion as to whether the quantization is changed from that in polar coordinates to a type giving stronger bond eigenfunctions is thus that the possible bond energy be greater than the s–p (or, if d eigenfunctions are also involved, s–d or p–d) separation.[20]

This criterion is satisfied for quadrivalent carbon. The energy difference of the states[21] $2s^22p^2\ ^3P$ and $2s2p^3\ ^3P$ of carbon is 9.3 v. e., and a similar value of about 200,000 cal. per mole is found for other atoms in the first row of the periodic system. The energy of *a* single bond is of the order of 100,000 cal. per mole. Hence a carbon atom forming four bonds would certainly have changed quantization, and even when the bond energy must be divided between two atoms, as in a diamond crystal, the criterion is sufficiently well satisfied. The same results hold for quadrivalent

---

[20] This criterion was expressed in Ref. 1.

[21] States with the same multiplicity should be compared, for increase in multiplicity decreases the term value, the difference between $2s^22p^2\ ^3P$ and $2s2p^3\ ^5S$ being only about 1.6 v. e., as mentioned above.

nitrogen, a nitrogen ion in the state N^+ $2s2p^3$ ^5S forming four bonds, as in $(NH_4)^+$, $N(CH_3)_4{}^+$, etc. But for bivalent oxygen there is available only about 200,000 cal. per mole bond energy, and the *s–p* separation for two *s* electrons corresponds to about 400,000 cal. per mole, so that it is very probable that the oxygen bond eigenfunctions in H_2O, for example, are *p* eigenfunctions, as assumed in a previous section. Trivalent nitrogen is a border-line case; the bond energy of about 300,000 cal. per mole is sufficiently close to the *s–p* energy of 400,000 cal. per mole to permit the eigenfunctions to be changed somewhat, but not to the extent that they are in quadrivalent carbon and nitrogen.

It may be pointed out that the *s–p* separation for atoms in the same column of the periodic table is nearly constant, about 200,000 cal. per mole for one *s* electron. The bond energy decreases somewhat with increasing atomic number. Thus the energies of a bond in the compounds H_2O, H_2S, H_2Se, and H_2Te, calculated from thermochemical and band spectral data, are 110,000, 90,000, 73,000, and 60,000 cal. per mole, respectively. Hence we conclude that if quantization in polar coordinates is not broken for a light atom on formation of a compound, it will not be broken for heavier atoms in the same column of the periodic system. The molecules HS, H_2Se, and H_2Te must accordingly also have a non-linear structure, with bond angles of 90° or slightly greater.

Let us now determine the zeroth-order eigenfunctions which will form the strongest bonds for the case when the *s–p* quantization is broken. The dependence on *r* of *s* and *p* hydrogen-like eigenfunctions is not greatly different,[22] and it seems probable that the effect of the non-Coulombian field would decrease the difference for actual atoms. We may accordingly assume that $R_{n0}(r)$ and $R_{n1}(r)$ are effectively the same as far as bond formation is concerned, so that the problem of determining the bond eigenfunctions reduces to a discussion of the 6, φ eigenfunctions of Equation 1. Arbitrary sets of 6, φ eigenfunctions formed from s, p_x, p_y, and p_z are given by the expressions

$$\left.\begin{aligned} \psi_1 &= a_1s + b_1p_x + c_1p_y + d_1p_z \\ \psi_2 &= a_2s + b_2p_x + c_2p_y + d_2p_z \\ \psi_3 &= a_3s + b_3p_x + c_3p_y + d_3p_z \\ \psi_4 &= a_4s + b_4p_x + c_4p_y + d_4p_z \end{aligned}\right\} \qquad (6)$$

in which the coefficients a_1, etc., are restricted only by the orthogonality and normalization requirements

$$\int \psi_i^2 d\tau = 1 \quad \text{or } a_i^2 + b_i^2 + c_i^2 + d_i^2 = 1 \qquad i = 1,2,3,4 \qquad (7a)$$

and

$$\int \psi_i\psi_k d\tau = 0 \quad \text{or } a_ia_k + b_ib_k + c_ic_k + d_id_k = 0 \quad i,k = 1,2,3,4 \quad i \neq k \qquad (7b)$$

---

[22] **See the curves given by Linus Pauling, *Proc. Roy. Soc.* (London). A114, 181 (1927), or A. Sommerfeld, "Wellenmechanischer Erganzungsband," p. 88.**

From Rule 5 the best bond eigenfunction will be that which has the largest value in the bond direction. This direction can be chosen arbitrarily for a single bond. Taking it along the *x* axis, it is found that the best single bond eigenfunction is[23]

$$\psi_1 = \frac{1}{2}s + \frac{\sqrt{3}}{2}p_x \tag{8a}$$

with a maximum value of 2, considerably larger than that 1.732 for a *p* eigenfunction. A graph of this function in the *xz* plane is shown in Fig. **3.**

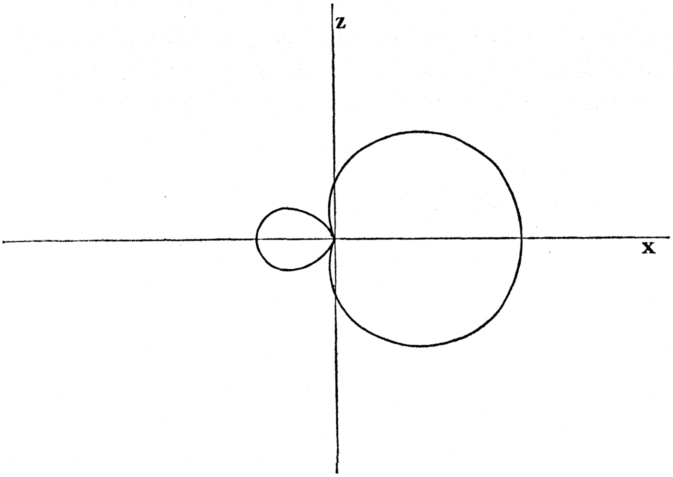

Fig. 3.—Polar graph of $\left| {}^1/_2 + {}^3/_2 \sin \theta \right|$ in the *xz* plane, representing a tetrahedral eigenfunction, the best bond eigenfunction which can be formed from *s* and *p* eigenfunctions.

A second bond can be introduced in the *xz* plane. The best eigenfunction for this bond is found to be

$$\psi_2 = \frac{1}{2}s - \frac{1}{2\sqrt{3}}p_x + \frac{\sqrt{2}}{\sqrt{3}}p_z \tag{8b}$$

---

[23] It is easily shown with the use of the method of undetermined multipliers that the eigenfunction with the maximum value in the direction defined by the polar angles θ_0, φ_0 has as coefficients of the initial eigenfunctions quantities proportional to $\psi_k(\theta_0,\varphi_0)$, and that the maximum value is itself equal to $\{\Sigma_k[\psi_k(\theta_0,\varphi_0)]^2\}^{1/2}$. For let $\psi(\theta,\varphi) = \Sigma_{k=1}^{n} a_k\psi_k(\theta,\varphi)$, with $\Sigma a_k^2 = 1$. We want $\psi(\theta_0,\varphi_0) = \Sigma a_k\psi_k(\theta_0,\varphi_0)$ to ***be a*** maximum with respect to variation in the *a*, 's. Consider the expression

$$\Lambda = \psi(\theta_0,\varphi_0) - \frac{\lambda}{2}\{\Sigma a_k^2 - 1\} = \Sigma\left\{a_k\psi_k(\theta_0,\varphi_0) - \frac{\lambda}{2}a_k^2\right\} + \frac{X}{2}$$

in **which** λ is an undetermined multiplier. Then we put

$$\frac{\partial\Lambda}{\partial a_k} = \psi_k(\theta_0,\varphi_0) - \lambda a_k = 0 \text{ or } a_k = \frac{\psi_k(\theta_0,\varphi_0)}{\lambda},\ k = 1,2\ldots n$$

in which X has such a value that $\Sigma a_k^2 = 1$; *i. e.*, $\lambda = \{\Sigma[\psi_k(\theta_0,\varphi_0)]^2\}^{1/2}$. $\psi(\theta_0,\varphi_0)$ is itself then equal to $\Sigma[\psi_k(\theta_0,\varphi_0)]^2/\lambda$ or $\{\Sigma[\psi_k(\theta_0,\varphi_0)]^2\}^{1/2}$.

This eigenfunction is equivalent to and orthogonal to ψ_1, and has its maximum value of 2 at $\theta = 19°28'$, $\varphi = 180°$, that is, at an angle of 109°28' with the first bond, *which is just the angle between the lines drawn from the center to two corners of a regular tetrahedron.* The third and fourth best bond eigenfunctions

$$\psi_3 = \frac{1}{2}s - \frac{1}{2\sqrt{3}}p_z - \frac{1}{\sqrt{6}}p_x + \frac{1}{\sqrt{2}}p_y \tag{8c}$$

and

$$\psi_4 = \frac{1}{2}s - \frac{1}{2\sqrt{3}}p_z - \frac{1}{\sqrt{6}}p_x - \frac{1}{\sqrt{2}}p_y \tag{8d}$$

are also equivalent to the others, and have their maximum values of 2 along the lines toward the other two corners of a regular tetrahedron.

An equivalent set of four tetrahedral eigenfunctions is[24]

$$\left.\begin{aligned}
\psi_{111} &= \frac{1}{2}(s + p_x + p_y + p_z) \\
\psi_{1\bar{1}\bar{1}} &= \frac{1}{2}(s + p_x - p_y - p_z) \\
\psi_{\bar{1}1\bar{1}} &= \frac{1}{2}(s - p_x + p_y - p_z) \\
\psi_{\bar{1}\bar{1}1} &= \frac{1}{2}(s - p_x - p_y + p_z)
\end{aligned}\right\} \tag{9}$$

These differ from the others only by a rotation of the atom as a whole.

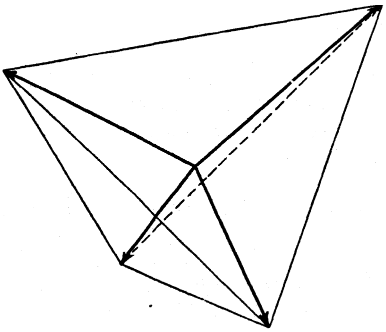

Fig. 4.—Diagram showing relative orientation in space of the directions of the maxima of four tetrahedral eigenfunctions.

The Tetrahedral Carbon Atom.—We have thus derived the result that *an atom in which only s and p eigenfunctions contribute to bond formation and in which the quantization in polar coördinates is broken can form one, two, three, or four equivalent bonds, which are directed toward the corners of a regular tetrahedron* (Fig. 4). This calculation provides the quantum mechanical justification of the chemist's tetrahedral carbon atom, present in diamond and all aliphatic carbon compounds, and for the tetrahedral quadrivalent nitrogen atom, the tetrahedral phosphorus atom, as in phosphonium compounds, the tetrahedral boron atom in B_2H_6 (involving single-electron bonds), and many other such atoms.

Free or Restricted Rotation.—Each of these tetrahedral bond eigen-

---

[24] It should be borne in mind that the bond eigenfunctions actually are obtained from the expressions given in this paper by substituting for s the complete eigenfunction $\Psi_{n00}(r,\theta,\varphi)$, etc. It is not necessary that the r part of the eigenfunctions be identical; the assumption made in the above treatment is that they do not affect the evaluation of the coefficients in the bond eigenfunctions.

functions is cylindrically symmetrical about its bond direction. Hence the bond energy is independent of orientation about this direction, so that there will be *free rotation about a single bond,* except in so far as rotation is hindered by steric effects, arising from interactions of the substituent atoms or groups.

A double bond behaves differently, however. Let us introduce two substituents in the octants xyz and $\bar{x}\bar{y}z$ of an atom, a carbon atom, say, using the bond eigenfunctions ψ_{111} and $\psi_{\bar{1}\bar{1}1}$. The two eigenfunctions $\psi_{1\bar{1}\bar{1}}$ and $\psi_{\bar{1}1\bar{1}}$ are then left to form a double bond with another such group. Now $\psi_{1\bar{1}\bar{1}}$ and $\psi_{\bar{1}1\bar{1}}$ (or any two eigenfunctions formed from them) are not cylindrically symmetrical about the z axis or any direction, nor are the two eigenfunctions on the other group. Hence the energy of the double bond will depend on the relative orientation of the two tetrahedral carbon atoms, and will be a maximum when the two sets of eigenfunctions show the maximum overlapping. This will occur when the two tetrahedral atoms share an edge (Fig. 5). Thus we derive the result, found long ago by chemists, that there are two stable states for a simple compound involving a double bond, a *cis* and a *trans* state, differing in orientation by 180°. *There is no free rotation about a double bond.*[25]

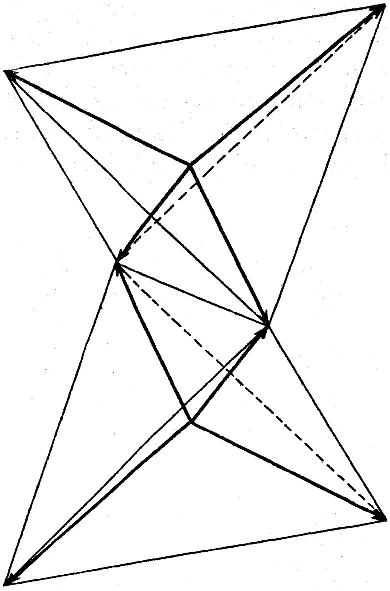

Fig. 5.—Directions of maxima of tetrahedral eigenfunctions in two atoms connected by a double bond.

The three eigenfunctions which would take part in the formation of a triple bond can be made symmetrical about the bond direction, for an atom of the type considered above, with only four eigenfunctions in the outer shell; but since the group attached by the fourth valence lies on the axis of the triple bond, there is no way of verifying the resulting free rotation about the triple bond.

The Angles between Bonds.—The above calculation of tetrahedral angles between bonds when the quantization is changed sets an upper limit on bond angles in doubtful cases, when the criterion is only approximately satisfied. For we can now state that the bond angles in H_2O and NH_3

---

[25] A discussion of rotation about a double bond on the basis of the quantum mechanics has been published by E. Hückel, *Z. Physik,* 60, **423** (1930), which is, I feel, neither so straightforward nor so convincing as the above treatment, inasmuch as neither the phenomenon of concentration of the bond eigenfunctions nor that of change in quantization is taken into account.

should lie between 90 and 109°28′, closer to 90° for the first and to 109°28′ for the second compound. The same limits should apply to other atoms with an outer &shell (counting both shared and unshared electron pairs). Direct evidence on this point is provided by crystal structure data for non-ionic crystals, given in Table I. Every one of the angles given in this table depends on one or more parameters, which have been determined experimentally from observed intensities of x-ray reflections. The probable error in most cases is less than 5°, and in many is only about ±1°. It will be observed that quadrivalent carbon and nitrogen and trivalent nitrogen form bonds at tetrahedral angles, whereas heavier atoms forming only two or three bonds prefer smaller bond angles. The series As, Sb, Bi is particularly interesting. We expect, from an argument given earlier,

TABLE I

ANGLES BETWEEN BONDS, FROM CRYSTAL STRUCTURE DATA[a]

Compound	Atom	Number of bonds	Angles between bonds
$C_6N_4H_{12}$	C	2 C—N, 2 C—H	112° between C—N bonds
$C_6N_4H_{12}$	N	3 N—C	108°
$(NH_2)_2CO$[b]	C	2 single C—N 1 double C=O	115° between single bonds
As	As	3	97°

$KBrO_3$	Br^{++}	3Br—0	109.5"

[a] Data for which no reference is given are from the *Strukturbericht* of P. P. Ewald and C. Hermann. [b] R. W. G. Wyckoff, *Z. Krist.*, **75**, **529 (1930)**. [c] W. H. Zachariasen, *ibid.*, *71*, **501, 517 (1929)**. [d] The very small paramagnetic susceptibility of pyrite requires the presence of electron-pair bonds, eliminating an ionic structure $Fe^{++}S_2^{=}$. Angles are calculated for FeS_2, for which the parameters have been most accurately determined. [e] The parameter value (correct value u = **0.371)** and interatomic distances for molybdenite are incorrectly given in the *Strukturbericht.*

that the bond eigenfunctions will deviate less and less from pure *p* eigenfunctions in this order, and this evidences itself in a closer approach of the bond angle to 90° in the series. Geometrical effects sometimes affect the bond angles, as in As_4O_6 and Sb_4O_6, where a decrease in the oxygen bond angle would necessarily be accompanied by an increase in that for the other atom, and in molybdenite and pyrite.

Many compounds with tetrahedral structures (diamond, sphalerite, wurzite, carborundum, etc.) are known, in which the four bonds have tetrahedral angles. Tetrahedral atoms in such crystals include C (diamond, SiC), Si, Ge, Sn, Cl^{3+} (in CuCl), Br^{3*}, I^{3+}, O^{++} (in Cu_2O and ZnO), S^{-*}, Se^{++}, Te^{++}, N^{+} (in AlN), $P+$, $As+$, Sb^{+}, Bi^{+}, $Cu^{\equiv}$, $Zn^{=}$, $Cd^{=}$, $Hg^{=}$, PI–, Ga^{-} and In^{-}.

The Valence of Atoms.—In the last paragraph and in Table I the atoms are represented with electrical charges which are not those usually seen. These charges are obtained by the application of Rule 1, according to which an electron-pair bond is formed by one electron from each of the two atoms (even though as the atoms separate the type of bonding may change in such a way that both electrons go over to one atom). Accordingly in determining the state of ionization of the atoms in a molecule or crystal containing electron-pair bonds each shared electron-pair is to be split between the two atoms. In this way every atom is assigned an electrovalence obtained by the above procedure and a covalence equal to the number of its shared electron-pair bonds.

It is of interest to note that a quantity closely related to the "valence" of the old valence theory is obtained for an atom by taking the algebraic sum of the electrovalence and of the covalence, the latter being given the positive sign for metals and the negative sign for non-metals. For example, oxygen in OH^- is O^- with a covalence of 1, in H_2O it is O with a covalence of 2, in H_3O^+ it is Of with a covalence of **3,** and in crystalline ZnO it is O^{++} with a covalence of 4; in each case the above rule gives -2 for its valence.

Trigonal Quantization.--We have seen that an atom with *s-p* quantization unchanged will form three equivalent bonds at 90° to one another. If quantization is changed, the three strongest bonds will lie at tetrahedral angles. But increase in the bond angle beyond the tetrahedral angle is not accompanied by a very pronounced decrease in bond strength. Thus three equivalent bond eigenfunctions in a plane, with maxima 120° apart, can be formed

$$\left.\begin{aligned}\psi_1 &= \frac{1}{\sqrt{3}}\,s + \sqrt{\frac{2}{3}}\,p_x \\ \psi_2 &= \frac{1}{\sqrt{3}}\,s - \frac{1}{\sqrt{6}}\,p_x + \frac{1}{\sqrt{2}}\,p_y \\ \psi_3 &= \frac{1}{\sqrt{3}}\,s - \frac{1}{\sqrt{6}}\,p_x - \frac{1}{\sqrt{2}}\,p_y\end{aligned}\right\} \qquad (10)$$

and these have a strength of 1.991, only a little less than that 2.000 of tetrahedral bonds (Fig. **6).** As a result, we may anticipate that in some cases the bond angles will be larger than 109°28′. The carbonate ion in calcite and the nitrate ion in sodium nitrate are assigned a plane configuration from the results of x-ray investigations. In these ions the oxygen atoms are only 2.25 Å. from one another, so that their characteristic repulsive forces must be large, resisting decrease in the bond angle (the smallest distance observed between oxygen ions in ionic crystals is *2.5* Å.). But repulsion of the oxygen atoms would not be very effective in increasing the bond angle in the neighborhood of 120°, so that we might expect equilibrium to be achieved'at a somewhat smaller angle, such as 118°. This would give $CO_3^=$ and NO_3^- a pyramidal structure, like that of NH_3. There would be two configurations possible for a given orientation of the O_3 plane, one in which the carbon (or nitrogen) atom was a short distance above this plane (taken as horizontal) and one with it below the plane. If there is appreciable interaction between these two, as there will be in case the pyramid is flat, the symmetric and antisymmetric combinations of the two will be the correct eigenfunctions, corresponding to the rapid inversion of the pyramid, with a frequency of the order of magnitude of the vibrational frequency of the complex ion along its symmetry axis. This inversion would introduce an effective symmetry plane normal to the three-fold axis, so that a pyramidal structure with rapid inversion is compatible with the x-ray observations.[26]

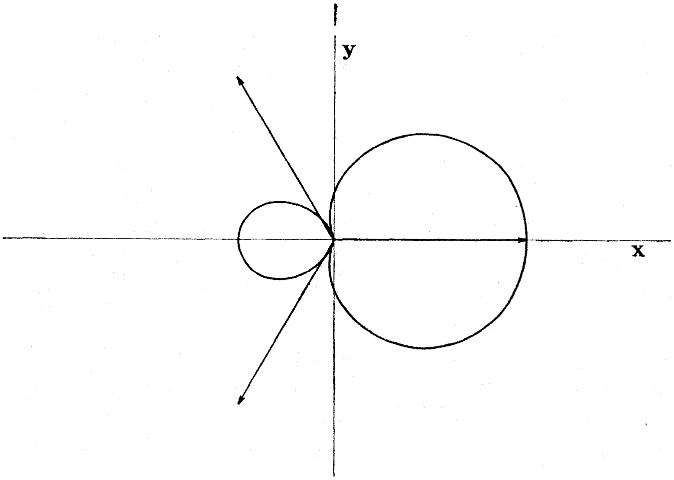

Fig. 6.—Polar graph of $\left|\frac{1}{\sqrt{3}} + \sqrt{2}\cos\varphi\right.$ in the xy plane, representing a trigonal eigenfunction. The maximum directions of the other two equivalent eigenfunctions are also shown.

---

[26] Simulation of symmetry by molecules or complex ions in crystals has been discussed by Linus Pauling, Phys. *Rev., 36,* **430** (1930).

Thus the x-ray data do not decide between this structure and a truly plane structure. Evidence from another source is at hand, however. A plane $CO_3^=$ or NO_3^- ion should show three characteristic fundamental vibrational frequencies. These have been observed as reflection maxima in the infra-red region. But two of the maxima, at 7μ and 14μ, are double,[27] and this doubling, which is not explicable with a plane configuration, is just that required by a pyramidal structure, the separation of the components giving the frequency of inversion of the pyramid.[28]

In graphite each carbon atom is bound to three others in the same plane; and here the assumption of inversion of a puckered layer is improbable, because of the number of atoms involved. A probable structure is one in which each carbon atom forms two single bonds and one double bond with other atoms. These three bonds should lie in a plane, with angles 109°28′ and 125°16′, which are not far from 120°. Two single bonds and a double bond should be nearly as stable as four single bonds (in diamond), and the stability would be increased by the resonance terms arising from the shift of the double bond from one atom to another. But this problem and the closely related problem of the structure of aromatic nuclei demand a detailed discussion, perhaps along the lines indicated, before they can be considered to be solved.

The Structures of Simple **Molecules.**—The foregoing considerations throw some light on the structure of very simple molecules in the normal and lower excited states, but they do not permit such a complete and accurate discussion of these questions as for more complicated molecules, because of the difficulty of taking into consideration the effect of several unshared and sometimes unpaired electrons. Often the bond energy is not great enough to destroy s–p quantization, and the interaction between a bond and unshared electrons is more important than between a bond and other shared electrons because of the absence of the effect of concentration of the eigenfunctions.

Let us consider an atom forming a bond with another atom in the direction of the z axis. Then p_z and s form two eigenfunctions designated σ, p_x and p_y two designated π (one with a resultant moment of $+1$ along the z axis, one with -1). If s–p quantization is not broken, the strongest bond will be formed by p_z and weaker ones by π. If s–p quantization is broken, new eigenfunctions σ_b and σ_a will be formed from s and p_z. In this case the strongest bond is formed by the σ_b eigenfunction, which extends out toward the other atom, weaker ones are formed by π_+ and π_-, and an extremely weak one, if any, by σ_a. We can also predict the stability of

---

[27] C. Schaefer, F. Matossi and F. Dane, *Z. Physik*, 45, **493** (1927).

[28] The normal states of these ions are similar to certain excited states of ammonia, which also show doubling. The frequency of inversion of the normal ammonia molecule is negligibly small.

unshared electrons; σ_o, involving s with its greater penetration of the atom core, will be more stable than **a.**

As examples we may discuss CO, CN, N_2 and NO. CO might be composed of normal or excited atoms, or even of ions. A neutral oxygen atom can form only two bonds. Hence a normal carbon atom, ^3P, which can also form two bonds, is at no disadvantage. We can write the following reaction, using symbols similar to those of Lennard-Jones[29] and Dunkel,[30] whose treatments of the electronic structure of simple molecules have several points of similarity with ours

$$\text{C } 2s^22p2p\ ^3P + \text{O } 2s^22p^22p2p\ ^3P \longrightarrow \text{CO } (2\sigma_o^2)(2\sigma_o^22\pi^2)\{2\sigma_b2\pi + 2\sigma_b2\pi\}^1\Sigma$$

$$:\text{C}. + \cdot\text{O}: \longrightarrow :\text{C}::\text{O}: \qquad \text{Normal state}$$

Here symbols in parentheses represent unshared electrons attached to C and **O**, respectively, and those in braces represent shared electrons. An excited carbon atom ^5S lies about 1.6 v. e. above the normal state, but can still form only a double bond with oxygen, so that the resultant molecule should be excited. We write

$$\text{C}^*\ 2s2p2p2p\ ^5S + \text{O } 2s^22p^22p2p\ ^3P \longrightarrow \text{CO}^*\ (2\sigma_o2\pi)(2\sigma_o^22\pi^2)\{2\sigma_b2\pi + 2\sigma_b2\pi\}\ ^3\Pi \text{ or } ^1\Pi$$

The resultant states are necessarily Π, for σ_b and one π are used for the bond, leaving on C a, and **a.** These two electrons may or may not pair with one another, giving $^1\Pi$ and $^3\Pi$, respectively. Of these $^3\Pi$ should be the more stable, for the two electrons are attached essentially to one atom, and the rules for atomic spectra should be valid. This is substantiated; the observed excited states $^3\Pi$ and $^1\Pi$ lie at 5.98 and 7.99 v. e., respectively. Another way of considering these three states is the following: to go from :C::O: to ·C::O: we lift an electron from the more deeply penetrating **a,** orbit to π; about 6–8 v. e. is needed for this, and the resultant state is either $^3\Pi$ or $^1\Pi$. This viewpoint does not necessitate the discussion of products of dissociation.

CN is closely similar. The normal nitrogen atom, $2s^22p2p2p\ ^4S$, can form three bonds, and more cannot be formed by an excited neutral atom (with five L electrons), so that there is no reason to expect excitation. But a normal carbon atom can form only a double bond, and an excited carbon atom, only 1.6 v. e. higher, can form a triple bond, which contributes about **3** v. e. more than a double bond to the bond energy. Hence we write

$$\text{C}^*\ 2s2p2p2p\ ^5S + \text{N } 2s^22p2p2p\ ^4S \longrightarrow \text{CN } (2\sigma_o)(2\sigma_o^2)\{2\sigma_b2\pi2\pi + 2\sigma_b2\pi2\pi\}^2\Sigma$$

$$.\text{C}. + \cdot\text{N}: \longrightarrow .\text{C}:::\text{N}: \qquad \text{Normal state}$$

The first excited state of the molecule, $:\text{C}::\underset{\cdot}{\text{N}}:$, is built from normal atoms, and has the term symbol $^2\Pi$. It lies 1.78 v. e. above the normal state.

[29] J. E. Lennard-Jones, Trans. *Faraday Soc.*, 25, 668 (1929).

[30] M. Dunkel, *Z. physik. Chem.*, B7, 81 (1930).

Two normal nitrogen atoms form a normal molecule with a triple bond.

$$2\mathrm{N}\ 2s^2 2p 2p 2p\ {}^4S \longrightarrow \mathrm{N}_2(2\sigma_o{}^2)(2\sigma_o{}^2)\{2\sigma_b 2\pi 2\pi + 2\sigma_b 2\pi 2\pi\}\,{}^1\Sigma$$

$$:\dot{\mathrm{N}}\cdot + \cdot\dot{\mathrm{N}}: \longrightarrow :\mathrm{N}:::\mathrm{N}: \qquad \textbf{Normalstate}$$

All other states lie much higher.

A normal oxygen atom and a normal nitrogen atom form a normal NO molecule with a double bond.

$$\mathrm{N}\ 2s^2 2p 2p 2p\ {}^4S + \mathrm{O}\ 2s^2 2p^2 2p 2p\ {}^3P \longrightarrow \mathrm{NO}(2\sigma_o{}^2 2\pi)(2\sigma_o{}^2 2\pi^2)\{2\sigma_b 2\pi + 2\sigma_b 2\pi\}\,{}^2\Pi$$

$$:\mathrm{N}. + \cdot\mathrm{O}: \longrightarrow :\underset{\cdot}{\mathrm{N}}::\underset{\cdot\cdot}{\mathrm{O}}: \qquad \textbf{Normal state}$$

This treatment sometimes fails for symmetrical molecules. Thus $:\ddot{\mathrm{O}}::\ddot{\mathrm{O}}:$ ${}^1\Sigma$ would be predicted for the normal state of O_2, whereas the observed normal state, ${}^3\Sigma$, lies 1.62 v. e. below this. It seems probable that the additional degeneracy arising from the identity of the two atoms gives rise to a new type of bond, the ***three-electron*** bond, and that in normal O_2 there are one single bond and two three-electron bonds, $:\mathrm{O}\overset{\cdots}{\underset{\cdots}{:}}\mathrm{O}:$, ${}^3\Sigma$; a definite decision regarding this question must await a detailed quantum-mechanical treatment. Evidence regarding the oxygen–oxygen single bond is provided by O_4, with the square structure $\begin{matrix} :\ddot{\mathrm{O}}:\ddot{\mathrm{O}}: \\ :\underset{\cdot\cdot}{\ddot{\mathrm{O}}}:\underset{\cdot\cdot}{\ddot{\mathrm{O}}}: \end{matrix}$. The 90° bond angles are expected, since quantization in s and p eigenfunctions is not changed. The equality in energy of O_4 and $2\mathrm{O}_2$ leads to an energy of 58,000 cal. per mole per single bond in O_4; the difference between this value and that for a carbon–carbon single bond (100,000 cal.) shows the greater bond-forming power of tetrahedral eigenfunctions over p eigenfunctions. Ozone, which very probably has the symmetrical arrangement , has 60° bond angles, and this distortion from the most favorable bond angle of 90° shows up in the bond energy, for the heat of formation of −34,000 cal. per mole leads to 47,000 cal. per mole per single bond, a decrease of 11,000 cal. over the favored O_4 bonds.

For some polyatomic molecules predictions can be made regarding the atomic arrangement from a knowledge of the electronic structure or ***vice versa.*** Thus $\cdot\mathrm{C}:::\mathrm{N}:$ ${}^2\Sigma$ can form a bond through the unpaired σ_o electron of carbon, and this bond will extend along the CN axis. Hence the molecules $\mathrm{H}:\mathrm{C}:::\mathrm{N}:$, $:\mathrm{N}:::\mathrm{C}:\mathrm{C}:::\mathrm{N}:$ and $:\ddot{\mathrm{Cl}}:\mathrm{C}:::\mathrm{N}:$ should be linear. This is verified by band spectral data.[31] The isocyanides, RNC, such as $\mathrm{H_3CNC}$, may be given either a triple or a double bond structure: $\mathrm{R}:\mathrm{N}:::\mathrm{C}:$ or $\mathrm{R}:\underset{\cdot\cdot}{\mathrm{N}}::\mathrm{C}:$. The first of these is built of the ions N^+ ${}^5S$ and C^- ${}^4S$, which may be an argument in favor of the second structure, built of normal

---

[31] Private communication from Professor Richard M. Badger of this Laboratory, who has kindly provided me with much information concerning the results of band spectroscopy.

atoms.[32] A decision between the two alternatives could be made by determining the atomic arrangement of an isocyanide, for the triple bond gives a linear molecule, bond angle 180°, and the double bond a kinked molecule, bond angle between 90 and 109°28′.

The molecules and complex ions containing three kernels and sixteen L electrons form an interesting group. Of these CO_2, formed from excited carbon ${}^5S$ and normal oxygen atoms, would have the structure $:\ddot{O}::C::\ddot{O}:$. The two double bonds make the molecule linear, which is verified by both crystal structure and band spectral data. Crystal structure data also show N_2O to be linear, although it is not known whether or not the molecule has oxygen in the middle or at one end, as first suggested by Langmuir[33] and supported by the kernel-repulsion rule.[34] The known linear arrangement eliminates structures built of neutral atoms, $:N:O:N:$ and $:N::N:\ddot{O}:$, for these have bond angles between 90 and 125°. The structures $:\underset{\cdot\cdot}{N}::N::\underset{\cdot\cdot}{O}:$ and $:\underset{\cdot\cdot}{N}::O::\underset{\cdot\cdot}{N}:$, built from $N\ N^+\ O^-$ and $N^-\ O^{++}N^-$, respectively, would both be linear, and so compatible with the known arrangement. An *a priori* decision between them is difficult, although previously advanced arguments favor the unsymmetrical structure. Band spectra should soon decide the question.

The trinitride, cyanate, and isocyanate ions, the first two of which are known[35] to be linear, no doubt have identical electronic structures.

$$:\underset{\cdot}{\ddot{N}}\cdot^{-}\ {}^3P + \cdot\underset{\cdot}{\dot{N}}\cdot^{+}\ {}^5S + \cdot\underset{\cdot}{\ddot{N}}:^{-} \longrightarrow :\ddot{N}::N::\ddot{N}:^{-}$$

$$N^- + N^+ + N^- \longrightarrow N_3^- \text{ Trinitride ion}$$
$$N^- + C + O \longrightarrow NCO^- \text{ Cyanate ion}$$

The fulminate ion, CNO^-, probably has a structure intermediate between $:C::N::\ddot{O}:^-$ and $:C:::N:O:^-$; for since these two bond types have the same bond angles and term symbols (${}^1\Sigma$), they can form intermediate structures lying anywhere between the two extremes. Which extreme is the more closely approached could be determined from a study of the bond angles in un-ionized fulminate molecules, such as AgCNO or ONCHgCNO, for the first structure would lead to an angle of 125° between the CNO axis and the metal–carbon bond, the second to an angle of 180°.

Bonds Involving *d*-**Eigenfunctions**.—When d eigenfunctions as well as *s* and *p* can take part in bond formation, the number and variety of bonds which can be formed are increased. Thus with an s, a *p* and a d subgroup as many as nine bonds can be formed by an atom. It is found from a

consideration of the eigenfunctions that all cannot be equivalent, but six equivalent bonds extending toward the corners of either a regular octahedron or a trigonal pyramid, four extending toward the corners of a tetrahedron or a square, etc., can be formed; and the strength and mutual orientation of the bonds are determined by the number of d eigenfunctions involved in their formation.

There are five d eigenfunctions in a subgroup with $l = 2$ and with given n. They are

$$\left.\begin{aligned} d_z &= \sqrt{5/4}\,(3\cos^2\theta - 1) \\ d_{y+z} &= \sqrt{15}\sin\theta\cos\theta\cos\varphi \\ d_{x+z} &= \sqrt{15}\sin\theta\cos\theta\sin\varphi \\ d_{x+,} &= \sqrt{15/4}\sin 2\theta\sin 2\varphi \\ d_x &= \sqrt{15/4}\sin^2\theta\cos 2\varphi \end{aligned}\right\} \qquad (11)$$

or any set of five orthogonal functions formed by linear combination of these. These functions are not well suited to bond formation. d_{y+z}, $d_{x+,}$ and d_{x+y}, which are similarly related to the x, y and z axes, respectively, have the form shown in Fig. 7. Each eigenfunction has maxima in four directions. d_x is similar in shape, differing from d_{x+y} only in a rotation of 45° about the z axis. d_z, shown in Fig. 8, has two maxima along the z axis, and a girdle about its waist.

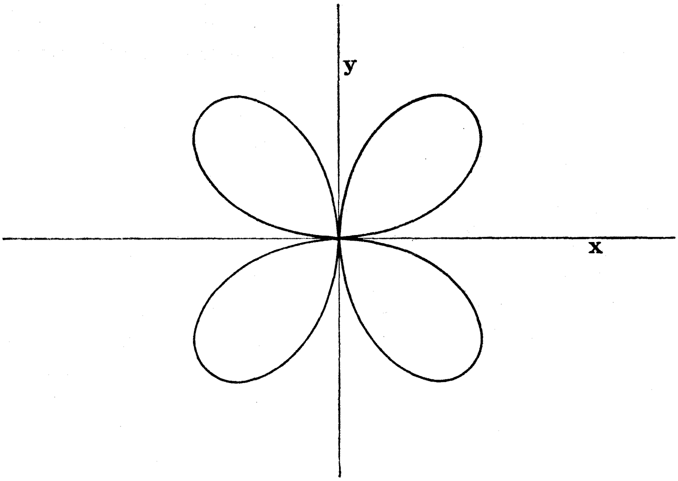

Fig. 7.—Polar graph of $\left|\frac{\sqrt{15}}{2}\sin^2\theta\sin 2\varphi\right.$ in the xy plane, representing the $d_x +$ eigenfunction.

Assuming as before that the dependence on r of the s, p and d eigenfunctions under discussion is not greatly different, the best bond eigenfunctions can be determined by the application of the treatment already applied to s and p alone, with the following results.

The best bond eigenfunction which can be obtained from s, p and d is

$$\frac{1}{3}s + \frac{1}{\sqrt{3}}p_z + \frac{\sqrt{5}}{3}d_z$$

and has a strength of 3. The best two equivalent bond eigenfunctions involving one d eigenfunction

$$\frac{1}{2\sqrt{3}}s + \frac{1}{\sqrt{2}}p_z + \frac{\sqrt{5}}{2\sqrt{3}}d_z \quad \text{and}$$
$$\frac{1}{2\sqrt{3}}s - \frac{1}{\sqrt{2}}p_z + \frac{\sqrt{5}}{2\sqrt{3}}d_z$$

are oppositely directed and have a strength of 2.96.

The atoms of the transition elements, for which d eigenfunctions need to be considered, are of such a size as usually to have a coordination number of 4 or 6, so that four or six equivalent bond eigenfunctions are here of especial interest. If there is available only one d eigenfunction to be combined with an s and three p eigenfunctions, then no more than five bond eigenfunctions can be formed. One may have the maximum strength 3, in which case the others are weak; or two may be strong and three weak; but *with a single d eigenfunction no more than four strong bonds can be formed, and these lie in a plane.* The fifth bond is necessarily weak. The four equivalent bond eigenfunctions formed from s, p and one d eigenfunction are

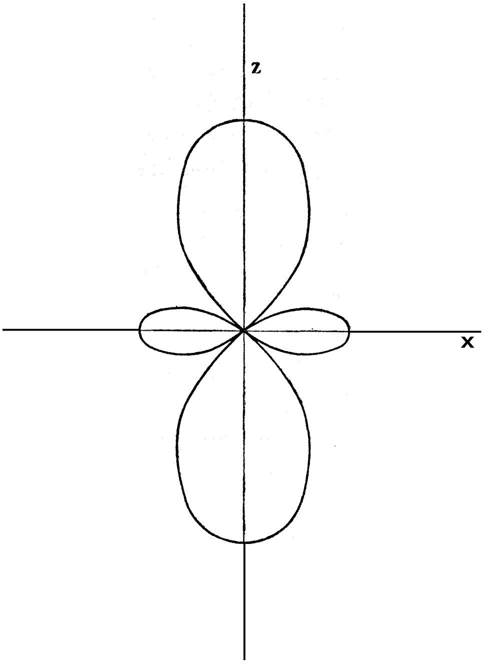

Fig. 8.—Polar graph of $\left|\frac{\sqrt{5}}{2}(3\cos^2\theta - 1)\right|$ in the xz plane, representing the d_z eigenfunction.

$$\left.\begin{aligned}
\psi_1 &= \frac{1}{2}s + \frac{1}{2}d_x + \frac{1}{\sqrt{2}}p_x \\
\psi_2 &= \frac{1}{2}s + \frac{1}{2}d_x - \frac{1}{\sqrt{2}}p_x \\
\psi_3 &= \frac{1}{2}s - \frac{1}{2}d_x + \frac{1}{\sqrt{2}}p_y \\
\psi_4 &= \frac{1}{2}s - \frac{1}{2}d_x - \frac{1}{\sqrt{2}}p_y
\end{aligned}\right\} \qquad (12)$$

One of these is shown in Fig. 9. These all have their maxima in the xy plane, directed toward the corners of a square. The strength of these bond eigenfunctions, 2.694, is much greater than that of the four tetrahedral eigenfunctions formed from s and p alone (2.00). But if three d eigenfunctions are available, stronger bonds directed toward tetrahedron corners can be formed. The equivalent tetrahedral bond eigenfunctions

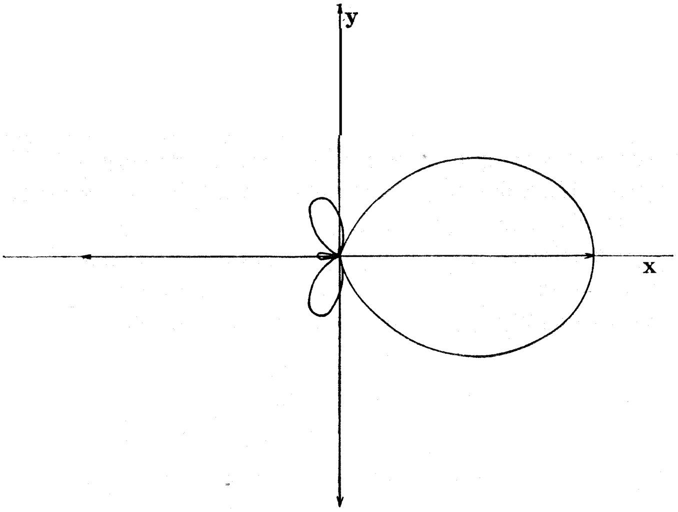

Fig. 9.—Polar graph of $\left| 1/2 + \sqrt{3/2}\cos\varphi + \frac{\sqrt{15}}{4}\cos 2\varphi \right|$ in the xy plane, representing one of the four equivalent dsp^2 bond eigenfunctions. The directions of the maxima of the four are represented by arrows.

$$\psi_{111} = \frac{1}{2}s + \frac{\sqrt{3}}{4\sqrt{2}}(p_x + p_y + p_z) + \frac{\sqrt{5}}{4\sqrt{2}}(d_{y+z} + d_{x+z} + d_{x+y})$$

$$\psi_{1\bar{1}\bar{1}} = \frac{1}{2}s + \frac{\sqrt{3}}{4\sqrt{2}}(p_x - p_y - p_z) + \frac{\sqrt{5}}{4\sqrt{2}}(d_{y+z} - d_{x+z} - d_{x+y})$$

$$\psi_{\bar{1}1\bar{1}} = \frac{1}{2}s + \frac{\sqrt{3}}{4\sqrt{2}}(-p_x + p_y - p_z) + \frac{\sqrt{5}}{4\sqrt{2}}(-d_{y+z} + d_{x+z} - d_{x+y})$$

$$\psi_{\bar{1}\bar{1}1} = \frac{1}{2}s + \frac{\sqrt{3}}{4\sqrt{2}}(-p_x - p_y + p_z) + \frac{\sqrt{5}}{4\sqrt{2}}(-d_{y+z} - d_{x+z} + d_{x+y})$$

have a strength of 2.950, nearly equal to the maximum **3.** These leave only two pure d eigenfunctions behind, however, the others being part d and part p. Thus we conclude that if there are three d eigenfunctions available, a transition group element forming four electron-pair bonds will direct them toward tetrahedron corners. Examples of such bonds are provided by $CrO_4^{=}$, $MoO_4^{=}$, etc. Only when one d eigenfunction alone is available will the four bonds lie in a plane. In compounds of bivalent nickel, palladium, and platinum, such as $K_2Ni(CN)_4$, $K_2Pd(CN)_4$, K_2PdCl_4, K_2PtCl_4, etc., there are eight unshared d electrons on each metal atom, which occupy four of the five d eigenfunctions. Hence the four added atoms or groups lie in a plane at the corners of a square about the metal atom. Such a configuration was assigned to palladous and platinous compounds by Werner because of the existence of apparent cis and *trans* compounds, and has been completely substantiated by the x-ray investigation of the chloropalladites and chloroplatinites.[36] The square configuration has not before been attributed to $K_2Ni(CN)_4$; it is supported by the observed isomorphism of the monoclinic crystals $K_2Pd(CN)_4 \cdot H_2O$ and $K_2Ni(CN)_4 \cdot H_2O$, and it will be shown in a following section that it is compatible with the magnetic data.

The non-existence of compounds K_3PtCl_5, etc., is explained by the weak bond-forming power (1.732) of the remaining eigenfunction p_z.

Now if two d eigenfunctions are available, six equivalent eigenfunctions

$$\left.\begin{aligned}
\psi_1 &= \frac{1}{\sqrt{6}}\,s + \frac{1}{\sqrt{2}}\,p_z + \frac{1}{\sqrt{3}}\,d_z \\
\psi_2 &= \frac{1}{\sqrt{6}}\,s - \frac{1}{\sqrt{2}}\,p_z + \frac{1}{\sqrt{3}}\,d_z \\
\psi_3 &= \frac{1}{\sqrt{6}}\,s + \frac{1}{\sqrt{12}}\,d_z + \frac{1}{2}\,d_x + \frac{1}{\sqrt{2}}\,p_x \\
\psi_4 &= \frac{1}{\sqrt{6}}\,s + \frac{1}{\sqrt{12}}\,d_z + \frac{1}{2}\,d_x - \frac{1}{\sqrt{2}}\,p_x \\
\psi_5 &= \frac{1}{\sqrt{6}}\,s + \frac{1}{\sqrt{12}}\,d_z - \frac{1}{2}\,d_x + \frac{1}{\sqrt{2}}\,p_y \\
\psi_6 &= \frac{1}{\sqrt{6}}\,s + \frac{1}{\sqrt{12}}\,d_z - \frac{1}{2}\,d_x - \frac{1}{\sqrt{2}}\,p_y
\end{aligned}\right\} \qquad (13)$$

can be formed. These form strong bonds, of strength 2.923, directed toward the corners of a regular octahedron; and no stronger octahedral bonds can be formed even though more d eigenfunctions be available (Figs. 10 and 11). Hence we expect transition group atoms with six or less unshared electrons to form six electron-pair bonds. Examples of such compounds are numerous: $PtCl_6^{=}$, $Fe(CN)_6^{=}$, etc., although the definite assignment of an electron-pair bond structure rather than an ionic structure (as in $FeF_6^{\equiv}$, formed of Fe^{+++} and 6 F^-) can be made only after the discussion of paramagnetic susceptibility.

I have not succeeded in determining whether or not these octahedral eigenfunctions are the strongest six equivalent bond eigenfunctions which can be formed when more than two d's are available. The known structure of molybdenite, MoS_2, suggests that six bonds directed toward the corners of a trigonal prism are stable; but only a small increase in bond strength can possibly be obtained (from 2.923 to not over 3), and the mutual re-

---

[36] R. G. Dickinson, This Journal, 44, 2404 (1922).

pulsion of the six atoms or groups will in most cases overcome this, if it does exist, and leave the octahedral configuration the stable one.

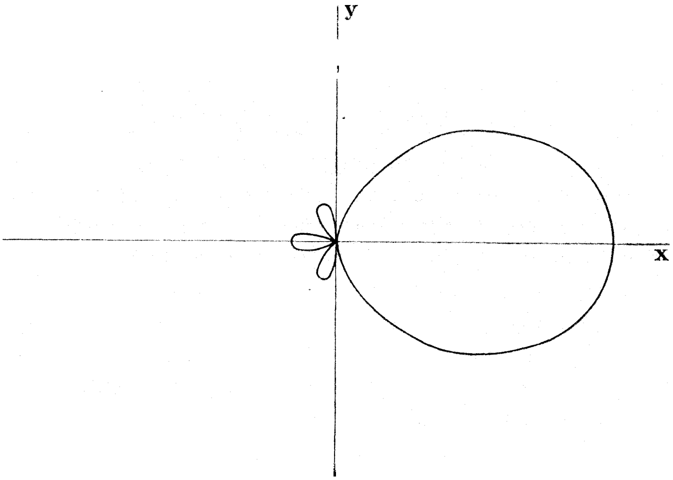

Fig. 10.—Polar graph of $|\psi_3|$ of Equation 13, in the *xy* plane, representing one of the six equivalent d^2sp^3 bond eigenfunctions (octahedral eigenfunctions).

II. The Magnetic Moments of Molecules and Complex Ions

The theory of the paramagnetic susceptibility of substances has been developed gradually over a long period of years through the efforts of a number of investigators. The theoretical calculation of the magnetic moments of complex molecules and ions has in particular attracted much attention recently, and both theoretical and empirical considerations have been used in developing rules applicable in various cases. The work reported in this paper provides little more than the justification and unification of previously developed rules. This finishing touch is, however, of much significance for the problem of the nature of the chemical bond; for it, in conjunction with the quantum mechanical discussion of the previous sections, permits definite conclusions to be drawn regarding type of bond in many molecules and complex ions from a knowledge of their magnetic moments, and conversely provides the basis for the definite prediction of magnetic moments from a knowledge of the type of bonds and the atomic arrangement.

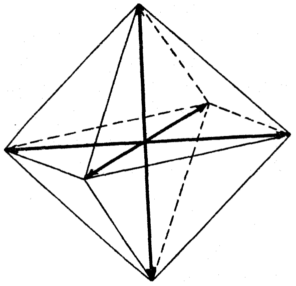

Fig. 11.—Diagram showing relative orientation in space of the directions of the maxima of the octahedral eigenfunctions.

The calculation of the magnetic moments of the rare-earth ions by

Hund[37] in 1926 and of oxygen and nitric oxide by Van Vleck[38] in 1928 were triumphs of the theory of spectra. The magnetic moment of an atom or monatomic ion with Russell–Saunders coupling of the quantum vectors is

$$\mu_J = g\sqrt{J(J+1)}$$

in which g, the Landé splitting factor, is given by

$$g = 1 + \frac{J(J+1) + S(S+1) - L(L+1)}{2J(J+1)}$$

Here L, S, and J are the quantum numbers corresponding to the total orbital angular momentum of the electrons, the total spin angular momentum, and the resultant of these two. Hund predicted values of L, S, and J for the normal states of the rare-earth ions from spectroscopic rules, and calculated μ-values for them which are in generally excellent agreement with the experimental data for both aqueous solutions and solid salts.[39] In case that the interaction between L and S is small, so that the multiplet separation corresponding to various values of J is small compared with kT, Van Vleck's formula[38]

$$\mu_{LS} = \sqrt{4S(S+1) + J(J+1)}$$

is to be used.

But similar calculations for the iron-group ions show marked disagreement with experiment, and many attempts were made to explain the discrepancies. The explanation is simple: *in many condensed systems the perturbing effect of the atoms or molecules surrounding a magnetic atom destroys the contribution of the orbital momentum to the magnetic moment, which is produced entirely by the spin moments of unpaired electrons.*[40]

This conclusion is easily deduced from the consideration of the nature of eigenfunctions giving rise to magnetic moments. In an atom containing unpaired p electrons, say, a component of orbital magnetic moment of $\pm(h/2\pi)\cdot(e/2mc)$ is obtained when an unpaired electron is in a state given by the eigenfunction $p_x \pm i\,p_y$. Now if the perturbing influence of surrounding atoms or molecules is such as to make the perturbation energy for the eigenfunction p_x or p_y or any combination of them other than $p_x \pm i\,p_y$ greater than the field energy, this will be the correct zeroth order eigenfunction, and the atom will show no orbital magnetic moment. In an atom with Russell–Saunders coupling the interaction energy of L and S takes the place of the field energy, so that the criterion to be satisfied in order that the magnetic moment due to L be destroyed is that the perturbation energy due to surrounding atoms and ions be greater than the multiplet separation, which for the iron-group ions is of the order of magnitude of 1 v. e.[41]

---

[37] F. Hund, *Z. Physik*, **33**, 345 (1925).

[38] J. H. Van Vleck, *Phys. Rev.*, 31, 587 (1928).

[39] The few discrepancies have been accounted for by S. Freed [THIS JOURNAL, 52, 2702 (1930)] and J. H. Van Vleck and A. Frank [*Phys. Rev.*, 34, 1494 (1929), and a paper delivered at the Cleveland meeting of the American Physical Society, December 31, 1930].

[40] This assumption was first made by E. C. Stoner, *Phil. Mag.*, 8, 250 (1929), in order to account for the observed moments of iron-group ions.

[41] Essentially the same conclusion has been announced by J. H. Van Vleck at the Cleveland meeting of the American Physical Society, December 31, 1930.

If the perturbation function shows cubic symmetry, and in certain other special cases, the first-order perturbation energy is not effective in destroying the orbital magnetic moment, for the eigenfunction p_x * i p_y leads to the same first-order perturbation terms as p_x or p_y or any other combinations of them. In such cases the higher order perturbation energies are to be compared with the multiplet separation in the above criterion.

In linear molecules only the component of orbital momentum normal to the figure axis is destroyed, that along the figure axis being retained. In non-linear molecules with strong interatomic interactions the concept of orbital angular momentum loses its significance.

The rare-earth ions owe their magnetic moments to an incompleted 4f subshell, which lies within an outer shell of 5*s* and 5*p* electrons, and is thus protected from strong perturbations by surrounding atoms. As a consequence the orbital magnetic moment is not destroyed, and the ion is not affected by its environment. But in the iron-group ions and other transition-group ions the incompleted subshell is the outermost one. Hence it is not surprising that the solvent molecules or the surrounding atoms or ions in a complex ion or a crystal interact sufficiently strongly with these atoms or ions to destroy, in whole, or in part, the orbital magnetic moment, leaving the spin moment, with perhaps a small contribution from the orbital moment in border-line cases. We can state with certainty that the formation of electron-pair bonds will destroy the orbital moment.

This greatly simplifies the theory of the magnetic moments of molecules and complex ions. *The magnetic moment of a molecule or complex ion is determined entirely by the number of unpaired electrons, being equal to*

$$\mu_S = 2\sqrt{S(S+1)}$$

in which S is one-half that number. The factor 2 is the g-factor for electron spin.

As a matter of fact, Sommerfeld[42] in 1924, a year before Hund's treatment of the rare-earth ions, noticed that the observed magnetic moments of K^+ and Ca^{++}, Ca^+ (spectroscopic), Ca (spectroscopic), Cr^{3+}, Cr^{++}, Mn^{++}, Fe^{++}, Co^{++}, Ni^{++}, Cu^{++} and Cu^+ are approximately reproduced by the above equation with $S = 0, {}^1/_2, 1, {}^3/_2, 2, {}^5/_2, 2, {}^3/_2, 1, {}^1/_2$ and 0, respectively. But with the development of spectral theory he apparently gave up this simple formula because of lack of a theoretical derivation of it, and it remained for Bose[43] in 1927 to state explicitly the assumption that only S contributes to the moment in these cases, without, however, explaining why L gives no contribution, and for Stoner[40] in 1929 to supply the explanation. The comparison of calculated and observed values is given in Table I. It may be pointed out that S increases to a maximum value of ${}^5/_2$ when the 3*d* subgroup is half filled; Pauli's principle requires that succeeding electrons decrease the spin, so that μ_S is symmetrical about

---

[42] **A.** Sommerfeld, "Atombau," 4th ed., p. 639.

[43] D. M. Bose, *Z. Physik*, 43, 864 **(1927).**

this point. The agreement with experiment, while much better than for μ_J, is not perfect; ions with more than five $3d$ electrons are found to have moments larger than μ_S, while V^{3+} deviates in the other direction. Bose suggested that perhaps S could in some cases exceed the maximum value allowed by Pauli's principle, but the obviously correct explanation is that the perturbing effect of surrounding atoms is not sufficient completely to destroy the L moment. Hence the observed moment should lie between μ_S and μ_J, which it does in every case.

Since the interaction is not strong enough to destroy the L moment, we conclude that in aqueous solution and in some crystalline salts the atoms[44] Fe^{II}, Co^{III}, Co^{II}, Ni^{II} and Cu^{II} do not form strong electron-pair bonds with H_2O, Cl, or certain other atoms, the bonds instead being ion-dipole or ionic bonds.

The formation of a stable coordination compound involving the four tetrahedral sp^3 eigenfunctions might decrease the L contribution appreciably. It was indeed pointed out by Bose that in the compounds listed in the last column of Table II the observed moments approach more closely the theoretical values μ_S.

The Magnetic Moments of Complexes **with** Electron-Pair Bonds.—The peculiar magnetic behavior of some complex ions has attracted much attention. $[Fe(CN)_6]^{3-}$ and $[Fe(CN)_6]^{4-}$, for example, have $\mu = 2.0$ and 0.00, respectively, instead of the values 5.9 and 4.9 for Fe^{3+} and Fe^{++}. Welo and Baudisch[45] and later Sidgwick and Bose expressed essentially the following rule: the magnetic moment of a complex is the same as that of the atom with the same number of electrons as the central atom of the complex, counting two for each electron-pair bond. Fe^{++} has 24 electrons; adding 12 for the six bonds gives **36,** the electron number of krypton, so that the diamagnetism of the ferrocyanide ion is explained. This rule is satisfactory in many cases,. but there are also many exceptions. Thus $[Ni(CN)_4]^=$ is diamagnetic, although the above rule would make it as paramagnetic as $[Ni(NH_3)_4]^{++}$.

The whole question is clarified when considered in relation to the foregoing quantum mechanical treatment of the electron-pair bond. For the iron-group elements the following rules follow directly from that treatment and from the rules of line spectroscopy.

1. Bond eigenfunctions for iron-group atoms are formed from the nine eigenfunctions $3d^6$*, 4s and* $4p^3$*, as described in preceding sections. One bond eigenfunction is needed for each electron-pair bond.*

2. The remaining (unshared) electrons are to be introduced into the 3d eigenfunctions not involved in bond formation.

---

[44] The symbol Fe^{II} is used for bivalent iron, etc., when the type of bond is undetermined.

[45] L. A. Welo and O. Baudisch, *Nature*, 116, 606 (1925).

[a] Observed magnetic moments, other than those in the last column, are from "International Critical Tables."

3. The normal state is the state with the *maximum* resultant spin S allowed by *Pauli's* principle.

These rules apply also to the palladium and platinum groups, the eigenfunctions involved being $4d^5 5s5p^3$ and $5d^5 6s6p^3$, respectively.

There are several important types of molecules and complexes to be given separate discussion.

If the bonds are ionic or ion-dipole bonds, the magnetic moments are those of the isolated central ions, given in the first column of moments in Table III. If the complex involves electron-pair bonds formed from sp^3 alone, such as four tetrahedral sp^3 bonds, the magnetic moments are the same, for the five d eigenfunctions are still available for the remaining electrons. The hydrazine and ammonia complexes mentioned above come in this class.

If four strong bonds involving a d eigenfunction are formed (giving a square configuration), only four d eigenfunctions are available for the additional electrons. The magnetic moments are then those given in the second column of the table. Examples of such compounds are $K_2Ni(CN)_4$, $K_2Pd(CN)_4 \cdot H_2O$, K_2PdCl_4, K_2PtCl_4, $K_2Pt(C_2O_4)_2 \cdot 2H_2O$ and $Pt(NH_3)_4SO_4$. With eight unshared d electrons, these should all be diamagnetic. This has been experimentally verified for the first and the last three compounds; data for the others are not available. The square configuration has been experimentally verified for the chloropalladites and chloroplatinites, as mentioned before. It can be predicted that in the $[Pt(C_2O_4)_2 \cdot 2H_2O]^=$ complex the two oxalate groups lie in a plane, each attached to the platinum atom by two electron-pair bonds of the type dsp^2. The two water molecules, if attached to the complex, are held by ion-dipole bonds.

In complexes in which the central atom forms a coördinated octahedron of six atoms or groups, the bonds may be any of several types. If they are all ionic or ion-dipole bonds, the moments are those in the first column. If four electron-pair bonds are formed, these must be dsp^2 and lie in a plane (sp^3 gives tetrahedral bonds); the $[Pt(C_2O_4)_2 \cdot 2H_2O]^=$ ion is of this type, assuming that the water molecules are part of the complex. The moments are then those of the second column. If six electron-pair bonds are formed, only three d eigenfunctions are left for the additional electrons, giving the magnetic moments of the third column. It is seen that in atoms with three or fewer unshared electrons magnetic data provide no information as to bond type with coordination number six, but that in other cases a definite statement can be made as to the type of bond when magnetic data are available. The observed magnetic moments are collected in Table IV. From them we deduce that trivalent and bivalent manganese, chromium, iron, and cobalt form six strong electron-pair bonds with cyanide groups, and in some cases with other groups, including NH_3, Cl and NO_2.[46] Tri-

---

[46] An electron-pair bond with a water molecule may perhaps be formed when induced by other strong bond-forming groups in the complex.

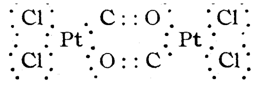
[a] Values quoted are from "International Critical Tables" or from W. **Biltz**, *Z. anorg. Chem.*, 170, 161 (1928), and D. M. Bose, *Z. Physik*, 65, 677 (1930). I am indebted to Mr. P. D. Brass for collecting from the literature some of the data in this table.

The moments of complexes containing NO offer a puzzling problem. The diamagnetism of compounds of iron and ruthenium suggests that Fe^{IV} and Ru^{IV} form a double bond with NO, making seven bonds in all, which woud lead to $\mu = 0$. But this structure cannot be applied to $[Co(NH_3)_5NO]Cl_2$, which has a moment corresponding to a triplet state. Further study of such complexes is needed.

The observed diamagnetism of the ions $[Mo(CN)_8]^{4-}$ and $[W(CN)_8]^{4-}$ shows that the central atom forms eight electron-pair bonds, involving the eigenfunctions d^4sp^3 (fourth column of Table III).

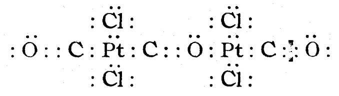
The metal carbonyls $Ni(CO)_4$, $Fe(CO)_5$, and $Cr(CO)_6$ are observed to be diamagnetic. This follows from the theoretical discussion if it is assumed that an electron-pair bond is formed with each carbonyl; for the nine eigenfunctions available ($3d^54s4p^3$) are completely filled by the n bonds and $2(9-n)$ additional electrons attached to the metal atom ($n = 4, 5, 6$). The theory also explains the observed composition of these unusual substances; for the formulas $M(CO)_n$, with n = 4, 5, and 6, respectively, follow at once from the assumption that CO molecules add on as long as bond eigenfunctions are available. Since a single unshared electron can occupy an eigenfunction, this assumption leads to the formula $Co(CO)_4$, which is known to be correct. This substance should have $\mu = 1.73$. The compounds $Mn(CO)_5$ and $V(CO)_6$ should also exist, and have $\mu = 1.73$. $Co(CO)_4$ and $Mn(CO)_5$ should form un-ionized diamagnetic cyanides, $[Co(CO)_4CN]$ and $[Mn(CO)_5CN]$, while $V(CO)_6$ would not form a stable cyanide, since steric effects would prevent the cyanide group from forming an electron-pair bond with the vanadium atom, and ionic cyanides are formed only by strong metals. It is interesting to note the effect of the four strong bond eigenfunctions and one weak one formed from dsp^3; whereas nickel forms no lower carbonyl than $Ni(CO)_4$, iron forms $Fe(CO)_4$ and $Fe_2(CO)_9$ in addition to $Fe(CO)_5$.

The palladium and platinum metals also form carbonyl compounds. Of the expected compounds $Pd(CO)_4$, $Pt(CO)_4$, $Ru(CO)_5$, $Os(CO)_5$, $Mo(CO)_6$, and $W(CO)_6$ only $Mo(CO)_6$ has been prepared, although some unsaturated ruthenium carbonyls have been prepared. The compounds $Pd(CO)_2Cl_2$, $Pt(CO)_2Cl_2$, $K[PtCOCl_3]$, etc., show the stability of the four dsp^2 bonds. It would be interesting to determine whether or not each CO is bonded to two metal atoms in compounds such as $[Pt(CO)Cl_2]_2$, whose structure is predicted to be



$$\begin{array}{ccccc} \vdots Cl \vdots & & .C::O\dot{} & & \vdots Cl \vdots \\ & \vdots Pt \vdots & & \vdots Pt \vdots & \\ \vdots Cl \vdots & & \dot{}O::C. & & \vdots Cl \vdots \end{array}$$

with the whole molecule in one plane. The compounds $2PdCl_2{\cdot}3CO$ and $2PtCl_2{\cdot}3CO$ probably have the structure



$$\begin{array}{c} :\ddot{Cl}: \qquad :\ddot{Cl}: \\ :\ddot{O}::C:\ddot{Pt}:C::\ddot{O}:\ddot{Pt}:C::\ddot{O}: \\ :\ddot{Cl}: \qquad :\ddot{Cl}: \end{array}$$

or one of the structures isomeric with this.

This by no means exhaustive discussion may serve to indicate the value of the information provided by magnetic data relative to the nature of the chemical bond. The quantum-mechanical rules for electron-pair bonds are essential to the treatment. Much further information is provided when these methods of attack are combined with crystal structure data, a topic which has been almost completely neglected in this paper. It has been found that the rules for electron-pair bonds permit the formulation of a set of structural principles for non-ionic inorganic crystals similar to that for complex ionic crystals; the statement of these principles and applications illustrating their use will be the subject of an article to be published in the *Zeitschrift für Kristallographie.*

Summary

With the aid of the quantum mechanics there is formulated a set of rules regarding electron-pair bonds, dealing particularly with the strength of bonds in relation to the nature of the single-electron eigenfunctions involved. It is shown that one single-electron eigenfunction on each of two atoms determines essentially the nature of the electron-pair bond formed between them; this effect is accentuated by the phenomenon of concentration of the bond eigenfunctions.

The type of bond formed by an atom is dependent on the ratio of bond energy to energy of penetration of the core (*s*–*p* separation). When this ratio is small, the bond eigenfunctions are *p* eigenfunctions, giving rise to bonds at right angles to one another; but when it is large, new eigenfunctions especially adapted to bond formation can be constructed. From *s* and *p* eigenfunctions the best bond eigenfunctions which can be made are four equivalent tetrahedral eigenfunctions, giving bonds directed toward the corners of a regular tetrahedron. These account for the chemist's tetrahedral atom, and lead directly to free rotation about a single bond but not about a double bond and to other tetrahedral properties. A single *d* eigenfunction with *s* and *p* gives rise to four strong bonds lying in a plane and directed toward the corners of a square. These are formed by bivalent nickel, palladium, and platinum. Two *d* eigenfunctions with *s* and *p* give six octahedral eigenfunctions, occurring in many complexes formed by transition-group elements.

It is then shown that (excepting the rare-earth ions) the magnetic moment of a non-linear molecule or complex ion is determined by the number of unpaired electrons, being equal to $\mu_S = 2\sqrt{S(S+1)}$, in which S is half that number. This makes it possible to determine from magnetic data which eigenfunctions are involved in bond formation, and so to decide between electron-pair bonds and ionic or ion-dipole bonds for various complexes. It is found that the transition-group elements almost without exception form electron-pair bonds with CN, ionic bonds with F, and ion-dipole bonds with H_2O; with other groups the bond type varies.

Examples of deductions regarding atomic arrangement, bond angles and other properties of molecules and complex ions from magnetic data, with the aid of calculations involving bond eigenfunctions, are given.

NOTES

A Method of Sealing Substances in Ampullae with Inert Gases.—Usually substances susceptible to oxidation can be sealed in the vacuum of the mercury pump. However, some substances (e. g., samples of vitamin-bearing extracts and the like) cannot thus be sealed, due to voluminous foaming, sputtering, etc. In such cases, the substances must be sealed in with an inert gas. There are several methods (and ampullae with two tubulures) which permit of this. The author uses a method which is almost self-explanatory from the accompanying figure, and among several other advantages permits the use of the ordinary routine ampullae with a single tubulure.

A short piece of rubber tubing is attached to the tubulure. The other end of this tubing is stoppered with a piece of glass rod, and (at A) is provided with a 1-cm. lengthwise slit, *i.* e., a Bunsen valve. In the figure, B represents a hollow pointed surgical needle, of adequate length and lumen. The needle is passed through one wall of the tubing, and is pushed down into the ampulla almost to the surface of the substance. An inert gas (carbon dioxide or nitrogen) is conducted into the needle through tubing C, until all the air in the ampulla has been displaced and driven out through slit A. At this point the source of the inert gas is shut off, and the needle is then drawn up until its point is on a level with D. The ampulla is thereupon sealed by fusing off at E. The arrangement of Bunsen valve and needle can be used repeatedly. Due to the fact that the point of the needle can be raised or lowered, it can be adjusted to approach the surface of the substance, no matter whether large or small amounts are being sealed up. This will frequently be found to be advantageous.

Preparation of Starch Solution for Use in Iodimetric Titrations.—Some years ago the writers and John Field, 2d [THIS JOURNAL 48, 1299 (1926)] pointed out that clear starch solutions showing little or no Tyndall effect could be obtained for iodimetric titrations by leaching dry starch that had been ground for a long time in a pebble mill. The writers have found that equally satisfactory solutions may be obtained by leaching the well-known breakfast food, puffed rice. The tedious grinding in the pebble mill can thus be avoided.

THE RATE OF HYDROGENATION OF ACETOACETIC ESTER, DEHYDROACETIC ACID, BENZENE, PHENOL AND ANILINE OVER NICKEL AT PRESSURES FROM 27 TO 350 ATMOSPHERES

BY HOMER ADKINS, HOWARD I. CRAMER AND RALPH CONNOR

RECEIVED JULY 28, 1930 PUBLISHED APRIL 6, 1931

There appears to be comparatively little information available as to the relation of the pressure of hydrogen to the rate of hydrogenation of liquids with nickel catalysts. Ipatiev believed that pressures of the order of a hundred atmospheres were advantageous, while others have been but little impressed by the advantages of such pressures.[1] The experimental work described in this paper was performed in order to find out, in the case of a few supposedly representative compounds, what pressures could most advantageously be used for their hydrogenation.

The disadvantages in the use of pressures above a few atmospheres are obvious. Glass apparatus and rubber tubing may not be used, so that the assistance of a mechanic and materials often not available in the laboratory are required for the construction of the apparatus. The advantages in the use of pressures up to 80 or 150 atmospheres are no less real. Pressures of these magnitudes raise the boiling points of all organic materials which are liquids under laboratory conditions to 190° or above. This makes it possible to use any of the common solvents and to subject in the liquid phase almost all organic compounds to the action of hydrogen and the nickel catalyst. It also makes it possible to store in the reduction chamber a much greater quantity of hydrogen and thus avoid any auxiliary tank such as is necessary in reduction of pressures of a few atmospheres. This makes it possible to use a very simple set-up which includes only one inexpensive valve of the type designed for holding pressure on but one side. (Such an apparatus is manufactured by the Burgess–Parr Co. of Moline, Ill.) At least for small-scale operation in the laboratory the advantages of using pressures in the range 60 to 120 or 150 atmospheres as compared with pressures below perhaps 5 atmospheres seem to be

---

[1] *Sabatier and Reid, "Catalysis in Organic Chemistry,"* D. *Van* Nostrand Co., New *York*, 1922, p. *207.*

quite considerable with no material increase in danger, inconvenience or expense. The use of pressures materially higher than these necessitates additional and more expensive equipment, for hydrogen is usually purchased in tanks holding the gas under a pressure of about 125 atmospheres, A bomb filled at this pressure and heated to 200°, which may be regarded as a reasonable upper limit necessary for operation with a nickel catalyst, would show a pressure of about 190 atmospheres. This represents then the maximum pressure which may be obtained without considerable additional equipment.

Acetoacetic ester, dehydroacetic acid, benzene, aniline and phenol were selected as representative compounds for testing out the practical advantages of various pressures up to 350 atmospheres. Acetoacetic ester and benzene absorbed one mole and three moles of hydrogen, respectively, while phenol and aniline were not completely reduced under the conditions selected, the ratio of catalyst to reactant and the temperature being too low for complete reduction. These compounds were completely reduced if a higher ratio of catalyst or temperature was used. In so far as our experience goes dehydroacetic acid requires a second or third application of catalyst in order to obtain complete reduction. "Complete reduction" in the two lower ranges of pressure means three moles of hydro-

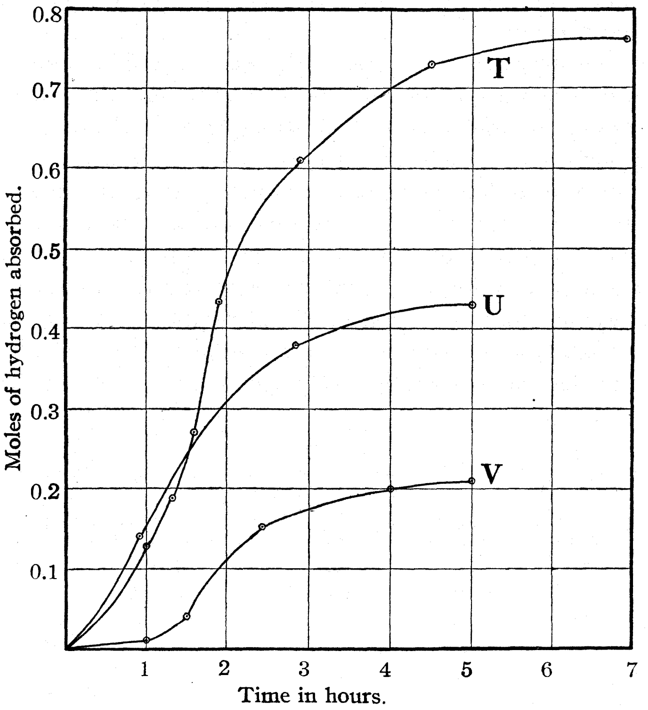
gen per mole of dehydroacetic acid, while at the higher pressure it means five moles of hydrogen per mole of acid. The products formed in the hydrogenation of acetoacetic ester and dehydroacetic acid have been considered in an earlier paper.[2]

There is shown in Fig. 1 the effect of increased pressure upon the rate and extent of absorption of hydrogen by dehydroacetic acid. The data given in Table I show the rate of progress toward complete reduction at different pressures for acetoacetic ester, benzene, phenol and aniline. Zero time was taken as the time at which the thermocouple in the bomb first showed the temperature which had been selected for allowing the reaction to proceed. The figures given in the tables are for individual experiments which have been duplicated at least once. The general effects have been observed in numerous experiments. The duplicate experiments showed



T, 323 atm.; U, 149 atm.; V, 108 atm.

Fig. 1.—The rate of absorption of hydrogen by dehydroacetic acid at various pressures. The moles of hydrogen absorbed at three pressures are plotted against the time in hours for the reduction of 50 g. (0.3 mole) of dehydroacetic acid in 100 ml. of methylcyclohexane, using 4 g. of a nickel catalyst at 185–190°.

[2] Adkins, Connor and Cramer, THIS JOURNAL, 52, 5192 (1930).

no variation greater than 3% from the values reported in the tables. The experimental methods, catalysts, etc., were those described in a recent paper.[3] It must be pointed out that in measuring the rate of reduction, the absorption of hydrogen at a given time must necessarily be calculated from measurements of pressure at the temperature of reduction. This presents no particular difficulties in measuring the rate of reduction of compounds which are quantitatively reduced under the experimental conditions, for the final drop in pressure at the temperature of reduction represents 100% reduction and the percentage reduction at various times may be simply and accurately calculated. If the compound under consideration is not completely reduced, then the drop in pressure must be evaluated in terms of the standardization figures for the apparatus determined for some other compound such as acetone which is quantitatively reduced. At the higher pressures and temperatures the results so obtained are less accurate than at lower pressure.

Summary

The relationship of pressure to the rate of catalysis by nickel of the hydrogenation of acetoacetic ester, dehydroacetic acid, benzene, phenol and aniline has been found to differ greatly among these five compounds. It was entirely feasible to reduce acetoacetic ester at pressures in the vicinity of 30 atmospheres but the rate of reduction was greatly increased by increases in pressure, especially in the range from 120 to 350 atmospheres. Dehydroacetic acid reduced more than twice as rapidly at 149 as at 108 atmospheres and about four times as rapidly at 323 as at 108 atmospheres. It was found impractical to reduce aniline in the 30 atmosphere range. Increasing the pressure greatly increased the rate of hydrogenation, but increasing the pressure in the higher ranges up to 350 atmospheres was not found to be particularly advantageous. The rate of reduction of phenol and of benzene proceeded well in the 30 to 40 atmosphere range, increased with pressure to the 150 to 170 atmosphere range but was not sensitive to further increase in pressure up to 330 atmospheres.

REDUCTION OF NITROSOPHENOL BY IRON AND HYDROCHLORIC ACID

BY KONOMU MATSUMURA AND CHUSABURO SONE

RECEIVED AUGUST 1, 1930 PUBLISHED APRIL 6, 1931

In a study of quinoline syntheses, 7-amino-5-acetyl-8-hydroxyquinoline was desired. On treating the corresponding nitroso compound either with stannous chloride and hydrochloric acid or with iron powder and dilute alcohol in the presence of a trace of hydrochloric acid, owing to side reactions, presumably, the anticipated amino compound was formed only in a poor yield, whereas the nitroso compound, on reduction by iron powder and dilute hydrochloric acid, gave the dihydroxyl compound in a satisfactory yield.

The diazo reaction which is not shown by the nitroso compound may serve as evidence that the nitroso radical, now introduced, occupies the position adjacent to the hydroxyl radical.

From 5-nitroso-8-hydroxyquinoline or *p*-nitrosophenol, by analogy, we could isolate the corresponding dihydroxyl compounds in satisfactory yields, while from p-nitrophenol, the corresponding aminophenol, and hydroquinone and from *o*-nitrophenol, *o*-aminophenol only could be isolated.

Experimental

7-Nitroso-5-acetyl-8-hydroxyquinoline.—On the gradual addition of a solution of sodium nitrite (3.2 g.) in water (30 cc.) to a solution of 5-acetyl-8-hydroxyquinoline (8 g.)[1] in a mixture of glacial acetic acid (25 g.) and water (35 cc.) at 0° with stirring, yellow crystals separated. They were filtered after being allowed to stand for several hours at the room temperature (yield, 7.8 g.) and carefully recrystallized from glacial acetic acid into yellowish-brown prisms which begin to decompose at 180° and decompose thoroughly at 190–195°. It is soluble in the usual organic solvents, water or dilute mineral acids. It gives a light brown color reaction with ferric chloride, but no color reaction with diazotized sulfanilic acid.

Anal. Calcd. for $C_{11}H_8O_3N_2$: N, 12.96. Found: N, 12.60.

7-Amino-5-acetyl-8-hydroxyquinoline.—7-Nitroso-5-acetyl-8-hydroxy-quinoline (2.5 g.) was reduced with stannous chloride (5.4 g.) and concd. hydrochloric acid (13 5 g.) in the presence of glacial acetic acid (30 g.), and the reduction product isolated in the usual way; yield, 0.7 g. It forms light yellow needles from ether, melting at 148–149° (dec.). It is soluble in the usual organic solvents.

Anal. Calcd. for $C_{11}H_{10}O_2N_2$: C, 65.35; H, 4.95; N, 13.86. Found: C, 65.56; H, 5.34; N, 13.59.

The picrate gives orange needles from alcohol, decomposing at 201–222°

Anal. Calcd. for $C_{11}H_{10}O_2N_2 \cdot C_6H_3O_7N_3$: N, 16.21. Found: N, 16.27.

The hydrochloride gives orange needles, sintering at 145°. It is easily soluble in water.

---

[1] Matsumura, THIS JOURNAL, 52, 4433 (1930).

5-Acetyl-7,8-dihydroxyquinoline.—3.75 g. of 7-nitroso-5-acetyl-8-hydroxyquinoline was dissolved in a hot solution (95°) of 27 g. of concd. hydrochloric acid in 900 cc. of water, 5 g. of iron powder was then gradually added during one hour with constant agitation, and the agitation continued for one hour more at the same temperature. On concentrating the reaction fluid, after filtration, under diminished pressure, 3.25 g. of yellow needles of the hydrochloride separated out This was dissolved in water and on neutralization with sodium carbonate, the deep red free base separated. On drying in a desiccator, it lost its red color and became colorless. It crystallizes as colorless prisms from alcohol, m. p. 235 236°. On dissolving in dilute hydrochloric acid and alkalifying, the initial red-colored substance can be regenerated. The red substance, on recrystallization from hot water, gives scarlet red needles.

Anal. Water of crystallization. Calcd. for $C_{11}H_9O_3N \cdot 1.5\ H_2O$: H_2O, 11.74. Found: H_2O, 11.07.

The red substance, on recrystallization from dilute alcohol which contains some acetic acid, gives deep red prisms or columns; m. p. 241–242° (dec.). It contains no water of crystallization and does not decolorize on drying at 100° but gradually decolorizes near its melting point. Its mixed melting point with the colorless form is at 236–240". On working up its alcoholic solution, after treatment with sulfur dioxide or sodium hydrosulfite, the initial substance can be recovered. It is moderately soluble in the usual organic solvents, dilute mineral acid or alkali. The solution in concd. sulfuric acid is light yellow. It gives a deep green color reaction with ferric chloride and a red color reaction with diazotized sulfanilic acid, only in highly concentrated solution.

Anal. Calcd. for $C_{11}H_9O_3N$: C, 65.02; H, 4.43; N, 6.89. Found: C, 65.40; H, 4.89; N, 7.00, 6.55.

The hydrochloride gives lemon-yellow needles from hydrochloric acid (10%), m. p. 280–305° (decomp.). It is difficultly soluble in alcohol but easily soluble in water.

Anal. Calcd. for $C_{11}H_9O_3N \cdot HCl$: C, 55.12; H, 4.18; N, 5.85. Found: C, 55.41; H, 4.51; N, 5.83.

The oxime gives red needles from dilute alcohol which contains some acetic acid; these decompose at 215–220° without melting.

Anal. Calcd. for $C_{11}H_{10}O_3N_2$: N, 12.84. Found: N, 12.55.

5-Acetyl-7,8-diacetoxyquinoline.—A mixture of 0.2 g. of 5-acetyl-7,8-dihydroxyquinoline (red form), 0.5 g. of sodium acetate and 2 g. of acetate anhydride was heated on a water-bath for one hour. On pouring the cooled reaction fluid on crushed ice, colorless crystals separated. These were recrystallized from ether into colorless columns, m. p. 121–122°, yield, 0.2 g. It is easily soluble in alcohol, benzene, ether or dilute hydrochloric acid.

Anal. Calcd. for $C_{15}H_{13}O_5N$: C, 62.72; H, 4.57; N, 4.88. Found: C, 62.59; H, 5.00; N, 4.97.

5,8-Dihydroxyquinoline.—2.85 grams of 5-nitroso-8-hydroxyquinoline was reduced in exactly the same manner that was described for 5-acetyl-7,8-dihydroxyquinoline, and 2.85 g. of orange needles of the hydroxychloride obtained. The free base gives colorless needles from benzene, m. p. 181–183".

Anal. Calcd. for $C_9H_7O_2N$: N, 8.70. Found: N, 9.01.

The sulfate gives orange needles from water and begins to decompose at 250°.

Hydroquinone.—Two grams of *p*-nitrosophenol was reduced in the way described above, except that the reaction mixture, on cooling, was directly shaken six times with ether. On evaporating the solvent, after decolorization with animal charcoal, 1 g. of light brown colored needles of hydroquinone was obtained, and recrystallized from hot water, m. p. 169–171°.

Anal. Calcd. for $C_6H_6O_2$: C, 65.45; H, 5.45. Found: C, 65.31; H, 5.46.

The mother liquor, after being made alkaline with sodium carbonate, was shaken six times with ether. On evaporating the solvent, 0.02 g. of almost colorless leaflets was obtained which after treatment with alcohol melted at 187–188°, and gave, in contact with calcium hypochlorite, color reactions specific to p-aminophenol.

Anal. Calcd. for C_6H_7ON: N, 12.84. Found: N, 12.94.

TABLE I

REDUCTION OF NITROPHENOL

Reactant	G.	Products	Yield, g.	M. p., and mixed m. p., °C.
p-Nitrophenol	2.8	Hydroquinone	0.45	169–170
		p-Aminophenol	.90	187
o-Nitrophenol	2.8	o-Aminophenol	1.65	179

The writers, hereby, desire to express their hearty thanks to Professor Hata for the interest which he has kindly taken in this work, and to Professor H. T. Clarke of Columbia University for his criticisms given to this article.

Summary

By reduction of nitrosophenols by iron and hydrochloric acid, the following compounds have been prepared: 5-acetyl-7,8-dihydroxyquinoline, 5,8-dihydroxyquinoline and hydroquinone.

PHENOLIC DECOMPOSITION OF CERTAIN MIXED ETHERS. II. THE EFFECT OF SUBSTITUTION. THE RATE CONSTANT

BY D. M. BIROSEL

RECEIVED AUGUST 25, 1930 PUBLISHED APRIL 6, 1931

In the first paper[1] of this series it was pointed out that the phenolic decomposition of mixed ethers is influenced by a number of factors. In the present investigation, the influence of substitution in the phenyl residue upon the decomposition of certain mixed ethers by hydrogen bromide in glacial acetic acid at the temperature of the steam-bath has been determined.

Experimental

Preparation of Materials.—When it was possible, the procedure adopted by Claisen[2] in preparing phenyl allyl ethers was followed to synthesize the mixed ethers used in this investigation. The scheme of procedure is

$$C_6H_5OH + C_3H_5I + K_2CO_3 \longrightarrow C_6H_5OC_3H_5 + KI + KHCO_3$$

Birosel, THIS JOURNAL, 52, 1944 (1930).

[2] Claisen, Ber., 45,3157 (1912); Ann., 401, 21 (1913); *ibid.*, 418, 69 (1919).

Claisen recommended a non-dissociating solvent for this reaction; otherwise, one obtains the isomeric phenol instead of the ether. Acetone was used in all the preparations. The above equation calls for a monomolecular proportion of the active components but in practice alkyl halide and anhydrous potassium carbonate are taken in excess of the theoretical amount. The mixture is digested on the water-bath at the boiling temperature of acetone in a reflux condenser during a period of from six to eight hours. At the end of the digestion, water is added to the mixture to dissolve the solid carbonate and the product separates as liquid which is

extracted with ether. The ether solution is separated, washed with dilute sodium hydroxide, and then with distilled water. The ether solution is dried with anhydrous sodium carbonate and filtered. The solvent is evaporated and if the residue is a liquid it is distilled and the portion which boils over at the temperature recorded in the literature for the particular compound is reserved for use. When the residue is a solid, it is crystallized from the appropriate solvent and the melting point and crystalline form are noted.

2,4,6-Trinitrophenetole.—Attempts to prepare this compound by Claisen's and Willgerodt's methods, respectively, were unsuccessful. The ether was successfully synthesized by following the method adopted by Raiford and Birosel (Ref. 7, Table I) in preparing 2,4,6-trinitrophenyl allyl ether. Silver picrate prepared from the ammonium salt was digested with ethyl iodide using acetate as reaction medium. During the course of digestion yellow silver iodide salt was precipitated. When digestion was complete, the salt was filtered and washed with acetone. The solvent was evaporated and the solid residue was dissolved in ether. The ether solution was washed with dilute sodium hydroxide, then with distilled water. The solvent was evaporated and the residue was crystallized from ethyl alcohol.

Procedure of Decomposition.—The extent of the phenolic decomposition of the mixed ethers recorded above and velocity constants were determined at the temperature of the steam-bath by a reflux condenser. The procedure is the same as that followed in a previous work.' The acid

[a] A nitro derivative, 2,4-dibromo-6-nitrophenol was prepared according to the directions of Kohn and Dömötör, *Monatsh.*, 48,211 (1927), from the dibromophenol obtained from the phenolic decomposition of 2,4-dibromophenyl ethyl ether; crystallization from alcohol gave small yellow plate crystals melting at 118°.

solution used in this present investigation was made in the same proportion as the material used in former work; one volume of constant boiling hydrobromic acid was added to two volumes of glacial acetic acid. The results obtained from experiments are given in the tables.

Discussion

In Table II are given the detailed results of experiments on the extent of decomposition of eight derivatives of phenyl ethyl ether by constant boiling hydrobromic acid in glacial acetic acid as reaction medium. The influence of substitution was determined with particular regard to four different radicals: nitro, chloro, bromo and methyl replacing the hydrogen atom attached to the p-carbon atom of the benzene nucleus. Comparing the figures obtained from experiments for the extent of decomposition of the mono substituted derivatives of phenetole, the influence of substitution is very apparent. When the substituting group is multiplied in the phenyl residue, the extent of the phenolic decomposition of certain mixed ethers decreases in magnitude. When *p*-bromophenyl ethyl ether was subjected to the action of constant boiling hydrobromic acid in glacial acetic acid as reaction medium at the temperature of the stem-bath for two hours, the decomposition was 85.95% complete; for 2,4-dibromophenyl ethyl ether the extent of decomposition is 60.59%; and for 2,4,6-tribromophenyl ethyl ether the magnitude of decomposition has decreased to 21.78%

which is about one-fourth the magnitude of the value obtained for the monobromo derivative. p-Chlorophenyl ethyl ether was decomposed to the extent of 85.28%, while the dichloro derivative for the same interval of time was only decomposed 40.35%, which is less than one-half of the value obtained for the monochloro derivative. The result for 2,4,6-trinitrophenyl ethyl ether shows that the compound is not stable toward hydrogen bromide.

In Table III are shown the results of the experiments on the velocity constant of the phenolic decomposition of 2,4,6-tribromophenyl ethyl ether at the temperature of the steam-bath. The rate constants K are those calculated from the integrated form of the differential equation for the first order reactions, using logarithms to the base e. It will be noted that the constancy of k is quite satisfactory. The calculated amount of decomposed ether was obtained by multiplying the amount of tribromophenol directly determined from experiment by the factor 1.0847.

In Table IV are recorded the rate constants of the phenolic decomposition of p-nitro-, p-bromo-, p-chloro-, p-methyl and 2,4-dibromophenyl ethyl ethers. The figures obtained for each compound from two or three experiments are in close agreement. The monohalogen derivatives give much higher rate constants than either the mononitro or monomethylphenyl ethyl ether. The magnitude of the rate constant is decreased when the same halogen substituent is multiplied in the phenyl residue. Comparing the velocity constants obtained for monobromo, dibromo and tribromo phenetoles, it appears that the rate constant is also dependent upon the number of substituents actually present in the benzene nucleus.

Summary

1. The kinetics of the phenolic decomposition of mixed ethers have been studied further in the case of 2,4,6-tribromophenyl ethyl ether and to a less extent with the case of p-nitro-, *p*-bromo-, p-chloro-, *p*-methyl- and 2,4-dibromophenyl ethyl ethers. Experiments were made in glacial acetic acid as reaction medium.

2. The rate constants of 2,4,6-tribromophenyl ethyl ether and of the other compounds were calculated from the experimental results and their constancy is quite satisfactory. The phenolic decomposition of mixed ethers appears to be a first order reaction.

3. The rate constant is influenced by the number of substituents actually present in the phenyl residue.

4. The phenolic decomposition of mixed ethers is influenced by the substituting group present in the benzene nucleus.

The influence of position of substitution on the phenolic decomposition of mixed ethers is being studied.

ERGOSTENOL CHLOROACETATE

BY MERRILL C. HART AND FREDERICK W. HEYL

RECEIVED NOVEMBER 5, 1930 PUBLISHED APRIL 6, 1931

Windaus and Grosskopf[1] catalytically reduced ergosterol from yeast and obtained the tetrahydro reduction product, a-ergostenol, to which, however, they assigned the hexahydro, or completely reduced formula and corresponding name, *i. e.*, ergostanol. Reindel and Walter[2] made a number of quantitative reductions and demonstrated that the catalytic reduction of ergosterol acetate with Willstatter's platinum black gave the tetrahydro derivative, a-ergostenol. This substance, according to Windaus and Lüttringhaus,[3] melts at 131°, $[\alpha]_D$ +11.4°; and a-ergostenol acetate, m. p. 109–110°, $[\alpha]_D$ 0°. Hart, Speer and Heyl[4] reported a-ergostenol, m. p. 133°, $[\alpha]_D$ +10.5°; a-ergostenol acetate, m. p. 110–111°, $[\alpha]_D$ 0°.

Reindel and Walter stated further that the reduction of ergosterol acetate in ether with Adams' platinum oxide catalyst gave a hexahydro derivative, but this has since been shown to be incorrect,[5] the mixture actually containing dihydro-ergosterol.

Reindel, Walter and Rauch[6] state that chloroacetyl chloride reacts with a-ergostenol to form β-ergostenol chloroacetate, m. p. 167°. The β-form is characterized by easy reducibility to a hexahydro-ergosterol. This hexahydro-ergosterol, which is a well-known derivative, is known as allo-α-ergostanol. In a previous paper[4] we have prepared so-called β-ergostenol chloroacetate and reported that upon saponification a mixture of alcohols melting at 110–112° was obtained.

In the present paper we describe the fractional crystallization of the chloroacetate prepared from a-ergostenol. This work was undertaken for the purpose of preparing pure β-ergostenol, which should, of course, be readily prepared from the β-chloroacetate.

Although a careful fractionation of a-ergostenol acetate failed to reveal lack of uniformity in the product obtained by the catalytic reduction of ergosterol, we found that the fractionation of the chloroacetate yielded small amounts of allo-a-ergostanol. Furthermore, ergostenol chloroacetate was found to consist largely of the a-isomer and not exclusively of the β-form as Reindel states. The chloroacetates contain, in addition to allo-a-ergostanol, a-ergostenol chloroacetate, β-ergostenol chloroacetate and an addition product, $C_{31}H_{49}O_3Cl_3$.

[5] Reindel and Detzel, *Ann.*, 475, 80 (1929).

[6] Reindel, Walter and Rauch, *ibid.*, 452, 34 (1927).

We have not been able to isolate pure β-ergostenol. That it is present is shown by the fact that upon catalytic reduction an increased amount of allo-a-ergostanol can be secured from the mixture of chloroacetates.

Attempts to separate a derivative of β-ergostenol from the mixture of the chloroacetates, by bromination or by oxidation with benzoyl hydroperoxide[7] failed to lead to any derivatives which might be characteristic for the β-form as contrasted with the a-form. One might expect, for example, to secure from an unsaturated sterol, which is readily reduced, either a dibromide or a peroxide.

Experimental

Fractionation of **Ergostenol Chloroacetate.**—Ergostenol chloroacetate was prepared from 25.6 g. of a-ergostenol (m. p. 132–133°) by gently refluxing with an excess of chloroacetyl chloride for twenty minutes. Hot acetic acid was added and the mixture stood aside to crystallize. The top fraction after five crystallizations from acetic acid weighed 16.1 g., m. p. 166–167°, and $[\alpha]^{22}_D$ +6.93.

Anal. Calcd. for $C_{29}H_{42}O_2Cl$: Cl, 7.66. Found: Cl, 7.71.

This material was systematically crystallized ten times from ethyl ether with the results shown in Table I.

TABLE I

FRACTIONATION OF ERGOSTENOL CHLOROACETATE

Fraction no.	Weight, g.	$[\alpha]_D$	M. p., °C.
1	0.909	+ 5.3	190–192
2	0.715	+ 5.5	169–170
3	1.187	+ 6.24	169–170
4	2.216	+ 4.86	168–169
5	3.650	+ 6.24	167–168
6	3.452	+ 6.94	165–166
7	2.490	+15.56	162–164
8	0.548	+20.82	153–156

Fraction 1 is practically pure allo-α-ergostenol; recrystallized from ether, m. p. 199–200°; $[\alpha]_D$ +2.3°. Reindel gives 200–201°. Upon saponification and subsequent acetylation pure allo-a-ergostanol acetate, m. p. 149–149.5°, was obtained.

Anal. Calcd. for $C_{27}H_{47}OCOCH_3$: C, 80.9; H, 11.7. Found: C, 81.0; H, 11.5.

The alcohol itself melted at 144°. Reindel gives 144–145°. The isolation of allo-α-ergostanol chloroacetate from the most insoluble fraction proves that the reduction of ergosterol acetate in acetic acid solution with platinum oxide (Adams') as a catalyst results in the formation of small amounts of the hexahydro derivative, allo-α-ergostanol.

Fractions 2 to 8 of the chloroacetate crystallization were separately saponified and the fractions showed melting points that varied from 118–120° to 129–131°, while the rotations varied from +11.8 to +17.3°. All these rotations are considerably higher than that required for α-ergostenol, and those fractions showing a rotation considerably higher than that reported by Reindel for β-ergostenol (+15.9°) were obviously mixtures. It may be predicted safely that β-ergostenol, when finally isolated, will show a higher positive specific rotation than +17.3°.

---

[7] Westphalen, Ber., 48, 1064 (1915).

In these fractions the a-isomer so largely predominated that it was possible to isolate it in comparatively pure form as the characteristic plates of the acetate. Fractions in which the a-form was present in much smaller amounts yielded acetatcs crystallizing in needles. The elementary composition of the fractions agreed with that required for $C_{29}H_{48}O_2$.

Isolation of ***an*** Addition Product of a-Ergostend Chloroacetate and Chloroacetyl Chloride.—During the main crystallizations of ergostenol chloroacetate, in addition to the top fraction weighing 16.1 g. and melting at 166–167°, four other fractions of ergostenol chloroacetate were obtained. These fractions melted at 157–159°, 144-147', 107–110° and 110–114°. The first three of these fractions were exhaustively fractionated from ethyl acetate, acetone and ether and various fractions melting from 110–160° were obtained.

The lowest fraction of ergostenol chloroacetate crystallization (m. p. 110–114°) was treated with hot alcohol. The material insoluble in the hot alcohol was crystallized twice from acetone and once from acetic acid; 0.3 g. of irregular plates melting at 129–130" were obtained, [a], +8.7°.

Anal, Calcd. for $C_{31}H_{49}O_3Cl_3$: Cl, 18.5. Found: Cl, 17.0, 17.3.

This substance on saponification from 3% methyl alcoholic and crystallization from alcoholic solution gave needles of a-ergostenol melting at 132–133°. The acetatcs prepared from acetic anhydride crystallized in plates melting at 110–111°. Mixed melting points with a-ergostenol and a-ergostenol acetate, respectively, were not depressed.

Catalytic Reduction of Ergostenol **Chloroacetate.**—Six grams of ergostenol chloroacetate, m. p. 166–167°, was reduced in acetic acid solution with Adams' platinum oxide as catalyst. The reduced chloroacetate after several crystallizations from ether, acetic anhydride and acetic acid, melted at 184–186°, and on saponification with 5% methyl alcoholic potash and after four crystallizations from alcohol and ether gave crystalline plates of allo-a-ergostanol melting at 144–145°, yield 1.1 g. The acetate crystallized in plates melting at 149–149.5°, $[\alpha]_D$ +4.7°. The benzoate prepared by means of benzoyl chloride and pyridine melted at 163–164°.

Attempt to Isolate a Bromide from the Isomerization Mixture.——When ergostenol chloroacetate (5.95 g.) in 450 cc. of ether was treated with 24 cc. of 9% bromine solution, no insoluble bromide separated. The yellow ether solution was washed with 10% sodium thiosulfate solution and water and then dried over anhydrous sodium sulfate. The product was free from bromine. It was saponified with methyl alcoholic potash and an extremely small yield of crystalline plates that melted at 144–145° was obtained. This in no way represented any characteristic derivative which should be useful in working with this mixture. Upon analysis it showed the composition of an oxidation product, $C_{27}H_{43}OH$. The acetate formed plates melting at 145–146".

Anal. Calcd. for $C_{29}H_{46}O_2$: C, 81.6; H, 10.9. Found: C, 81.7; H, 11.0.

It gave a-ergostenol acetate upon catalytic reduction. This is undoubtedly a dehydro-ergostenol but it shows a rather wide divergence from the compound isolated by Windaus and Lüttringhaus[3] by the action of bromine or benzoyl hydroperoxide on α-ergostenol acetate. They found 135–136° for the melting point of the acetate of their dehydro compound and 141° for that of the alcohol. We attempted to establish the identity of our product by preparing the dehydro derivative by the action of benzoyl hydroperoxide[8] on a-ergostenol acetate. Similarly a slight yield of a dehydro derivative, the acetate of which melted at 145–146°, was obtained (C, 81.8; H, 10.9). When this acetate was mixed with the acetate obtained by the action of bromine on the chloroacetate as described above there was no depression of the mixed melting point.

---

[8] Baeyer and Villiger, *Ber.*, **33**, 1569 (1900).

Summary

1. a-Ergostenol, prepared by the catalytic reduction of ergosterol acetate in acetic acid solution with platinum oxide (Adams') as a catalyst, contains small amounts of allo-a-ergostanol.

2. Ergostenol chloroacetate was found to be very largely a-ergostenol chloroacetate with smaller amounts of the chloroacetates of β-ergostenol and of allo-a-ergostanol.

3. Ergostenol reacts with chloroacetyl chloride to form, in small amount, an addition product, $C_{31}H_{49}O_3Cl_3$.

4. Ergostenol chloroacetate forms neither a bromide nor a peroxide nor does it react with potassium permanganate. Upon reduction evidence of some degree of isomerization is found in the increased yield of the reduction product, allo-a-ergostanol.

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

THE PREPARATION OF DIMETHYLACETOACETIC ESTER AND OF Δ^3,2,2-DIMETHYLBUTENOL-1

BY KARL FOLKERS AND HOMER ADKINS

RECEIVED NOVEMBER 6, 1930 PUBLISHED APRIL 6, 1931

A considerable quantity of A^3,2,2-dimethylbutenol-1 was desired in order to study its behavior over oxide catalysts.' It appeared that this compound could be most easily prepared from acetoacetic ester through the following series of compounds: (1) monomethylacetoacetic ester, (2) dimethylacetoacetic ester, (3) 3-hydroxy-2,2-dimethylbutyric ester, (4) A^3,2,2-dimethylbutyric ester, (5) Δ^3,2,2-dimethylbutenol-1.

There does not seem to be available in the literature adequate directions for the methylation of acetoacetic ester, although the two derivatives have been prepared in a more or less pure state by a number of investigator~.The method of preparation described below has been developed.

Ethyl 2-Methylacetoacetate.—Thirty-nine and eight-tenths grams (1.73 moles) of sodium was very finely powdered in xylene so that it was like sand. After decanting the xylene, the sodium was washed with two 75-ml. portions of dry toluene (Note **1).** The sodium was then covered with one liter of dry toluene, and the flask fitted with a **reflux** condenser, immersed in an ice-bath, and allowed to cool for fifteen minutes, after which **218.3** g. (1.68 moles) of ethyl acetoacetate (Note 2) was added down the condenser during the course of ten to fifteen minutes (Note **3)** while the flask was vigorously shaken and kept in the ice-bath. The top of the condenser was now fitted with a calcium chloride tube and, after an additional ten minutes' cooling, was allowed to stand at room

---

[2] Frankland and Duppa, ***Ann.*, 138, 328 (1860);** Conrad and Limpach, *ibid.*, 192,153 **(1878);** Michael, ***Ber.*, 38,2083 (1905);** Clark, **THIS JOURNAL, 33,527 (1911).**

temperature for seven to ten hours, with an occasional vigorous shaking during the first hour. The reflux condenser was then temporarily removed, a long-stem funnel pushed down into the semi-solid salt, and 253 g. (1.78 moles) of methyl iodide added. After standing overnight, the flask was heated on the steam-bath for four to six hours with an occasional vigorous shaking. The sodium iodide settled out completely at the end of this time. The sodium iodide was then filtered off with suction through a 20-cm. Büchner funnel (Note 4). The filter cake was pressed with a cork and sucked as dry as possible. The filtrate was then fractionated through a 25-cm. Widmer column. The toluene was conveniently fractionated at about 250 mm. pressure, or at atmospheric pressure with the use of a heater around the column. The yield of ethyl 2-methylacetoacetate was 170 g. (70–71%) (Note 5), boiling at 75–76' at 15 mm.

Ethyl 2,2-Dimethylacetoacetate.—The sodium salt of ethyl 2-methylacetoacetate was prepared as above using 35.6 g. (1.55 moles) of sodium, 216 g. (1.50 moles) of ethyl 2-methylacetoacetate and one liter of dry toluene. After adding 227 g. (1.6 moles) of methyl iodide and allowing to stand overnight, the flask was heated for fourteen hours on the steam-bath with a vigorous shaking every other hour. Because the closeness of the boiling points of the mono- and dimethylacetoacetic esters makes fractionation impossible, the di-substituted ester was purified by treatment with more sodium and methyl iodide to react with the mono-substituted ester (Note 6). To carry out this purification the sodium iodide was next filtered, and the filtrate distilled through a 25-cm. Widmer column until approximately 350 ml. of distillate had been collected and the temperature of the vapor was 109–110°. This distillate was chiefly toluene, with a little water and the greater portion of the lower-boiling by-products. Then, assuming the presence of 1.1 moles of substituted acetoacetic ester (75% of the original 1.5 moles), 10% of which is the monomethyl derivative, the distillation residue was added to this calculated amount of powdered sodium (2.5 g.). The flask was fitted under a reflux condenser, and after standing from four to five hours, 7 ml. of methyl iodide added. After standing overnight and a half hour's heating on the steam-bath, the reaction was complete. The sodium iodide was then filtered off and the toluene and ester fractionated through a Widmer column. The yield of ethyl 2,2-dimethylacetoacetate was 128 g. (54% of the theoretical amount based on ethyl 2-methylacetoacetate) and boiled at 72–73" at 14 mm.

Notes.—1. Due to the closeness of the boiling points of xylene and the mono- and dimethyl substituted acetoacetic esters, the fractionation of the product is facilitated by washing out all of the xylene. Absolute ethanol may be used in the preparation of the monomethyl substituted ester (70% yields) as the solvent; however, the high solubility of sodium iodide in alcohol makes its removal very difficult. Benzene may be used as the solvent to prepare the monomethyl substituted ester in 70–80% yields and the dimethyl substituted ester in 50–60% yields (without purification); however, the use of ordinary benzene (or toluene) containing thiophene introduces sulfur-containing compounds into the product, which make it impractical to reduce the ester over a nickel catalyst. Mallinckrodt's c. p. quality toluene was distilled, until the distillate was no longer turbid, before using as the solvent.

2. Ethyl acetoacetate, b. p. 70° (16 mm.) from the U. S. Industrial Alcohol Company was redistilled before using.

3. No difficulty was encountered in agitating the bulky sodium salt, if the ester was added quite rapidly and the solution kept well cooled. If the ester was added more slowly, the salt became too solid for thorough mixing before all of the ester could be added. The sodium salt prepared in this manner had a bluish-white color.

4. The finely divided sodium iodide precipitate was easily filtered if a 25-cm. filter paper was used in a 20-cm. funnel, the edge of the paper being held to the side of the funnel with gummed paper.

5. By cutting the fractionation of the toluene solution at 71–72° at 14 mm., 78% yields of crude ethyl 2-methylacetoacetate map be obtained, and used directly for the preparation of the dimethyl substituted ester in 50% yields.

6. This method of purification gave a product which showed a slight test for enol with ferric chloride, indicating the presence of some monomethyl substituted ester.

Ethyl **2,2-dimethyl-3-hydroxybutyrate**, b. p. 94–95' (21 mm.), was obtained in 88–93% yields by the reduction with a nickel catalyst of ethyl 2,2-dimethylacetoacetate.[3]

Ethyl **Δ^3,2,2-dimethylbutyrate**, b. p. 139–141°, was obtained in 74–80% yields by the dehydration of ethyl 2,2-dimethyl-3-hydroxybutyrate with phosphorus pentoxide.[4]

Δ^3,2,2-Dimethylbutenol-1.—Courtot[5] stated that he reduced ethyl Δ^3,2,2-dimethylbutyrate with sodium and ethanol by the method of Bouveault and Blanc but gives no further information on the preparation. At least three modifications of the procedure of Bouveault and Blanc have been proposed as advantageous for the reduction of various esters to the corresponding alcohols through the use of sodium and ethanol. Levene and Allen[6] used a hydrocarbon (toluene) as a reaction medium, and added the ester slowly to the sodium completing the reaction in one hour. Adams and Marvel[7] did not use a hydrocarbon solvent and added the sodium as rapidly as possible (one hour) to the ester. Ford and Marvel[8] used a hydrocarbon as a reaction medium and added the ester very rapidly (two to five minutes) to the sodium.

The methods of Adams and Marvel and of Ford and Marvel were compared for the reduction of the ethyl Δ^3,2,2-dimethylbutyrate, and it was found that the method of adding the ester rapidly to powdered sodium in a hydrocarbon medium (methylcyclohexane) was very much inferior to that of Adams and Marvel in that the yield of alcohol was only 25% and in that the corresponding acid was produced in large amounts, *i. e.*, 48%. The low yield of alcohol and the high yield of acid was not due to the quality of the reagents, because the same materials were used in the procedure described below.

The preferred method for carrying out the reduction was as follows. One hundred and thirteen grams (0.8 mole) of ethyl Δ^3,2,2-dimethylbutyrate and 927 ml. of absolute ethanol (dried once over lime and twice over magnesium methoxide) were placed in a three-necked, 5-liter flask, which was fitted with a rapid mechanical stirrer and *a* condenser 85 cm. in length and of 2.5 cm. bore. Through the other neck was added 110.5 g. (4.8 moles) of sodium in small pieces during the course of fifty minutes. At the end of this time only a few pin heads of sodium remained, which were dissolved after five minutes. A small flame was used toward the end of the addition to keep the solution hot enough so that the sodium remained melted. The color of the solution was now only light yellow. While still hot, the solution was poured into a 3-liter flask fitted with a 25-cm. Widmer column and 300 ml. of ethanol was distilled (oil-bath, 140–170°). Then 500 ml. of water (part of which was used to rinse out

[8] Ford and Marvel, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1930, Vol. X, p. 62.

the reaction flask) was cautiously added. The distillation was continued until the vapors were at 83.5° and 687 ml. of distillate was collected.

Since some A^{S},2,2-dimethylbutenol-1 distilled over with this aqueous ethanol, it was recovered by adding 150 ml. of water to the 687 ml. of distillate and distilling this mixture through a 50-cm. Widmer column until the vapors were at 84°. The residue (about 150 ml.) was transferred to an ordinary 500-ml. distilling flask and distilled. Two 25-ml. portions of distillate were collected. Each of these was salted out with anhydrous potassium carbonate to give about 15 ml. (total) of ethanol and the unsaturated alcohol, which was added to the bulk of the alcohol before drying. The original distillation residue was steam distilled until about 300 ml. of distillate was collected. The alcohol layer was separated. The water layer was treated with potassium carbonate and distilled after removal of the alcohol layer. Twenty-five ml. distillates were collected and salted out until all the alcohol had been obtained. All the alcohol layers were combined and dried twice over anhydrous potassium carbonate. Ether was used as a solvent to prevent mechanical loss. The yield of Δ^{3},2,2-dimethylbutenol-1, b. p. 128.5–131°, on fractionation through a 20-cm. Widmer column was 49.5 g. or 61.8% of the theoretical. The steam distillation residue, after removal of the alcohol, contained only very little non-volatile insoluble material. It was acidified with sulfuric acid and the Δ^{3},2,2-dimethylbutyric acid was steam distilled. The entire distillate was just neutralized with a sodium hydroxide solution and evaporated to dryness. The yield of sodium A^{3},2,2-dimethylbutyrate, dried to constant weight at 125°, was 8.6 g. or 7.9%.

Summary

Procedures are described for the preparation in good yields of dimethylacetoacetic ester from acetoacetic ester and for the reduction with sodium and ethanol of A^{3},2,2-dimethylbutyric ester to **A^{3},2,2-dimethylbutenol-1.** In the latter preparation the method of Adams and Marvel for the reduction of esters is shown to be very much superior to that which Ford and Marvel found to be advantageous in several such reductions.

MADISON, WISCONSIN

[A Communication from the Laboratory of Organic Chemistry of the University of Wisconsin]

CATALYSIS BY ALUMINA AND ZINC OXIDE OF THE DISPROPORTIONATION OF CERTAIN ALCOHOLS, ETHERS AND HYDROXY ESTERS

By Homer Adkins and Karl Folkers

Received November 6, 1930 Published April 6, 1931

It has been shown in previous papers[1] that over alumina allyl alcohol apparently undergoes intramolecular rearrangement to form propionaldehyde according to equation (I).

$$CH_2{=}CHCH_2OH = CH_3CH_2CHO \qquad (I)$$

It has also been demonstrated that alumina and zinc oxide may catalyze the reduction by alcohols of 2,3-unsaturated aldehydes such as acrolein and cinnamic aldehyde to the corresponding saturated aldehydes as indicated in equation (II).

$$CH_2{=}CHCHO + RCH_2OH = CH_3CH_2CHO + RCHO \qquad (II)$$

In connection with a study of the mechanism of the reactions of various organic compounds over oxide catalysts, it was considered of some importance to ascertain whether these reactions were encountered with compounds whose region of unsaturation was further removed from the alcohol or aldehyde group. In order to test this point the behavior of Δ^3,2,2-dimethylbutenol-1, $CH_2{=}CHC(CH_3)_2CH_2OH$, over alumina and zinc oxide was studied. The structure of this compound is such that the double linkage cannot migrate to the 2,3-position nor can it undergo dehydration to a diene.

The dimethylbutenol was passed over alumina and zinc oxide under the experimental conditions and with the results stated in Table I.

Table I

Reaction of Δ^3-2,2-Dimethylbutenol-1 over Aluminum and Zinc Oxides

			Rate per hour of passage of alcohol and formation of products				Gas analysis (%) (excluding N_2)				
	Catalyst	Temp. °C.	Alcohol, ml.	Aldehyde, moles	Hydrogen, moles	Gas, ml.	CO_2	CO	C_nH_{2n}	O_2	H_2
1	Alumina	300	19.3	0.030	0.0001	174	11.5	41.2	25.3	3.8	1.1
2	Zincoxide	300	20.5	.019	.0181	705	14.1	10.1	13.5	3.2	57.5
3	Zincoxide	330	19.4	.029	.0405	1652	8.1	18.0	18.3	2.0	55.0
4	Zinc oxide	330	16.0	.024	.0434	1360	3.5	19.9	7.0	...	71.5

The weight of aldehyde given in Expt. 4 was obtained by fractionation, while the amounts given in Expts. 1, 2 and 3 were obtained by weighing the amount of p-nitrophenylhydrazone formed as previously described. The same aldehyde, *i. e.*, A^3,2,2-dimethylbutenol-1, $CH_2{=}CHC(CH_3)_2$-CHO, was produced over both zinc and aluminum oxides, as was evidenced

---

[1] Weston and Adkins, This Journal, 50, 1930 (1928); 51, 2430 (1929).

by the melting points of mixtures of the semicarbazones of the product from different experiments. There was also produced over both catalysts an unsaturated hydrocarbon boiling at **37–39'.** This hydrocarbon was apparently 3,3-dimethylbutene-1.

The behavior of the dimethylbutenol differed over the two catalysts in that practically no hydrogen was produced over alumina, while over zinc oxide there was a considerable amount of dehydrogenation.

It is obvious from the above facts that over alumiria, aldehyde was produced only through the autosxidation–reduction of the unsaturated alcohol (Equation III) while over zinc oxide this reaction occurred along with the dehydrogenation reaction (Equation IV) common to primary and secondary alcohols.

$$2CH_2{=}CHC(CH_3)_2CH_2OH = CH_2{=}CHC(CH_3)_2CHO + CH_2{=}CHC(CH_3)_2CH_3 \quad (III)$$

$$CH_2{=}CHC(CH_3)_2CH_2OH = CH_2{=}CHC(CH_3)_2CHO + H_2 \quad (IV)$$

This is in marked contrast to the behavior of allyl alcohol over zinc oxide which results in only a small amount of dehydrogenation but in the formation of large amounts of propionaldehyde according to reactions V and VI.

$$CH_2{=}CHCH_2OH = CH_2{=}CHCHO + H_2 \quad (V)$$

$$CH_2{=}CHCHO + CH_2{=}CHCH_2OH = CH_3CH_2CHO + CH_2{=}CHCHO \quad (VI)$$

Benzyl alcohol is similar to Δ^3,2,2-dimethylbutenol-1 in that it is a primary alcohol without a hydrogen atom on the 2-carbon atom and with unsaturation in the 3,4-position. When passed over alumina it behaved similarly to the dimethylbutenol in that disproportionation took place with the formation of benzaldehyde and toluene as in Equation VII. The experimental details are given in Table II.

$$2C_6H_5CH_2OH = C_6H_5CH_3 + C_6H_5CHO + H_2O \quad (VII)$$

$$C_6H_5CH_2OCH_2C_6H_5 = C_6H_5CH_3 + C_6H_5CHO \quad (VIII)$$

TABLE II

REACTIONS OF BENZYL ALCOHOL AND OF DIBENZYL ETHER OVER ALUMINA

Substance	Temp., °C.	Ml./hr.	Toluene per hour, g.	Dibenzyl ether, %	Toluene, %	Benzaldehyde, %
Dibenzyl ether	340	22.5	2.93	..	27.0	25.8
Benzyl alcohol	340	21.8	3.15	22.0	32.6	27.6
Benzyl alcohol	340	16.6	2.20	24.0	31.0	31.0
Benzyl alcohol	340	13.5	2.10	25.6	35.0	38.0

It is possible that the auto-oxidation reduction of benzyl alcohol involves the disproportionation of dibenzyl ether formed through the catalytic action of alumina on benzyl alcohol (Equation VIII) as dibenzyl ether is formed in a good yield when benzyl alcohol is passed over alumina. Toluene and benzaldehyde are formed in similar amounts irrespective of whether the alcohol or the ether is passed over the catalyst. It is reported that dibenzyl ether disproportionates under the influence of high temperatures but under the experimental conditions used in this investigation the amount of disproportionation of the ether was shown to be quite negligible except in contact with alumina.

The catalytic dehydration of a hydroxy ester over alumina is apparently accompanied by a considerable amount of disproportionation and rupture of the molecule. When the ethyl ester of β-hydroxybutyric acid was passed over alumina the dehydration (Equation IX) was accompanied by an almost equal amount of disproportionation (equation X).

$$CH_3CHOHCH_2COOC_2H_5 = CH_3CH{=}CHCOOC_2H_5 + H_2O \qquad (IX)$$
$$CH_3CHOHCH_2COOC_2H_5 = CH_3CHO + CH_3COOC_2H_5 \qquad (X)$$

A summary of the experimental results is given in Table III.

TABLE III

REACTION OF ETHYL β-HYDROXYBUTYRATE OVER ALUMINA

Temperature	325°	325"	325"	350°
Rate of passage of hydroxy ester, ml./hr.	10	17.7	26	20
Percentage split to acetaldehyde and ethyl acetate	26.4	24.2	19.2	29.3
Ethylcrotonate, %	35.2	32.6	26.2	33.3
Recovered ethyl β-hydroxybutyrate, %	25.4	33.4	45.5	22.0

The disproportionation of the hydroxy ester is not a reaction of ethyl crotonate, for that ester is quite stable over alumina at 325'. A reaction takes place exclusively in the sense of Equation X if the α,α-dimethyl-β-hydroxy ester is used. The yield of ethyl isobutyrate was 35.7% when 15.5 ml. of the hydroxy ester was passed over 2.5 g. of alumina at 325° for one hour. Ethyl 2-methyl-2-ethyl-3-hydroxybutyrate also reacts over alumina in the sense of Equation X. The yield of ethyl 2-methylbutyrate was 61% when 12.5 g. of the hydroxy ester was passed over 2.5 g. of alumina at 315° for one hour.

It has been shown that alumina catalyzes several types of reactions in hydroxy compounds: (1) dehydration of alcohols to ethers; (2) dehydration of alcohols and hydroxy esters to alkenes or unsaturated esters; (3) reduction of 2,3-unsaturated aldehydes and oxidation of alcohols; (4) intramolecular rearrangement of hydrogen in 2,3-unsaturated alcohols; (5) disproportionation without rupture of the molecule of alcohols having no hydrogen on the carbon atom alpha to the carbinol group; (6) disproportionation with rupture of the molecule of the ether of an alcohol of the type noted above; (7) disproportionation with rupture of the molecule of hydroxy esters, especially if there are substituents on the carbon adjacent to the carbinol group.

It is clear from a consideration of the diversity of the reactions noted above that it is a mistake to describe alumina as a dehydrating catalyst, for this characterization rests upon the chance that chemists first and most conveniently tested its activity toward simple saturated alcohols. The fact that water is split out of these simple alcohols should not therefore be allowed to bulk very large in devising an hypothesis to account for the catalytic activity of the oxide. Since the type of reaction induced varies with the space relationships in the organic molecule, it is reasonable to suppose that space relationships or the surface of different catalysts are factors in the type of reaction catalyzed. For the present it seems unwise to *go* beyond the conception that alumina activates or labilizes the organic molecule (and in the case of bimolecular reaction, orients molecules in juxtaposition) so that any one of several reactions is possible. The reaction actually resulting then depends upon the chemical and physical characteristics of the organic molecule.

Experimental Part

The data given under Expts. 1, 2 and **3** in Table I were obtained as described in a previous paper.' Two ml. of catalyst was used in studying the reactions of the alcohols and ethers while 2.5 ml. was used for the esters. Two and three-tenths grams of an unsaturated hydrocarbon boiling at 38–40° was fractionated out of the condensate from the passage of 15.5 g. of the dimethylbutenol over alumina at 300'. Five grams of the unsaturated hydrocarbon was obtained in three hours forty-four minutes (Expt. 4, Table I) from the alcohol over zinc oxide at 330°. On drying and redistillation it boiled at 37–39°. In all probability it is 3,3-dimethylbutene-1. Formin and Lochanski reported this hexylene to boil at 41.2' at 760 mm.[2] It was converted to the dibromide derivative, which boiled at 57–57.5° at 17 mm.; however, the quantities were too small to purify for a proper analysis. The yield of aldehyde in Expt. 4 was 9 g. and on redistillation and drying it boiled at 98.5 to 99.5'; d_{25}^{25} 0.8184; n_D 1.4072 at 25°. *Molecular refraction.* Calcd. for 2,2-dimethyl-Δ^3-butenal: 29.45. Found: 29.51. The aldehyde was converted to the semicarbazone derivative, which after two recrystallizations melted at 158.5–160.5" and was not changed by a third recrystallization.

Anal. Calcd. for $C_7H_{13}ON_3$: C, 54.19; H, 8.39. Found: C, 53.88, 53.97; H, 8.57, 8.55.

It was demonstrated that the aldehyde produced over alumina was identical with the aldehyde produced over zinc oxide by a mixed melting point of the semicarbazone derivatives, which was 158.5–160°. The melting point was 157.5–159° for the derivative of the aldehyde produced by alumina.

The toluene and benzaldehyde (Table II) from benzyl alcohol and dibenzyl ether were characterized by the formation of 2,4-dinitrotoluene and the phenylhydrazone of benzaldehyde. The percentage split to ethyl acetate and acetaldehyde (Table III) was determined by saponifying the 25 to 95° fraction of the condensate and titrating the acetic acid formed. The percentages of ethyl crotonate and percentages of recovered ethyl β-hydroxybutyrate were calculated from the results of the fractionation of the condensate. The acetaldehyde was characterized by the p-nitrophenylhydrazone, and the acetic acid by the *p*-toluidide.

The preparation of Δ^3,2,2-dimethylbutenol-1 is described in the preceding paper.[3]

Ethyl 2-methyl-2-ethyl-3-hydroxybutyrate was obtained by the reduction of ethyl a-methyl-a-ethylacetoacetate with a nickel catalyst in 87% yield;[4] b. p. 97–98' at 14.5 mm.; d_{25}^{25} 0.9775; n_D 1.4340 at 25°. Molecular *Refraction.* Calcd., 46.94. Found, 46.39.

---

Anal. Calcd. for $C_9H_{18}O_3$: C, 62.02; H, 10.42. Found: *C*, 61.64. 61.49. H, 10.42, 10.40.

Ethyl **2,2-dimethyl-3-hydroxybutyrate** was obtained by the reduction with a nickel catalyst of ethyl dimethylacetoacetate. Yields of 87–88% of the product were obtained which boiled from 94–95° at 21 mm.[4]

Ethyl **Δ^3,2,2-dimethylbutyrate** was obtained by the dehydration of ethyl 2,2-dimethyl-3-hydroxybutyrate with phosphorus pentoxide: b. p. 139–141°; yields, 74–80%.[5]

Catalysts.—Two hundred grams of aluminum nitrate was dissolved in two liters of cold water and concentrated ammonium hydroxide added with stirring until slightly ammoniacal. The precipitate was then filtered with suction and added to two liters of water, and stirred well to dissolve any soluble salt. The precipitate was filtered and added to one liter of water and well stirred again. After filtration the precipitate was dried in an oven at 125'. The alumina was then pulverized in a mortar and again placed in the oven until thoroughly dry. While it was still hot from the oven it was plunged into one liter of water. At this point some was lost due to the alumina forming a non-filterable suspension. After filtration, the oven drying at 125° was repeated. The dry powder was then pressed into pill form. This alumina had fair activity which was increased by heating at 400° for four hours. The zinc oxide was the same as that prepared by Weston from zinc oxalate.

Summary

Alumina does not catalyze (as with allyl alcohol) the reduction of the alkene linkage in Δ^3,2,2-dimethylbutenol-1 either through the rearrangement of hydrogen from the carbinol group of the same molecule or through the oxidation of a second molecule of the alcohol to an unsaturated aldehyde. Zinc oxide catalyzes the dehydrogenation of the alcohol to the aldehyde. Alumina and zinc oxide catalyze the autooxidation–reduction of Δ^3,2,2-dimethylbutenol-1 with the formation of an unsaturated aldehyde and unsaturated hydrocarbon. Benzyl alcohol and dibenzyl ether disproportionate in an analogous fashion. Alumina catalyzes the disproportionation of β-hydroxybutyric ester, and α,α-dialkyl-β-hydroxybutyric esters with the formation of acetaldehyde and a saturated ester.

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

THE HYDROGENATION OF CERTAIN BRANCHED COMPOUNDS OVER NICKEL

BY HOMER ADKINS, WALTER H. ZARTMAN AND HOWARD CRAMER

RECEIVED NOVEMBER 10, 1930 PUBLISHED APRIL 6, 1931

It has been generally recognized that the catalytic hydrogenation of substituted compounds is usually more difficult than in the case of the simpler compounds. Whether this apparent lowering in reactivity is due to spatial effects or otherwise is uncertain, but it seems worth while to study rather completely and carefully the hydrogenation of compounds which may be considered to fall into this group. Therefore the hydrogenations of triphenylcarbinol, triphenylmethane, dicyclohexylphenylmethane, 1,3,5-triphenylbenzene, triphenylamine, 1,3,5-trimethylbenzene and 2,2',4,4',6,6'-hexamethyldiphenyl have been investigated. The experimental methods and apparatus were essentially the same as those previously described.[1]

The significance for the present of most of the results reported in this paper lies in the establishment of experimental conditions under which these hydrogenations may be carried out, so that little need be written in addition to the tabulation. There is recorded in Table I a summary of the experimental conditions and results obtained in typical experiments in the hydrogenation of the above list of compounds. There are reported: (1) the name of the compound, (2) the amount submitted to hydrogenation, (3) the amount of hydrogen absorbed, (4) in the time and (5) at the temperature, (6) and pressure, (7) over the catalyst, (8) and in the amount of solvent indicated; (9) the yield(s) of, (10) product(s) having, (11) the physical constants compared with, (12) the physical constants, (13) previously reported.

The most noteworthy observation made in connection with the hydrogenation of these compounds was that water or ethanol inhibited the reduction of the benzenoid ring in dicyclohexylphenylmethane, while they were without effect upon the hydrogenation of two of the benzenoid rings in triphenylmethane. Dicyclohexylphenylmethane was formed quantitatively by the hydrogenation of triphenylcarbinol in alcohol or methylcyclohexane, and of triphenylmethane in alcohol or in methylcyclohexane containing water. Dicyclohexylphenylmethane in ethanol solution absorbed no hydrogen over an active nickel catalyst at 200° under a pressure of 100 atmospheres of hydrogen.

Tricyclohexylmethane was readily formed by the hydrogenation in methylcyclohexane of triphenylmethane or dicyclohexylphenylmethane.

Abstracts*, **23**, 3897 (1929)].

It was found to be a white crystalline substance melting at 58.5–59.5° rather than a liquid as reported by Zelinski and Goverdovskaia and by Godchot or a solid melting at 48° as observed by Ipatiev and Dolgov.

Tricyclohexylamine was found to be a solid melting at 160–161°. Both the absorption of hydrogen in its formation and the analysis of the product indicated quite definitely that the three phenyl groups in triphenylamine had been converted to cyclohexyl groups. Adams and Hiers obtained a liquid as the result of the hydrogenation of triphenylamine over platinum which they reported on the basis of its nitrogen content as being tricyclohexylamine. Their results have been duplicated in this Laboratory but it is believed that the product is not pure tricyclohexylamine. Analyses for carbon and hydrogen on this material were about 2% from the theoretical values. Analyses for nitrogen are not significant in this case because the presence of rather considerable percentages of impurities such as dicyclohexylphenylamine do not greatly modify the nitrogen content.

Symmetrical tricyclohexylcyclohexane and hexamethyldicyclohexyl have been prepared for the first time.

Experimental Part

Triphenylcarhinol (m. p. 162–162.5°), triphenylmethane (m. p. 92–93°), triphenylamine (m. p. 126–126.5°) and mesitylene (1,3,5-trimethylbenzene) (b. p. 163.5–164.5") were prepared by standard methods. 2,2′,4,4′,6,6′-Hexamethyldiphenyl (dimesityl) (m. p. 100–100.5°) and the intermediate bromomesitylene were prepared *as* by Adams and Moyer, and by Smith and MacDougall.[2] The 1,3,5-triphenylbenzene (m. p. 172–173") was prepared as by Fischer, Wille and Vorländer.[3] Dicyclohexylphenylmethane was prepared by the hydrogenation, as indicated in Table I, of triphenylcarbinol or of triphenylmethane. Both mesitylene and dimesityl were refluxed for many hours over sodium for the removal of traces of halogen-containing compounds. Dimesityl was further treated five times for three or four hours with reduced nickel (no support) in methylcyclohexane at 200° under 100 atmospheres.

The catalysts referred to as H. C. 12, and Z 5 were made as by Cramer. Catalysts Z 7 and 8 were made similarly except that sodium bicarbonate was used as the precipitant for nickel. Catalysts 7 and 8 were different preparations in which the same method was used.

Summary

Experimental conditions for the successful hydrogenation over nickel of triphenylcarbinol, triphenylmethane, dicyclohexylphenylmethane, 1,3,5-triphenylbenzene, triphenylamine, 1,3,5-trimethylbenzene and 2,2′,4,4′-6,6′-hexamethyldiphenyl have been determined. Water and ethanol have been found to inhibit the hydrogenation of dicyclohexylphenylmethane. 1,3,5-Tricyclohexylcyclohexane and 2,2′4,4′,6,6′-hexamethyldicyclohexyl have been prepared for the first time. Tricyclohexylmethane and tricyclohexylamine have been found to have physical properties very different from those previously reported.

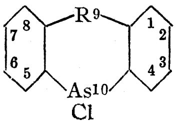
MADISON, WISCONSIN

DERIVATIVES OF THE ARSENIC ANALOG OF 9,10-DIHYDROACRIDINE. I[1]

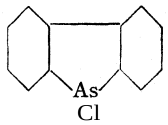
BY WILLIAM GUMP AND HUGO STOLTZENBERG

RECEIVED NOVEMBER 25, 1930 PUBLISHED APRIL 6, 1931

Compounds of the type represented by the Formula I are known in which R is: NH, (10-chloro-9,10-dihydrophenarsazine);[2] 0, (10-chloro-9,10-dihydrophenoxarsine);[3] S, (10-chloro-9,10-dihydrophenthiarsine);[4] AsCl, (9,10-dichloro-9,10-dihydroarsanthrene).[5] This series contains the arsenic as a hetero atom in a six-membered ring; an example of a five-membered ring is the *o,o′*-diphenylylene arsenious chloride (II).[6]



I



II

The synthesis of these compounds can be accomplished in the cases of R=NH and O by heating arsenic trichloride with diphenylamine and with diphenyl ether, but this reaction does not take place with diphenyl,

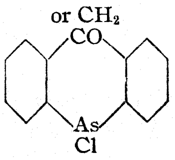
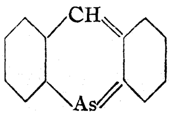
diphenylsulfide, diphenylmethane or benzophenone, and other methods have to be used to synthesize these arsenical ring compounds.

Analogs of acridone, 9,10-dihydroacridine and acridine where the nitrogen is replaced by arsenic and which have the structure shown by the Formulas III and IV, thus belonging to the general type I, have not yet been prepared although several attempts have been made to secure such compounds.

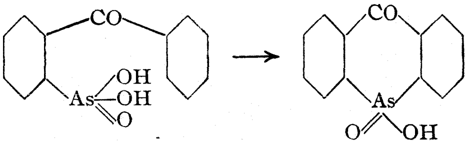


III

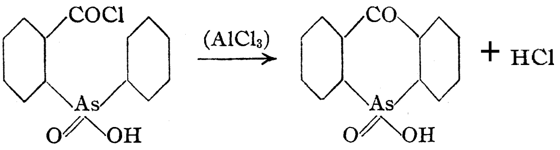


IV

Aeschlimann and McCleland[7] had studied the synthesis of the acridone analog (III) by different methods. They tried to close the ring from benzophenone-o-arsonic acid by removing the elements of water by means of sulfuric acid or phosphorus pentoxide in the same way that anthraquinone is prepared from o-benzoylbenzoic acid. This method was used successfully in some syntheses of arsenic ring compounds, but the ring formation did not occur here.



Another way was to start from o-carboxydiphenylarsinic acid. Aeschlimann prepared the acid chloride and tried to split off hydrogen chloride by means of aluminum chloride in order to close the ring, but the desired compound could not be obtained. Sakellarios[8] was also unsuccessful in his attempts to form the ring from the o-carboxydiphenylarsinic acid, using water-removing condensation agents.



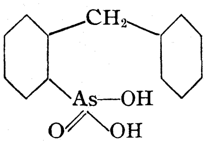
The work done already showed that the synthesis of an arsenic acridone analog is a difficult task. The object of our research was to see if the CH_2 group instead of the CO group would make the ring formation easier and would give the possibility of obtaining acridine and acridone rings with arsenic instead of nitrogen. We propose the name acridarsine for this new

---

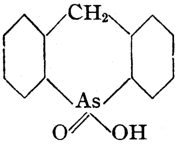
[7] Aeschlimann and McCleland, *J. Chem. Soc.*, 125,2025 (1924).

[8] Sakellarios, *Ber.*, 59, 2552 (1926).

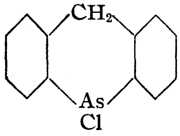
series. We were able to prepare the acridarsinic acid (VI) and the 10-chloro-9,10-dihydroacridarsine (VII).



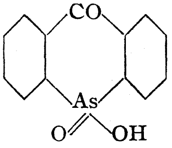
V



VI



VII

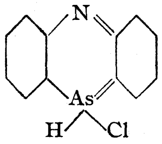


VIII

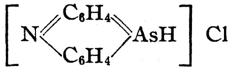
The first step was the preparation of diphenylmethane-*o*-arsonic acid (V) from o-aminodiphenylmethane. The well-known method of Bart was used; the diazo solution of o-aminodiphenylmethane was coupled with sodium arsenite to the diphenylmethane-o-arsonic acid. This arsonic acid could be closed to a ring by means of concentrated sulfuric acid without difficulty, in contrast to the benzophenone-o-arsonic acid. Acridarsinic acid (VI) was so formed.

The acridarsinic acid was then reduced to the 10-chloro-9,10-dihydroacridarsine (VII) by means of sulfur dioxide and hydrochloric acid. This compound forms beautiful, yellow-greenish prisms and has distinct physiological properties. It shows the disagreeable qualities of acridine in an increased degree. When dusted in the air in smallest amounts, it causes severe burning of the face, the lips and the tongue. In addition to that, the trivalent arsenic strongly irritates the mucuous surfaces of the bronchial organs in the same way as 10-chloro-9,10-dihydrophenarsazine and other organic arsenic compounds.

In a recent publication, Kappelmeier[9] suggested a new formula for 10-chloro-9,10-dihydrophenarsazine by reason of his experimental results, namely

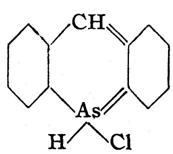


or

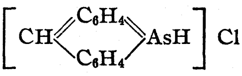


$\left[\mathrm{N}\begin{array}{c}\diagup\mathrm{C_6H_4}\diagdown\\ \diagdown\mathrm{C_6H_4}\diagup\end{array}\mathrm{AsH}\right]\mathrm{Cl}$

As the 10-chloro-9,10-dihydroacridarsine behaves like acridine in its skin-irritating properties, it may be also an arsonium salt and have a figuration which is derived from acridine and not from 9,10-dihydroacridine.



or



$\left[\mathrm{CH}\begin{array}{c}\diagup\mathrm{C_6H_4}\diagdown\\ \diagdown\mathrm{C_6H_4}\diagup\end{array}\mathrm{AsH}\right]\mathrm{Cl}$

The preparation of the acridine analog (III) from the 10-chloro- or the 10-methoxy-9,10-dihydroacridarsine will be investigated.

---

[9] Kappelmeier, *Rec. trav. chim.*, **49**, 64 (1930).

Another reaction which will be studied is the oxidation of acridarsinic acid. By means of chromic acid–sulfuric acid mixture a new acid, melting above 260°, was obtained from acridarsinic acid. This is probably the 9-oxo-acridarsinic acid (VIII) and the oxidation would lead to the compounds which Aeschlimann was not able to synthesize.

Experimental Part

***o*-Aminodiphenylmethane.**—The preparation of this starting material is quite troublesome. Commercial o-nitrotoluene was chlorinated to o-nitrobenzyl chloride according to the method of Haussermann and Beck[10] using sulfur as chlorine transporter. The yield was always low and could not materially be increased by exposing the reaction mixture to sun or artificial light. For future experiments, it may be more advantageous to nitrate benzyl chloride and to separate the o- and *p*-nitrobenzyl chlorides.

The o-nitrobenzyl chloride, benzene and aluminum chloride resulted in *o*-nitrodiphenylmethane in a yield of about *75%;* the method of Geigy and Königs,[11] modified by Tanasescu,[12] was applied.

o-Nitrodiphenylmethane was reduced to the amino compound with tin and hydrochloric acid. Fischer and Schütte[13] claim that the reduction proceeds very slowly; we found, however, that *50* g. of nitrodiphenylmethane was reduced completely in about one hour. The yield of pure o-amino diphenylmethane is at least 80%.

The alkaline reduction of o-nitrodiphenylmethane, described by Carre,[14] did not give satisfactory results.

Diphenylmethane-*o*-arsonic Acid.—Thirty-seven grams of *o*-aminodiphenylmethane was dissolved in about *100* cc. of ether. The ether solution was allowed to drop with stirring upon a mixture of *70* cc. of hydrochloric acid and *700* g. of finely crushed ice. The separated hydrochloride was brought into solution by diazotizing with $N/10$ sodium nitrite solution.

Forty grams of arsenious oxide was dissolved in *120* cc. of *5* N sodium hydroxide and *300* cc. of sodium carbonate solution *(106* g. of anhydrous sodium carbonate in a liter of solution), *25* cc. of an ammoniacal solution of copper sulfate (1:10) and *600* cc. of water were added. This mixture and the diazonium solution were dropped onto *500* g. of ice under stirring during one hour. On the next morning the tar was filtered off, the boiling liquor was decolorized with Darco or Nuchar and hydrochloric acid was added until the solution was neutral. The small amounts of a by-product were filtered off, and the arsonic acid *(16* g.) was precipitated by the further addition of hydrochloric acid until congo paper showed blue color.

The diphenylmethane-o-arsonic acid is obtained in beautiful, white needles by recrystallization from a large amount of water. The acid, melting at 161–162°, is very slightly soluble in cold water, and somewhat soluble in boiling water. Glacial acetic acid is a good solvent for the arsonic acid.

Anal. Subs., *0.2034:* $Mg_2As_2O_7$, *0.1070.* Calcd. for $C_{13}H_{13}O_3As$: As, *25.7.* Found: As, *25.4.*

Acridarsinic Acid.—Ten grams of diphenylmethane-o-arsonic acid was dissolved in *40* cc. of concentrated sulfuric acid; the solution was heated in boiling water for five

minutes, and poured into about 500 cc. of water. Glittering, colorless crystals separated which were filtered and washed with water. The yield is almost quantitative. The crystals melt at 230–235°, becoming yellow at 200° and brown shortly before melting. The acid is obtained in small needles by recrystallization from dilute acetic acid, which melt at 235–236° with disintegration. The acridarsinic acid is almost insoluble in cold and also in boiling water; in warm glacial acetic acid, it is easily soluble.

Anal. Subs., 0.2026: $Mg_2As_2O_7$, 0.1164. Calcd. for $C_{13}H_{11}O_2As$: As, 27.5. Found: As, 27.7.

10-Chloro-9,10-dihydroacridarsine.—Ten grams of acridarsinic acid was finely pulverized and suspended in 100 cc. of hydrochloric acid; 100 cc. of chloroform was added to the suspension. By means of a wide tube which was submerged below the surface of the chloroform, sulfur dioxide and hydrogen chloride were passed through. After five minutes, a little potassium iodide was added and the reduction was completed on the steam-bath under refluxing.

The chloroform solution was separated from the aqueous liquor and the chloroform was distilled off on the steam-bath. The 10-chloro-9.10-dihydroacridarsine (9 g.) remained in large crystals of brownish color. The substance was obtained in beautiful, yellow prisms by recrystallization from benzene. The 10-chloro-9,10-dihydroacridarsine is soluble in the common organic solvents and melts at 114–115°.

Anal. Subs., 0.1411: $Mg_2As_2O_7$, 0.0778. Subs., 0.2318: AgCl, 0.1200. Calcd. for $C_{13}H_{10}ClAs$: As, 27.1; Cl, 12.83. Found: As, 26.7; Cl, 12.81.

Summary

Starting with o-aminodiphenylmethane, the diphenylmethane-o-arsonic acid and derivatives of the arsenic analog of 9,10-dihydroacridine, such as acridarsinic acid and 10-chloro-9,10-dihydroacridarsine have been synthesized.

BINGHAMTON, NEW YORK

THE PIRIA REACTION. I. THE OVER-ALL REACTION[1]

BY W. H. HUNTER AND MURRAY M. SPRUNG

RECEIVED NOVEMBER 28, 1930 PUBLISHED APRIL 6, 1931

Aminosulfonic acids can be obtained directly from aromatic nitro compounds by heating the latter with metal sulfites and then boiling with mineral acids. This reaction was discovered by Piria[2] in 1851, and will therefore be referred to in the following pages as "the Piria reaction." Piria, at that time, subjected α-nitronaphthalene to the action of ammonium sulfite in dilute alcoholic solution, and isolated two reduction products: the ammonium salts of naphthionic acid and of α-naphthylsulfaminic acid, respectively.

---

[1] The work described in this paper formed part of a thesis submitted to the Graduate Faculty of the University of Minnesota by Murray M. Sprung in partial fulfilment of the requirements for the degree of Doctor of Philosophy, September, 1928. Presented before the Division of Organic Chemistry of the American Chemical Society at the Minneapolis Meeting, September 9–16, 1929.

[2] Piria, *Ann.*, 78, 31 (1851).

It would naturally be expected that this reaction would be of importance in the manufacture of intermediates for azo dyes and some such hope undoubtedly has inspired many workers, for in the eighty years which have intervened since its discovery, the Piria reaction has been studied by a large number of investigators.[3]

However, the information which has been obtained has been of a decidedly general nature. No systematic investigation, from a theoretical point of view, of a series of nitro compounds has been carried out; no two investigators have used identical procedures for carrying out the reduction, or for isolating the products. The original ammonium sulfite has in many cases been replaced by sodium or potassium sulfite of various concentrations, or by equally varied concentrations of bisulfite. Also, much of the information is in the usual none too clear specifications of *an* organic chemical patent of the early days.

Further, with the exception of Raschig,[4] no one has given any particular consideration to the mechanism of the changes involved.

Now the Piria reaction is carried out in two distinct stages: a reduction stage, in which the nitro group is known to be transformed into an amino group, a sulfaminic acid group, or both; and an acid treatment stage, in which an amine or an aminosulfonic acid appears. It is entirely fair, it would seem, to say that neither of these stages is understood, though many opinions have been expressed about both of them taken singly and together.

This situation is due primarily to the fact that most previous investigators other than Raschig, and perhaps Weil,[5] have been primarily interested in finding the best reagent and the best conditions for the production of a single desired compound, usually an aminosulfonic acid.

Aside from its value, or lack of it, as *a* source of intermediates, the

reaction presents interesting problems, as a study in oxidation–reduction, and as a problem in the effect of hydrogen-ion concentration.

However, the methods of carrying out the reaction have been so various that it was impossible to gain a viewpoint on previous work. It therefore seemed wise to set up certain standard conditions, into which any nitro compound would be forcibly fitted, both for the reduction stage and the acid-treatment stage, in order to arrive at some uniformity of treatment. This was done, and a series of eight somewhat coherently related nitro compounds was studied, under these standard conditions, as well as with some deliberate variation, in certain cases. In the discussion of this treatment it is convenient to use the terms "standard reduction," "standard acid treatment," and in addition, the term "over-all reaction," the latter referring to the use of both operations in sequence.[6]

The results of this preliminary survey of the reaction are set forth in the table. . It will be noted that the standard procedure is not indicated for two of the nitro compounds. In these cases the standard procedure was used, but it failed to give satisfactory reduction, and the actual procedures are included, to illustrate the possibilities of variation, and as examples of the types of variation to be found in existing literature.

Discussion of the Results

It will be noted that in every case the over-all reaction produced an aminosulfonic acid, and in every case but one (*p*-nitrophenol)[7] an amine

---

[6] STANDARD REDUCTION.—To a weighed quantity of the nitro compound was added enough of a 5.2 N (2.6 M) solution of sodium bisulfite to constitute approximately 75% excess over that calculated on the basis of 3 moles of bisulfite per mole of nitro compound. Enough 5 normal sodium hydroxide was then added to neutralize one-fourth of the bisulfite, and to the whole was added water in the ratio of 1250 cc. for each mole of nitro compound. This mixture, contained in a round-bottomed flask, was heated to boiling under a reflux condenser (with continual mechanical stirring) until homogeneous. (At this time the odor of nitro compound should be no longer noticeable.)

STANDARD ACID TREATMENT.—The mixture was evaporated on the steam-bath to about half the original volume, and treated while hot with 250 cc. of concentrated (12 N) hydrochloric acid for each mole of original nitro compound. It was boiled for one-half to two hours, and then allowed to cool.

ISOLATION.—In all cases where the amine produced was volatile with steam, excess alkali was added at this point, and the amine distilled out in a current of steam. The sodium salt of the aminosulfonic acid usually crystallized from the cooled residue, since such sodium salts are quite insoluble in an alkaline salt solution of the concentration here produced. This method of isolating the products was varied whenever it was necessary or more convenient to use other means. The procedure was especially different in case of those reactions which gave rise to amines which are not volatile with steam. These reactions are described separately, as a general statement cannot be made about them.

[7] For reasons stated in the experimental part of the paper, we believe that very little, if any, amine was produced in this case.

TABLE I

NATURE AND QUANTITY OF PRODUCTS OBTAINED IN THE "OVER-ALL" PIRIA REACTION

Nitro compound	Experimental condition	Time for reduction phase, hours	Amine isolated	Av., %	Aminosulfonic acid isolated	Av., %	Other product isolated	Av., %
Nitrobenzene	St. proc.	1.25	Aniline	26	Sulfanilic	27	......	..
α-Nitronaphthalene	St. proc.	5	α-Naphthyl-	2	Naphthionic	25	1-Naphthylamine-2,4-disulfonic acid	66
o-Nitrotoluene	Same	12	*o*-Toluidine	40	2-Toluidine-5-sulfonic	34	Sodium *o*-tolylsulfaminate	12
p-Nitrotoluene	Same	5	*p*-Toluidine	72	4-Toluidine-3-sulfonic	11	......	..
Nitro-*p*-xylene	3 Times[a] usual amt. water	17	*p*-Xylidine	60	3-Amino-1,4-xylene-6-sulfonic	16	......	..
m-Dinitrobenzene	*A* 10% excess Na_2SO_3(HCl used[c])	2	*m*-Nitroaniline	Tr.	*A* *m*-Nitraniline *p*-sulfonic	64	......	..
	B 110% excess $NaHSO_3$(H_2SO_4 used)	8.5[b]	......	..	*B* *m*-Nitraniline *p*-sulfonic	1	*m*-Phenylenediamine-*p*-sulfonic acid	10
p-Nitrobenzoic acid	St. proc.	4.5	*p*-Aminobenzoic acid	21[d]	*p*-Amino-*m*-sulfobenzoic	61[e]	......	..
p-Nitrophenol	St. proc.	11[f]	......	..	*p*-Aminophenol-*m*-sulfonic	14	......	..

[a] When the normal amount of water was used, the reaction was found to be incomplete even after twenty or twenty-five hours of boiling. [b] The reaction was not complete at this time. [c] The standard reduction gave an abnormal reaction. [d] Isolated partly as such, and partly as the *p*-amino-*m*-sulfobenzoic acid salt of *p*-aminobenzoic acid. [e] Isolated partly as such and partly as the *p*-amino-*m*-sulfobenzoic acid salt of *p*-aminobenzoic acid. [f] The reduction was probably complete, in this case, in a much shorter time than is here indicated. Since there was no external evidence indicating just when the reduction phase was ended (as there was in all other cases) the heating was continued until we were sure that no unreacted nitro compound remained.

could be obtained. However, the relative amounts of these products varied widely, indicating that their formation is very probably largely governed by constitution factors. This is probably the most striking result of the present work. Without presuming to be arbitrary, since the evidence available at present is still not very extensive, we may recognize several definite influences. Thus it is apparent that a ring methyl group favors the formation of amines, while the presence of a carboxyl group, a second nitro group, or a condensed ring favors the formation of aminosulfonic acids. In the few cases studied, the position of the second substituent seems to be of comparatively small influence.

In most cases, the combined yields of the two chief products (amine and mono-sulfonated amine) was slightly in excess of 80%. Only in two cases was it less. In the case of α-nitronaphthalene, the chief product was found to be an amino-disulfonic acid (isolated in 66% yield), and the total yield of this plus those of the two normal products was close to 95%. In the second case, that of nitrobenzene, we have not as yet succeeded in isolating a disulfonic acid. It is possible that the production of a very soluble disulfonic acid (extremely difficult to separate from the admixed inorganic salts) may account for the low total yield. We also believe it highly probably that in most of the other cases (that of *p*-nitrophenol is an exception, due to the inadequacy, in this case, of the methods used to isolate the product) the difference between the combined yields of the two chief products and 100% may be largely due to the occurrence of other very soluble amino-disulfonic acids, which we have not as yet attempted to isolate.

Another significant observation should be mentioned. It was noted that the speed of the first phase of the reaction (reduction) increased with dilution. This effect was particularly noted in experiments with nitrobenzene and with 2-nitro-1,4-xylene.[8] This led us to suspect that one of the early stages of the reaction is an *ionic* reduction, a suspicion which was lent further support by other observations. Thus it was noticed, in the case of α-nitronaphthalene, that the use of alcoholic aqueous media appreciably slowed down the reaction, contrary to expectation. It was also noted that neutral sodium sulfite was able to reduce dinitrobenzene in two hours, whereas bisulfite required over eight and one-half hours. All these observations can be reconciled with the view that for these reductions, the activity of the sulfite ion is of great importance.

On the contrary, however, it has been determined that partially neutralized sodium bisulfite is more effective in these reactions than normal

---

[8] It should be mentioned that the velocity of the first phase of the reaction (usually a heterogeneous reaction) depended upon the efficiency of agitation. However, it was attempted to keep this factor as constant as possible, and the results recorded are therefore comparable.

sodium sulfite. At present we can harmonize this with the above observation relative to dinitrobenzene only by the assumption that another stage in the reduction is favored by higher hydrogen-ion concentration than is furnished by neutral sulfite, and that this factor, in the case of dinitrobenzene, is of secondary importance, for some reason which is not as yet clear. In this connection it should also be stated that the addition of alkali had little or no effect upon the speed of reduction of α-nitronaphthalene. Completely neutralized bisulfite and un-neutralized bisulfite, in this case, were about equally effective. We hope to throw more light upon these problems by virtue of further investigations now being carried out in this Laboratory.

Experimental Part

Experiments with a-Nitronaphthalene

(A) With Bisulfite and Aqueous Alcohol.—Twenty-five grams of α-nitronaphthalene (m. p. 57–57.5°), 76 cc. of 5.2 N sodium bisulfite (15% excess), 100 cc. of 95% alcohol, and 200 cc. of water were heated under a reflux condenser. At the boiling point of the solution the reduction was incomplete at the end of thirteen hours. By working up the mixture there was obtained 9.5 g. of naphthionic acid, 7 g. of a-nitronaphthalene (unchanged), and 0.8 g. of a-naphthylamine; yields (on the basis of the nitro compound used): amine, 10%; aminosulfonic acid, 58%.

(B) With Aqueous Bisulfite.—A typical run is given. Thirty-five grams (0.2 mole) of a-nitronaphthalene, 200 cc. of 5.2 N sodium bisulfite (75% excess) and 250 cc. of water were heated under a return condenser until the mixture was completely homogeneous. The contents of the flask, evaporated to 300 cc. and treated with 50 cc. of 12 N hydrochloric acid, gave a heavy white precipitate, which was filtered from the cooled solution. This mixture was warmed with 300 cc. of water, which dissolved the salts present, leaving the naphthionic acid (soly., 0.024 g. in 100 cc. of water); 13.5 g. (29%) of the aminosulfonic acid was thus obtained.

The combined filtrates were saturated with sodium chloride, and the precipitate produced was filtered off. It was nearly free from inorganic salts. When dry it weighed 31 g., which, on the basis of a monosodium salt of a naphthylamine disulfonic acid is equivalent to a yield of 66%.

(C) With Aqueous Bisulfite and Alkali.—Thirty-five grams was reduced according to the standard procedure. The reduction required five hours. Acidification with 50 cc. of 12 N hydrochloric acid gave 10 g. (22%) of naphthionic acid. Seventy-five grams of stick sodium hydroxide was added to the combined filtrates and steam passed through, giving 0.5 g. or 2% of α-naphthylamine (m. p. 48–48.5°). The residue was made acid and was again distilled with steam, but no volatile substance was present, and therefore no naphthol was produced during the reaction.

Identification of the **Products.—a-Naphthylamine** was identified by melting point and mixed melting point with a sample of known purity. Naphthionic acid was identified by conversion to the diazonium salt, according to the method of Erdmann.[9] The diazonium salt thus obtained decomposed instantaneously at 140.5°. It gave characteristic azo dyes with alkaline β-naphthol and with phenol.

A sample of the monosodium salt of the naphthylamine disulfonic acid was crystallized four times from 70% alcohol. It still retained a slight pinkish tint, but was completely free from inorganic salts. It was dried at 140° and analyzed.

---

Anal. Calcd. for $C_{10}H_8S_2O_6Na$: S, 19.68; Na, 7.07. Found: S, 19.28; Na, 6.94, *7.00*

It is almost certain from these analyses and the method of synthesis that this compound is the monosodium salt of 1-aminonaphthalene-2,4-disulfonic acid, described in an early German patent.[10] No further time was spent on its orientation at this time, as we were interested only in the groups introduced by the reagent and not in their positions.

Experiments with Nitrobenzene

(A) The Standard Procedure.——Fifty grams was reduced in one and one-half hours. The contents of the flask were evaporated to 500 cc., decomposed with 100 cc. of concentrated hydrochloric acid, and re-evaporated to 500 cc. One hundred and twenty grams of solid sodium hydroxide was then immediately added, and the mixture steam distilled. The distillate, on extraction with ether, drying of the ethereal extracts, and distillation, gave 7 g. of aniline, boiling at 181–183" (16%, on the basis of the nitro compound used). The residue from the distillation was filtered, while still hot, from precipitated inorganic salts (sodium chloride and sodium sulfate). On cooling the filtrate to room temperature, crystals were obtained which were rendered almost colorless by repeated washing on the filter with methyl alcohol. These were nearly pure sodium sulfanilate, and when dry, weighed 38 g. (35%).

(B) Bisulfite Followed by Sulfuric Acid.—The standard procedure was followed, using 50 g. of the nitro compound. The reduction stage again required one and one-half hours.[11] One hundred cc. of concentrated sulfuric acid was used to decompose the solution. There were obtained 16 g. (20%) of sulfanilic acid and 12 g. (32%) of pure aniline.

Identification of Sodium Sulfanilate.—Bromination with liquid bromine gave tribromoaniline, identified by melting point and mixed melting point with a reliable specimen. The phosphorus pentachloride reaction product[12] was prepared by heating the sodium salt with phosphorus pentachloride in dry benzene. It melted at 154–155°, whereas the "trichloro compound" of Laar, when very pure, melts at 158'. Oxidation of the sodium salt with chromic acid and sulfuric acid in a current of steam gave benzoquinone, m. p., 113°; mixed m. p. with known sample of quinone, 113'. A purified sample of the sodium salt was analyzed, after drying at 140°.

Anal. Calcd. for $C_6H_6NSO_3Na$: Na, 11.53. Found: Na, 11.77.

Experiments with p-Nitrotoluene

Fifty grams was reduced, according to the standard procedure, in five hours. The mixture was evaporated to 500 cc., and decomposed with 100 cc. of 12 *N* hydrochloric acid. After re-evaporating to 500 cc., the solution was cooled, 100 g. of sodium hydroxide dissolved in 100 cc. of water was added, and this mixture was distilled with steam. From the distillate, 30.5 g. (72%) of nearly pure *p*-toluidine was obtained (m. p., 44.5°; b. p., 198–199°; acetyl derivative, m. p., 147–147.5'). The residue from the steam distillation deposited, on cooling, a white organic salt mixed with sodium chloride and sodium sulfate. This was dissolved in water, filtered hot, and the cooled filtrate acidified with hydrochloric acid. Eight grams (11%) of 4-toluidine-3-sulfonic acid was obtained.

---

[10] Meister, Lucius and Brüning, German Patent 92,082, *Friedländer*, 4, 528 (1895).

[11] In one run the standard procedure was varied by diluting with 2000 cc. rather than the usual 500 cc. of water. At this dilution the reduction stage required only forty minutes. A 25% yield of sulfanilic acid was obtained.

[12] Laar, *J. prakt.* Chem., [2] 20, 250 (1879).

Identification of **the** Aminosulfonic Acid.—Bromination gave 3,5-dibromo-4-toluidine, m. p., 70–71°. **A** sample prepared by bromination of *p*-toluidine melted at 74–75°. A mixture of the two melted at 72–73°. The sodium salt (from the aminosulfonic acid and excess dilute sodium hydroxide) lost no weight when heated at 150°. It was analyzed for sodium.

Anal. Calcd. for $C_7H_8SO_3NNa$: Na, 10.99. Found: Na, 10.80, 10.92.

Experiments with o-Nitrotoluene

Using the standard procedure, the reduction required twelve hours. After treatment with 100 cc. of 12 *N* hydrochloric acid, the mixture was allowed to cool. Large, white, silky plates separated, which were filtered. When dry, they weighed 11 g., and proved to be sodium *o*-toluene-sulfaminate. That this salt should precipitate from a solution which was both hot and quite strongly acid was rather unexpected. The filtrate was now boiled on the steam-bath for an hour, cooled again, treated with 100 g. of solid sodium hydroxide, and steam distilled. By extracting the distillate with ether, and evaporating the ether, there was obtained 17 g. (40%) of o-toluidine, boiling at 196–197°; acetyl derivative, m. p., 106–106.4°. The distillation residue was filtered, while hot, from inorganic salts. On cooling, white, lustrous, scaly crystals of sodium 2-toluidine-5-sulfonate were deposited. After drying at 90°, they weighed 27.5 g., or 34% of the calculated yield.

Identification **of** the Sodium **Sulfaminate.**—This salt, when heated at 140–150°, decomposed, losing 23–24% of its weight, and giving a strong toluidine odor. **A** sample, purified until free from sulfate, was boiled with hydrochloric acid, after which it gave a heavy precipitate of barium sulfate when treated with barium chloride, and when made alkaline, it gave a positive carbylamine test, indicating the presence of a primary amine. **A** diazotized sample gave dyes of the same shade as a known solution of diazotized sodium o-tolyl-sulfaminate.

Anal. Calcd. for $C_7H_8NSO_3Na\cdot H_2O$: Na, 10.13. Found: Na, 10.04, 10.15.

Identification of the Sodium Salt of the Amine **Sulfonic** Acid.—Anal. Calcd. for $C_7H_8NSO_3Na$: Na, 11.01. Found: Na, 11.10, 11.13. Oxidation with chromic acid in sulfuric acid gave toluquinone, m. p. 67.5°; m. p. of known sample of toluquinone, 66.5°; mixed m. p., 66.5°. Acidification of a concentrated water solution yielded the free sulfonic acid, which gave reactions characteristic of a substance of its type. Toluquinone was obtained from it, by oxidation as above.

Experiments with 2-Nitro-1,4-xylene

Preparation of **2-Nitro-1,4-xylene.**—*p*-Xylene was nitrated according to Willstatter's chloroform **method.**[13] Ten grams of the hydrocarbon was nitrated at one time. Fractional distillation of the oil resulting from ten nitrations gave 73 g. of 2-nitro-1,4-xylene, boiling at 238–242° (740 mm.).

Reduction of **2-Nitro-1,4-xylene.**—Thirty and seven-tenths g. (0.2 mole) was reduced, using the standard procedure except that 1000 cc. of water was added instead of the usual 300 cc. The products were as follows: 14.8 g. (60%) of 1,4-xylidine (b. p. 218.5°, corr.; acetyl derivative, m. p. 139.7–140°); and 6.2 g. (15.5%) of 2-amino-1,4-xylene-5-sulfonic acid.

Identification of the **Aminosulfonic** Acid.—The diazotized acid gave the usual coupling reactions. 1,4-Xyloquinone was obtained by oxidation with chromium trioxide and dilute sulfuric acid, and identified by the method of mixed melting points. The sodium salt was obtained from the free acid and excess sodium hydroxide as white

---

[13] Willstätter, *Ber.*, 42, 4151 (1909).

scale-like crystals, containing two molecules of water of crystallization. Heated at 50–60° it loses one molecule of crystal water, and at 140–150° it loses the second molecule of water. Although Nolting, Witt and Forel[14] and also Nolting and Kohn[15] reported that the salt crystallized water-free, our results indicate that this is not the case.

Anal. (air-dried salt). Calcd. for $C_8H_{10}NSO_3Na\cdot 2H_2O$: Na, 8.87. Found: Na, 8.80, 8.66, 8.77, 8.91, 8.75. (50° dried salt.) Calcd. for $C_8H_{10}NSO_3Na\cdot H_2O$: H_2O, 7.47. Found (by heating at 150° to constant weight): H_2O, 7.51, 7.46. (150° dried salt.) Calcd. for $C_8H_{10}NSO_3Na$: Na, 10.33. Found: Na, 10.46, 10.48.

Experiments with *m*-Dinitrobenzene

(A) Reduction with Neutral **Sulfite.**—The procedure approximated to that used previously by Nietzki.[16] Forty-three grams of m-dinitrobenzene and 400 cc. of a solution (5.2 N) of sodium bisulfite (10% excess on the basis of the reduction of one nitro group) was heated just above the melting point of the solid until, upon cooling, no dinitrobenzene precipitated (two hours). One hundred and twenty-five cc. of 12 *N* hydrochloric acid was then added and the mixture boiled for thirty minutes. Yellow needles of m-nitranilinesulfonic acid separated, which weighed, when dry, 35 g. or 64% of the calculated quantity. They were purified by repeated reprecipitation, with hydrochloric acid, from a sodium hydroxide solution; followed by two recrystallizations from water, and thorough washing on the filter with methyl alcohol. They were dried at 140° and analyzed.

Anal. Calcd. for $C_6H_6O_5N_2S$: S, 14.62. Found: S, 14.16, 14.14.

The filtrate from which the m-nitraniline sulfonic acid separated was made alkaline with sodium hydroxide, the Glauber's salt was filtered off, and the filtrate was extracted with ether. Evaporation of the ether left a small amount of long needles, m. p. 110–112°; m. p. of m-nitraniline, 114°.

(B) Reduction with **Bisulfite.**—Seventy-two grams of the dinitro compound was heated for eight and one-half hours with 500 cc. of 5.2 N sodium bisulfite (110% excess for the reduction of one nitro group), and 500 cc. of water. One hundred cc. of concentrated sulfuric acid was then added. The cooled solution, after evaporation to 500 cc., contained a black cake of solid. This was extracted, first with hot 95% alcohol, and then with hot water. The part insoluble in water was discarded. From the alcohol solution was obtained 5 g. of unchanged dinitrobenzene. From the water solution was obtained about a gram of a substance, which, from its properties and a sulfur analysis on the crude material, was found to be the m-nitraniline-p-sulfonic acid. The filtrate from which this precipitated, on standing in a total volume of 400 cc. for several days, deposited purplish colored crystals, weighing 20 g. They were purified from admixed sodium sulfate by extraction with cold water, leaving 8 g. of an organic substance, which proved to be 1,3-diaminobenzene-4-sulfonic acid. It was identified by its amphoteric nature, the readiness with which it could be diazotized, and its crystalline habits. It crystallized in two distinct modifications—large monoclinic plates and elongated prisms.[17]

Anal. Calcd. for $C_6H_8N_2SO_3$: S, 17.00. Found: S. 16.66, 16.40.

Experiments with *p*-Nitrophenol

The standard procedure was used, except that solid sodium hydroxide was added, equivalent to the phenol used, and in addition to the alkali added normally. From 55.6

---

[14] Nolting, Witt and Forel, *Ber.*, 18, 2667 (1885).

[15] Nolting and Kohn, *ibid.*, 19, 141 (1886).

[16] Nietzki, *Ber.*, 29, 2448 (1896).

[17] Cf. Post, *Ann.*, 205, 105 (1880).

g. of p-nitrophenol, 10.5 g., or 14% of the theoretical weight of *p*-aminophenol-*m*-sulfonic acid, was obtained, by extracting the mixture of salts obtained after the acid treatment with water at 30°, and filtering the insoluble portion. It was impossible to isolate any other product, or to increase the yield of the aminosulfonic acid. It is probable, however, that the aminosulfonic acid is the chief product of the reaction, but it is impossible to isolate more of it without resorting to a laborious series of fractional crystallizations of the mixture obtained after the usual acid treatment. (The aminosulfonic acid is soluble in water to the extent of about 3 parts per 100.) Evidence was obtained which indicated the presence of considerable quantities of the aminophenol sulfonic acid in later crystalline fractions and mother liquors. Thus, the pure aminophenolsulfonic acid shows an interesting and characteristic fluorescence—violet in pure water, and bluish-purple in alkaline solution. The acidified solutions do not fluoresce. Now, in an attempt to separate more of the product from the inorganic salts produced in the reaction, after acid treatment, by a process of fractional crystallization, it was noted that all succeeding crystalline fractions, mother liquors, and filtrates showed this same fluorescence. Furthermore, other typical color reactions of this compound persisted throughout these later fractions. Moreover, solutions of p-aminophenol (the other expected product) in aqua ammonia are lavender and do not fluoresce. This affords evidence that very little, if any, of this amine is produced, and that the amount of aminosulfonic acid isolated constitutes but a minimum yield.

Identification of the Aminophenol Sulfonic Acid.—This substance, when heated with 25% sulfuric acid in a sealed tube for six hours at 165–170°, gave p-aminophenol, m. p., 183–183.5° (decomp.); m. p. of a sample of p-aminophenol of known origin, 183.4–183.8° (decomp.); mixed m. p. 182.8–183.2" (dec.). The aminophenol sulfonic acid gave a diazonium sulfate which did not decompose upon boiling with water. This is in accord with the observation of Schultz and Stable,[18] who state that the diazo compound of this aminophenol sulfonic acid is stable toward boiling water. Our diazo salt melted at 171°, after two crystallizations from water. Schultz and Stable report a melting point of 189°. The diazo compound, when heated with 25% sulfuric acid in a sealed tube at 180" for two hours, gave hydroquinone, identified by the method of mixed melting points.

Experiments with p-Nitrobenzoic Acid

Twenty-five grams was reduced according to the standard procedure, except that sodium hydroxide was again added in quantity sufficient to convert the acid to its sodium salt. The reduction stage required four and one-half hours. Fifty cc. of 12 *N* hydrochloric acid was then added and the mixture boiled again for two and one-half hours. Upon cooling, a fluffy, white solid separated, weighing 11 g., when dry. This was shown to be the p-aminobenzoic acid salt of *p*-amino-*m*-sulfobenzoic acid. The filtrate was evaporated to 250 cc. and allowed to stand. A second solid substance separated, weighing, when dry, 6 g.[19] This was shown to be p-aminobenzoic acid sulfate. On further evaporation of the filtrate to 150 cc. and cooling to −10°, a precipitate of 37 g. of Glauber's salt was obtained, and 40 g. more was thrown out by the addition of 250 cc. of 95% alcohol. The Glauber's salt was extracted with hot methyl alcohol. Evaporation of the alcohol left 1.5 g. of p-aminobenzoic acid sulfate. Three grams more was obtained by evaporating the aqueous ethyl alcoholic filtrate to 50 cc., extracting the resulting

---

[18] Schultz and Stable, J. prakt. *Chem.*, [2] 69, 336 (1904).

[19] In another run, the filtrate was divided into two parts at this point. One part was extracted with ether as it was, but gave no appreciable ether-soluble material. The other part was made feebly alkaline, and then extracted with ether. Three *grams* of p-aminobenzoic acid was obtained.

precipitate of impure sodium chloride with hot methyl alcohol, and expelling the alcohol. The filtrate was now evaporated to dryness, the residue extracted with hot 95% ethyl alcohol, the alcohol evaporated to a volume of 25 cc. and cooled. A precipitate of 0 5 g. of p-aminobenzoic acid, melting, without purification, at 183–185°, was obtained.

Properties of the **p-Aminobenzoic** Acid Salt of ***p*-Amino-*m*-sulfobenzoic** Acid.—This is an acidic salt, which burns completely without melting. It is soluble in dilute alkali, and is reprecipitated unchanged by dilute acids. It is insoluble in acids, dilute or concentrated, and in ordinary organic solvents. It is practically insoluble in cold water, but appreciably soluble in hot water. Qualitative tests showed that it is neither an amine sulfate nor an amine hydrochloride. It crystallized from water in needles, showing a silky, fibrous nature under the microscope. A sample was purified for analysis by repeated reprecipitation from an alkaline solution (both ammonium and potassium hydroxides were used) with dilute hydrochloric acid, and then by repeated crystallization from water. It was then washed repeatedly on the filter with methyl alcohol and dried at 140°. The analytical results agree most closely with those calculated for a salt consisting of one molecule of p-aminobenzoic acid and one molecule of *p*-amino-*m*-sulfobenzoic acid.

Anal. Subs., 0.2747, 0.2982, 0.3005, 0.2627, 0.3865: $BaSO_4$, 0.1704, 0.1831, 0.1826, 0.1607, 0.2407. Subs., 0.1391, 0.1159: CO_2, 0.2378, 0.1988; H_2O, 0.0543, 0.0422. Calcd. for $C_{14}H_{14}O_7N_2S$: C, 47.5; H, 4.2; S, 9.04. Found: C, 46.7, 46.9; H, 4.0, 4.3; S, 8.53, 8.45, 8.35, 8.37, 8.55. *Titration equivalent.* Subs., 0.4376, 0.4355: 0.2230 N NaOH (phenolphthalein), 16.79, 16.60 cc. Calcd. for $C_{14}H_{14}O_7N_2S$ (tribasic): 16.61, 16.53 cc.

This insoluble salt was split into its components as follows. To 1.1664 g. of an analytically pure sample was added 29.54 cc. of 0.2230 *N* sodium hydroxide, the exact amount calculated to neutralize two mono-acidic groups of a molecule of molecular weight 354. A slight insoluble portion was brought into solution by adding a little water. The solution showed an acid reaction toward litmus. It was extracted thirteen times with ether. The thirteenth extract, evaporated separately, gave 0.003 g. of the ether-soluble material. In all 0.401 g. of this material (p-aminobenzoic acid, m. p. 184–185°) was obtained.

Titration equivalent. 0.2301 g. required 7.63 cc. of 0.2230 *N* NaOH. Calcd. for $C_7H_7O_2N$ (monobasic), 7.54 cc.

To the water solution was added hydrochloric acid until a precipitate formed This weighed 0.1152 g., after drying at 80° and required 4.36 cc. of 0.2230 N NaOH. Calcd. for $C_{14}H_{14}O_7N_2S$: 4.37 cc. Thus it appears that thirteen extractions with ether did not remove quite all of the p-aminobenzoic acid. When acid was added, this precipitated as the *least soluble salt* of the ions present in the solution, namely, as the aminosulfobenzoic acid salt. Since 0.115 g. of this salt is equivalent to 0.044 g. of *p*-aminobenzoic acid, the total yield of the latter was $0.401 + 0.044 = 0.445$ g.; calculated for 1.1664 g. of the salt, 0.451 g.[20] The filtrate, after separation of the salt, was evaporated to a small volume. This gave 0.51 g. of a white substance (dried at 115°). This was a sulfur-containing acid which crystallized from water in small plates characteristic of p-amino-m-sulfobenzoic acid.[21]

Titration equivalent. 0.2659 g. required 10.90 cc. of 0.2230 N NaOH. Calcd. for $C_7H_7O_5NS$ (dibasic): 11.00 cc.

---

[20] In a previous run, in which only three extractions with ether were made, 0.27 g. of aminobenzoic acid as such, and 0.155 g. as the reprecipitated salt, or a total of 0.425 g., was obtained from 1.116 g. of the substance; calculated, 0.432 g.

Identification of *p*-Aminobenzoic Acid Sulfate.—A sample was dissolved in the least possible *N* potassium hydroxide, and carefully acidified with 2 N hydrochloric acid. At the neutral point, a substance precipitated which was identified as *p*-aminobenzoic acid by mixed melting points. With bromine water it gave trihromoaniline and an ammonia soluble substance. The latter, after reprecipitation with acid, showed a decomposition range of 266–286°. (Reported by Sudborough for dibromo-*p*-aminobenzoic acid, 260–270°.)

Summary

1. A number of aromatic nitro compounds have been reduced with sodium bisulfite, and the solutions thus obtained have been boiled with mineral acids.

3. The quantities of amines and aminosulfonic acids which are produced in this manner have been determined.

3. Several other reduction products have been isolated and identified.

4. A standard procedure for studying the Piria reaction has been adopted, and comparable results thereby obtained.

5. Factors have been pointed out which affect the reaction and require further investigation.

THE PIRIA REACTION. II. THE ROLE OF THE SULFAMINIC ACIDS[1,2]

BY W. H. HUNTER AND MURRAY M. SPRUNG

RECEIVED NOVEMBER 28, 1930 PUBLISHED APRIL 6, 1931

When the acid treatment which follows the reduction of a nitro compound in the "over-all" Piria reaction[3] is omitted, the principal product which can be isolated is a sulfaminic acid salt, of the general formula $RNHSO_3M$. The isolation of an N-sulfonated compound of this type was included among the original findings of Piria,[4] and thereafter similar products were mentioned by other early investigators.[5] However, that these sulfaminic salts were the *chief* products of the reaction when acid treatment was avoided was first emphasized by Weil,[6] who investigated a variety of aromatic nitro compounds, including alkyl nitrobenzenes,

---

[1] The work described in this paper formed part of a thesis submitted to the Graduate Faculty of the University of Minnesota by Murray M. Sprung in partial fulfilment of the requirements for the degree of Doctor of Philosophy, September 1928.

[6] (a) Weil, German Patents 147,552 and 151,134, *Friedländer*, 7, 58, (b) 61 (1902); (c) Weil and Moser, *Ber.*, 55, 732 (1922); *(d)* Weil and Wassermann, *ibid.*, 55, 2533 (1922).

the alkyl esters of nitrocarboxyiic acids, acylaminonitro compounds, nitrophenols, nitroamines and halogenated nitro compounds.

This consideration alone suggests a reasonable mechanism for the course of the "over-all" Piria reaction, which may be stated as follows: in the reduction stage, the nitro group is reduced to an amine or a sulfaminic acid or both; in the acid treatment stage, the sulfaminic acid is partly hydrolyzed to sulfuric acid and the same amine, and is partly rearranged to an aminosulfonic acid. In fact, it was this simple conception of the reaction which we set up as a working hypothesis at the start of our work. It is readily suggested by two considerations.

1. Many investigators have shown that the salts of sulfaminic acids are converted into aminosulfonic acids by baking, and in one or two cases the same is true of the free acid.[7]

2. Weil especially[6b] has pointed out that the addition of concentrated mineral acid aids the transformation of sulfaminic acids to the aminosulfonic acid derivatives. In more or less vague terms, other investigators have mentioned the same reaction.[8]

Against the hypothesis must be considered four opposed considerations.

1. The statement of certain investigators that "dilute" mineral acids hydrolyze the sulfaminic acids quantitatively,[9] though we were unable to find any who stated the concentration of acid used, or gave any quantitative data in support of this contention.

2. Weil himself, in another place,[6b] explicitly states that he does not believe that the sulfaminic acids are transformed into the aminosulfonic acids. He suggests that sulfonation may actually occur in the reduction stage, but offers no experimental evidence, nor any theoretical reason for his opinion.

3. Raschig[10] has suggested a mechanism of formation of sulfaminic acids and amino sulfonic acids, from a hypothetical common intermediate, an arylimino disulfonate, $ArN(SO_3Na)_2$.[11]

[8] We know of only one set of experiments concerning the effect of concentrated acids on sulfaminic acids which was both carefully performed and adequately reported, that of Bamberger and Kunze [*Ber.*, 30, 2274 (1897)], who showed that potassium phenylsulfaminate, when treated with a few drops of concentrated sulfuric acid in glacial acetic acid and allowed to stand for eighty hours in the ice box, was converted to *o*-anilinesulfonic acid and that this, in turn, could be converted to sulfanilic acid by heating at 180–190° with concentrated sulfuric acid.

[9] See, for example, Traube, ***Ber.***, **23, 1653 (1890);** ***ibid.***, **24,360 (1891);** Junghahn, ***ibid.***, **31, 1234 (1898).**

[11] The isolation of a compound of this type has recently been reported by Engel

$$NaSO_3—Ar—NHSO_3Na \xleftarrow{\text{Rearr.}} ArN(SO_3Na)_2 \xrightarrow{\text{Hydrolysis}} ArNHSO_3Na$$

4. Disulfonic acids have been isolated at the end of the acid treatment stage,[12] and their presence is unaccounted for by any scheme ever suggested.

Viewing these conflicting ideas, it seemed that the first constructive step would be to ascertain, not whether sulfaminic acids could be rearranged, but whether they could be rearranged by acid of the concentrations ordinarily used in the acid treatment stage of the Piria reaction. Our own practice being to bring the reaction mixture to a concentration in the neighborhood of 2 *N* with respect to hydrochloric acid, it was decided to take representative sulfaminic acids and subject them to the action of a wide range of acid concentrations on each side of this point, in order to attain quantitative certainty on this single point. At the same time, it was planned that if two parallel reactions were actually found, kinetic studies would be carried out. The event showed, however, that over the range of concentration from about 0.5 to 5.35 N, only hydrolysis occurs. Though the opinion that the sulfaminic acids were not the precursors of the aminosulfonic acids has already been expressed, we believe that this is the first time that quantitative data of this type have been brought forward to settle the point.

Experimental Method

A definitely standardized procedure was employed. Several of the sodium salts of sulfaminic acids were prepared and purified. Weighed samples of these salts (contained in 50-cc. Erlenmeyer flasks) and measured volumes of a standardized hydrochloric acid were brought to temperature in a thermostat. Then the acid was added to the sulfaminate, the flask stoppered, and replaced in the thermostat until the reaction was complete.[13] The contents of the flask were then washed out into a beaker, heated to boiling and a boiling solution of barium chloride added. The precipitate of barium sulfate was filtered, washed, dried and weighed. The weight of sulfuric acid produced was calculated from the weight of the barium sulfate.

Materials

The sodium sulfaminates were prepared by the action of partially neutralized sodium bisulfite upon the corresponding nitro compounds, and

[THIS JOURNAL, 51, 3483 (1929)] in a paper dealing with the cleavage of azo compounds by alkali sulfites.

[12] For example, Walter, German Patent 109,487, *Friedländer*, 5, 70 (1899); Bucherer and Borsch, *J. prakt. Chem.*, [2] 111, 329 (1925); Meister, Lucius und Brüning, German Patent 92,082, *Friedländer*, 4, 528 (1895); and numerous other patent citations.

[13] Preliminary runs, made to determine approximate speeds, indicated that with the most dilute acid used (ca. 0.5 N) the reactions were complete in about forty hours at 40°. The later runs were made in the neighborhood of 50°.

purified by repeated crystallization from water to which a few drops of alkali were added to prevent decomposition. In some cases it was impossible to free them entirely from admixed inorganic salts.

Sodium Phenyl **Sulfaminate.—This** is the most soluble of the salts used, and consequently was the most difficult to purify. After five recrystallizations from water, appreciable quantities of sodium chloride and sodium sulfate were still present. Therefore, to characterize the sulfaminate a small amount of the compound, further recrystallized until free from these salts, was dried for several days in a vacuum desiccator over calcium chloride. On analysis, it was found to contain one molecule of water of crystallization.

Anal. Calcd. for $C_6H_6NSO_3Na \cdot H_2O$: Na, **10.81.** Found: Na, **10.85, 10.90.**

The material which had been crystallized five times was then analyzed and found to contain **6.55%** of sodium chloride, **4.78%** of sodium sulfate and **13.99%** of sodium, total. The composition of the sample was therefore as follows

Na_2SO_4, %............	**4.78, equiv.** to	2.62% Na
NaCl, %..............	6.65, **equiv.** to	1.55% Na
$C_6H_6NSO_3Na \cdot H_2O$, %...	88.58, **equiv.** to	**9.574** Na
	Total	13.74% Na
	Found **by** analysis,	**13.99%** Na

Sodium p-Tolyl **Sulfaminate.—The** salt was purified by several recrystallizations from water and dried in a vacuum desiccator for seven days.

Anal. Calcd. for $C_7H_8NSO_3Na$ (anhydrous): Na, **11.01.** Found: Na, **11.19, 11.28.**

There was still a slight admixture of sodium sulfate, which caused the sodium analysis to be higher than the theoretical. A **0.4-g.** sample gave **0.0071** g. of barium sulfate, equivalent to 0.0030 g. of sulfuric acid, or **1.08%** of sodium sulfate.

Sodium o-Tolyl **Sulfaminate.—A** sample was crystallized from water until free from sodium sulfate. It was dried in a vacuum desiccator over calcium chloride for four days.

Anal. Calcd. for $C_7H_8NSO_3Na$ (anhydrous): Na, **10.13.** Found: Na, **10.25.**

Sodium p-Acetaminophenyl **Sulfaminate.—The** salt was crystallized **from** water until free from inorganic impurities and dried *in vacuo* over calcium chloride for sixty hours. It contained two molecules of water of crystallization.

Anal. Calcd. for $C_8H_9O_4N_2S \cdot 2H_2O$: Na, **8.00.** Found: Na, **8.18, 8.15.**

Results

The sodium sulfaminates were allowed to react with solutions of hydrochloric acid varying in concentration from 0.47 to **5.35** N. The results thus obtained are presented in tabular form.

ANALYTICAL DATA ON THE REACTION BETWEEN SODIUM **SULFAMINATES** AND HCl[a]

.1346	.0004

[a] The reactions were carried out at temperatures between 47–50°, varying not more than ±1° during a given run. [b] The sample contained 4.78% of sodium sulfate, as mentioned above. The sulfate due to this admixture was, of course, considered in the calculations. [c] The sample contained 1.08% sodium sulfate. The correction was applied as before.

For all four of these salts the quantity of sulfuric acid produced was therefore, within analytical error, the amount which should have resulted from complete hydrolysis of the sulfaminate to the corresponding amine and sulfuric acid. This was true for all acid concentrations.

According to the standard procedure used in the study of the "over-all" Piria reaction,[3] the solutions were approximately 2 normal with respect to hydrochloric acid, after the addition of this reagent. Since the quantitative experiments covered a sufficiently wide range of concentrations on either side of this figure, we consider this to be definite proof that sulfaminic acids play no part in the production of nuclear sulfonated compounds during the Piria reaction.

The investigations are being continued in the attempt to discover the intermediate which does give rise to the sulfonated amines.

Conclusions

Several sodium salts of sulfaminic acids have been prepared and carefully purified, and their reactions with varying concentrations of hydrochloric acid studied. It has been shown that with acid concentrations from 0.5 to 5.35 normal, these sulfaminates hydrolyze quantitatively to sulfuric acid and the corresponding amines, giving absolutely no trace of aminosulfonic acids.

Hence the aminosulfonic acids which are produced by the "over-all" Piria reaction are certainly not formed by rearrangement of sulfaminic acids.

It is worthy of passing notice that this work affords one more instance of a suspected indirect substitution, which in fact does not occur.

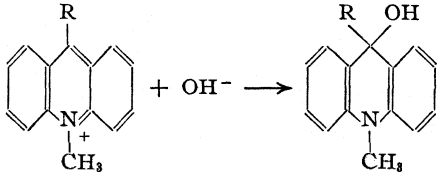
PSEUDO BASES. II. EQUILIBRIA AND RATE OF CHANGE OF TAUTOMERIC BASES IN THE PYRAZINE SERIES. THE EFFECT OF CONJUGATION

BY JOHN G. ASTON

RECEIVED DECEMBER 5, 1930 PUBLISHED APRIL 6, 1931

In this paper is described a kinetic study of the reaction of sodium hydroxide on certain quaternary pyrazinium salts, namely, 1,2,5-trimethylpyrazinium iodide, 1,2,2,5,5-pentamethyldihydropyrazinium iodide and 1,2,2,3,5,5,6-heptamethyldihydropyrazinium iodide, using a conductivity method to follow the progress of the reaction. The bases isolated from these salts were described in the first paper of this series.[1] Further information upon the relationship of these bases to the other possible tautomeric forms is now presented.

Hantzsch and Kalb,[2] in their work on pseudo bases, made a kinetic study of the reaction between aqueous potassium hydroxide and N-methylpyridinium, N-methylquinolinium and N-methylacridinium salts, using a conductivity method to measure the concentration of strong base, and showed that in the first two cases the equilibrium in the system  $[\mathrm{R{-}N{=}C{-}R}]^{+}\ \mathrm{OH}^{-} \longrightarrow \mathrm{R{-}N{-}C(OH){-}R}$ favored the strong quaternary base. In the case of 5-phenyl-10-methylacridinium sulfate quite anomalous results were obtained which were not at all in keeping with the reaction which they postulated



as the rate determining step. However, the compound isolated from the reaction has all the properties of the pseudo base.

Preliminary experiments consisting of solubility determinations described in this paper have shown that the rate determining step is probably the crystallization of the so-called "pseudo base" from the solution and that in the reaction written above the equilibrium is shifted to the right in virtue of the insolubility of the product.

No similar anomalies were found in the pyrazine series, where all the bases are soluble in water. Here there is certain evidence for the type of

---

[1] Aston, THIS JOURNAL, 52, 5254 (1930).

[2] Hantzsch and Kalb, *Ber.*, 32, 3109 (1899).

reaction postulated by Hantzsch in addition to reactions of an entirely different type. These were discussed in the previous paper.

Experimental Method and Results

Preparation of Materials.—1,2,5-Trimethylpyrazinium iodide was recrystallized from absolute alcohol to constant analysis. 1,2,2,5,5-Pentamethyl and 1,2,2,3,5,5,6-heptamethyldihydropyrazinium iodide were recrystallized from methyl alcohol–*n*-butyl alcohol mixtures to constant analysis.

Conductivity water was prepared by distillation from alkaline permanganate with the usual precautions. Its specific conductance was always less than 2 × 10^{-6} ohm^{-1} cm.$^{-1}$.

Sodium hydroxide solutions of known concentration were prepared by dilution of an accurately standardized carbonate-free stock solution with conductivity water.

Standard hydrochloric acid solutions were prepared by dilution of constant boiling hydrochloric acid with conductivity water and their strengths checked gravimetrically. Potassium chloride, used for cell constant determination, was recrystallized to constant conductivity.

Apparatus for Measuring Conductivities.—A Wheatstone bridge arrangement was used.[3]

A calibrated Kohlrausch slide wire bridge with end coils, an enclosed dial six decade resistance box, wound for use with high frequencies, and Brown tunable telephone receivers with a total resistance of 120 ohms were used. The alternating current (1000 cycles) was furnished by a microphone hummer. These instruments were those furnished by Leeds and Northrup. The bridge was neither grounded nor shielded.[4] The lead resistances were each 0.05 ohm. The capacity of the conductivity cell was balanced in all measurements with suitable fixed and variable radio condensers. Readings were always taken within a few tenths of a per cent. of the center of the bridge. A thermostat was used which kept constant temperature to 0.01°. It was filled with ordinary water grounded through the cooling coils. Temperatures were measured accurately to 0.05° by thermometers certified by the Bureau of Standards.

Weights and volumetric apparatus were calibrated.

Conductivity of 1,2,5-Trimethylpyrazinium Iodide.—Washburn conductivity cells were used, Type B for solutions above 0.002 N and Type A for more dilute solutions. The constant of cell B was determined at 25.11° to 0.03% using a solution containing 0.7455 g. of potassium chloride in 500 cc., which has a specific conductance of 0.002770 at 25.10° according to Kohlrausch.[5] The Kohlrausch standard was used because the data were to be used in conjunction with other data using this standard. The constant of cell A was measured to 0.05% by intercomparison with cell B.

The 1,2,5-trimethylpyrazinium iodide used was found to have an equivalent weight of 252.8 (calcd., 250.05) by the Volhard method. Solutions were made up by dissolving weighed quantities of salt and diluting to a known volume with conductivity water. The found equivalent weight was used in computing the normality. All conductivity measurements were made at 25.11° with a precision of at least 0.05%. The results are given in Table I.

The values of the specific conductance (Col. 2) have been corrected for the specific conductance of the water. The limiting equivalent conductance Λ_0 was obtained using the extrapolation method of Randall.[6]

TABLE I

CONDUCTIVITY OF 1,2,5-TRIMETHYLPYRAZINIUM IODIDE AT 25°

G. per liter	Specific conductance ohm^{-1} cm.$^{-1}$ × 10^3	Concn. eqts. per liter × 10^2	Λ	$\frac{\Lambda}{\alpha \text{ LiIO}_3}$
15.758	5.467	6.235	87.65	106.9
7.878	2.953	3.115	94.75	109.95
3.950	1.5705	1.5630	100.5	112.3
1.971	0.8143	0.7795	104.5	113.4
0.9830	.4153	.3889	106.8	113.4
.24575	.1081	.09720	113.1	114.8
	Extrapolated 0		115.0	

The values of the equivalent conductance Λ (Col. 4) were divided by $\alpha = \Lambda/\Lambda_0$ for lithium iodate at 18° at the same concentration, obtained from his tables. The quotients thus obtained (Table I, Col. 5) were plotted against $\sqrt{C}$ and the curve extrapolated to zero concentration. The value of Λ_0 thus obtained was checked by reference to the Λ/Λ_0 values for hydrochloric acid. The two agreed within 0.4%. By subtracting the value of the limiting conductance of the iodide ion at 25.11° ($\Lambda_{0I} = 76.7$)[7] from this value of Λ_0, the limiting conductance of the positive ion is found to be $\Lambda_{0Py^+} = 38.3$ at 25.11°.

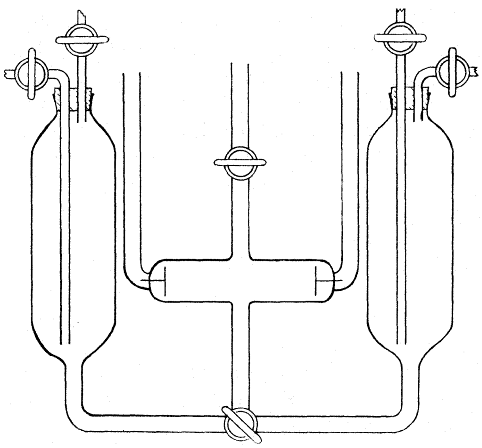

Fig. 1.—Mixing apparatus and cell.

By the use of indicators it was estimated that the basic nitrogen atom in 1,2,5-trimethylpyrazinium iodide had a basic dissociation constant of less than 3×10^{-10}, corresponding to less than 0.02% dissociation in 0.001 N solution. The effect of basic dissociation is thus not detectable in our measurements and does not affect the value of the limiting conductance.

Kinetics of the Reaction of 1,2,5-Trimethylpyrazinium Iodide and Sodium Hydroxide.—The mixing apparatus and cell used in this reaction is illustrated in Fig. 1.

The quantities of the solutions of alkali and salt to be mixed were placed, respectively, in the two cylinders, which were then swept out with a current of carbon dioxide-free nitrogen and allowed to reach the temperature of the thermostat. The solutions were then mixed by forcing the contents of one cylinder completely into the other. The start of the reaction was taken as the end of this operation. Thorough mixing was effected by a

---

[7] Noyes, THIS JOURNAL, 34, 479 (1912).

current of nitrogen and forcing the mixture back and forth from one cylinder into the other. The solution was then forced into the conductivity cell, which had been previously swept with nitrogen. The constant of this cell was determined as previously. A measurement of the conductivity of the mixture was made as soon as possible after mixing and at

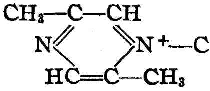
convenient intervals thereafter. Times were measured using an ordinary watch except for the first part of the reaction, when a stop watch was used. The conductivity of the mixture at zero time was obtained by extrapolation. Representative results of runs at different concentrations are given in the Tables II, III, IV.

In Cols. 1 and 2 are given, respectively, the time after the start of the reaction (*t*) and the value of the specific conductance (κ) of the reacting solution at that time. Duplicate experiments showed that values of κ were reproducible to 0.1%.

Initially the reacting solution contains the ions

Na^+, I^-,



(denoted by Py$^+$) and OH−

Its initial conductivity shows that the base formed from the last two ions is a strong electrolyte. The fall in conductivity is due to the change of this base into one very much weaker whose dissociation will be assumed to be negligible. The four strong electrolytes which can be formed from the above ions will be assumed to be completely dissociated. In Tables II and III, Col. 3, and Table IV, Cols. 3 and 4, the calculated concentrations of Py$^+$ and OH− are given.

At the end of the runs where equivalent quantities of the salt and sodium hydroxide are mixed, the final solution will contain the weak base and sodium iodide at concentrations equal to those of the reactants, $a = b$, at the start. At any previous time during the reaction, the composition of the solution with respect to the ions would be reproduced by adding 1,2,5-trimethylpyrazinium hydroxide (x equivalents per liter) to the final solution until the conductivity reached the measured value, assuming the effect of the weak base to be negligible, so that $(\mathrm{Py}^+) = (\mathrm{OH}^-) = x$.

In the run with the sodium hydroxide in excess of the pyrazinium salt, their initial stoichiometrical concentrations in the mixture being, respectively, a and b, the final concentrations of sodium iodide and sodium hydroxide are b and $(a - b)$ at any previous time $(\mathrm{Py}^+) = x$ and $(\mathrm{OH}^-) = x + a - b$, where x has the same significance as before.

If Λ/Λ_0 were unity for all the electrolytes, x could be calculated from the difference between the observed and final values of the specific conductance using the value of Λ_0 for the pyrazinium hydroxide. As this was not the case, x was calculated by a method similar to that which Sherrill used to calculate the conductivity of mixtures of potassium sulfate and sodium chloride.[8] This method gave values accurate to 0.1%. Although based on the theory of constant ion mobility and incomplete dissociation, its validity as an empirical method is not altered when complete ionization is assumed. It amounts to applying corrections for the changing deviation of the Λ/Λ_0 values from unity. In making the calculations the following data were used: limiting conductances of the four ions at 25.11°, $\Lambda_{0\mathrm{Na}^+} = 51.3$, $\Lambda_{0\mathrm{I}^-} = 76.7$, $\Lambda_{0\mathrm{OH}^-} = 193.0$,[9] $\Lambda_{0\mathrm{Py}^+} = 38.3$, and also plots of "$K$" $= (\Lambda/\Lambda_0)^2C/1 - \Lambda/\Lambda_0$ against $\Sigma i = \Lambda/\Lambda_0 C$ for sodium iodide, sodium hydroxide, 1,2,5-trimethylpyrazinium iodide and its hydroxide for which the following values were used: NaI:Σi: 0.05439, 0.02800, 0.00733; "K": 0.3639, 0.2428, 0.1119;[10] NaOH:Σi: 0.04421, 0.01818, 0.00943, 0.00829, 0.006698; "K": 0.6635, 0.3743, 0.2809, 0.2469, 0.2324;" PyI: Σi: 0.04752, 0.02568, 0.01366, 0.007085; "K": 0.1522, 0.1202, 0.09433, 0.07085. Values of Σi and "K" for the pyrazinium hydroxide were obtained from the extrapolated zero time value of the specific conductance in each of the runs where the concentrations of all the substances present are known, using the Σi — "K" curves for the other three salts and the limiting conductances of the four ions, by a method obvious from the definitions of these quantities and the calculations in Sherrill's paper.

The values thus obtained were: PyOH:Σi: 0.05028, 0.02153, 0.01413; "K": 0.7585, 0.2012, 0.1647. Comparison with the values of "K"

---

[8] Sherrill, THIS JOURNAL, 32, 741 (1910).

[9] Values obtained from the tables of Noyes and Falk, THIS JOURNAL, 34, 479 (1912), the temperature coefficients of Kohlrausch, Landolt–Börnstein–Roth–Scheel, "Tabellen," 1923, p. 1104, and the data of Randall and Scalione for NaOH, THIS JOURNAL, 49, 1491 (1927).

[10] From the data of Jones, Landolt–Börnstein–Roth–Scheel, "Tabellen," 1923, p. 1091.

[11] From the data of Randall and Scalione, Ref. 9.

for sodium hydroxide shows that the base is a strong electrolyte. The calculation of x from the observed specific conductances is most simply made by Plotting for each run the concentration of pyrazinium hydroxide against the specific conductance, calculated by Sherrill's method for mixtures of sodium iodide and sodium hydroxide at the fixed concentrations b and $a - b$, with the pyrazinium hydroxide at various rounded concentrations. Values of x are then read from the plot.

The values of k_3 in Tables II and III, Col. 4, and Table IV, Col. 5, are calculated from the equation

$$\frac{d(Py^+)}{dt} = \frac{d(OH^-)}{dt} = k_3(Py^+)^2(OH^-) \tag{1}$$

applying to the consecutive reactions

$$2Py^+ + OH^- \longrightarrow (products)^+ \tag{a-1}$$

$$(products)^+ + OH^- \longrightarrow products \tag{a-2}$$

(a-1) controlling the rate $d(Py^+)/dt$.

Those of k_4 in Tables II and III, Col. 5, and Table IV, Col. 6, are calculated from the equation

$$\frac{d(Py^+)}{dt} = \frac{d(OH^-)}{dt} = k_4(Py^+)^2(OH^-)^2 \tag{2}$$

applying to the reaction

$$2Py^+ + 2OH^- \longrightarrow products \tag{b}$$

Both k_3 and k_4 are instantaneous values calculated by the method of Bray,[12] using the slopes of tangents to plots of $1/(2Py^+)^2$ against the time when $(Py^+) = (OH^-)$ and of $1/(Py^+)$ against the time when $(OH^-) > (Py^+)$. The plot of $1/2(Py^+)^2$ against time for the data in Table III is shown in Fig. 2. The values of k_3 and k_4 are accurate to about 5%. **A comparison** between trends of their values points to a simultaneous disappearance of base by reactions (a-1) and (b), whence

$$\frac{d(Py^+)}{dt} = k'_{iii}(Py^+)^2(OH^-) + k'_{iv}(Py^+)^2(OH^-)^2 \tag{3}$$

where k'_{iii} and k'_{iv} are, respectively, the true specific reaction rate constants of (a-1) and (b). Combination of (1) and (3) gives

$$k_3 = k'_{iii} + k'_{iv}(OH^-) \tag{4}$$

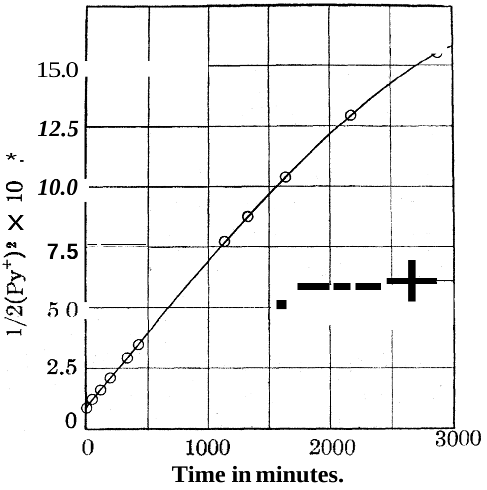


Fig. 2.—*Graph from data* in Table III.

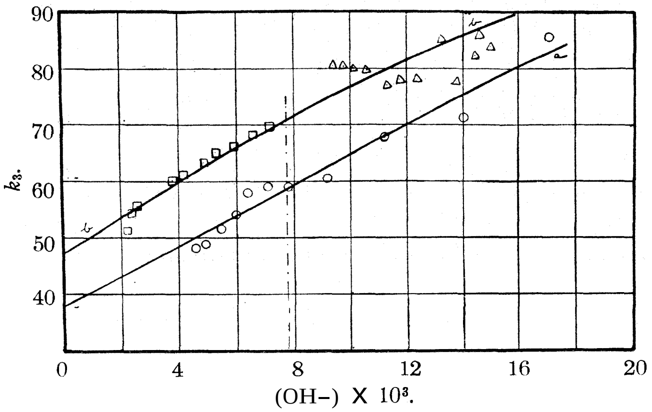
---

[12] Bray, *J. Phys. Chem.*, 9, 573 (1906).

Since k'_{iii} and k'_{iv} will vary with the salt concentrations, for any particular starting concentrations (4) defines a curve. If such a curve can be extrapolated to (OH−) = 0 at this point $k_3 = k'_{\text{iii}}$ gives the value of k'_{iii} at the total salt concentration which the solution reaches when (OH−) = 0. Thus, in general, (4) defines a family of curves. In Fig. 3 the values of k_3 for each of the runs are plotted against (OH−). The data of Tables II and III lie on two distinct curves aa and bb. Extrapolation of each curve to (OH−) = 0 gives $k'_{\text{iii}} = 38$ and $k'_{\text{iii}} = 47$, respectively. The only electrolyte present at (OH−) = 0 in both cases is sodium iodide at concentrations 0.03118 and 0.00771, respectively. According to the Brönsted[13] theory of reaction rate, the limiting relation for the effect of salts on the specific reaction rate constant k' for a reaction between ions of the type, $2A + B \longrightarrow$ products, is



⊙, Table II; ⊡, Table III; △, Table IV.

Fig. 3.—Effect of (OH−) and concn. of total salt on k_3.

$$\log k' = \log k + (Z_A^2 + 2Z_AZ_B)\sqrt{\mu}$$

where μ is the ionic strength of the solution and Z_A and Z_B are the charges on the ions, k being the value of the constant when $\mu = 0$.

For the above reactions where all the electrolytes are uni-univalent, μ is the total concentration of electrolyte, $Z_A = +1$ and $Z_B = -1$ whence

$$\log k'_{\text{iii}} = \log k_{\text{iii}} - \sqrt{\mu} \tag{5}$$

Similar considerations give rise to the limiting equation

$$\log k'_{\text{iv}} = \log k_{\text{iv}} - 2\sqrt{\mu} \tag{6}$$

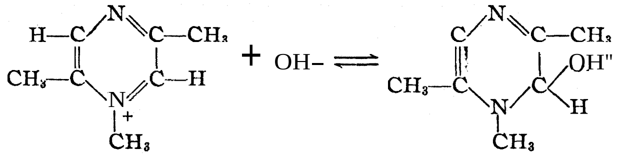
for calculating the effect of salt on k'_{iv}. Using (5) and the value of $k'_{\text{iii}} = 47$ at $\mu = 0.00771$ obtained by extrapolation of bb to (OH−) = 0, it is found that $k_{\text{iii}} = 57.5$ at $\mu = 0$ and that $k'_{\text{iii}} = \mathbf{38.3}$ at $\mu = 0.03118$. The agreement of this value with that obtained by extrapolating curve aa

---

[13] Bronsted, Z. *physik.* Chem., 102, 169 (1922); Bronsted and Livingston, THIS JOURNAL, 49, 439 (1927); Beard and Taylor, *ibid.*, 51, 1975 (1929).

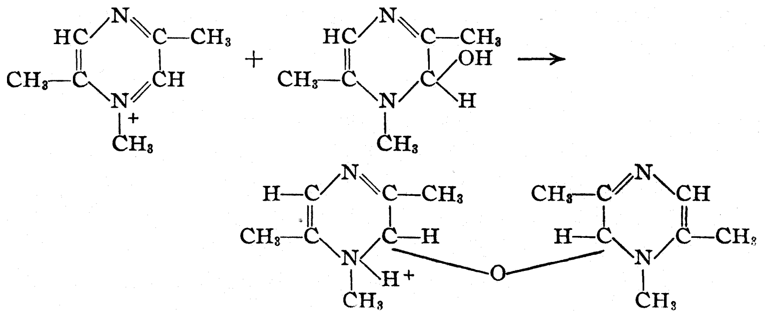
is closer than the accuracy of the extrapolation or that of (5) at such high values of the ionic strength. The data of Table IV are in accord with our assumptions. At the end of this run the values of (OH–), the sodium iodide concentration, and the total salt concentrations are the same as those at the start of the run in Table III. This point is indicated in Fig. **3** by the broken vertical line. The two sets of data fall into the same curve bb at this point. For the run in Table III after 19.5 minutes, when $\mu = 0.01486$, the value of $k'_{\text{iii}} = 43.44$ (calculated from (5) and $k_{\text{iii}} = 57.5$ at $\mu = 0$). From the values $k_3 = 69.9$ and (OH–) $= 0.00715$ at this point, using (4), $k'_{\text{iv}} = 37.1$ X 10^2. By relation (6) k_{iv} at $\mu = 0$ is then calculated to be 65.0 X 10^2. The values of k_3 calcd. in Table III (Col. 6) and Table IV (Col. 7) are calculated from the above values of k_{iii} and k_{iv} at $\mu = 0$ and (OH–) using relations (5), (6) and (4). The agreement with the experimental values is within the experimental error. Further, relations (5) and (6) are limiting relations which, although holding quite well when $\mu < 0.01$, become far from accurate as μ increases. For this reason no values of k_3 calcd. are given for Table II.

Since, from statistical considerations, reaction through triple or quadruple collisions is generally regarded as improbable, reactions (a-1) and (b) must be considered as taking place in two steps, the first step being a rapid equilibrium and the second a dimolecular reaction. It will be assumed that both (a-1) and (b) have the same reversible step



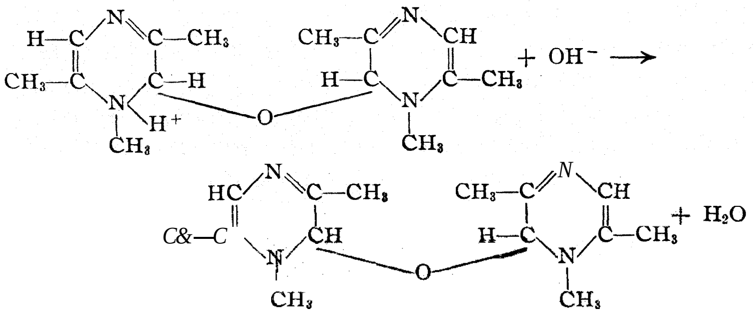
(A)

The initial value of the conductivity points to only very small equilibrium amounts of the pseudo base. Denoting the pseudo base by P – OH, $K_A = (\text{P} - \text{OH})/(\text{Py}^+)(\text{OH}^-)$ is the equilibrium constant of reaction A. If this is followed by the slow reaction



(B-1)

succeeded by the rapid reaction



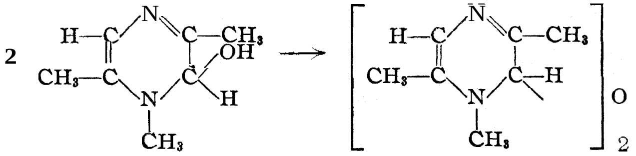
(B-2)

(B-1) therefore controlling the rate of the entire process, then

$$\frac{d(Py^+)}{dt} = k_B(P - OH)(Py^+)$$

$$\frac{d(Py^+)}{dt} = K_A k_B (Py^+)^2(OH^-) = k'_{iii}(Py^+)^2(OH^-).$$

If the slow reaction taking place is



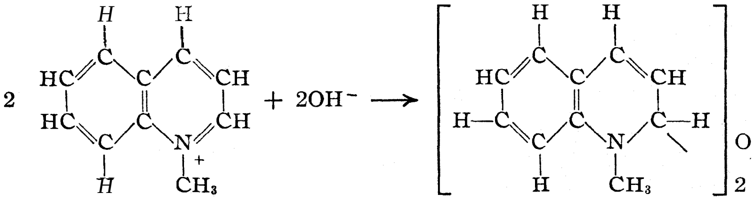
(C)

yielding the same ether as above

$$\frac{d(Py^+)}{dt} = \frac{d(P - OH)}{dt} = k_c(P - OH)^2 = K_A^2 k_c (Py^+)^2(OH^-)^2$$

$$dt \quad = k'_{iv}(Py^+)^2(OH^-)^2.$$

The formation of such ethers is characteristic of pseudo bases in the quinoline series.[14] Hantzsch and Kalb found that such an ether precipitated from dilute solution of N-methylquinolinium hydroxide (*N*/16)



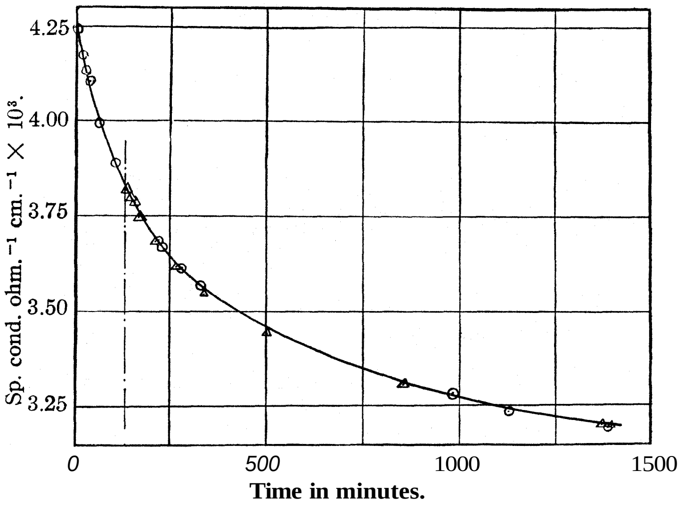
with a corresponding decrease in conductivity.[2] Such ethers yield the salt of the original base upon treatment with acid.[2,15] It has been shown that the final product obtained in the above reactions can be changed back into the original pyrazinium salt by the addition of acid. A run was made using the same concentrations as that in Table II in which 25

---

[14] La Coste, *Ber.*, 15, 189 (1882).

[15] Decker, *ibid.*, 35. 3073 (1902).

cc. of 0.06237 N sodium hydroxide and 25 cc. of 0.06237 N 1,2,5-trimethylpyrazinium iodide were allowed to react for 307 minutes (83.6% completion) in the absence of oxygen, at 25.00'; 50 cc. of 0.06268 N hydrochloric acid was then added and the mixture allowed to stand for six days at 25.00'; 25 cc. of this mixture was then mixed with 25.0 cc. of 0.03128 N sodium hydroxide at 25.11° in the apparatus of Fig. 1. The conductivity of the solution was followed and compared with that of a blank, using exactly the same quantities but adding the 0.06268 N hydrochloric acid before the original sodium hydroxide, and thus preventing the original reaction. The values of the specific conductance at various times after mixing are shown in Fig. 4 for both runs. The zero time for the blank run is at zero, that for the reversed run is indicated by the broken vertical line at 130 minutes, the time scales being the same. Both sets of data are thus seen to lie on the same curve. The results show that 72.8% of the original salt was present after reversal; that is, that 67.5% of the reacted 1,2,5-trimethylpyrazinium iodide had been regenerated.



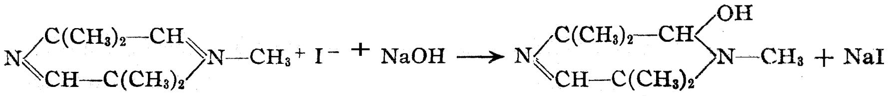
⊙, Blank; A, reversed run.

Fig. 4.—Specific conductances in reversed and blank runs

An attempt to isolate this ether, described in the previous paper, resulted in a product which decomposed so rapidly that analytical evidence as to its nature was meaningless. Its reactions are now being studied.

The reactions B and C above present certain analogies with hemiacetal and acetal formation, respectively. Such reactions are known to occur simultaneously.

The Reaction between 1,2,2,5,5-Pentamethyldihydropyrazinium Iodide and Sodium Hydroxide in Water at 0°.—A preliminary study of this reaction by the method just described showed that the changes were too rapid to measure both at 25 and 0°. When equivalent quantities of the two solutions were mixed the conductivity of the solution was 14% greater than that calculated for a concentration of sodium iodide,[16] corresponding to that formed in the reaction



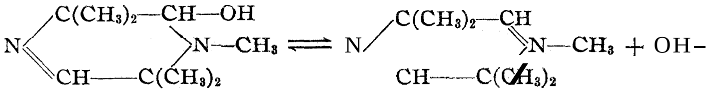
Pseudo base

which has already been shown to take place by the isolation of the pseudo base.[1]

Ten cc. of 0.01092 N sodium hydroxide was mixed with 10 cc. of 0.01092 *N* 1,2,2,5,5-pentamethyldihydropyrazinium iodide (specific conductance 5.59×10^{-4} ohm^{-1} cm.$^{-1}$ at 0°. The observed specific conductance of the solution immediately after mixing at 0° was 4.06×10^{-4} ohm^{-1} cm.$^{-1}$ calculated for 0.00546 N NaI at 0°, 3.57×10^{-4} ohm^{-1} cm.$^{-1}$; diff. due to base, 0.49×10^{-4}).[17]

A value of the limiting equivalent conductance at 25.00° $\Lambda_0 = 109.6$ for 1,2,2,5,5-pentamethyldihydropyrazinium iodide was calculated approximately from $\Lambda = 97.6$ at 0.01092 N, measured at 25.00°, assuming $\Lambda/\Lambda_0 = 0.89$ (the value for 1,2,5-trimethylpyrazinium iodide at the same concentration). For 1,2,2,5,5-pentamethyldihydropyrazinium hydroxide $\Lambda_0 = 226.9$ at 25.00° calculated from Λ_0 for the iodide and the limiting equivalent conductances $\Lambda_{0OH^-} = 192.7$ $\Lambda_{0I^-} = 76.5$ at 25.00°.

Below are given values of K for the equilibrium



calculated from conductance measurements on 1,2,2,5,5-pentamethyl-6-hydroxytetrahydropyrazine, using the relationship $K = (\Lambda/\Lambda_0)^2C/(1 - \Lambda/\Lambda_0)$, taking $\Lambda_0 = 226.9$ as found above.

TABLE V

EXPERIMENTAL DATA

Concn. eqts./liter	Specific conductance ohm^{-1} cm.$^{-1}$ $\times 10^5$	Λ	Λ/Λ_0	$K \times 10^6$
0.00589	6.21	10.6	0.0466	1.34
.01100	7.59	6.9	.0303	1.34

The values of the specific conductance taken within fifteen minutes of mixing increased 60% on standing for twenty-four hours. They are in rough agreement with the difference obtained above at 0° (0.49×10^{-4}

---

[16] Compare Stewart and Maeser, THIS JOURNAL, 46, 2583 (1924).

[17] From the data of Jones, "International Critical Tables," Vol. VI, p. 235.

ohm^{-1} cm.$^{-1}$ due to 0.005 N solution of the base). These values of K are probably much too high for the pseudo basic system which, in the previous paper, was shown to be a weaker base than the unmethylated nitrogen, to which therefore a large part of the conductivity must be due. The complete stability of the base in water for intervals of at least an hour was shown in the previous paper and therefore these results indicate that the equilibrium between 1,2,2,5,5-pentamethyldihydropyrazinium hydroxide and 1,2,2,5,5-pentamethyl-6-hydroxytetrahydropyrazine is established rapidly and greatly favors the latter.

Conductivity of 1,2,2,3,5,5,6-Heptamethyldihydropyrazinium Iodide at 25.00°.—Two Freas conductivity cells with cell constants 0.3496 and 0.3370 were used. The constants were determined using a solution of 0.7476 g. of potassium chloride in 1000 g. of water whose specific conductance was taken as 0.0014104 (the Kohlrausch value corrected to the standards of Parker and Parker).[18] The results are given in Table VI. The theoretical equivalent weight of 308.2 was used in the computations. The accuracy is the same as previously.

TABLE VI

CONDUCTIVITY OF 1,2,2,3,5,5,6-HEPTAMETHYLDIHYDROPYRAZINIUM IODIDE AT 25.00°

G. per liter	Specific conductance, ohm^{-1} cm.$^{-1}$ × 10^3	Concn. eqts. per liter × 10^2	Λ	$\frac{\Lambda}{\alpha \text{ std.}}$[a]
3.438	1.0343	1.1155	92.8	104.4
3.387	1.0148	1.0985	92.5	103.9
1.695	0.5283	0.5500	96.1	104.5
0.8468	.2708	.2748	98.5	104.5
.8465	.2694	.2746	98.2	104.2

	Extrapolated	0	104.7	104.7

[a] α std. = Λ/Λ_0 for 1,2,5-trimethylpyrazinium hydroxide.

The value of Λ_0 was obtained using the extrapolation method of Randall. From $\Lambda_{0\,I^-} = 76.9$ and $\Lambda_{0\,OH^-} = 194.0$,[19] the limiting equivalent conductance of 1,2,2,5,5,6-heptamethyldihydropyrazinium hydroxide at 25.00° was calculated to be $\Lambda_0 = 222.0 \pm 1\%$.

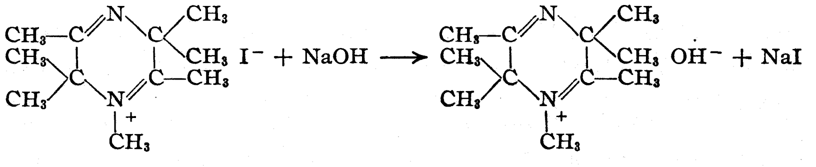
The Reaction between 1,2,2,3,5,5,6-Heptamethyldihydropyrazinium Iodide and Sodium Hydroxide in Water at 25.00°.—This reaction was studied using the same Freas cells at 25.00 ± 0.05°. 10 cc. of the solution of the pyrazinium salt was allowed to come to temperature in the thermostat; 10 cc. of the sodium hydroxide solution, withdrawn from the thermostat, was then introduced into the cell by a pipet and the contents of the

---

[18] "International Critical Tables," Vol. VI, p. 230.

[19] Calculated from data in "International Critical Tables," Vol. VI, p. 230, $\Lambda_{0\,OH^-}$ being somewhat weighted by comparison with a value calculated from the data of Randall on sodium hydroxide.

cell mixed by thorough shaking in the thermostat. The temperature in the cell immediately after mixing, by actual test, was never more than 0.1" above that of the thermostat, due to the transference of the sodium hydroxide. The conductivity of the solution was measured as soon as possible after mixing. The specific conductances of certain mixtures at various time intervals are given in Col. 2, Tables VIII, IX, X and XI, the times being given in Col. 1. To save space only a few of the values are given for each run. The zero time values were obtained by extrapolation. Times were measured as before. The fall in conductivity is due to the slow production of a weaker base, whose dissociation was shown to be negligible from the final conductivity of the reaction mixture. For the runs using equal quantities the initial specific conductance due to the base was obtained from the extrapolated zero time values of the specific conductance by subtracting the estimated specific conductance due to the sodium iodide assuming that the metathesis reaction



(A)

takes place completely. For the runs where excess of the dihydropyrazinium iodide was present the estimated specific conductance of this excess was also subtracted. The values of A for sodium iodide and the dihydropyrazinium iodide used in the calculation were read from plots of Λ against $\sqrt{C}$ and were taken at a concentration equal to the sum of the over-all concentrations of the sodium iodide and dihydropyrazinium iodide plus the concentration of ionized pyrazinium base. A decrease in the mobility of one pair of ions due to the presence of the remaining ions was thus corrected for as far as possible. The data on sodium iodide were from Jones.[20] Assuming that the pyrazinium base yielded the same positive ion as the salt, the limiting equivalent conductance of the base was taken as that of 1,2,2,3,5,5,6-heptamethylpyrazinium hydroxide $\Lambda_0 = 222.0$. This does not allow for a decrease in mobility of the type mentioned above. The error thus introduced is probably not more than 5%. From these results the values of the basic dissociation constants in Table VII were calculated. The concentrations of the pyrazinium base, C_b, pyrazinium iodide, C_{PyI}, and sodium iodide, calculated on the assumption of complete metathesis, are given in Cols. 1, 2 and 3, respectively. Columns 4 and 5 contain, respectively, the total specific conductance and that due to the base. The calculated values of Λ/Λ_0 for the base are given in col. 6. The values of K_B given in Col. 7 are calculated from the relations

[20] "International Critical Tables," Vol. VI, p. 230

$$K_B = \frac{(\Lambda/\Lambda_0)^2 C_b}{1 - \Lambda/\Lambda_0} \quad (1)$$

$$K_B = \frac{\Lambda/\Lambda_0 C_b \,(C_{PyI} + \Lambda/\Lambda_0\, C_b)}{(1 - \Lambda/\Lambda_0)\, C_b} \quad (2)$$

where C_b and C_{PyI} are, respectively, the concentrations of pyrazinium base and iodide. Relation 1 was used when C_{PyI} was zero and relation 2 when the pyrazinium iodide was present.

In Col. 3, Tables VIII, IX, X and XI, the values of the concentration of pyrazinium base whose dissociation constant is calculated above were estimated from the total specific conductance given in Col. 2 with the aid of graphs prepared for each run as follows: the specific conductance due to rounded concentration of the base was estimated from the Λ/Λ_0 values calculated from K_B appearing at the head of the table using either (1) or (2). The specific conductances, calcuated as above, due to the sodium iodide and to the pyrazinium iodide, when present, were added

and when no excess of either ion is present

$$\frac{dC_b}{dt} = k(\Lambda/\Lambda_0)^2 C_b^2$$

$$\frac{d\frac{1}{C_b}}{dt} = (\Lambda/\Lambda_0)^2 k = \alpha^2 k \qquad (4)$$

For the runs in Tables VIII, IX and X, where the reactants were in equal concentrations, the values of $1/C_b$ were plotted against t. Such a plot from the data of Table VIII is given in Fig. 5. The slopes of the tangents to these curves are given in Col. 4 of these tables. Column 6 gives the values of k calculated from these slopes using Equation 4, and the values of $a = \Lambda/\Lambda_0$ (Col. 5), calculated from (1) and the value of K_B. For the run in Table XI, where the reactants were not equal, the values of k in Col. 7 were calculated by Equation 3 from the slopes of the tangent to a plot of the concentration of pyrazinium base against time (Col. 4), and the values of $(OH^-) = \Lambda/\Lambda_0 C_b$ and $(Py^+) = \Lambda/\Lambda_0 C_b + 0.002747$ (Cols 5 and 6), $\alpha = \Lambda/\Lambda_0$ being calculated from (2).

The Rate of Disappearance of 1,2,2,3,5,5-Hexamethyl-6-methylenetetrahydropyrazine from its Water Solutions at 25.00°.—This base was obtained as an oil on adding 40% potassium hydroxide to solutions of 1,2,2,3,5,5,6-heptamethyldihydropyrazinium iodide. It was described in the previous paper. A freshly distilled sample (b. p. (6.5 mm.) 78°) was used. Twenty cc. of water in the type of cell used in the previous experiment was allowed to come to equilibrium with the thermostat;

0.0489 g of base was added and the cell shaken. The change in conductivity of the resulting **0.01357** *M* solution was observed as it fell with

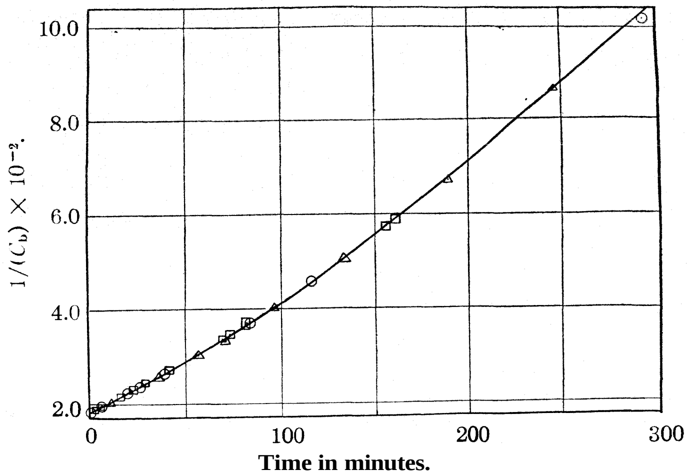

Fig. 5. —Graph from the data of Table VIII: ⊙, El, △, respective points of three runs.

the time. Zero time was taken as that just after shaking. The results are given in Table XII. From the extrapolated zero time value of the

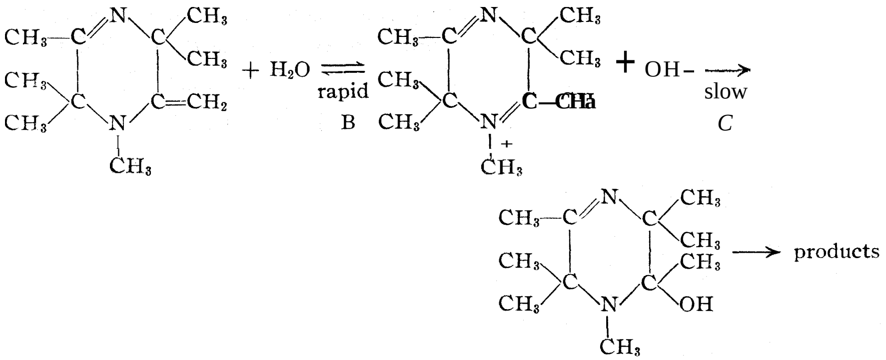
specific conductance, **1.226** $\times 10^{-2}$ ohm^{-1} cm.$^{-1}$, assuming dissociation into 1,2,2,3,5,5,6-heptamethyldihydropyrazinium and hydroxide ions (*i. e.*, $\Lambda_0 = 222$) a value of K_B for the dissociation B



was calculated. This gave

$$K_B = \frac{(\mathrm{Py}^+)(\mathrm{OH}^-)}{(\text{undissociated base})} = \frac{(\Lambda/\Lambda_0)^2}{1 - \Lambda/\Lambda_0} = 3.79 \times 10^{-3}$$

which compares very favorably with those in Table VII. The difference is probably caused by the uncertainty of the extrapolation due to difficulty in estimating the starting time. The concentrations of the base (C) given in Col. 3, Table XII, are calculated from the specific conductances in Col. 2, assuming $K_B = 4.1 \times 10^{-3}$ (taken from Table VII). Column 6 gives the values of k calculated from the a-values in Col. 5 and the slopes of the tangents to the curve $1/C$ against time (Col. 4), using Equation 4 as was done in Tables VIII to X, with which the results agree quite well.

These results show that on mixing 1,2,2,3,5,5,6-heptamethyldihydropyrazinium iodide with sodium hydroxide, the equilibrium B is rapidly established, giving rise to the same system yielded by dissolving 1,2,2,3,5,5-hexamethyl-6-methyl-tetrahydropyrazine in water. In the previous paper the decrease in basicity of the solution was shown to be accompanied by decomposition. Reversal experiments as in the case of 1,2,5-trimethylpyrazinium hydroxide pointed to decomposition also. The rates show that this decomposition is probably controlled by the rate of formation of the pseudo base from its ions (reaction C above). In support of this view, the strong basicity of the system indicates that equilibrium, with the pseudo base, which, as in the case of 1,2,2,5,5-pentamethyldihydropyrazinium hydroxide, would give rise to a weak base, is not reached. Consequently, as was pointed out in the previous paper, the equilibrium B must be reached through an enolic type of change, not through the pseudo base.

Methylphenylacridinium Hydroxide.—In Fig. 6 is shown a graph of $1/(\Lambda - \Lambda_0)$ against the time where Λ is the total equivalent conductance of the solution at various times after mixing 1/128 N solutions of 5-phenyl-10-methylacridinium chloride and sodium hydroxide at 0° and

Λ_∞ is the equivalent conductance due to sodium chloride at the end of the reaction at 0°.[21] $\Lambda - \Lambda_\infty$ is thus the equivalent conductance of methylphenylacridinium hydroxide. This graph points to a heterogeneous reaction.

5-Phenyl-10-methylacridinium hydroxide (methylphenylacridol) was precipitated from phenylmethylacridinium sulfate with sodium hydroxide and its solubility determined at room temperature (25°) by shaking the base with boiled distilled water. The excess solid was filtered off and an excess of sulfuric acid added. The concentration of phenylmethylacridinium salt in the resulting solution was estimated colorimetrically by comparison with a solution of 5-phenyl-10-methylacridinium sulfate of known concentration containing the same concentration of acid. The original yellow color of the solution of the base did not change in shade or intensity on adding the acid. Since the solid base is colorless, this indicates that the color of the solutions of the salt and base are due to the acridinium ion, and that in the saturated solution the phenylmethylacridinium hydroxide is almost completely ionized. The solubility was found to be 1.25×10^{-4} mole per liter. This value is 3.2% of the concentration responsible for the initial $1/\Lambda - \Lambda_\infty$ value in Fig. 6, which must, therefore, be due to supersaturation. The fall in conductivity is due to precipitation from the supersaturated solution. The value of $\Lambda - \Lambda_\infty$ at equilibrium should, therefore, be less than 3.2% of the initial value, since the solubilities were determined at 25°. The corresponding value of $1/\Lambda - \Lambda_\infty$ is seen to be in agreement with this. It thus appears that the equilibrium in the reaction

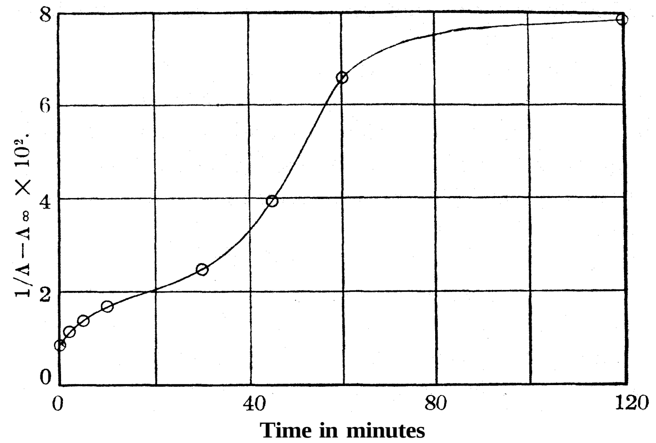


Fig. 6.—Graph of Hantzsch's data on phenylmethylacridinium hydroxide.

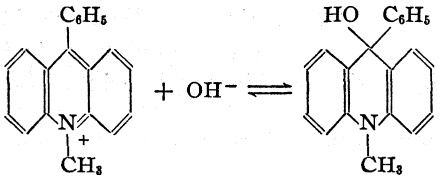
---

[21] Hantzsch and Kalb, Ref. 2. For convenience these authors' terms are used.



is shifted to the right due to the insolubility of the base, which is largely ionized into the two ions on the left. The rate-controlling step in the measurements of Hantzsch is this rate of crystallization.

Discussion of Results

On the basis of the above results and a reinterpretation of the data of Hantzsch and Kalb, it seems that the position of equilibrium in the reaction

$$(\mathrm{R{-}N{=}CH^+}) + \mathrm{OH^-} \rightleftharpoons \mathrm{R{-}N{-}CH{-}OH}$$

Pseudo base

depends on the conjugation in the ring and the tendency of the N=C double linkage to add OH–. In the case of 1,2,5-trimethylpyrazinium hydroxide and 5-phenyl-10-methylacridinium hydroxide, for example, the equilibrium is to the left.

The experiments of Hantzsch and Kalb[2] and of Decker[22] have demonstrated this to be true also for methylpyridinium, methylquinolinium, and methylisoquinolinium hydroxides. In all of these compounds the ring is completely conjugated. In the quinolinium series the condensation reaction yielding an ether is a general reaction. 1,2,5-Trimethylpyrazinium hydroxide also undergoes this reaction, yielding an ether.

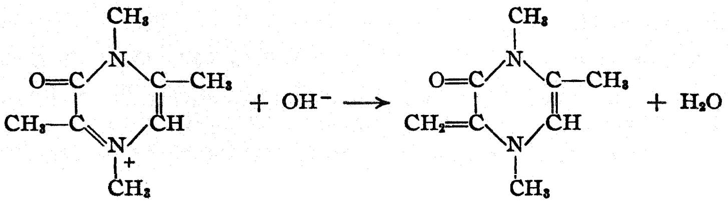
In the case of 1,2,2,5,5-pentamethyldihydropyrazinium hydroxide the double linkage forming part of the pseudo basic system is not conjugated through the ring system, and consequently the double bond has a greater tendency to become saturated by adding OH–. In consequence the equilibrium favors the weakly basic pseudo base.

The rapid equilibrium 1,2,2,3,5,5,6-heptamethyldihydropyrazinium hydroxide with 1,2,2,3,5,5-hexamethyl-6-methylene-tetrahydropyrazine accounts for the apparently weak basicity of the quaternary base (K_B = 4 × 10^{-3}). Such an equilibrium is possible in the case of 1,2,5-trimethylpyrazinium hydroxide but not in the case of 1,2,2,5,5-pentamethyldihydropyrazinium hydroxide. The conjugation in the pyrazinium nucleus probably opposes the reaction in the case 1,2,5-trimethylpyrazinium hydroxide and hence accounts for lack of evidence of a similar equlibrium in this case.

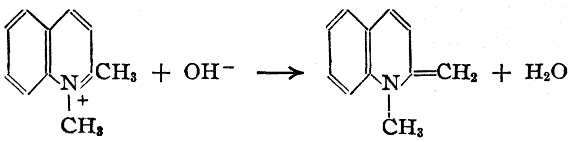
Gastaldi and Princivalle[23] have recently obtained evidence for the reaction

[22] Decker, J. *prakt. Chem.*. 192, 425 (1911).

[23] Gastaldi and Princivalle, *Gazz. chim. ital.*, 59, 791 (1929); 60, 296 (1930); Princivalle, *ibid.*, 60, 298 (1930).



In this case the conjugation in the pyrazine nucleus is also not complete. In this connection, however, it should be mentioned that Konig has obtained 1-methyl-2-methylene-1,2-dihydroquinoline by the action of sodium hydroxide on 1,2-dimethylquinolinium hydroxide[24]



This reaction will be investigated further by the foregoing methods.

Summary

1. The conductivities of 1,2,5-trimethylpyrazinium hydroxide and 1,2,2,5,5-pentamethyldihydropyrazinium hydroxide have been measured at 25°. Their Λ/Λ_0 values are the same at equivalent concentrations and almost the same as those of lithium iodate.

2. The disappearance of strong base from mixtures of 1,2,5-trimethylpyrazinium iodide and sodium hydroxide has been found to take place by two reactions. The one takes place at a rate proportional to the square of the concentration of pyrazinium ion and the first power of the hydroxyl-ion concentration, and the other at a rate proportional to the squares of the concentrations of both of these ions, when allowance is made for a salt effect according to the Brönsted theory. The same primary equilibrium between the quaternary base and the pseudo base hypothesized in both cases is shown to be inappreciably in favor of the pseudo base. Evidence is brought out to show that the final product is the ether of the pseudo base. The similarity between these reactions and those of pseudo bases in the pyridine and quinoline series is discussed.

3. The equilibrium between 1,2,2,5,5-pentamethyldihydropyrazinium hydroxide and 1,2,2,5,5-pentamethyl-6-hydroxytetrahydropyrazine has been found to be in favor of the latter. The equilibrium is established at a rate too rapid to measure even at 0°. The basic dissociation constant of the equilibrium mixture is $K_B < 10^{-5}$.

4. The equilibrium between 1,2,2,3,5,5,6-heptamethyldihydropyrazinium hydroxide and 1,2,2,3,5,5-pentamethyl-6-methylene-tetrahydropyrazine is established at an unmeasurable rate at 25°. The over-all

---

[24] König, Ber., 56, 1543 (1923).

base strength of the system is $K_B = 4 \times 10^{-3}$. A decomposition takes place at a rate proportional to the first power of the concentrations of the pyrazinium and hydroxide ions. The rate of formation of the pseudo base is hypothesized as the controlling step in this reaction.

5. The solubility of 5-phenyl-10-methylacridinium hydroxide has been found to be 1×10^{-4} mole/liter at room temperature and solutions of the base appear to be highly ionized. The initial high value of the conductivity on mixing 5-phenyl-10-methylacridinium chloride and sodium hydroxide is shown to be due to supersaturation.

6. The significance of the results is discussed in the light of ring conjugation, which seems to be the determining factor in the quaternary base–pseudo base equilibria.

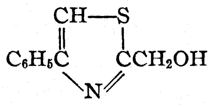
SYNTHESIS OF 4-PHENYLTHIAZOLE-2-METHANOL AND SOME OF ITS DERIVATIVES. VIII

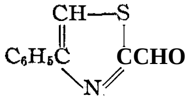
BY JOHN F. OLIN[1] AND TREAT B. JOHNSON

RECEIVED DECEMBER 8, 1930 PUBLISHED APRIL 6, 1931

In the carrying out of our research program dealing with the chemistry of thiazoles, it was necessary to develop practical methods of synthesizing certain thiazoles containing the simplest primary alcohol and an aldehyde group in position 2 of the thiazole ring. The derivatives selected for synthesis were the alcohol and aldehyde of 4-phenylthiazole which are represented by formulas I and II, respectively. These have been prepared by



I



II

methods-which undoubtedly will be of general application for further important syntheses in this series.

The starting points of our research were the thioamides of benzoylglycolic and ethoxyacetic acids, which are represented by formulas III and IV, respectively.

$C_6H_5COOCH_2CSNH_2$ III

$C_2H_5OCH_2CSNH_2$ IV

By interaction of these thioamides III and IV with bromoacetophenone, the benzoate and ethyl ether of the alcohol I are obtained easily in excellent yields. Both derivatives are convertible by hydrolysis into the alcohol I. The benzoate undergoes saponification with alkali easily, while acid hydroly-

---

[1] Metz Research Fellow in Organic Chemistry, 1929–1930.

sis with 80% sulfuric acid proved to be the best method for converting the thiazole ether into the alcohol I.

In order to prepare the aldehyde II we applied the usual technique of oxidizing the alcohol in acetic acid solution with chromic acid. This aldehyde II and its precursor the alcohol I are the first representatives of their types to be described in the thiazole series. In the experimental part of this paper are described several derivatives of the alcohol I which are proving to be of immediate service for new synthetic operations now being carried on in our thiazole researches. The work is being continued.

Experimental Part

4-Phenylthiazole-2-methyl Alcohol, C_6H_5T[2]CH_2OH.—The benzoate of this alcohol was prepared as follows. Fifty grams of benzoyl-oxyacetthioamide,[3] 38 g. of bromol acetophenone and 20 cc. of pyridine were dissolved in 100 cc. of alcohol and the solution heated for one hour on a steam-bath. The mixture was then poured into ice water and the insoluble residue washed three times with dilute hydrochloric acid. The benzoate separated and solidified, and was purified by crystallization from 95% alcohol. It separated in the form of rosets melting at 73–74' and the yield was 80% of the theoretical.

Anal. Calcd. for $C_{17}H_{13}O_2NS$: N, 4.74; C, 69.15; H, 4.40. Found: N, 4.52, 4.66; C, 68.95; H, 4.45.

Twenty grams of this benzoate was saponified by warming with potassium hydroxide in alcohol solution. On pouring the hydrolysate into water an oil separated which was extracted with ether, dried over sodium sulfate and finally distilled under diminished pressure. The alcohol boiled at 210–215° at 20 mm. and on cooling solidified immediately. It separated from hot dilute alcohol solution in the form of colorless cubical crystals melting at 88–89°.

Anal. Calcd. for $C_{10}H_9ONS$: N, 7.32; S, 16.77. Found: N, 7.27, 7.45; S, 16.55.

Ethyl Ether of 4-Phenylthiazole-2-methyl Alcohol, $C_6H_5TCH_2OC_2H_5$.—Ethoxyacetonitrile was first prepared according to the method of Gauthier[4] by the action of cuprous cyanide on chloromethyl ethyl ether. The corresponding thioamide was then made by Sommelet's procedure6 and allowed to react in alcohol with the calculated quantity of bromoacetophenone. After two hours of heating on the steam-bath the excess solvent was removed by distillation, the residue washed with dilute sodium hydroxide solution and the thiazole extracted with ether and dried over sodium sulfate. The thiazole ether boiled at 187–188° at 15 mm. and was obtained as an amber-colored oil which is feebly basic. The ether was not altered by digesting with 40% hydrobromic acid solution for four hours.

Anal. Calcd. for $C_{12}H_{13}ONS$: N, 6.39; S, 14.63. Found: N, 6.29, 6.26, 6.30, 6.21; S, 14.51.

[4] Gauthier, *Ann. chim. phys.*, [8] *16*, 302 (1909).

[5] Sommelet, *Compt. rend.*, 142, 828 (1906).

Conversion of the **Ether** into **its** Alcohol.—Fifty grams of the above ether was dissolved in 150 g. of 80% sulfuric acid and the solution heated in an oil-bath at 145–150° for half an hour. The liquid was then poured upon crushed ice and the resulting solution made alkaline with sodium hydroxide. The thiazole separated as an oil and was extracted by ether and purified by distillation. It was obtained in these experiments as a pale yellow, viscous oil which boiled as follows: 210° at 20 mm., 202° at 12 mm. and 178° at 4 mm. The oil solidified on cooling and was purified further by crystallization from dilute alcohol. It separated in the form of cubical crystals melting at 89°. The yield was 65% of the theoretical.

Acetate, $C_6H_5TCH_2OCOCH_3$.—Prepared by heating the thiazole methanol **with** acetic anhydride. It distilled at 193° at 4 mm. and crystallized from petroleum ether in the form of colorless plates melting at 40°.

Anal. Calcd. for $C_{11}H_{11}O_2NS$: N, 6.33. Found: N, 6.15.

Benzoate, **$C_6H_5TCH_2OCOC_6H_5$.—This** is formed by heating the thiazole methanol with benzoyl chloride at 120'. It crystallized from 80% alcohol in the form of rosets melting at 73–74'.

4-Phenylthiazole-2-methyl Bromide, **$C_6H_5TCH_2Br$.—Nineteen** grams of the above methanol was dissolved in 75 cc. of acetic anhydride and hydrogen bromide gas bubbled through the solution, while being warmed on a steam-bath, until saturated. After standing for two hours, the solution was then boiled for forty-five minutes and finally poured into cold water. The bromide separated as an oil. It was washed with sodium carbonate solution, dried in ether over sodium sulfate and finally purified by distillation. It boiled at 195° at 15 mm. The yield was 90% of the theoretical.

Anal. Calcd. for $C_{10}H_8NSBr$: N, 5.51; Br, 31.46. Found: N, 5.38; Br, 31.58.

The corresponding **4-phenylthiazole-2-methyl** chloride, **$C_6H_5TCH_2Cl$**, is easily obtained by the action of phosphorus oxychloride on the thiazole methanol and boils at 184' at 16 mm.

4-Phenylthiazole-2-aldehyde, C_6H_5TCHO.—This is easily obtained by oxidation of the thiazole methanol with sodium dichromate in acetic acid solution. This was accomplished by dissolving 19 g. of the methanol and 20 g. of sodium dichromate in 135 cc. of acetic acid and digesting the mixture at 100° for two hours. After pouring into water and extracting the aldehyde with ether, it was then purified by fractional distillation. It was obtained as a colorless oil possessing a fragrant odor and boiling at 160–162° at 14 mm.

Anal. Calcd. for $C_{10}H_7ONS$: N, 7.40; C, 63.49; H, 3.70. Found: N, 7.48, 7.55, C, 63.37; H, 3.62.

The **phenylhydrazone crystallizes** in canary yellow **prisms** melting at 131–132'.

Anal. Calcd. for $C_{16}H_{13}N_3S$: N, 15.06. Found: N, 15.28.

4-Phenylthiazole-2-aldoin, $C_6H_5TCOCHOHTC_6H_5$.—The above aldehyde behaves normally as an aromatic aldehyde and is converted quantitatively into its aldoin by digestion in alcohol solution in the presence of potassium cyanide. The compound crystallizes from boiling alcohol as yellow needles which turn red on heating and melt at 256°. The compound is insoluble in dilute acids and alkalies and belongs to a new class of compounds corresponding to the benzoins in the benzene series.

Anal. Calcd. for $C_{22}H_{14}O_2N_2S$: N, 7.40. Found: N, 7.40, 7.42.

Summary

1. Methods of synthesizing 4-phenylthiazole-2-methanol and 4-phenylthiazole-2-aldehyde have been described.

2. This alcohol and the aldehyde are the first representatives of their types to be described in the thiazole series.

3. Several derivatives of the thiazole methanol have also been described.

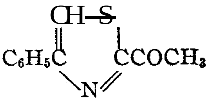
SYNTHESIS OF 4-PHENYL-2-ACETOTHIAZOLE. IX

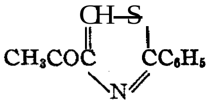
BY JOHN F. OLIN[1] AND TREAT B. JOHNSON

RECEIVED DECEMBER 8, 1930 · PUBLISHED APRIL 6, 1931

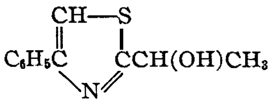
So far as the authors are aware, no thiazole ketones have hitherto been described in the chemical literature. Several of the aryl substituted ketone constructions, for example, as represented by the type formulas I and II, have assumed considerable importance in our thiazole researches because they promise to serve as practical starting points for the synthesis of some new types of amino alcohols possessing physiological interest. Such ketone combinations being available, it should then be possible, theoretically, to transform them by an established technique into bridged thiazole amino alcohols having pharmacological properties similar to those of compounds of the adrenaline type. In this paper we now describe a method for preparing the thiazole ketone I.



I



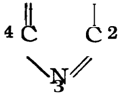
II



III

The ketone I is easily obtained by oxidation of the thiazole ethanol, III. The latter is a new alcohol which can be prepared easily in quantity by application of a normal thiazole synthesis with bromoacetophenone and the benzoate of lactic-thioamide, which has recently been described by Olin and Johnson.[2] The resulting benzoyl derivative is easily transformed into the alcohol III by the action of alkali. This is the first secondary alcohol of this type to be described in the thiazole series. It is a stable compound and can be oxidized smoothly to the ketone I without destruction of the thiazole ring. This change is accomplished by means of chromic acid in acetic acid solution. The ketone I may be considered as a bridged thiazole ketone corresponding to acetophenone, in which the aryl group is separated from the acetyl radical by the thiazyl nucleus. The ketone exhibits many of the properties of acetophenone and is attacked by bromine in a similar manner with formation of the bromide, $C_6H_5T^*COCH_2Br$.

T* is the thiazyl nucleus



---

[1] Metz Research Fellow in Organic Chemistry, 1929–1930.

[2] Olin and Johnson. *Rec. trav. chim.*, 50.72 (1931).

Experimental Part

Benzoate of 4-Phenylthiazole-2-or-ethanol, $C_6H_5TCH(CH_3)OCOC_6H_5$.—Fifty-three grams of benzoyl lactic-thioamide[2] and 50 g. of bromo-acetophenone are dissolved in 150 cc. of alcohol and the solution heated on a steam-bath'for one and one-half hours. Part of the alcohol is then allowed to evaporate and the mixture is made alkaline by the addition of dilute sodium hydroxide solution. The benzoyl thiazole separates as an oil and is extracted by ether and dried over sodium sulfate. The ester was purified by distillation and boiled at 252–254° at 14 mm. Thirty-five grams of a viscous oil was obtained which showed no signs of crystallizing on standing. The thiazole is very feebly basic and possesses a characteristic thiazole odor.

Anal. Calcd. for $C_{18}H_{15}O_2NS$: N, 4.53. Found: N, 4.55, 4.59.

4-Phenylthiazole-2-a-ethanol. 111.—This alcohol is prepared by digesting its corresponding benzoate (above) in alcohol with potassium hydroxide. From 28 g. of the benzoate we obtained 17 g. of the alcohol boiling at 191–194° at 16 mm. It was obtained as an amber-colored viscous oil which solidified on standing. It crystallized from chloroform in the form of large, yellow cubical crystals which melted at 76°. The alcohol is very soluble in all the common organic solvents except petroleum ether, and is insoluble in cold water. Attempts to dehydrate the alcohol by the action of phosphorus pentoxide were unsuccessful. Fifteen grams was digested in benzene with 20 g. of phosphorus pentoxide for fifteen hours without change.

Anal. Calcd. for $C_{11}H_{11}ONS$: N, 6.83; S, 15.61; C, 64.39; H, 5.36. Found: N, 6.80.6.83; S, 15.54; C, 64.20; H, 5.21.

4-Phenyl-2-acetothiazole. I.—Ten grams of the alcohol III is dissolved in 100 cc. of acetic acid and to the solution is added 8 g. of sodium dichromate dissolved in 10 cc of water. After heating this mixture on a steam-bath for one hour, it is poured upon crushed ice, when there is an immediate precipitation of the crude ketone in crystalline condition. It was purified by crystallization from hot dilute alcohol and separated in the form of yellow needles melting at 78–79°. The yield was 9 g. A mixture of this ketone and the alcohol III melted at 55–60". The ketone is much less soluble in the common organic solvents than the alcohol III.

Anal. Calcd. for $C_{11}H_9ONS$: N, 6.89; C, 65.00; H, 4.43. Found: N, 6.75, 6.81; C. 64.91; H, 4.30.

Phenylhydrazone.—Crystallizes in yellow needles melting at 208–209°.

4-Phenyl-2-bromoacetothiazole, $C_6H_5TCOCH_2Br$.—Forty-three grams of the above ketone dissolved in 300 cc. of hot carbon tetrachloride was combined with 34 g. of bromine. There was an immediate reaction with evolution of hydrobromic acid and separation of the hydrobromide of the thiazole. After cooling the mixture and decanting the carbon tetrachloride, the reaction product was triturated with an aqueous solution of potassium hydroxide and the ketone bromide extracted with ether. On evaporating the ether a semi-solid residue was left which dissolved in hot alcohol. On cooling the alcohol solution the above bromide separated in the form of buff-colored needles melting at 106–107°. When the compound was warmed in dilute alkaline solution or with an amine (methylamine), it readily lost its bromine, indicating that the halogen occupies a reactive position in the methyl radical of the ketone group.

Anal. Calcd. for $C_{11}H_8ONSBr$: N, 4.97; Br, 28.3. Found: N, 5.05, 5.07 Br, 27.8.

Summary

1. Benzoyl lactic-thioamide interacts with bromoacetophenone to form the benzoate of 4-phenylthiazole-2-a-tthanol. The corresponding alcohol is obtained by saponification of this ester.

2. 2-Phenylthiazole-2-a-ethanol is oxidized practically quantitatively to the ketone, 4-phenyl-2-acetothiazole, by the action of chromic acid in acetic acid solution.

New Haven, Connecticut

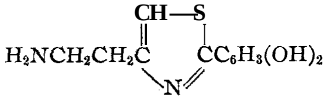
[Contribution from the Department of Chemistry, Yale University]

SYNTHESIS OF SOME NEW THIAZOLE AMINES CONTAINING THE CATECHOL GROUP. X

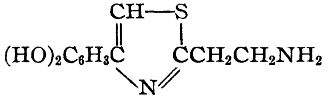
By John F. Olin[1] and Treat B. Johnson

Received December 8, 1930 Published April 6, 1930

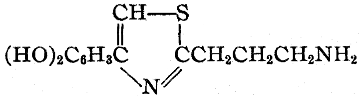
In the first paper of this series Johnson and Gatewood[2] reported the use of chloroacetocatechol as a reagent for thiazole syntheses, and described several thiazoles containing the catechol group in position 4 of the thiazole ring. Suter and Johnson[3] continued the work and described several thiazoles containing the catechol group in both positions 2 and 4 of the thiazole ring. The next contribution to the chemistry of these catechol derivatives was a paper by Hinegardner and Johnson,[4] who described a method of preparing the new thiazole amine represented by formula I.



I



II



III

This was found to be a potent substance physiologically, and, therefore, it was decided to synthesize its isomer represented by formula II in which the positions of the aliphatic amine and catechol groups in the thiazole nucleus are reversed. It became very important to determine which one of these two amines would be the most active substance when submitted to a comparative pharmacological study. In this paper is described the synthesis of this new thiazole amine II and also its next higher homolog, or the propyl derivative represented by formula III.

Our method of synthesis involved first the preparation of cyanethyl- and cyanpropylphthalimide, second, their conversion into their corresponding thioamides and third, interaction of these respective thioamides with

chloroacetocatechol to form the phthalimido derivatives of the bases II and III, respectively. Both of these phthalimide compounds can be obtained easily by our method of synthesis in good yields. They are converted almost quantitatively into the amines II and III, respectively, when heated with hydrazine hydrate according to the technique of Ing and Manske.[5] A description of the various stages of our two syntheses is given in the experimental part of this paper.

Experimental Part

γ-Phthalimido-butyrothioamide, $C_6H_4(CO)_2NCH_2CH_2CH_2CSNH_2$.—γ-Chlorobutyronitrile was first prepared by the action of potassium cyanide on trimethylene chlorobromide in alcohol solution.[6] This nitrile was then converted into the phthalimido derivative according to the method of Gabriel[7] by heating it with the potassium salt of phthalimide at 150°. After crystallizing from alcohol, this melted at 81° and the yield was 80% of the theoretical. This nitrile was then converted into its corresponding thioamide by dissolving in alcoholic ammonium sulfide solution and allowing this to stand for seventy-two hours after saturating with hydrogen sulfide. The thioamide crystallizes from 50% alcohol in plates melting at 181–182".

Anal. Calcd. for $C_{12}H_{12}O_2N_2S$: N, 11.29; S, 12.91. Found: N, 11.13, 11.26; S. 12.67.

4-(3,4-Dihydroxyphenyl)-2-γ-phthalimidopropyl-thiazole was prepared by the action of the above thioamide on chloroacetocatechol in alcohol solution. It crystallized from 50% acetone solution in the form of yellow, cubical crystals and melted at 114–115° to an oil.

Anal. Calcd. for $C_{20}H_{16}O_4N_2S \cdot H_2O$: H_2O, 4.52; N, 7.03; S, 8.07. Found: H_2O, 4.22; N. 7.13; S, 8.11.

4-(3,4-Dihydroxyphenyl)-2-γ-aminopropyl-thiazole. III.—The sulfate of this base was prepared as follows. Twenty-five grams of the phthalimide derivative was dissolved in hot alcohol, 6 g. of hydrazine hydrate added and the mixture warmed at boiling water-bath temperature until the solvent evaporated. Dilute hydrochloric acid was then added and the mixture heated to boiling, when phthalylhydrazine separated. After filtering and making the solution alkaline, the above thiazole amine separated. After washing with cold water this was then dissolved in 50% alcohol, acidified with sulfuric acid. On cooling, the sulfate separated in the form of needles. On recrystallizing from hot water this deposited in the form of minute colorless needles resembling very much the crystalline appearance of quinine sulfate. A sample of this salt was dried at 107°, when it lost 16.73% of its weight, indicating a hydrate constitution corresponding to the formula $2C_{12}H_{14}O_2N_2S \cdot 2H_2SO_4 \cdot 7H_2O$. This hydrate melted at 120–140° with decomposition when heated in a closed tube. The anhydrous salt melts at 226–228' to a clear liquid.

Anal. Calcd. for $C_{12}H_{14}O_2N_2S \cdot H_2SO_4$: N, 8.04; S as sulfate, 9.20; total S, 18.41. Found: N, 8.01; S as sulfate, 9.28; total S, 18.61.

Preparation of **4-(3,4-Dihydroxyphenyl)-2-β-aminoethyl-thiazole. II.**—β-Chloropropionitrile was first prepared as follows: 200 g. of thionyl chloride and 100 cc. of chloroform were mixed in a 1-liter two-necked flask to which an Allihn condenser and a

[7] Gabriel, *Ber.*, 22, 3335 (1889).

dropping funnel were attached. The end of the dropping funnel tube was drawn out to a capillary ending and arranged so as to approach about one inch above the surface of the chloroform–thionyl chloride solution. One hundred and ten grams of ethylene-cyanhydrin was then added to the boiling chloroform–thionyl chloride solution at the rate of about 3 cc. per minute and the final reaction mixture refluxed for thirty minutes. The chloropropionitrile was separated by fractional distillation under diminished pressure and different preparations were observed to boil as follows: (a) 84° at 30 mm., (b) 80° at 25 mm., 76° at 20 mm. The yield was 127 g. or 91% of the theoretical. Our product always contained a trace of thionyl chloride which could not be removed easily by distillation. By shaking the chloride with dilute sodium carbonate solution the thionyl chloride is removed easily, giving a pure colorless nitrile.

Phthalimido-propionitrile.—This is prepared by heating the above chloride with the potassium salt of phthalimide at 145°. The phthalimide crystallized from methyl alcohol in plates melting at 147–148°. The yield here is greatly reduced by the formation of acrylic nitrile, which is always produced during the fusion with potassium phthalimide.

Anal. Calcd. for $C_{11}H_8O_2N_2$: N, 14.00. Found: N, 14.12, 14.20.

Phthalimido-propionic-thioamide.—This was prepared by heating the above nitrile with an excess of alcoholic ammonium sulfide in a bomb tube at 90°. It crystallized from a mixture of chloroform and absolute alcohol in the form of rosets melting at 187–189°. The yield was good.

Anal. Calcd. for $C_{11}H_{10}O_2N_2S$: N, 11.96; S, 13.69. Found: N, 11.72, 11.85; S, 13.54.

4-(3,4-Dihydroxyphenyl)-2-β-phthalimidoethyl-thiazole.—The above thioamide and chloroacetocatechol interacted smoothly in alcohol solution After warming for thirty minutes at the boiling water-bath temperature this new thiazole separated and was obtained in a crystalline condition after treating the crude reaction product with dilute sodium carbonate solution. It was purified by crystallization from boiling alcohol and separated, on cooling, in the form of needles melting at 203–205°.

Anal, Calcd. for $C_{19}H_{14}O_4N_2S$: N, 7.65; S, 8.75. Found: N, 7.58, 7.53; S, 8.63.

Sulfate of 4-(3,4-Dihydroxyphenyl)-2-β-aminoethyl-thiazole. 11.—The above phthalimide compound was dissolved in hot alcohol and the theoretical quantity of hydrazine hydrate added to the solution. On evaporating the solvent, the reaction product was treated with dilute hydrochloric acid and the insoluble phthalylhydrazide separated by filtration. The hot acid filtrate of the thiazole amine was then mixed with a slight excess of dilute sulfuric acid, when the sulfate of the amine separated immediately in the form of colorless needles.

Anal. Calcd. for $C_{11}H_{12}O_2N_2S{\cdot}H_2SO_4$: N, 8.38; S, as sulfate, 9.59; total S, 19.19; C, 39.52; H, 4.19. Found: N, 8.27; S as sulfate, 9.64; total S, 19.37; C, 39.33; H, 4.05.

Summary

1. In this paper are described methods of synthesizing the two bridged thiazole amines, namely, 4-(3,4-dihydroxyphenylthiazole)-2-β-ethylamine and 4-(3,4-dihydroxyphenylthiazole)2-γ-propylamine.

2. The pharmacological study of both of these amines is now in progress.

NITRIDATION STUDIES.
III. PHENYL IODIDE DICHLORIDE AND THE N-CHLORO ACID AMIDES AS NITRIDIZING AGENTS[1]

BY A. LAURENCE CURL AND W. CONARD FERNELIUS

RECEIVED DECEMBER 8, 1930 PUBLISHED APRIL 6, 1931

In the development of Franklin's ammonia system of compounds, attention has been directed largely to reactions of double decomposition and to the existence of nitrogen analogs of the familiar oxygen acids, bases, and salts. in the field of inorganic chemistry, and to nitrogen alcohols, aldehydes, etc., among the carbon compounds. Recently, attention has been directed to the oxidation–reduction type of reaction. There is available for liquid ammonia work perhaps the best reducing agent known —a solution of an alkali metal in that solvent—and much work has been and is being carried out using this reagent.[2] The reverse process for nitrogen compounds, nitridation,[3] as it has been called, has not been so thoroughly studied, and only a few nitridizing agents are known.[4] The present investigation had for its purpose the examination of several substances for nitridizing power.

The main requirements of a good nitridizing agent aside from its ease of preparation and purification are: first, that it be of such a nature as to permit its ready and quantitative introduction into a liquid ammonia solution and, second, that its reactivity be such that it does not react with ammonia more readily than with substances in solution in that solvent. Of all substances so far examined, iodine is the most satisfactory although, even with this reagent, special precautions must be taken when introducing it into liquid ammonia.[5] The reactivity of the elements chlorine and bromine toward both gaseous and liquid ammonia is so great as to render

---

[1] The material presented in this paper is an abstract of a portion of a thesis submitted by A. Laurence Curl in partial fulfilment of the requirements for the degree of Master of Science at The Ohio State University. The major portion of this material was presented at the 79th meeting of the American Chemical Society, Atlanta, Georgia, April, 1930.

[2] For bibliography see Johnson and Fernelius, J. Chem. *Education*, 6, 20–35 (1929).

[3] The term nitridizing agent was first employed by Turrentine [THIS JOURNAL, 34, 386 (1912)] to describe substances which although they contain no oxygen are nevertheless capable of reacting in a fashion essentially similar to an oxidizing agent. Browne [*ibid.*, 33, 1728 (1911)] and Franklin [J. Phys. Chem., 27, 169 (1923)] applied the term "nitridation" to all those reactions which for the ammonia system of compounds are essentially similar to oxidation reactions for the familiar water compounds. Although nitridation reactions are today classed under the broader conception of oxidation reactions, the newer term does have its use in a specific sense.

[4] For bibliography of nitridation reactions see Schurman and Fernelius, THIS JOURNAL, 52, 2425 (1930).

[5] Ref. 4, p. 2428.

these elements almost useless in the present connection. A halogen may, however, as the present investigation shows, be introduced into liquid ammonia solutions in the form of an addition compound, such as phenyl iodide dichloride, $C_6H_5ICl_2$, which is less reactive toward ammonia than the elementary halogen.

When phenyl iodide dichloride is added to a solution of hydrazobenzene in liquid ammonia at its boiling point, red azobenzene precipitates. The reaction probably takes place as represented by the equation

$$C_6H_5ICl_2 + C_6H_5NH{\cdot}NHC_6H_5 + 2NH_3 \longrightarrow C_6H_5I + 2NH_4Cl + C_6H_5N{=}NC_6H_5$$

although a portion of the dichloride reacts directly with the liquid ammonia. Phenyl iodide dichloride reacts vigorously with both gaseous and liquid ammonia, in accordance with the equation

$$3C_6H_5ICl_2 + 8NH_3 \longrightarrow 3C_6H_5I + N_2 + 6NH_4Cl$$

iodine chloride, ICl, also precipitates azobenzene when added to an open Dewar test-tube containing a liquid ammonia solution of hydrazobenzene.

The oxidizing power of substances containing chlorine in a positive valence state and attached to nitrogen is well known.[6] It was felt that such compounds might be used in a similar capacity in liquid ammonia. However, dichloramine-T, N-chloroacetanilide and N-chlorosuccinimide react so readily with liquid ammonia that they nitridize it preferentially to any hydrazobenzene which may be in solution. Hence these compounds are useless as nitridizing agents. The reaction of the N-chloro acid amides with ammonia, both liquid and gaseous, may be summarized in the equations[7]

$$3\ p\text{-}CH_3C_6H_4SO_2NCl_2 + 10NH_3 \longrightarrow 3\ p\text{-}CH_3C_6H_4SO_2NH_2 + 2N_2 + 6NH_4Cl$$
$$3(CH_2CO)_2NCl + 5NH_3 \longrightarrow 3(CH_2CO)_2NH + N_2 + 3NH_4Cl$$

Such reactions are frequently so vigorous and evolve so much heat that a part of the reacting halogen compound is destroyed.

Chloramine-T is much less reactive than the other compounds. The hydrated compound reacts slowly with gaseous ammonia at room temperature while the anhydrous compound reacts very slowly or not at all. On gentle warming (50°) the hydrated compound reacts more rapidly while the anhydrous form gives a very mild explosion with the formation of a white cloud and a carbonized residue. Both the hydrated and anhydrous forms of chloramine-T go quietly into solution in liquid ammonia and *p*-toluenesulfonamide remains after evaporation of the ammonia. Chlor-

[6] Hofmann, *Ber.*, 15, 410 (1882); Seliwanow, *ibid.*, 25, 3618 (1892); Lengfeld and Stieglitz, *Am. Chem. J.*, 15, 216 (1893); Chattaway, *J. Chem. Soc.*, *87*, 145 (1905).

[7] Hoogewerff and Van Dorp [*Rec. trav. chim.*, *6*, 381 (1887)] state that potassium benzene sulfonebromoamide reacts with ammonium hydroxide to form the parent amide and a colorless gas. Similarly ammonium hydroxide reacts with N-bromosuccinimide [Lengfeld and Stieglitz, Ref. 6] and chloramine-T [Engfeldt, *Z. physiol. Chem.*, 126, 24 (1923)] to liberate nitrogen. Gebauer-Fiilnegg and Jusa [*Monatsh.*, 50, 65 (1928)] obtained benzene sulfonanilide by adding benzene sulfonechloroanilide to liquid ammonia.

amine-T does not nitridize a liquid ammonia solution of hydrazobenzene at room temperature even in acid solution.[8]

In order to test further the oxidizing (dehydrogenating) properties of both phenyl iodide dichloride and the N-chloro acid amides, the reaction of each of the above substances with hydrazobenzene in chloroform solution was studied. In each case azobenzene and benzidine resulted. The reactions may be summarized

$$C_6H_5ICl_2 + C_6H_5NHNHC_6H_5 \longrightarrow C_6H_5I + C_6H_5N{=}NC_6H_5 + 2HCl$$

$$2(CH_2CO)_2NCl + C_6H_5NHNHC_6H_5 \longrightarrow 2(CH_2CO)_2NH + C_6H_5N{=}NC_6H_5 + 2HCl$$

$$CH_3C_6H_4SO_2NCl_2 + C_6H_5NHNHC_6H_5 \longrightarrow CH_3C_6H_4SO_2NH_2 + C_6H_5N{=}NC_6H_5 + 2HCl$$

$$C_6H_5NHNHC_6H_5 + 2HCl \longrightarrow H_2NC_6H_4C_6H_4NH_2{\cdot}2HCl$$

It is evident that the hydrogen chloride liberated in the oxidation reaction causes a part of the hydrazobenzene to undergo the benzidine rearrangement.

Experimental

Preparation of Materials.—The hydrazobenzene (m. p. 129") was prepared as described elsewhere,[9] and used within a few days of preparation.

Phenyl iodide dichloride was prepared by conducting a stream of dry chlorine into an ice-cold solution of phenyl iodide in chloroform.[10]

To obtain iodine chloride, a stream of chlorine was passed over a few grams of iodine until the liquid first formed began to solidify. The reaction mixture was then warmed gently to decompose whatever iodine trichloride had formed.[11]

The chloramine-T, dichloramine-T and succinimide (m. p. 123") used in these experiments were Eastman Kodak Co. products.

N-chloroacetanilide was prepared by the method of Slosson[12] by adding a solution of potassium hypochlorite to an ice-cold solution of acetanilide: m. p. 88–90"; Slosson gives 91°.

N-chlorosuccinimide was prepared by the method of Tscherniac,[13] which consists of adding a cold solution of snccinimide in dilute acetic acid to an ice-cold solution of potassium hypochlorite: m. p. 149°; Tscherniac gives 150°.

Action upon Hydrazobenzene in Liquid Ammonia. Phenyl Iodide Dichloride.—Using a technique previously described: a solution of 1 g. of hydrazobenzene in liquid ammonia at −33° was treated with 1.53 g. (1.03 equivalents) of phenyl iodide dichloride. A vigorous reaction ensued, resulting in the evolution of a gas and the formation of a red precipitate. Upon evaporation of the ammonia, the reaction products were treated with ligroin. After evaporating the ligroin, a red liquid remained which crystallized on cooling; m. p. 65–67°.

The ligroin insoluble residue was washed with water and the filtrate shown to con-

---

[8] Chloramine-T has been found to be more reactive when in an acid solution [Schiemann and Novák, *Z. angew.* Chem., 40,1032 (1927)].

tain ammonium chloride. A light brown substance remained behind (m. p. 115–123°; mixed m. p. with hydrazobenzene 117–120°) in an amount roughly half that of the azobenzene formed.

Iodine Chloride.—Upon adding iodine chloride to a solution of hydrazobenzene in liquid ammonia contained in an open Dewar, a red precipitate formed immediately. After the ammonia had evaporated the residue was washed with ligroin. Upon evaporating the red ligroin solution a red liquid remained which crystallized on cooling; m. p. 58°, mixed melting point with azobenzene 61–63°.

Chloramine-T, N-chloroacetanilide, N-chlorosuccinimide and dichloramine-T failed to give a precipitate of azobenzene when added to liquid ammonia solutions of hydrazobenzene at $-33°$.

Chloramine-T in the presence of ammonium chloride likewise produced no azobenzene at room temperature over a period of nine days.[14]

Action upon Liquid Ammonia. Phenyl Iodide Dichloride.—Upon adding phenyl iodide dichloride in small portions to liquid ammonia, a gentle evolution of gas took place on each addition. A white solid and brown liquid remained after the evaporation of the ammonia. The white solid dissolved in water leaving the brown liquid, which had the odor of phenyl iodide, as a lower layer. The aqueous solution gave tests for ammonium and chloride ions—no iodide. The brown liquid was dissolved in chloroform and treated with chlorine. On standing yellow needles similar to phenyl iodide dichloride deposited.

Two samples of phenyl iodide dichloride, 0.650 g. and 0.769 g., were added to liquid ammonia as above. After evaporation of the ammonia, the residue was washed with ligroin, removed almost quantitatively, filtered and dried in a current of air. Ammonium chloride obtained: 0.240 g. and 0.288 g.; yields based on the equation, $3C_6H_5ICl_2 + 8NH_3 \longrightarrow 3C_6H_5I + N_2 + 6NH_4Cl$: 94.9 and 96.2%.

Chloramine-T.—Both the hydrated and anhydrous forms of chloramine-T dissolved quietly in liquid ammonia. The residues remaining after evaporation of the ammonia were thoroughly washed with water and dried: m. p. 135–136 and 136.0–136.5°, respectively (p-toluenesulfonamide, 137°).

Dichloramine-T, N-chloroacetanilide and N-chlorosuccinimide reacted vigorously with liquid ammonia. The residues remaining after evaporation of the ammonia were shown to consist of ammonium chloride and the respective amide: m. p. 134–136, 113–114 and 120–124°, respectively; mixed melting point of the two latter substances with acetanilide and succinimide, respectively, 113–114 and 121–123°. The *p*-toluenesulfonamide from dichloramine-T was further identified by its solubility in a potassium hydroxide solution.

Action upon Gaseous Ammonia.—The reaction of all of these substances except chloramine-T with gaseous ammonia was vigorous, producing white fumes and a brown and white residue, The reaction of dichloramine-T was so vigorous as to evolve both heat and light. The reaction of hydrated chloramine-T was very slow and attended only by a frothing of the solid. Anhydrous chloramine-T appeared to react not at all with gaseous ammonia at room temperature. Upon warming to 50° in a current of ammonia, there resulted a very mild detonation with considerable increase in pressure and the formation of a white cloud. A tarry charred mass remained behind. Determinations of the nitrogen evolved in these reactions were discouraging. Only in the case of phenyl iodide dichloride is the yield of nitrogen approximately quantitative and seldom did two runs on the same substance check.

---

[14] Hydrazobenzene in liquid ammonia solution in the presence of ammonium chloride (an acid in liquid ammonia) is not converted to benzidine over a space of twenty-four days at room temperature.

Action upon Hydrazobenzene in Chloroform Solution.—For these experiments a solution of **2–5 g.** of hydrazobenzene in **50** ml. of chloroform was immersed in an ice-bath and a solution of an equivalent amount of the halogen compound in cold chloroform added slowly with stirring. In each case the color of the solution changed from yellow to red and a precipitate collected at the surface of the chloroform. These precipitates were filtered off, washed with chloroform, dried and dissolved in water. The resulting solutions were neutralized with potassium hydroxide and the brown precipitate resulting recrystallized from hot water. The filtrates were evaporated to dryness and the residues washed with ligroin to remove azobenzene.

	Benzidine		Azobenzene		N-Compd	
Substance	M. p., °C.	Mixed m. p., °C	M. p., °C.	Mixed m. p., °C	M. p., °C	Mixed m. p., °C
Phenyl iodide dichloride	Insufficient		68	68	...	....
Dichloramine-T	115	121–124	62–66	63–67	120–123	131–133
N-Chloroacetanilide	101	115–120	64–67	66–68	113	113–114
N-Chlorosuccinimide	Insufficient		58-65	64-67	114–119	121–124

Summary

1. Phenyl iodide dichloride and iodine chloride may be used as nitridizing agents in liquid ammonia but the N-chloro acid amides so far investigated are valueless in this connection.

2. Phenyl iodide dichloride reacts with ammonia, either liquid or gaseous, to give nitrogen, phenyl iodide and ammonium chloride.

3. The N-chloro acid amides react with ammonia to give the parent amides, ammonium chloride, nitrogen and under certain conditions, tarry decomposition products.

4. In chloroform solution, phenyl iodide dichloride, dichloramine-T, N-chloroacetanilide, and N-chlorosuccinimide convert hydrazobenzene into a mixture of azobenzene and benzidine hydrochloride.

ESTERIFICATION WITH THIOLACETIC ACID

BY FRANCIS B. STEWART AND PAUL V. McKINNEY

RECEIVED DECEMBER 13, 1930 PUBLISHED APRIL 6, 1931

The relative reactivity of primary, secondary and tertiary alcohols with acid chlorides, hydrochloric acid, and in acetal formation has received considerable attention in the past few years. As early as 1879 N. Menschutkin[1] observed a similar marked influence of the structure of alcohols upon their rates of esterification. He measured the rates with which fourteen widely different alcohols react with acetic acid at 154° in the absence of catalyst, and observed that with the exception of methyl alcohol, primary and secondary alcohols show only slight variation among themselves, while the tertiary alcohols show greater differences but invariably esterify one-tenth to one-twentieth as rapidly as do the

---

[1] Menschutkin, **Ann., 195, 334 (1879); 197, 193 (1879).**

secondary alcohols. Arthur Michael[2] has studied the reaction rates of these same alcohols with trichloroacetic acid at 25°. Here there is a marked difference between the esterification rates of primary and secondary alcohols with the reactivity of the tertiary alcohols slightly greater than that of the latter. Recently an attempt has been made by Petrenko-Kritchenko, Bogatsky and Lubman[3] to reconcile these results. As these data are of considerable interest to the present paper they are given in part in Tables I and II. The marked difference in the behavior of secondary and tertiary alcohols observed by Menschutkin is absent in the later results, The constants for trichloroacetic acid on the other hand agree well with those of Michael. In the case of the constants for hydrochloric acid the order is entirely reversed from that of acetic acid, with trichloroacetic acid occupying an intermediate position. The phenyl substituted alcohols bring out these effects even more clearly.

In an outstanding contribution to the knowledge of the mechanism of esterification, Reid and his collaborators[4] found that thiolbenzoic acid and a primary alcohol gave hydrogen sulfide and a normal ester, whereas benzoic acid and a primary mercaptan gave water and a thiol ester. Using Henry's hypothesis that an intermediate product is formed, this would suggest that the mercaptan adds H- and C_2H_5S- rather than HS- and C_2H_5-. From analogy it is therefore commonly stated that in esterification the hydroxyl used in the formation of water is furnished by the acid and not by the alcohol. This is undoubtedly true for the cases investigated, but the question at once arises whether this is invariably so, especially

in view of the great differences shown in the reactivity of primary, secondary and tertiary alcohols.

Purpose of Investigation.—The method used by Reid was of a qualitative rather than a quantitative nature. He reports that hydrogen sulfide was either present or absent. When present it was tentatively assumed that the reaction was entirely of one kind. Considering the following reactions

$$\begin{array}{ll} \text{A} & \text{RCO·SH} + \text{R}'\text{O·H} \longrightarrow \text{RCO·OR}' + \text{H}_2\text{S, and} \\ \text{B} & \text{RCOS·H} + \text{R}'\text{·OH} \longrightarrow \text{RCOS·R}' + \text{H}_2\text{O} \end{array}$$

reaction A may take place to the exclusion of B. However, it is also possible that both may be taking place simultaneously. This can only be determined by following quantitatively the disappearance of the acid and the formation of hydrogen sulfide. Furthermore, if the reaction between thiolacetic acid and ethyl alcohol is found to take place in the proportion of 75% according to reaction *A* and 25% according to *B*, it does not necessarily follow that all alcohols will behave in the same way. It was with the hope of being able to determine the proportions of the two reactions A and B occurring in the esterification of a number of alcohols that this work was undertaken. It was also believed that such information might to some extent explain the apparent anomalies in the reaction rates of various alcohols with several different acids. The reactions selected were the esterification of methyl, ethyl, isopropyl and *tert.*-butyl alcohols and triphenylcarbinol with thiolacetic acid.

Experimental Method

The alcohols were purified by the usual methods, the removal of water being the primary object.

Thiolacetic acid at first offered some difficulty as commercial samples invariably contained considerable quantities of hydrogen sulfide. This is best removed by freezing the sample at about —40°, evacuating and allowing the acid to distil *in vacuo* into a trap surrounded by Dry-ice and ether at —70 to —80°. During this distillation the system was continually evacuated. In this way the hydrogen sulfide was entirely pumped off and the freshly distilled acid showed no test for the dissolved gas. This acid was used immediately as it was found that on prolonged standing unless protected from air and moisture hydrogen sulfide was regenerated.

The solvent used was benzene which had been purified by repeated shakings with concd. sulfuric acid, washed and dried.

2 N solutions of the alcohols and acid in benzene were made, equal quantities mixed and the reaction mixture titrated for the acid present; 10-cc. portions of this reaction mixture were introduced into several small hard glass bulbs by means of a capillary. These bulbs were so constructed as to be of uniform volume and have a maximum capacity of 12–13 cc. They were then frozen with liquid air, evacuated and sealed *in vacuo* by means of the capillary. They were then placed in a steel-jacketed vessel fitted with a reflux condenser into which there was a constant stream of carbon tetrachloride vapor. This ensured an even temperature of 76.7°. From time to time the bulbs were removed, frozen with liquid air, opened at the capillary and immediately connected with the hydrogen sulfide analysis train.

This train consisted of three traps, **A,** B and *C*, kept at −40, −80 and −180°, respectively. Trap *C* was connected with an oil pump and the whole system continually evacuated. As the bulb approached room temperature the reaction mixture rapidly distilled into trap A where it again solidified. The sublimation from A to B required a much longer time, but the advantage of passing from one solid phase to another without liquefying permitted the absolute separation of the hydrogen sulfide from the reaction mixture. Trap B then contained the acid–alcohol–benzene mixture which after warming was pipetted out and titrated for the acid present. Trap *C* containing the solid hydrogen sulfide was then disconnected and attached to an absorption bulb containing an ammoniacal solution of cadmium chloride. As the temperature of C was gradually raised the hydrogen sulfide was evolved and precipitated in the absorption bulb as cadmium sulfide. The whole system was finally blown out with a stream of nitrogen and the cadmium sulfide titrated in acid solution with iodine. **A** number of blanks were run and the data in Table III show the method to be entirely satisfactory for the present purpose. Indeed it can be recommended for the analysis of hydrogen sulfide in the presence of any non-gaseous reducing agent.

TABLE III

ANALYTICAL DATA

The amounts are in terms of milliequivalents present in 10 cc. of benzene solution.

	Reagents		**Recovered**

.866		3.052	.842	3.000

[a] Subsequent test proved hydrogen sulfide present in the original thiolacetic acid from which these samples were taken.

In the subsequent tables and drawings the course of the reaction is followed under the heading "Esterification" in terms of the millimoles of acid which reacted in the time *t*. For convenience the per cent. of esterification is given in the third column. If the reaction takes place entirely according to Equation **A** previously given, the millimoles of hydrogen sulfide produced should be equal to the millimoles of acid disappearing. The amount of hydrogen sulfide actually produced is given in column four of the tables and by the broken curves. If both reactions expressed by Equations **A** and B are taking place simultaneously, the millimoles of hydrogen sulfide produced will be less than the millimoles of acid disappearing and the fraction of the acid reacting according to Equation **A** is expressed in per cent. in the last column.

Discussion of Data

The data for methyl and ethyl alcohols presented in Tables IV and V (Figs. 1 and 2) would indicate that the percentage of hydrogen sulfide

TABLE IV

produced per mole of acid esterified is the same within experimental error. These results may also be interpreted as indicating that with primary alcohols about 78% of thiolacetic acid esterifies according to equation A and about 22% according to equation B.

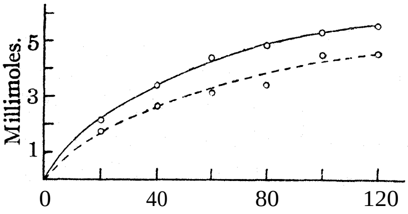

Fig. 1.—Methyl alcohol, 76°: ——, esterification; – – –, H_2S production.

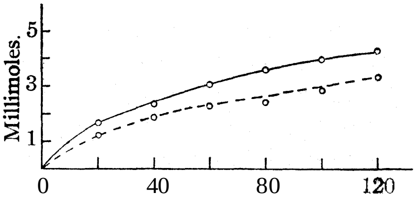

Fig. 2.—Ethyl alcohol, 76°: ——esterification; – – – –, H_2S production.

The behavior of a secondary alcohol, in this case isopropyl, is markedly different, since practically the theoretical quantity, 97.7%, of hydrogen sulfide is produced; Table VI and Fig. 3. It may therefore be assumed that with isopropyl alcohol thiolacetic acid esterifies entirely according to equation A.

As an example of a tertiary aliphatic alcohol the esterification of *tert.*-butyl alcohol was attempted. This reaction is, however, exceedingly

slow and under prolonged heating was accompanied by decomposition of either the thiolacetic acid or its ester, so that from the data obtained it was impossible to follow the course of the reaction. However, the relative rates of esterification of the secondary and tertiary alcohols are in the same order as obtained by Menschutkin with acetic acid. If possible the velocity constants of the reactions with thiolacetic acid will be investigated.

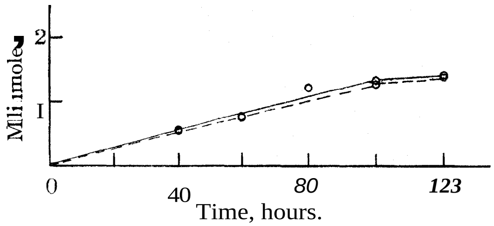

Fig. 3.—Isopropyl alcohol, 76°: ———, esterification; - - - H_2S production.

Triphenylcarbinol, Table VII, and Fig. 4, offers an interesting contrast. Since the reaction was found to proceed too slowly at 76° it was carried out at 100°. As will be shown later at this temperature the acid slowly hydrolyzes to produce hydrogen sulfide. When the data in Table VII are corrected for this hydrolysis they show the entire absence of hydrogen sulfide. In this case, then, only water is produced and the course of the esterification may be satisfactorily represented by equation B.

As a control, bulbs containing only thiolacetic acid and benzene were subjected to prolonged heating. At 76° little or no hydrogen sulfide was observed, but at 100° the quantity became appreciable. From the data in Table VIII, however, it seems that the reaction soon reaches completion, for after ninety-six hours there is neither production of hydrogen sulfide nor disappearance of acid. To determine whether the presence of small amounts of water were responsible for the production of the hydrogen sulfide, a blank was run with thiolacetic acid and benzene 1 N in water, Table IX. Hydrogen sulfide was evolved in larger quantities and the acid disappeared more rapidly. If a decomposition of the acid were taking place we should expect that for a mole of hydrogen sulfide produced at least a mole of acid would disappear. If on the other hand the reaction were purely hydrolytic the total acid concentration would remain constant, since for every mole of thiolacetic acid hydrolyzed a mole of acetic acid would be formed. It is interesting to note in Tables VIII and IX the hydrogen sulfide cannot be quantitatively accounted for by the decrease in the acid concentration. That water is playing an important part, however, is shown by the fact that the acid disappears more rapidly in Table IX than in Table VIII, It is quite possible that both a thermal decomposition and hydrolysis are taking place, but for the purpose of correcting the data in Table VII it is sufficient to know the magnitude of the combined effect.

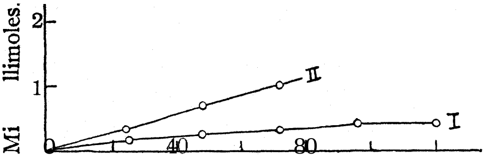

Fig. 5.—H_2S production: I, blank 100°; II, hydrolysis of thiolacetic acid by water.

Theoretical

It seems that the reaction between various alcohols and thiolacetic acid is by no means simple. From the percentage esterification given in Tables IV, V and VI methyl alcohol appears to esterify somewhat more rapidly than ethyl, but both are much more reactive than isopropyl alcohol. The data for triphenylcarbinol, Table VII, are at 100° so that no quantitative comparison can be made, but since the higher temperature was necessary to obtain accurate results, it is unquestionably less reactive than isopropyl alcohol. This is in good agreement with the data given by Petrenko-Kritchenko for these alcohols with acetic acid in Table II. The quantities of hydrogen sulfide evolved by these three reactions show, however, that we are dealing with three distinct processes. Triphenylcarbinol, although the most unreactive, yields only water, which means that only its hydroxyl group enters into the reaction. Methyl and ethyl alcohols while much more reactive can split off either hydroxyl or hydrogen. Isopropyl alcohol is but moderately reactive, yet only its hydrogen takes part in the reaction.

In dealing with esterification processes it is not sufficient to know the relative strengths of the bindings of the —OH and —H in the alcohols only, but one must also consider these bonds in the acids with which they react. For example, in the reaction

$$RC\overset{a}{\text{—}}O\overset{b}{\text{—}}H + H\overset{c}{\text{—}}S\overset{d}{\text{—}}\overset{O}{\overset{\cdot\cdot}{C}}\cdot CH_3$$

when R is $(C_6H_5)_3C$— the bonds a and c split much more easily than the bonds b and d; therefore water is the only product obtained. When R is $(CH_3)_2CH$— bonds b and d are much more easily broken than a and c; therefore only hydrogen sulfide is obtained. When, however, R is CH_3— or C_2H_5— the total energy necessary to break the bonds a and c cannot be very different from that required to break b and d, so that in this case both water and hydrogen sulfide are obtained. From the relative amounts of the two, however, it seems that b and d are the more easily split. Other alcohols will undoubtedly show great differences in the ease with which these two pairs of bonds are split and consequently yield varying proportions of water and hydrogen sulfide.

Since the rate and also the products formed depend not only upon the relative strength of binding in the alcohol but in the acid as well, the same alcohols may not react in the same manner with different acids. In the case of hydrogen chloride the —OH must be furnished by the alcohol so that the constants in Table II are probably a good indication of the relative strengths of binding of this group in the six alcohols studied. This is not the case, however, with trichloroacetic acid, whose —OH is probably more firmly bound than that in acetic acid. If we further assume that the —H is more labile in trichloroacetic than in acetic acid, then one can understand why the constants for the tertiary alcohols are higher than those for their secondary homologs when trichloroacetic acid is used but lower with acetic acid. Trichlorothiolacetic acid should yield water or hydrogen sulfide or both depending upon the structure of the alcohol, but undoubtedly in proportions quite different from thiolacetic acid. These should be interesting in comparison with the data in Table II and it is our hope to consider them in a later communication.

Summary

The products of the reaction of thiolacetic acid with a number of alcohols have been studied quantitatively. Isopropyl alcohol yields only hydrogen sulfide and the normal ester; triphenylcarbinol only water and the thiol ester; methyl and ethyl alcohol give about 78% hydrogen sulfide and 22% water. The question of the mechanism of esterification in general is considered and an explanation of certain anomalies is attempted.

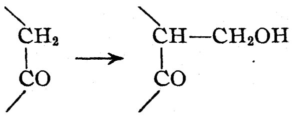
CONDENSATIONS BETWEEN FORMALDEHYDE AND MONOKETONES. I. CONDENSATION OF 5-ACETYL-8-HYDROXYQUINOLINE WITH ALDEHYDES

BY KONOMU MATSUMURA AND CHUSABURO SONE

RECEIVED DECEMBER 16, 1930 PUBLISHED APRIL 6, 1931

Many researches relating to the condensation between a methyl or methylene group adjacent to a ketone and aromatic or cyclic aldehyde have been published, whereas, as far as the authors are aware, except in the case of the pyrazolone series, there are only a few previous records of condensation with formaldehyde. K. Goto and his co-workers,[1] in the course of investigations of sinomenine, an alkaloid from *sinomenium acutum*, have found that on refluxing sinomenine, which contains a methylene group adjacent to a carbonyl in its molecule, with an excess of formaldehyde a condensation between them results in the formation of an hydroxymethyl compound in accordance with the scheme

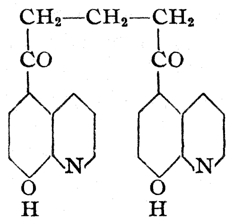


In the present investigation, on treating 5-acetyl-8-hydroxyquinoline with formaldehyde (40%) in a manner similar to that used for sinomenine, it is found that a condensation has taken place between them, but contrary to expectation, resulting in the formation of ω-methylene-bis-5-acetyl-8-hydroxyquinoline (I).

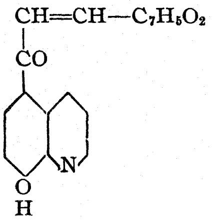
Furthermore, the reaction of 5-acetyl-8-benzoyloxyquinoline and formaline gives ω-methylene-bis-5-acetyl-8-benzoyloxyquinoline. It is evident in view of the latter fact that the presence of a free hydroxyl

---

[1] Goto, Shishido and Inaba, *Bull. Chem. Soc., Japan*, 5, 315 (1930).



I



II

group in the molecule would not have any necessary part in the condensation. On the other hand, on treating acetophenone with formaldehyde in the same way or even in the presence of pyridine, acetophenone can be recovered without any notable loss (the, identification is confirmed by the melting point and mixed melting point test of its oxime (m. p. 160–161.5°)). This last failure makes it seem likely that the presence of an amino group in the molecule may serve to facilitate the condensation in any way. A search of the literature reveals that the reaction of salicylaldehyde with acetophenone[2] gives chiefly salicylidene-diacetophenone, while under similar conditions, with **indanone,**[3] it gives salicylidene-indanone. The reaction of 5-acetyl-8-hydroxyquinoline and piperonal, in the **present** work, is found to afford w-piperonylidene-5-acetyl-8-hydroxyquinoline (II), following the course of the latter kind of condensation.

Experimental

α-Methylene-bis-5-acetyl-8-hydroxyquinoline.—A mixture of 0.5 g. of 5-acetyl-8-hydroxyquinoline and 2.5 cc. of formaldehyde (40%), which contains an appreciable amount of a precipitate of paraformaldehyde, is refluxed for two hours. The resulting white precipitate is filtered, on cooling, and washed; yield, 0.5 g. It is recrystallized from nitrobenzene into colorless columns, m. p. >315°. It is sparingly soluble in boiling benzene and alcohol. Its alcoholic solution gives a green coloration with ferric chloride.

Anal. Subs., 5.325 mg.: CO_2, 13.942; H_2O, 2.014. Subs., 4.200: CO_2, 11.019; H_2O, 1.893. Subs., 5.554: N_2, 0.368 cc. (28°, 753.5 mm.). Calcd. for $C_{23}H_{18}O_4N_2$: C 71.50; H, 4.66; N, 7.25. Found: C, 71.41, 71.55; H, 4.20, 5.01; N, 7.17.

The hydrochloride gives yellow needles from hydrochloric acid (10%). It is insoluble in water and does not melt at 300°, decolorizing at 170–220".

Anal. (Water of crystallization). Subs., 0.0830: H_2O, 0.0168. Calcd. for $C_{23}H_{18}O_4N_2 \cdot HCl \cdot 6\ H_2O$: H_2O, 20.36. Found: H_2O, 20.24. Subs., 4.640: AgCl, 1.553. Calcd. for $C_{23}H_{18}O_4N_2 \cdot HCl$: Cf, 8.40. Found: Cl, 8.28.

The **monoxime** gives colorless prisms from nitrobenzene, m. p. 295–300° (decomp.).

Anal. Subs., 3.777: N_2, 0.327 cc. (13.5°, 768 mm.). Calcd. for $C_{23}H_{19}O_4N_3$: N, 10.47. Found: N, 10.29.

ω-Methylene-bis-5-acetyl-8-acetoxyquinoline.—A mixture of 0.2 g. of ω-methylene-bis-5-acetyl-8-hydroxyquinoline, 8 g. of acetic anhydride and 0.5 g. of sodium acetate is

[3] Feuerstein, *ibid.*, 34, 413 (1901).

warmed for two and one-half hours on the water-bath. On pouring into crushed ice, after being cooled, the reaction product separates as oily drops which soon turn to a colorless solid (0.2 g.). It crystallized from ethyl acetate into colorless prisms, m. p. 234–235°. It is easily soluble in chloroform, hot alcohol (with a partial hydrolysis). and moderately in hot benzene, but sparingly in ether.

Anal. Subs., 4.783: CO_2, 12.130; H_2O, 2.075. Subs., 3.842: N_2, 0.218 cc. (31°, 760 mm.). Calcd. for $C_{27}H_{22}O_6N_2$: C. 68.94; H, 4.68; N, 5.96. Found: C, 69.16; H, 4.82; N, 6.10.

5-Acetyl-8-benzoyloxyquinoline gives colorless columns from hot alcohol, m. p. 168°. It is easily soluble in benzene and chloroform but sparingly in ether.

Anal. Subs., 5.037: N_2, 0.212 cc. (15°, 767.5 mm.). Calcd. for $C_{18}H_{13}O_3N$: N, 4.81. Found: N, 4.95.

ω-Methylene-bis-5-acetyl-8-benzoyloxyquinoline.—A mixture of 0.6 g. of 5-acetyl-8-benzoyloxyquinoline. 7 cc. of formaldehyde and some alcohol is refluxed for fourteen hours. On cooling, the separated solid (0.3 g.) is filtered and recrystallized from nitrobenzene. It gives colorless prisms, m. p. >315°.

Anal. Subs., 6.738: N_2, 0.282 cc. (15°, 772 mm.). Calcd. for $C_{37}H_{26}O_8N_2$: N, 4.71. Found: N, 4.95.

ω-Piperonylidene-5-acetyl-8-hydroxyquinoline.—A solution of 0.4 g. of sodium hydroxide in the same quantity of water is added to the warm solution of 0.19 g. of 5-acetyl-8-hydroxyquinoline and 0.15 g. of piperonal in 2 g. of alcohol with stirring. The resulting yellow paste, after standing for twenty-four hours with some water added, is acidified with dilute hydrochloric acid, and then an excess of sodium acetate is added. The resulting yellow precipitate is filtered and washed; yield, 0.3 g. It crystallizes from alcohol into yellow needles, m. p. 178–179°.

It is soluble in alcohol, benzene and ether, but insoluble in dilute mineral acid and alkali. The alcoholic solution gives a green color reaction with ferric chloride and the solution in concd. sulfuric acid assumes a purple-red color but decolorizes on addition of water.

Anal. Subs., 3.284: CO_2, 8.600; H_2O, 1.291. Subs., 5.475, 6.115: N_2, 0.214 cc. (30.5°, 762 mm.), 0.233 cc. (25.5°, 760 mm.). Calcd. for $C_{19}H_{13}O_4N$: C, 71.47; H, 4.08; N, 4.39. Found: C, 71.42; H, 4.37; N, 4.07, 4.21.

The writers, hereby, desire to express their hearty thanks to Professor Hata for the interest which he has kindly taken in this work and to Professor Kakuji Goto for the suggestion at which this work was done.

Summary

1. Condensation of 5-acetyl-8-hydroxyquinoline with formaldehyde gives ω-methylene-bis-5-acetyl-8-hydroxyquinoline.

2. Condensation of 5-acetyl-8-hydroxyquinoline with piperonal gives w-piperonylidene-5-acetyl S-hydroxyquinoline.

THE BECKMANN REARRANGEMENT WITH QUINOLINE COMPOUNDS

BY KONOMU MATSUMURA AND CHUSABURO SONE

RECEIVED DECEMBER 16, 1930 PUBLISHED APRIL 6, 1931

Schroeter, in an earlier research, found that the Beckmann rearrangement with pivalophenone oxime may be able to proceed in two opposite directions in accordance with the type of reagent used.[1] This paper represents a similar instance in the quinoline series. In the previous paper[2] it was definitely established that 5-acetyl- and 5-benzoyl-8-hydroxyquinoline oximes in the Beckmann rearrangement with hydrogen chloride, glacial acetic acid and acetic anhydride, give 5-acetamino- and 5-benzoylamino-8-hydroxyquinoline (I and II), respectively.

$$\underset{\text{I}}{CH_3CONHC_9H_6ON} \qquad \underset{\text{II}}{C_6H_5CONHC_9H_6ON} \qquad \underset{\text{III}}{C_6H_5NHCOC_9H_6ON}$$

In a subsequent investigation it was found that 5-benzoyl-8-hydroxyquinoline oxime, on treatment with thionyl chloride, gave an anilide of 8-hydroxyquinoline-5-carboxylic acid (111), and on hydrolysis with hydrochloric acid, the latter gave 8-hydroxyquinoline-5-carboxylic acid [m. p. 273° tdec.)]. On treating 8-hydroxyquinoline with carbon tetrachloride and potassium hydroxide in alcohol solution, Lippmann and Fleissner obtained an 8-hydroxyquinoline-carboxylic acid [m. p. 280° (dec.)] which gave quinolinic acid on oxidation with potassium permanganate and dibromo-8-hydroxyquinoline (m. p. 193°) on bromination.[3] The experimental data given by these authors make it seem likely that the compound which they obtained would be 8-hydroxyquinoline-5-carboxylic acid, identical with what we have now obtained, but some inconformities in their properties are noticed between them (on pouring in water, the hydrochloride of the authors' compound separates free base, while that of Lippmann and Fleissner is stated to be easily soluble). In order to clear up this matter, the experimental work of Lippmann and Fleissner was repeated and the identity was definitely established. To return to the oxime rearrangement, 5-benzoyl-8-hydroxyquinoline oxime, on treatment with concd. sulfuric acid, is found to give a sulfonated 8-hydroxyquinoline-5-carboxylic acid anilide, and on hydrolysis with hydrochloric acid (20%), the latter gives 8-hydroxyquinoline-5-carboxylie acid. Concerning the position of the sulfonic acid group, no definite proof can be obtained, but the sulfonated compound gives a red color reaction with diazotized sulfanilic acid in alkaline solution. This seems to indicate that the position ortho to the hydroxyl group is not occupied.

---

[1] Schroeter, *Ber.*, 44, 1201 (1911).

[2] Matsumura, THIS JOURNAL, 52, 4433 (1930).

[3] Lippmann and Fleissner, Ber., 19, 2467 (1886); *Monatsb.*, 8, 311 (1887).

Moreover, 5-acetyl-8-hydroxyquinoline oxime, in a similar treatment, does not give rise to sulfonation. These facts seem to favor the opinion that the sulfonic acid group might perhaps be in the aniline molecule and then probably in the para position to the amino group.

5-Acetyl-8-hydroxyquinoline oxime, on the other hand, on treating either with thionyl chloride or with sulfuric acid, gives, in either case, 5-acetamino-8-hydroxyquinoline, the same product that is obtainable on treatment with hydrogen chloride, glacial acetic acid and acetic anhydride.

Experimental

8-Hydroxyquinoline-5-carboxylic Acid Anilide.—Thionyl chloride (10 cc.) is added to the cooled solution (0°) of 5-benzoyl-8-hydroxyquinolineoxime (1 g.) in dry ether (150 cc.) with stirring. The resulting yellow precipitate is filtered, after standing for three hours at room temperature (25°), and washed with ether.

On dissolving the precipitate in cold water and making alkaline with sodium carbonate, colorless crystals separated; yield, 1 g. It gives yellowish-white thin plates with a silky luster from alcohol, m. p. 211–212°. It is easily soluble in alcohol, fairly soluble in hot benzene and chloroform, sparingly in ether and insoluble in water.

In this reaction, on using chloroform instead of ether as solvent, the same reaction product can be obtained in a far inferior yield.

Anal. Subs., 4.145 *mg.*: N_2, 0.376 cc. (23°, 769 mm.). Calcd. for $C_{16}H_{12}O_2N_2$: N, 10.60. Found: N, 10.28.

The sulfate gives yellow needles from alcohol, decomposing at 211–215°. When water is poured in, it separates as the free base.

Hydrolysis of **8-Hydroxyquinoline-5-carboxylic Acid Anilide.**—Two tenths gram of 8-hydroxyquinoline-5-carboxylic acid anilide and 8 g. of hydrochloric acid (20%) were refluxed for six hours. On cooling, the resulting crystals of the hydrochloride of 8-hydroxyquinoline-5-carboxylicacid were filtered. The filtrate, on being made alkaline, gave an odor specific to aniline, and a deep violet coloration when in contact with a solution of bleaching powder. The hydrochloride was dissolved in dilute ammonia and on acidification with acetic acid, yellow needles of 8-hydroxyquinoline-5-carboxylic acid separated; yield, 0.1 g. It crystallizes from alcohol to egg-yellow, stout needles, melting at 273° (uncorr.) with decomposition, after preliminary subliming in a sealed capillary. It is moderately soluble in hot alcohol and hot acetone, but difficultly so in ether, chloroform and benzene, and easily soluble in dilute mineral acid and alkali. The alcoholic solution gives a green color reaction with ferric chloride. An attempt to prepare the chloroplatinate was unsuccessful.

Anal. Subs., 4.977: CO_2, 11.608; H_2O, 1.770. Subs., 3.603: N_2, 0.245 cc. (29°, 760.5 mm.). Calcd. for $C_{10}H_7O_3N$: C, 63.49; H, 3.70; N, 7.40. Found: C, 63.61; H, 3.95; N, 7.35.

The **hydrochloride** gives colorless columns from hydrochloric acid (10%), m. p. 239° (decomp.), and separates free base on pouring in water.

Anal. Subs., 5.000: AgCl, 3.149. Calcd. for $C_{10}H_7O_3N{\cdot}HCl$: Cl, 15.74. Found: Cl, 15.58.

The neutral barium salt gives yellow needles from hot water. It is fairly soluble in water but insoluble in alcohol.

Anal. (water of crystallization) Subs., 0.0315: H_2O, 0.0061. Calcd. for $(C_{10}H_6O_3N)_2Ba{\cdot}5.5H_2O$: H_2O, 16.18. Found: H_2O, 16.19. Subs., 5.889: $BaSO_4$, 2.651. Calcd. for $(C_{10}H_6O_3N)_2Ba$: Ba. 26.75. Found: Ba, 26.51.

8-Acetoxyquinoline-5-carboxylic acid gives light yellow prisms from ethyl acetate, decomposing at 312°.

Anal. Subs., 5.101: CO_2, 11.638; H_2O, 1.838. Subs., 5.215: N_2, 0.281 cc. (20°, 754.5 mm.). Calcd. for $C_{12}H_9O_4N$: C, 62.33; H, 3.90; N, 6.05. Found: C, 62.22; H, 4.00; N, 6.09.

8-Methoxyquinoline-5-carboxylic Acid.—A methyl alcohol suspension of 8-hydroxyquinoline-5-carboxylic acid was treated with ethereal diazomethane and the resulting difficultly crystallizable dimethyl derivative was hydrolyzed with alcoholic potassium hydroxide solution. The final product was recrystallized from alcohol into small yellow crystals, m. p. 225–226° (dec.).

Anal. Subs., 3.634: AgI, 4.116 Calcd. for $C_{11}H_9O_3N$: OCH_3, 15.27. Found: OCH_3, 14.95.

Sulfonated **8-Hydroxyquinoline-5-carboxylic** Acid **Anilide.**—A solution of 5-benzoyl-8-hydroxyquinoline oxime (0.5 *g.)* in concd. sulfuric acid *(5* g.) was kept at 100° for an hour. On pouring onto crushed ice (20 g.), a resinous precipitate, which soon turned to a yellow crystalline mass, was formed. It was dissolved in dilute sodium carbonate, reprecipitated with dilute sulfuric acid, and repeatedly washed with cold water; yield, 0.4 g.; m. p. >300°.

It forms in yellowish-white thin plates, practically insoluble in the usual organic solvents, but easily soluble in dilute alkali, and moderately so in boiling water. It gives a green color reaction with ferric chloride, and a red color reaction with diazotized sulfanilic acid and alkali. On hydrolysis with hydrochloric acid (20%), this compound gives 8-hydroxyquinoline-5-carboxylic acid [m. p. 273° (dec.)] in a good yield. An attempt to isolate another component, perhaps sulfanilic acid, failed.

The reaction fluid, however, on being made alkaline, gave no odor of aniline, and after treatment with nitrous acid gives a red coloration with alkaline β-naphthol.

Anal. Subs., 4.545: N_2, 0.339 cc. (28°, 760 mm.). Subs., 5.939: $BaSO_4$, 3.754. Calcd. for $C_{16}H_{11}O_5N_2S$: N, 8.16; S, 9.35. Found: N, 8.15; S, 8.68.

The Reaction of **8-Hydroxyquinoline** and Carbon Tetrachloride.—The compound prepared from 8-hydroxyquinoline (20 g) and carbon tetrachloride by following the method of Lippmann and Fleissner[3] for 8-hydroxyquinoline-carboxylic acid, gives yellow needles from alcohol, melting at 273° (dec.) alone or mixed with 8-hydroxyquinoline-5-carboxylic acid; yield, 3 35 g. The hydrochloride [m. p. 239" (dec.)] separates free base on pouring into water and its methyl ether and acetoxyl derivatives melt at 223–224" (dec.) and 310° (dec.), respectively.

The Beckmann rearrangement of 5-acetyl-8-hydroxyquinoline oxime either with thionyl chloride in chloroform solution or with concd. sulfuric acid gives 5-acetamino-8-hydroxyquinoline (m. p. 217–218°), identified by the mixed melting point test with an authentic specimen.

The writers, hereby, wish to express their hearty thanks to Professor Hata for the interest which he has kindly taken in this work.

Summary

1. 5-Benzoyl-8-hydroxyquinoline oxime, on treatment with thionyl chloride, gives 8-hydtoxyquinoline-5-carboxylic acid anilide and with concd. sulfuric acid gives sulfonated 8-hydroxyquinoline-5-carboxylic acid anilide. Both reaction products, on hydrolysis with hydrochloric acid, give 8-hydroxyquinoline-5-carboxylic acid.

2. 5-Acetyl-8-hydroxyquinolineoxime on treatment either with thionyl chloride or with concd. sulfuric acid gives 5-acetamino-8-hydroxyquinoline.

THE TITRIMETRIC AND SPECTROMETRIC ANALYSIS OF KETO-ENOL MIXTURES. ALPHA-PHENYLACETOACETIC ESTER

BY KARL V. AUWERS

RECEIVED JANUARY 2, 1931 PUBLISHED APRIL 6, 1931

In a recent paper[1] on the keto-enol equilibrium in a-phenylacetoacetic ester, Post and Michalek have attempted to determine the percentage of the enolic modification, both titrimetrically and spectrometrically. Indirect titration with bromine, by the Kurt Meyer method, gave them an average value of 28.6% of enol, whereas, from its molecular refraction, they calculate the impossible value of 137.13%, which they attribute to the "anomalous" structure of the phenyl group.

These authors also mention, incidentally, that from its molecular refraction the enol content of the unsubstituted acetoacetic ester is 59.2%, whereas, according to the bromine titrations, it contains only 7.7%.

These statements make it appear that spectrochemistry would lead to entirely false results with substances of this type and would not be useful for the analysis of keto-enol mixtures.

However, these authors have overlooked the fact that this problem of the apparent contradiction between the results of the bromine titrations and those of spectrochemistry has long since been investigated and explained.[2]

It has been found that both methods in reality give results which are in sufficient agreement, if certain well-known spectrochemical regularities are correctly taken into account.

Post and Michalek[3] arrive at their values for the enol content by comparing the experimental molecular refraction with the values which they calculate, theoretically, on the basis of atomic refractions. By this procedure, however, correct values are obtained only for the keto forms; those for the enol forms are too low. The molecules of the enolic acetoacetic ester contain a conjugated system of double bonds, the exaltation of which is increased by the hydroxyl group attached to it,[4] since the partial valences

---

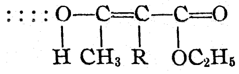
[1] Post and Michalek, THIS JOURNAL, 52, 4358 (1930).

[2] K. v. Auwers, Ann., 415, 169 (1918); K. v. Auwers and H. Jacobsen, *ibid.*, 426, 161 (1921).

[3] Post and Michalek state erroneously that their values have been calculated with the old Brühl refraction equivalents, whereas they have actually used the new Eisenlohr values. It may be mentioned, incidentally, that the accompanying reference number 9, as well as numbers 5 and 7 are not apropos.

[4] K. v. Auwers, Ber., 44, 3514 (1911).

of the oxygen atom, together with the double bond, form a sort of "cumulative" conjugation, as can be seen from the formula



$$::::\underset{H}{O}-\underset{CH_3}{C}=\underset{R}{C}-\underset{OC_2H_5}{C}=O$$

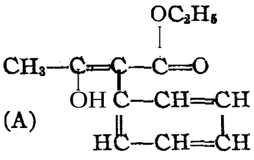
It has been previously shown[6] that by considering all the factors that should be taken into account, the molecular refraction for 100% enolic acetoacetic ester is calculated to be 34.42 instead of 32.62, and this value coincides exactly with the results of Knorr's observations. Furthermore, it has been shown that, according to its molecular refraction, the enol content of the equilibrium ester is 8%, which is in excellent agreement with the titrimetrically determined value. Therefore there is no contradiction, in this case, between the two methods.

α-Phenylacetoacetic Ester.—Post and Michalek calculate the enol content of this compound, refractometrically, from the following figures.

100% Ketone (calcd.)	Found	100% Enol
55.66	57.10	56.71[6]

The third of these figures is, for the reasons previously given, too low. The correct value for the molecular refraction can be approximated with a sort of accuracy by taking into account the following facts.

The specific exaltation of β-hydroxycrotonic ester, *i.* e., the pure enol of acetoacetic ester, has been found to be +1.38. However, substituents introduced into a conjugated system exert an influence on its spectrochemical behavior. The α-phenylacetoacetic ester molecule contains a "crossed conjugation, as shown by the structural formula (A).



(A)

The optical activity of a crossed conjugation, compared to that of a simple conjugation, varies both according to the nature of the parent system and the kind of "disturbing" substituent. In the case under consideration it can be concluded from analogies, which will not be discussed here, that the specific exaltation of the phenylated acetoacetic ester will be approximately as great as that of the parent substance, or at least will not be greater, and probably will be somewhat smaller. Assuming the two to be equal, the molecular exaltation of the pure enol of phenylacetoacetic ester is +2.84, *i. e.*, the molecular refraction of this substance is not 56.71 but 59.56. Then it follows from Post and Michalek's experimental value that the equilibrium ester contains 36.6% enol and not 137.13%.

This value is about 10% higher than those determined titrimetrically by other authors, for their observations yield an average of 26.8%.[7]

---

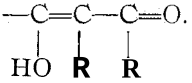
[5] K. v. Auwers, Ref. 4, p. 3530.

[6] The actual values are 55.68 and 56.72.

[7] Post and Michalek calculate, from their investigations, the somewhat higher value of 28.6%.

The difference might mean that the specific exaltation of the phenyl derivative is not equal to that of the parent substance, as assumed; but then it would follow, from the amount of enol which the authors found titrimetrically, that the specific exaltation of the enol of phenylacetoacetic ester, is higher than that of the enol of acetoacetic ester, and therefore that the exalting effect of the crossed conjugated systems is greater than that of simple conjugations. This is, however, in the light of previous spectrochemical experience, unlikely.

Therefore it is necessary to consider the possibility that the indirect bromine titration of α-phenylacetoacetic ester results in too low values, for this has already been established with certainty for various sorts of substances containing the atomic arrangement[8]



$$\underset{\text{HO}}{\overset{|}{—\text{C}}}=\underset{\text{R}}{\overset{|}{\text{C}}}—\underset{\text{R}}{\overset{|}{\text{C}}}=\text{O}.$$

In order to clear this up, I have repeated, in collaboration with Dr. E. Wolter, to whom I extend my sincere thanks for his valuable assistance, the spectrometric and titrimetric investigation of a-phenylacetoacetic ester.

We used both a collection preparation, which was redistilled, and a preparation that was freshly made according to Dimroth and Feuchter's modified directions[9] of Beckh's method.[10] Both preparations had the same properties; they boiled at 141° under a pressure of 9 mm.

SPECTROCHEMICAL CONSTANTS

$d_4^{16.5}$ 1.08915; d_4^{20} 1.086; $n_\alpha^{16.5}$ 1.51065; $n_{\text{He}}^{16.5}$ 1.51513; $n_\beta^{16.5}$ 1.52630; $n_\gamma^{16.5}$ 1.53610; n_{He}^{20} 1.5136

Calculated for....................	M_α	M_D	$M_\beta - M_\alpha$	$M_\gamma - M_\alpha$
$C_{12}H_{14}O{<}O_2''\overline{|3}$ (206.11)	55.32	55.68	1.16	1.86
Found	56.66	67.08	1.45	2.36
M. E.	+1.34	+1.40	+0.29	+0.50
Sp. E.	+0.65	+0.68	+25%	+27%

These data agree satisfactorily with the observations of Post and Michalek; further determinations were therefore considered unnecessary.

Bromine Titrations.—The following titrations, for which samples from both preparations were used, were carried out by the indirect method of Kurt Meyer, in Jena glass vessels. The first two trials were heated for twenty minutes after the addition of potassium iodide, numbers III and IV for thirty minutes and numbers V and VI, one hour.

	Substance, g.	$N/10$ $Na_2S_2O_3$,[a] cc.	Enol, %
I	0.4379	16.4	38.6
II	.3458	12.8	38.1
III	.3732	14.3	39.5

---

[8] K. v. Auwers and H. Jacobsen, Ref. 2, p. 165.

[9] Dimroth and Feuchter, *ibid.*, 36, 2243 (1903).

[10] Beckh, *Ber.*, 31, 3160 (1898).

	Substance, g.	$N/10$ $Na_2S_2O_3$,[a] cc.	Enol. %
IV	0.4379	16.5	38.8
V	4385	17.3	40.7
VI	.3579	13.9	40.0

[a] These volumes were calculated by means of the factors of the solutions actually used.

It is apparent that the length of heating has no material effect on the result. This means that conversion was, in every case, complete, and therefore that the indirect procedure is applicable to this substance.

In order to be absolutely certain, the enol content was determined directly, in a final experiment, and verified by indirect titration.

VII *Subs.*, 0.2640 *g.*; $N/10$ Br,[a] 10 *cc.* = 39.0% Enol; $N/10$ $Na_2S_2O_3$,[a] 9.9 *cc.* = 38.7% Enol

The average of all the determinations is 39.2% enol, a value which is approximately that deduced from the refractive index.

It is impossible to state why Post and Michalek found a materially lower value, although their preparation had the same physical constants as that which we investigated. The supposition that in their investigation of the ester it had become more ketonic in alcoholic solution can hardly be correct, for we found the higher values of the enol content, also, when the solutions had stood for several hours or had come to room temperature.

The noteworthy fact that a-phenylacetoacetic ester enolizes to a much greater extent than a-alkyl acetoacetic esters[11] can be explained, following Post and Michalek, by the ionizing influence which the phenyl group exerts on the a-hydrogen atom. It may, however, also be due to the fact that there is present in the enol of that compound the atomic arrangement (C_6H_5—C=C—) which is actually characteristic of styrols. It is known that A^2-styrols, C_6H_5—C—C=C—, have a tendency to pass over into the A^1-isomers, whereas a shift of the double bond in the opposite direction does not take place. In contrast to this, in the olefinic acid a mutual interconversion of Δ^1 and A^2 is possible. Therefore the system  $-\underset{HO}{\underset{|}{C}}=\underset{C_6H_5}{\underset{|}{C}}-C=O$ will show a stronger resistance to conversion into  $-\underset{O}{\underset{\|}{C}}-\underset{C_6H_5}{\underset{|}{C}}-C=O$ than the enols of acetoacetic ester and its alkyl derivatives, and this must result in an increase in the enol content of the equilibrium ester.

Summary

1. The rule that titrimetric **and** spectrometric determinations of the enol content of tautomeric mixtures gives results in satisfactory agreement holds also for a-phenylacetoacetic ester.

---

[11] Dieckmann [*Ber.*, 55, *2476* (1922)] has already pointed out the high "enol constants" of phenyl derivatives.

2. Titrimetrically, the enol content of this substance is found to be 39.2% and spectrometrically 36–37%, therefore materially higher than for a-alkyl acetoacetic esters.

3. For a-phenylacetoacetic ester, in contrast to a-alkylacetoacetic ester, the direct bromine titration is just as applicable as the indirect bromine titration.

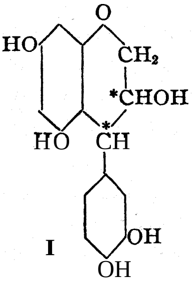
STEREOISOMERIC CATECHINS

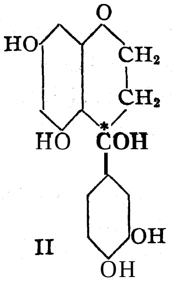
BY R. P. BIGGS, W. L. COOPER, EDITH O. HAZLETON, M. NIERENSTEIN AND PHYLLIS H. PRICE

RECEIVED JANUARY 5, 1931 PUBLISHED APRIL 6, 1931

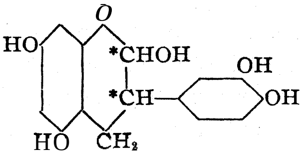
Six stereoisomers are to be expected from acacatechin (I) and three from iso-acacatechin (II), but so far only four have been identified in Nature, namely, *l*- and dl-acacatechin and *l*- and dl-iso-acgcatechin.



I



II



III

The present communication describes two new stereoisomeric catechins, d acacatechin and d-iso-acacatechin. d-Acacatechin accompanied by *dl*-acacatechin was found in mahogany wood from South America and the West Indies and in the Australian Kinos from *Eucalyptus viminalis*, Lab., E. Leucoxylon, Müll. and *Angophora intermedia* D. C., whereas *d*-iso-acacatechin only was identified in the heartwood of *Anarcadium occidentale*, L. Of the other plant materials investigated in the course of the present work, the Malabar Kinos from *Myristica Malabarica*, Larn. and *Pterocorpus Marsupium*, Roxb , and the Australian Kino from *Eucalyptus corymbosa*, Smith, were found to contain 1-acacatechin and dl-acacatechin, whilst Chinese rhubarb, Guarana paste, Kola nuts and the leaves of Uncaria gambir, Roxb. and of *Uncaria acida*, Roxb. all contain *d*-gambir-catechin and dl-gambir-catechin.

The investigation, in view of their red-brown color suggesting the presence of catechin, was also extended to the following plant materials: oak bark,[1] chestnut bark, quebracho wood, hemlock bark, almond skins and cured Virginian and Rhodesian tobacco. None of these materials, however, was found to contain catechin.

The identification of d-iso-acacatechin in Nature completes the iso-acacatechin (II) series, whereas the discovery of d-acacatechin (I) still leaves three more stereoisomeric acacatechins to be accounted for, since they cannot, with any degree of certainty, be identified with d- and *dl*-gambir-catechin.[2]

Whatever the interrelationship between gambir-catechin and acacatechin may prove to be, the chemistry of catechin is faced with the fact that ***eight*** catechins have now been identified in Nature. This, in our opinion, finally disproves the contention that all catechins are stereoisomerides of one and the same parent substance containing ***two*** asymmetric carbon atoms, *as* postulated by Freudenberg's[3] hypothesis, already criticized[4] on other grounds.

On the other hand, if one assumes that gambir-catechin is represented by Formula III, as evident from the work of Drumm, Carolan and Ryan,[5] one realizes that ***fifteen*** catechins are theoretically possible, namely, six stereoisomeric acacatechins (I), three stereoisomeric iso-acacatechins (II) and six stereoisomeric gambir-catechins (III). So far only eight catechins have been identified, which still leaves seven more to be accounted for, and it is proposed to continue the work in this direction. Meanwhile reference is made to a suggestion put forward over a hundred years ago by Nees von Esenbeck,[6] to reserve the name catechin for the substance present in the cutch of *Acacia Catechu* and to refer to the corresponding product present in the cutch of *Nauclea* (syn. *Uncaria*) *gambir* as nauclein. It is perhaps now too late to adopt this suggestion, but there is not the slightest doubt whatever that if catechin and nauclein had been dealt with separately much confusion would have been avoided. In this connection attention must be drawn to the definite line of demarcation between the occurrence of aca- and iso-acacatechin on the one hand and gambir-

---

[1] Casparis, *Pharm. Acta Helv.*, 4, 181, 189 (1929), found a catechin-like substance in oak bark. This, however, has not been confirmed by Freudenberg and Oehler, *Ann.*, 483, 140 (1930), who are of the opinion that Casparis had mistaken ellagic acid for catechin.

catechin on the other, although it must be noted that Freudenberg and Oehler[7] report the presence of l-acacatechin and d-gambir-catechin in the Kola nut, a point not confirmed by us, since we only found d- and *dl*-gambir-catechin in the material investigated by us, and also in a specimen of Kola nut catechin kindly sent us by Dr. Ultée.

Historical

Some of the materials investigated by us have already been studied by previous workers. Thus mahogany wood was found by Latour and Caseneuve[8] to contain a catechin-like substance, and this was confirmed by Freudenberg, Bohme and Purrmann,[9] who showed it to be dextrorotatory.

Catechin-like substances were also found in the Kinos of Eucalyptus *viminalis* and *Eucalyptus* Leucoxylon by Heckel and Schlagdenhauffen,[10] whereas Maiden[11] and Smith[12] reported the presence of such substances in the Kinos of *Angophora* intermedia and *Pterocorpus Marsupium*, respectively.

The catechin in Chinese rhubarb was investigated by Gilson,[13] who proved it to be d-gambir-catechin. This was confirmed by Freudenberg, Böhme and Purrmann,[9] and now also by us. As regards the presence of catechin in Guarana paste, it must be noted that Kirmsse[14] and Freudenberg and his collaborators[15] have investigated it with no definite success, and similar indefinite results were obtained by Goris[16] and Goris and Fluteaux,[17] and by Casparis[18] in the case of the Kola nut. The results of Freudenberg and Oehler on the catechins present in the Kola nut have already been mentioned.

Experimental

The Kinos, the Guarana paste and the different kinds of wood, in the form of sawdust, were exhaustively extracted with ethyl acetate in a large Soxhlet apparatus. The Kinos and the Guarana paste were finely powdered, passed through a 30-mesh sieve and mixed with ten times their own weight of sand.[19] The ethyl acetate extracts were evaporated to dryness under

[19] The sand used was at first treated with dilute hydrochloric acid, then washed with water, alcohol and ether. It was then dried at 100° and powdered.

reduced pressure and the remaining solid powdered and mixed with ten times its own weight of sand. It was then extracted in a Soxhlet apparatus with ether free from alcohol Extraction was continued until no solid was obtained on evaporation of the ether. The solids obtained on evaporation of the ether were dissolved in hot water slightly acidulated with acetic acid,[20] and the solid collected after standing for some time, when as a rule the dl-forms separated first. The catechin fractions thus obtained were recrystallized from water, dried in a vacuum desiccator over concentrated sulfuric acid for several days and acetylated by heating with acetic anhydride. The solid obtained on precipitation with water crystallized from alcohol and a few drops of acetone. The filtrates of the crude catechins were evaporated by standing over concentrated sulfuric acid, the solids thus obtained were then powdered and mixed with sand, again extracted with ether and worked up in the manner described above. The aqueous filtrates were then again solidified and examined in the same way. It was generally found that these third solids contained little or no catechin.

In the case of the leaves of the *Uncaria* species and the Chinese rhubarb, no ethyl acetate extractions were carried out, but the materials were at first exhaustively extracted in a Soxhlet apparatus with chloroform so as to remove chlorophyll, and in the case of Chinese rhubarb chrysophanic acid and such-like substances. The removal of chrysophanic acid from Chinese rhubarb was very tedious, and required continuous extraction for nearly two months. After the extraction with chloroform, the leaves and rhubarb were powdered in a mill and extracted with ether as described. In the case of the Kola nut it was also found necessary to subject the finely broken up material to chloroform extraction before extraction with ether.

In the identification of the different catechins, reliance was laid on the pentaacetyl derivatives, which are remarkable for the ease with which they crystallize and for the sharpness of their melting points. Nearly thirty years' experience with catechin has convinced Nierenstein[21] that very little reliability can be placed on the melting points of the catechins themselves, as these are greatly affected by moisture. This is best illustrated in the case of gambir-catechin,[22] which is reported to melt at 96, 175–177 and 210°, respectively, these variations being due to water of crystallization. In a similar manner, Nierenstein[23] has come to the conclusion that not much confidence can be attached to the melting points of the methoxy derivatives if prepared in the usual way by the action of dimethyl sulfate

and alkali, since these derivatives are generally contaminated with by-products, formed through fission of the chromane ring. The following summary gives the melting points and rotations in tetrachloroethane of the pentaacetyl derivatives as used by us as evidence of identity and purity.

	M. p., °C.	$[\alpha]_D$
Pentaacetyl-*l*-acacatechin	151	−12.0°
Pentaacetyl-d-acacatechin	151	+12.0°
Pentaacetyl-dl-acacatechin	160	.....
Pentaacetyl-*l*-iso-acacatechin	171	−29.3"
Pentaacetyl-d-iso-acacatechin	171	+29.3°
Pentaacetyl-dl-iso-acacatechin	193	...
Pentaacetyl-d-gambir-catechin	137	+37.6°
Pentaacetyl-dl-gambir-catechin	156	...

As a check on our melting points of pentaacetyl-dl-acacatechin and pentaacetyl-dl-iso-acacatechin obtained from the naturally occurring *dl*-catechins, these pentaacetates were also prepared by admixture of equal parts of pentaacetyl-*l*-acacatechin with pentaacetyl-d-acacatechin and of pentaacetyl-*l*-iso-acacatechin with pentaacetyl-d-iso-acacatechin. These synthetic pentaacetates proved to be in every respect identical with the pentaacetates of natural origin. Unfortunately, no such check could be carried out on pentaacetyl-dl-gambir-catechin, as only pentaacetyl-*d*-gambir-catechin has so far been identified in Nature.

In the identification of the different pentaacetyl derivatives, we strongly adhered to the constants given above. Where lower melting points or lower rotations were observed, the products were repeatedly recrystallized until these constants were reached. In this we have succeeded in every case. With the single exception of pentaacetyl-d-iso-acacatechin, which has so far only been found in *Anarcadium occidentale*, mixed melting points were taken, and in no case could depressions be observed. All the pentaacetates, dried at 110°, were analyzed in duplicate and were found to agree within the limits of experimental error for $C_{15}H_9O_6(COCH_3)_5$.

We append the following summary showing the quantities of material investigated and the approximate yields of the different catechins obtained.

(1) 56 Kilos mahogany wood from South Africa: 12 g. d-acacatechin and 3.5 g. dl-acacatechin
(2) 42 Kilos mahogany wood from the West Indies: 6 g. d-acacatechin and 6 g. *dl*-acacatechin
(3) 8 Kilos Australian Kino from *Eucalyptus viminalis:* 16 g. d-acacatechin and 22 g. dl-acacatechin
(4) 6 Kilos Australian Kino from *Eucalyptus Leucoxylon:* 5 g. d-acacatechin and 10 g. dl-acacatechin
(5) 9 Kilos Australian Kino from *Angophora intermedia:* 14 g. d-acacatechin and 8 g. dl-acacatechin
(6) 86 Kilos heartwood of *Anarcadium occidentale:* 29 g. d-iso-acacatechin

(7) **4** Kilos Malabar Kino from *Myristica Malabarica:* **3** g. l-acacatechin and **11 g.** dl-acacatechin
(8) **7** Kilos Malabar Kino from *Pterocorpus Marsupium:* **9** g. *l*-acacatechin and **17** g. dl-acacatechin
(9) 6 Kilos Australian Kino from Eucalyptus *corymbosa:* 4 g. *l*-acacatechin and **9** g. dl-acacatechin
(10) **28** Kilos *Uncaria* gambir leaves: **56** g. *d*-gambir-catechin and **6 g.** dl-gambir-catechin
(11) **2.8** Kilos *Uncaria acida* leaves: **9** g. d-gambir-catechin and **4.5** g. *dl*-gambir-catechin
(12) **11** Kilos Chinese rhubarb: **17** g. d-gambir-catechin and **3** g. dl-gambir-catechin
(13) **2** Kilos Guarana paste: **5** g. d-gambir-catechin and 4 g. dl-gambir-catechin
(14) **19** Kilos Kola nuts: **58** g. d-gambir-catechin and 8 g. dl-gambir-catechin

In conclusion, the authors wish to express their thanks to the Colston Research Society of the University for many generous grants, without which this investigation would not have been possible.

Summary

Eight stereoisomeric catechins have been shown to exist in Nature, of which d-acacatechin and d-iso-acacatechin have been discovered in the course of the present investigation.

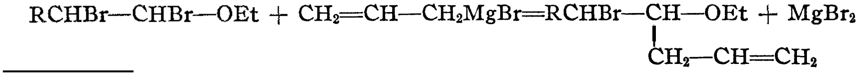
NUCLEAR SYNTHESES IN THE OLEFIN SERIES.
II. 1,4-DIOLEFINS[1]

BY BERNARD H. SHOEMAKER[2] AND CECIL E. BOORD

RECEIVED JANUARY 5, 1931 PUBLISHED APRIL 6, 1931

The nuclear synthesis of unsaturated hydrocarbons previously described[3] has been extended to the synthesis of 1,4-diolefins. This extension has been made possible through the preparation of allylmagnesium bromide by the method described by Gilman and McGlumphy.[4]

The addition of an α,β-dibromoalkyl ethyl ether to a slight excess of allylmagnesium bromide in ether solution leads to the formation of an α-allyl-β-bromoalkyl ethyl ether. It has been found in general that β-bromo



$$\mathrm{RCHBr{-}CHBr{-}OEt + CH_2{=}CH{-}CH_2MgBr = RCHBr{-}\underset{\displaystyle CH_2{-}CH{=}CH_2}{\underset{|}{CH}}{-}OEt + MgBr_2}$$

---

[1] Presented before the Organic Division of the American Chemical Society, at Atlanta, Georgia, April, **1930.**

[2] Abstracted from the dissertation presented by Bernard H. Shoemaker in partial fulfilment of the requirements for the Ph.D. degree to the Faculty of the Graduate School of The Ohio State University, June, **1930.**

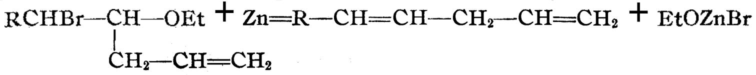
ethers are most readily purified by steam distillation. This procedure serves to destroy the residual dibromo ether and yields the desired product in a form which may be further purified by direct distillation under diminished pressure. The p-bromo ethers so purified are obtained as water-white limpid liquids and have been kept for many months without apparent deterioration.

The conversion of the β-bromo ethers into the corresponding unsaturated compounds has also been improved. When the ethyl alcohol, as a medium for the decomposition by zinc, is replaced by n-propyl or n-butyl alcohol, both the speed of the reaction and the yield are greatly increased. The increase in reaction velocity is doubtless due in part to the higher boiling point temperatures of the new solvents but it is also due in part to the greater solubility of ethoxyzinc bromide in the new media, so that the surface of the metal is kept clean.



$$RCHBr{-}\underset{\displaystyle CH_2{-}CH{=}CH_2}{\underset{|}{CH}}{-}OEt + Zn = R{-}CH{=}CH{-}CH_2{-}CH{=}CH_2 + EtOZnBr$$

The observations previously made upon the relation of the boiling points of the a-olefins to the corresponding saturated hydrocarbons has been fully confirmed.[5] The data as relating to diolefins having five, six and seven carbon atoms all in a continuous chain are shown in Table I. It will be observed that those dienes having a double bond at each end of the chain boil lower than the corresponding a-olefins. When one of the double bonds is moved away from the end of the chain, the boiling point is raised. As one of the double bonds is moved stepwise toward the one at the opposite end of the chain, the boiling point continues to rise. If both are moved away from the ends of the chain, the boiling point is still higher. The data for the seven carbon atom chains are not complete but in so far as available they stand in good agreement with the above rules.

It has been observed frequently that the tetrabromo paraffins exist in isomeric forms.[6] The same phenomena exist among the polybromo fatty acids.[7] The tetrabromides of the 1,4-diolefins show this same tendency to isomerism. In the case of 1,4-pentadiene the solid phase is obtained in

---

[5] It has come to our attention that Baudenghien, Bull. *soc. chim. Belg.*, *31*, 160 (1922), has used the same principle in discussing the identity of certain butenols. He cites the following cases

$CH_3{-}CHOH{-}CH{=}CH_2$	b. p. 97°	$CH_3{-}CHCl{-}CH_2{-}CH_3$	b. p. 68°
$CH_3{-}CHOH{-}CH_2{-}CH_3$	b. p. 99°	$CH_3{-}CHOAc{-}CH{=}CH_2$	b. p. 111"
$CH_3{-}CHCl{-}CH{=}CH_2$	b. p. 64°	$CH_3{-}CHOAc{-}CH_2{-}CH_3$	b. p. 113°

So far as we are aware the relationship has not been generalized.

Soday, in unpublished work done in this Laboratory, finds 94.3°.

Experimental Part

a-Chloroalkyl Ethyl Ethers, $R-CHCl-O-C_2H_5$.—The method previously described[8] has been improved and extended to the preparation of α-chloropropyl-, and a-chloro-n-butyl ethyl ethers. The darkening of the chloro ether may be avoided if the reaction is conducted so as to avoid undue mixing of the ethereal and aqueous layers. The preparation is best made by placing equimolar quantities of the aldehyde and absolute alcohol in a short-stemmed separatory funnel immersed in a freezing mixture. Hydrogen chloride is then led in in such a manner that it does not pass through the aqueous layer which soon begins to form and violent agitation is avoided. This addition is discontinued when the gain in weight corresponds to a 5% excess over the theoretical value. The aqueous layer is drawn off and the crude chloro ether dried over granular calcium chloride. The excess hydrogen chloride is removed by maintaining the product under diminished pressure, the granules of calcium chloride serving as bumping stones during this process. The product from a well-regulated experiment will be water white. For the purpose of synthesis this crude product is not distilled because of loss by decomposition. The yields of crude chloro ethers are shown in Table II. The physical constants and analyses are for the purified products.

[a] Swallen and Boord, Ref. 8. [b] James Vaughn (unpublished Master's Thesis, The Ohio State University, 1926) obtained this compound in a yield of 37% of purified product, b. p. 55° (40 mm.); chlorine found, 26.03%.

α,β-Dibromoalkyl Ethyl Ethers, $R—CHBr—CHBr—O—C_2H_5$.—In the bromination of the α-chloro ethers it has been found advantageous to avoid aspirating the product with a current of air as previously has been done. A few granules of calcium chloride were added and the reaction mixture maintained under diminished pressure for several hours. The granular calcium chloride serves the dual purpose of drying agent and bumping stones in freeing the product of dissolved hydrogen chloride. The dibromo ethers prepared in this way are pale straw colored liquids. The yields given in Table III are for the crude products. The physical constants and analyses are for products further purified by a single fractionation.

Allylmagnesium Bromide, $CH_2{=}CH—CH_2MgBr$.—Seventy-five grams of magnesium turnings was placed in a three-necked flask and covered with 200 cc. of anhydrous ether. The flask was fitted with a mechanical stirrer and a reflux condenser and submerged in an ice-bath. One gram mole of allyl bromide dissolved in 570 cc. of anhydrous ether was added dropwise over a period of eight to nine hours. The formation of the Grignard reagent was started by crushing one or two pieces of magnesium turnings in a test-tube under an ether solution of allyl bromide and adding this to the main portion. The reaction started immediately.

After the addition of allyl bromide was completed, 500 cc. of the ether solution of the Grignard reagent was decanted and the remaining solution replenished by an additional portion of 30–35 g. of magnesium. One-half gram mole of allyl bromide dissolved in 285 cc. of anhydrous ether was then added at the same rate as before. After the addition had been completed, the reaction mixture was allowed to stand for one-half hour. The ether solution was then decanted, care being taken to avoid carrying over any metallic magnesium. The turnings were washed with anhydrous ether and the washings added to the main portion.

The ether solution of allylmagnesium bromide was made up to a definite volume and titrated for reagent content by the method of Gilman, Wilkinson, Fishel and Meyers.[9] The yield of allylmagnesium bromide varied from 70 to 82% and was higher for the larger runs.

α-Allyl-β-bromoalkyl Ethyl Ethers, $R—CHBr—CH(C_3H_5)—O—C_2H_5$.—The ether

---

[9] Gilman, Wilkinson, Fishel and Meyers, THIS JOURNAL, 45, 150 (1923).

solution of allylmagnesium bromide was placed in a two-liter three-necked flask which had been provided with a mechanical stirrer and reflux condenser. The flask was surrounded by a freezing mixture and the appropriate dibromoalkyl ethyl ether dissolved in an equal volume of anhydrous sulfuric ether added slowly to a slight excess of the Grignard reagent. The condensation proceeded very rapidly. After all of the dibromo ether had been added the flask was allowed to stand at room temperature for one or two hours.

The reaction mixture always separated into two layers, the lower one consisting essentially of magnesium bromide etherate. The entire mass was hydrolyzed by pouring into a beaker of cracked ice and acidifying with dilute hydrochloric acid. The ether layer was separated and slowly distilled on a steam-bath until all of the sulfuric ether had been removed. The residual oil was then distilled with steam. The β-bromo ether, which separated at the bottom of the steam distillate, was drawn off, washed with water and dried over calcium chloride and a small amount of solid sodium hydroxide. The α-allyl-β-bromoalkyl ethyl ethers were finally purified by fractional distillation under diminished pressure.

In all cases a low-boiling portion was obtained which became larger in amount as the molecular weight of the β-bromo ether increased. This proved to be due to the decomposition of the main product by loss of hydrogen bromide and was so pronounced in the case of the branching chained product from isobutyraldehyde that pure α-allyl-β-bromoisobutyl ethyl ether could not be isolated.

The yields, physical constants and analyses of the α-allyl-β-bromoalkyl ethyl ethers prepared are shown in Table IV.

Preparation of 1,4-Diolefins

It has been found advantageous to substitute the higher boiling propyl and butyl alcohols for ethyl alcohol as the solvent medium in the decomposition of the β-bromo ethers with zinc. The yield of 1,4-pentadiene by the action of zinc dust upon α-allyl-β-bromoethyl ethyl ether in n-butyl alcohol is above 65% in four hours, whereas in ethyl alcohol it is not more than 30% at the end of five days.

1,4-Pentadiene, $CH_2═CH—CH_2—CH═CH_2$.—One hundred and eight grams of a-allyl-j3-bromoethyl ethyl ether was dissolved in 125 cc. of n-butyl alcohol in a one-liter three-necked flask. The flask was provided with a mechanical stirrer and a reflux condenser. The water in the condenser was kept between 35–60° so that the solvent medium was largely condensed and returned to the generating flask while the more volatile 1,4-pentadiene (b. p. 30°) passed through the reflux into a second condensing system and was collected in a receiver immersed in an ice-bath. One hundred grams of zinc dust was added portion-wise as the reaction proceeded. The speed of the reaction was so regulated that the pentadiene distilled over at approximately one drop per second as a maximum. In four hours 25 g. or 65.8% of the theoretical yield was obtained. After drying over calcium chloride it was distilled twice from metallic sodium to remove any traces of butyl alcohol. The yield of purified product was 20 g. or 52.6%. The boiling range of the major portion was 28.5–29.2° (742 mm.).[9a]

1,4-Hexadiene, $CH_2{=}CH{-}CH_2{-}CH{=}CH{-}CH_3$.—One hundred ten grams of α-allyl-β-bromopropyl ethyl ether, 225 cc. of n-propyl alcohol and 100 g. of zinc dust were refluxed for fifteen hours. Thirty-eight grams of crude distillate was collected and washed five times with one-half its volume of ice cold water. The product was dried over calcium chloride and distilled twice from metallic sodium to remove absorbed alcohol. The purified product weighed 29.4 g., had a boiling range of 63–64.8° and represented a 67.4% yield. The major portion distilled at 64.3–64.6" under 745 mm. pressure.

This boiling point is in good agreement with 64–66° as given by Griner[10] for a compound prepared by the action of hydriodic acid upon diallyl and subsequent decomposition of the iodide thus obtained by alcoholic potassium hydroxide. Merling[11] has also described a product as 1,4-hexadiene. This product was obtained by heating pentenyltrimethylammonium hydroxide in an oil-bath to 160° or in better yield by heating the same quaternary ammonium hydroxide with water in a sealed tube at 180°. Since the boiling point of his diene (80–83°) was too high for diallyl, which he had expected to obtain, he has offered a reaction mechanism to show isomerization to 1,4-hexadiene. In the light of the present work and that of Griner it would seem probable that the isomerization at the high temperatures used was more deep-seated than Merling had supposed.

1,4-Heptadiene, $CH_2{=}CH{-}CH_2{-}CH{=}CH{-}CH_2{-}CH_3$.—Since the boiling point of this diolefin lies close to that of n-propyl alcohol, no attempt was made to separate the product from the reaction mixture as formed. After the refluxing had been continued for several hours, the condenser was replaced by a distilling tube and the diene together with a portion of propyl alcohol distilled off. The mixture began distilling at 83°, the temperature gradually rising to 94° when the distillation was stopped. This process of refluxing and distilling was continued until no more of the diolefin could be separated from the distillate upon dilution with water. One hundred grams of *a*-allyl-β-bromobutyl ethyl ether, 225 cc. of n-propyl alcohol and 100 g. of zinc dust yielded 37 g. of crude 1,4-heptadiene. After purification, as described above, there remained 23 g. of product having a boiling range of 90.2–92.6° of which 18 g. distilled at 92.0–92.3° at 755 mm.

[9a] While this paper was being written for publication, an article by Kogerman on the "Synthesis of 1,4-Pentadiene," THIS JOURNAL, 52, 5060 (1930) has appeared. The author was unaware of our previous communication, ibid., 52, 3396 (1930), in which the same compound is described. Kogerman prepared 1,4-pentadiene in 15% yield by the action of allylmagnesium bromide on vinyl bromide. The work was evidently done with great care and the product obtained in almost exceptional purity. He gives the following physical constants: b. p. 25.8–26.2° at 756 mm., d_4^{20} 0.6594; n_D^{20} 1.3883; mol. refraction calcd., 24.26, found, 24.26.

Diolefin Tetrabromides

The tetrabromides of the diolefins were prepared by slowly adding bromine to a well-cooled solution of the hydrocarbon in chloroform. The reaction proceeded quite definitely in two steps; bromine was absorbed rapidly until approximately one-half of the required amount had been added; the remainder was absorbed more slowly. No attempt was made to isolate the intermediate diolefin dibromides.

1,4-Pentadiene Tetrabromide, $CH_2Br—CHBr-CH_2—CHBr\ CH_2Br$. -Eighteen grams of 1,4-pentadiene was dissolved in five times its volume of chloroform and the solution cooled in a freezing mixture. Bromine was added drop by drop until the solution maintained a permanent red coloration. The reaction mixture was placed under diminished pressure and the excess of bromine removed. Upon evaporation of the solvent the tetrabromide almost wholly solidified to a crystalline mass. After a third recrystallization from absolute alcohol, the product melted at 85.5 to 86°. The yield of purified product was 65%.

The oily residue from the crystals was filtered and distilled under diminished pressure. Analysis showed this liquid phase to be low in bromine.

1,4-Hexadiene Tetrabromide, $CH_3—CHBr—CHBr—CH_2—CHBr—CH_2Br$.—More difficulty was encountered in crystallizing 1,4-hexadiene tetrabromide. The viscous oil, free from chloroform, failed to crystallize at room temperature or in the ice-bath. Crystals were finally obtained by dissolving the liquid tetrabromide in absolute alcohol and chilling the solution in a bath of liquid ammonia. The crystals thus obtained were used to seed the remaining solutions cooled in a bath of ice and salt. After recrystallization, 8 g. of solid tetrabromide, m. p. 63.5–64°, was obtained together with 60 g. of the liquid isomer. The liquid tetrabromide was freed from volatile impurities by placing in a vacuum for four hours at a temperature of 40° and analyzing without further purification.

Griner[6] has described 1,4-hexadiene tetrabromide in three forms; the a-form melted at 182.3°, the β-form melted at 63–64' and the γ-form was a liquid which could not be distilled. The a-form was not obtained in the present work. Merling[11] gives the melting point of 1,4-hexadiene tetrabromide as 160–162° but his diolefin boiled 20° higher than the product herein described.

1,4-Heptadiene Tetrabromide, $CH_3—CH_2—CHBr—CHBr—CH_2—CHBr—CH_2Br$.—All attempts to crystallize this tetrabromide failed. When chilled in a liquid ammonia bath it solidified to a glass which melted completely upon removing from the bath. After volatile impurities had been removed in a vacuum, the product was analyzed without further purification. The yield was 97% on the basis of diolefin used. The physical characteristics and analyses of these 1,2,4,5-tetrabromo paraffins are shown in Table VI.

Summary

By the use of allylmagnesium bromide the β-bromo ether synthesis of olefins has been extended to the preparation of 1,4-diolefins. 1,4-Pentadiene, 1,4-hexadiene and 1,4-heptadiene and the corresponding α-allyl-β-bromoalkyl ethers have been described.

The rule that unsaturated compounds with a double bond in the alpha position boil lower than the corresponding saturated hydrocarbons has been confirmed. It has been further shown that in any given family the continuous chain diolefins form a definite series with gradually increasing boiling points depending upon the relative position of the double bonds.

The 1,2,4,5-tetrabromo paraffins corresponding to the diolefins described have been prepared and found to show evidences of isomerism analogous to other polybromo aliphatic derivatives.

THE OXIDATION OF METHANOL WITH AIR OVER IRON, MOLYBDENUM, AND IRON-MOLYBDENUM OXIDES

BY HOMER ADKINS AND WESLEY R. PETERSON

RECEIVED JANUARY 10, 1931 PUBLISHED APRIL 6, 1931

The oxidation of methanol with air over various metal and oxide catalysts at 300 to 700° results in the formation of varying amounts of formaldehyde, carbon monoxide and carbon dioxide. Sabatier and more recently Lowdermilk and Day have given a review of the literature on this oxidation to which little need be added at this time.[1]

In 1926 a catalyst containing equal amounts of iron and molybdenum was found to be very efficient for the oxidation of methanol to formaldehyde.[2] The investigation described in this paper was initiated in order to correlate the characteristics of the iron–molybdenum catalyst with those of the catalyst containing only iron or molybdenum, with the hope of throwing some light upon the mechanism of the oxidation.

Catalysts. Molybdenum Oxide.—Five grams of ammonium molybdate and 4.5 g. of malic acid were dissolved in water and made ammoniacal with ammonium hydroxide.

---

[1] Sabatier–Reid, "Catalysis in Organic Chemistry," Van Nostrand Company, New York, 1922, pp. 90--97; Lowdermilk and Day, THIS JOURNAL, 52, 3535 (1930).

[2] Homer Adkins and Virgil E. Meharg, in an application for a U. S. Patent (1927) assigned to the Bakelite Corporation. The authors of the present paper are indebted to Mr. Meharg and the Bakelite Corporation for the design of the very efficient washing tower and for the design and construction of the catalyst chamber, which were used in this investigation. The senior author is also grateful to Mr. Meharg for many pleasant associations and very valuable and willing cooperation while the former was temporarily employed by the Bakelite Corporation during the summer of 1926.

To this solution was added 60 cc. of three-sixteenths inch steel ball bearings, previously pitted with dilute hydrochloric acid and washed with distilled water until free of all acid. The solution was slowly evaporated almost to dryness with stirring. The steel balls, covered with the paste, were then poured onto a watch glass in layers of one thickness. The catalyst balls were further dried by placing in an oven at 60° for several hours.

Iron Oxide.—Three grams of iron reduced by hydrogen was added to a water solution of **6** g. of malic acid. The iron was almost completely dissolved by gently boiling the solution for three or four hours and the undissolved iron removed by decantation. The solution of ferrous malate was made ammoniacal by the addition of ammonium hydroxide. Sixty cubic centimeters of pitted steel ball bearings was added and the preparation of catalyst continued as described above.

Iron–Molybdenum Oxide.—One and one-fourth grams of iron reduced by hydrogen was added to a water solution of 4.5 g. of malic acid. The iron was almost completely dissolved by gently boiling the solution for three or four hours and the undissolved iron removed by decantation. To this solution of ferrous malate was added with stirring a water solution of **3 g.** of ammonium molybdate The combined solution was made ammoniacal by the addition of ammonium hydroxide, steel balls were added and the catalyst prepared as described above.

The catalysts thus prepared were placed in the aluminum reaction tube and decomposed in a slowly moving current of air for an hour or more at 360–375°. They were then ready for use.

Apparatus

The apparatus used in the experimental work is shown in Fig. 1 The air, which was supplied by a compressed air line **A,** was dried by passing it through a bottle B of concentrated sulfuric acid. The rate of flow of air was varied by means of a constant pressure valve. The flow of air was determined by means of a calibrated flowmeter C. The air was passed through a bottle D, containing the dried methanol. The vaporization of the alcohol was regulated by controlling the temperature of the vaporizer. The alcohol–air mixture was passed through a U-shaped aluminum catalyst tube. The U-

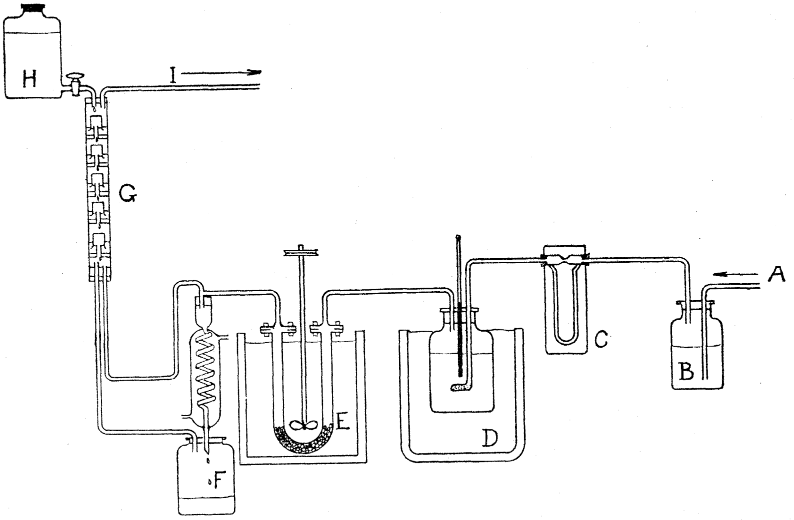

Fig. 3.—Apparatus for the oxidation of methanol.

tube was made of a flattened piece of aluminum tubing 75 cm. in length and 50 X 6 mm. (I. D.) in cross section. It was filled in the bottom and inlet side with glass rod and balls. A 15-cm. depth of catalyst was placed in the outlet side. The catalyst tube was immersed in an electrically heated bath (E) of sodium and potassium nitrates. The temperature of the bath was controlled by means of a Leeds and Northrup potentiometer controller. The products of the reaction were passed through a water-cooled coil condenser and then through a bubbling tower G 60 cm. in length, down which water was passed at the rate of about 100 ml. per hour from the reservoir H. All the formaldehyde and methanol in the gases were collected in the wash tower and flowed back through the condenser into bottle F. I is an exit tube for gaseous products leading to an Orsat apparatus.

Examination of Products.—The water-insoluble gaseous products were analyzed in an Orsat apparatus. The carbon dioxide was determined by absorption in potassium hydroxide solutions. The remaining oxygen was removed by yellow stick phosphorus. The carbon monoxide was removed by bubbling through an acid solution of cuprous chloride. The water-soluble products collected in bottle F were analyzed for formaldehyde by the method of Haywood and Smith.[3] The unreacted methanol was determined by oxidation with chromic acid.[4]

The percentage efficiency as used in this paper refers to the percentage of oxygen used in the conversion of methanol to formaldehyde and was calculated from gas analysis data in the following manner

$$\%\ \text{Efficiency} = \frac{\%\ \text{oxygen used} - (1.5 \times \%\ \text{carbon dioxide} + \%\ \text{CO})}{\%\ \text{oxygen used}}$$

The percentage efficiency so calculated agrees quite closely with the percentage efficiency calculated from the weight of formaldehyde obtained, the amount of methanol passed over the catalyst and the weight of methanol which was found unchanged in the distillate.

The Formation of **Methylal.**—Under certain conditions of operation formaldehyde reacts with methanol in the catalyst chamber with the formation of the methyl acetal of formaldehyde. The compound is only partially condensed with the other liquid products and some escapes with the gaseous products of the reaction. This acetal is not at all readily hydrolyzed. The method of Lowdermilk and Day[5] for the determination of unchanged methanol may give quite inaccurate results because methylal would appear with methanol in their procedure for analysis. The presence of methylal among the reaction products may be suspected if there is a 0.5 to 2% reduction in the volume of the effluent gas when bubbled through sulfuric acid, or if there is a discrepancy between the efficiency as calculated from the gas analysis and from the formaldehyde and methanol in the distillate. Methylal was formed in considerable quantities in one series of experiments, apparently due to the accumulation of alumina on the walls of the catalyst chamber. No further difficulty was experienced after the chamber had been thoroughly cleaned with a sodium hydroxide solution and with hydrochloric acid. Methylal was also formed when rather completely oxidized aluminum turnings were used as a support for the catalysts.

General Procedure.—The catalyst was put in place and decomposed and methanol and air passed over it continually (except for the removal of samples) for several days or weeks. Two or three times during each twenty-four hours the passage of the reactants was stopped and the amount of methanol which had been passed over the catalyst de-

termined by weighing the methanol left in the vaporizer. The condensate was taken out of the receiver and made up for analysis. Gas analyses were made from time to time on the effluent gases. The temperature of the catalyst and amount and ratio of air and methanol were changed as desired. After a given variation in the conditions of reaction had been studied, the conditions were again made standard, *i. e.*, 93 liters of air and 9 g. of methanol per hour at 373° and assurance was obtained that the catalyst had not been permanently modified. In this way a given sample of catalyst could be used for several weeks for the study of a variety of experimental conditions. Duplicate preparations of catalyst were used in the testing of all important points. The catalyst can be readily and precisely duplicated. Preparations made and tested independently by the two authors gave results which agreed almost as well as the data for the three typical experiments given below: 1–2–3. Iron–molybdenum oxide, 373°, 93 liters of air, 8.9, 9.38, 8.97 g. of methanol per hr., % converted to formaldehyde as actually obtained, 91.6, 91.8, 90.3%; % recovered methanol, 5.03, 6.47, 5.6 g. Gas analysis: % CO_2, 0.1, 0.1, 0.1; % oxygen, 18.0, 18.0, 17.5; % CO, 0.1, 0.1, 0.2; % efficiency based on gas analysis, 93, 93, 91.

Statement of Experimental Results

Space is not available for the tabulation of the complete data of the more than a hundred experiments upon the oxidation of methanol over oxide catalysts which have been carried on in the course of this investigation. It must suffice to give the following abstract of these data.

The characteristics of a molybdenum oxide catalyst as concluded from a study of its behavior toward oxidation of methanol with air to formaldehyde were found to be as follows.

1. The catalyst was highly efficient as evidenced by the fact that all of the methanol which was oxidized was converted into formaldehyde with no formation of the oxides of carbon.

2. The activity of the catalyst decreased during the first twenty-four hours of use, after which a steady state was reached in which its activity was approximately constant for several days. For example, a molybdenum oxide catalyst was capable of causing the oxidation of 6.8 g. of methanol (57.8% yield) to formaldehyde per hour during its first five hours of use; 5.17 g. of methanol (48.6%) to formaldehyde per hour for three and one-half hours after being used for five hours; and 4.73 g. of methanol (45.9%) to formaldehyde per hour the next three and one-half hours as compared to a 35.5% yield under comparable conditions after the steady state was reached.

3. The amount of methanol oxidized to formaldehyde per hour was a linear function of the rate of passage of the methanol over the catalyst. When 2.26, 5.28, 12.95, 18.4 and 20.0 g. of methanol per hour was passed over the catalyst with 50 or 93 liters of air, 1.58, 2.25, 3.72, 4.93 and 5.36 g. of the methanol, respectively, was converted into formaldehyde. However, the amount of methanol oxidized to formaldehyde per hour did not increase (over the range investigated) with increase in the rate of passage of the air over the catalyst. When 6.17 g. of methanol and

136 liters of air were passed over the catalyst in an hour, 2.31 g. of the methanol was converted into formaldehyde, as compared to the conversion of 2.41 g. of methanol when 6.67 g. of methanol in 50 liters of air were passed over the catalyst.

4. The percentage conversion of methanol to formaldehyde rose with decrease in the rate of passage of the methanol over the catalyst. When 20.0, 10.2, 6.67 and 2.57 g. of methanol were passed over the catalyst with 50 liters of air, the yields were 26.9, 33.3, 36.2 and 54.2%, respectively.

5. The conversions of methanol to formaldehyde at 373, 390 and 400° were approximately the same. However, at 361° lower conversions were obtained. When approximately 9.5 g. of methanol in 93 liters of air was passed over the catalyst at 361, 373, 390 and 400°, yields of 23.8, 31.5, 32.1 and 32.4%, respectively, were obtained when the catalyst had reached its "steady state."

The characteristics of an iron oxide catalyst, as concluded from a study of its behavior when methanol mixed with air was passed over it, were found to be as follows.

1. The catalyst was very active, the methanol being oxidized almost wholly to carbon dioxide. When the amount of methanol passed over the catalyst was varied from 11.2 to 33 g. per hour (373°, 93 liters of air per hour), there were only traces of formaldehyde and this only with a catalyst that had been in operation for several days and with more methanol passing over the catalyst than could be oxidized to carbon dioxide by the available oxygen.

2. The activity of the catalyst became less as the temperature of the reaction was lowered and increased as the temperature was raised. At 310°, with 20 g. of methanol and 93 liters of air, 9.4% of the methanol passed over the catalyst was converted to formaldehyde; 81.0% remained unreacted, the remaining 9.6% having been converted into carbon dioxide. At 340° approximately 18% of the methanol was converted into formaldehyde, with about 68% remaining unreacted; the remaining 14% was converted into carbon dioxide. At 400 or 443°, no formaldehyde was formed, 4.92% of the methanol remained unreacted, the remainder having been lost as oxides of carbon.

3. An iron oxide catalyst that has been used at a low temperature (340°) when raised to 373° was less active toward oxidizing methanol and produced more formaldehyde than it formerly did at 373°. It gradually recovered its original activity, giving results identical within experimental error with those obtained previously at 373°. Previous to the lowering of the temperature, the results obtained at 373° showed the formation of 1.3% of formaldehyde with very little methanol (5.1%) remaining unreacted. After raising the temperature again to 373°, the results obtained for the first two experiments showed conversions

of methanol to formaldehyde of 4.67 and 4.16%, respectively; the amounts of methanol remaining unreacted were 21 9 and 7.88%, respectively.

The characteristics of an iron–molybdenum oxide catalyst, as concluded from a study of its behavior when methanol was oxidized with air on the surface of the catalyst, were as follows.

1. The activity and efficiency of the catalyst increased during the first few hours of use, after which a steady state was reached in which its activity was constant for weeks. During the first twelve hours of use, the average conversion of methanol to formaldehyde was 82.0%. During the next five hours, the average conversion was 88.5%, and for the next six and one-half hours, the average conversion was 90.8%. The air flow was kept at 93 liters per hour, while the passage of methanol varied from 8.8 to 10.1 g. per hour in these experiments.

2. More carbon monoxide than dioxide was produced from methanol over molybdenum–iron oxide catalysts.

3. The iron–molybdenum oxide catalyst was relatively inactive toward formaldehyde. A 5-cm. depth of catalyst produced the same yield of formaldehyde as did a 15-cm. depth of catalyst using 93 liters of air per hour carrying approximately 10 g. of methanol per hour. The efficiency for the 5-cm. depth of catalyst was 92.3% and for the 15-cm. depth 85.6%. The above conclusion may also be drawn from the results obtained by passing alcohol and air in the same ratio but at different rates over a 15-cm. depth of catalyst. Considering air flows of 93 and 136 liters per hour, the efficiencies were found to be 90.7 and 93.8%, respectively. However, with an air flow of 50 liters per hour, the yield (80.8%) as well as the efficiency (66.5%) decreased considerably. The "space-time-velocities" in passing 136 and 50 liters of air over a 15-cm. depth of catalyst were the same as for the passage of 93 liters of air over 10.3 and 27.9-cm. depths of catalyst, respectively.

4. Increasing the rate of passage of methanol increased the grams of methanol oxidized to formaldehyde, but there was also a decrease in efficiency if the methanol passage became too high. With 93 liters of air carrying 9.38 g. and 15.0 g. of methanol per hour, the weight of methanol converted to formaldehyde was 8.61 and 12.8 g., respectively. The efficiencies were 90.7 and 85.5%, respectively.

5. The maximum activity was obtained when equimolecular proportions of iron and molybdenum were present in the oxide mixture. A high percentage of iron oxide in the catalyst showed more of the carbon dioxide forming properties of an iron oxide catalyst, while a high percentage of molybdenum oxide in the catalyst showed properties intermediate between those of an iron–molybdenum oxide catalyst and a molybdenum oxide catalyst, that is to say, the efficiency was higher and the conversion of methanol to formaldehyde was lower than for the mixed oxide catalyst.

6. Lower conversion of methanol to formaldehyde was obtained at 353 than at 373 and at 400°. The efficiency was less at 400 than at 373 and 353°. With 93 liters of air and approximately 9 g. of methanol passing over the catalyst per hour, the conversions of methanol to formaldehyde at 353, at 373 and at 400° were 85.2: 91.8 and 91.9%, respectively, and the efficiencies were 90.0, 90.7 and 85.3%, respectively.

Discussion of Results

The catalyst surface of these oxide catalysts was constantly undergoing change as measured by the amount of oxidation of methanol or by the ratio of products. For example, in the case of molybdenum oxide a new catalyst rapidly decreased in activity for several hours until a steady state was reached for the particular temperature, rate and ratio of methanol and air involved. The new iron and iron–molybdenum catalysts showed a change in the ratio of products during several hours before a steady state was reached. When the experimental conditions were changed the catalysts rather slowly shifted in activity until a new steady state was reached. The former steady state could be slowly regained if the experimental conditions which produced it were reproduced. The constant change and renewal of the active surface was also indicated by the fact that the catalysts are active for weeks and months of continuous use. It is extremely unlikely that any surface would remain active for any such lengths of time unless it was being continually renewed. Thus the relationship between an effective catalyst and the reactants must not only be such that the former brings about the reaction of the latter, but the reactants must maintain the state of the catalyst which is favorable to the desired reaction.

A desirable catalyst for the oxidation of methanol to formaldehyde would therefore be one that required only a low concentration of methanol in the effluent gas stream in order to maintain it in the optimum state of reduction; in other words, a desirable catalyst would be one which would stay reduced without an excess of methanol. It should not be active toward formaldehyde, that is, it should desorb it rapidly. Molybdenum oxide is an efficient but undesirable catalyst because too much methanol is required to keep it reduced to the active state. Iron oxide is an undesirable catalyst because it goes into such a high state of oxidation that any formaldehyde formed is not desorbed, but is oxidized to carbon dioxide. The mixture of iron and molybdenum oxide apparently requires no considerable excess of methanol to maintain it in the desired state of oxidation and has a low activity toward formaldehyde. The mixture of oxides differs from either of the pure oxides not only in these facts but in that the mixture produces the monoxide rather than the dioxide of carbon.

Langmuir[6] in his classical paper on the oxidation over platinum of carbon monoxide by oxygen, pointed out that there are three possible mechanisms for such an oxidation: (1) the oxygen may be absorbed by the platinum and then be struck by a molecule of carbon monoxide; (2) the carbon monoxide may be absorbed by the platinum and then be struck by a molecule of oxygen; (3) the two reactants may be adsorbed on adjacent active points on the catalyst surface sufficiently close together so that the reaction may ensue.

Oxidation of methanol on the basis of cases (1) and (3) involves successive addition and removal of oxygen from the catalyst, the difference between the two cases being as to whether the methanol reacts from the vapor state or from the adsorbed state. The adsorbed oxygen postulated in both cases might be adsorbed on the catalyst or might be held as a so-called definite oxide. For the purpose of the discussion that follows, it is immaterial which is the case.

If either case (1) or (2) holds for the oxidation of methanol over molybdenum oxide, then it should be possible by using a proper ratio of reactants either to consume almost all of the oxygen or convert almost all of the methanol to formaldehyde. The experimental results very definitely show that this is not true, as the percentage conversion of methanol to formaldehyde cannot be raised very high no matter how much the excess of oxygen or how long the time of contact, *i. e.*, how slowly the reactants are passed over the catalyst. The amount of methanol oxidized per hour is a linear function of the amount of methanol passed over the catalyst for a 10-fold increase in rate of passage. No more than 10% of the total available amount of oxygen could be consumed no matter how large the excess of methanol. It is probable, therefore, that the two reactants must both be adsorbed on adjacent active points on the surface of the catalyst before reaction may ensue.

Summary

The characteristics of molybdenum oxide, iron oxide and a mixed iron–molybdenum oxide catalyst as displayed in the catalysis of the oxidation of methanol with air have been described. In brief it may be said that molybdenum oxide was 100% efficient for the oxidation of methanol to formaldehyde, since this is the only reaction which occurred. However, only about 38% of the methanol could be converted to formaldehyde. Iron oxide was a very active catalyst but it induced the formation of carbon dioxide almost exclusively. A catalyst containing equal atomic amounts of iron and molybdenum converted over 90% of the methanol passed over it into formaldehyde, the other product being carbon monoxide. It is thus by far the best catalyst, so far described, for the oxidation

---

[6] Langmuir, Trans. *Faraday Soc.*, 17, 3, 653 (1922).

of methanol. The catalyst was quite stable and may be used continually for months.

At least in the case of molybdenum oxide there is evidence that the reaction between methanol and oxygen takes place when both reactants are on the surface of the catalyst.

Evidence has been presented which indicates that the catalyst surface of these oxide catalysts is continually renewed during use; therefore the relationship between an effective catalyst and the reactants must not only be such that the former brings about the reaction of the latter, but the reactants must maintain the catalyst in the state of oxidation which is favorable to the desired reaction.

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

THE EFFECT OF COPPER UPON THE YIELDS OF GRIGNARD REAGENTS

BY GEORGE JOHNSON AND HOMER ADKINS

RECEIVED JANUARY 10, 1931 PUBLISHED APRIL 6, 1931

It is well known that the reaction of alkyl halides and magnesium results in the formation of Grignard reagents and of hydrocarbons, as indicated in equations I and II.

$$RX + Mg = RMgX \qquad (I)$$

$$2RX + Mg = R_2 + MgX_2 \qquad (II)$$

There has been in progress for some time in this Laboratory a study of the factors which determine the ratio of these two competitive reactions. During the course of this investigation some observations have been made in regard to the effect of copper upon the ratio of the reaction products which are of such practical importance that it seems desirable to publish them in advance of a more comprehensive paper, especially in view of the results of Gilman, Peterson, Schultz and Heck,[1] who reported that magnesium in certain copper–magnesium alloys reacted more rapidly with alkyl halides than did pure magnesium. Upon the basis of these findings it seemed that the use of the alloy might be advantageous in the preparation of Grignard reagents and this practice has been followed by a number of investigators.

The determination of the effect of various experimental conditions upon the ratio of the Grignard and Wurtz reactions was made in the following manner. The apparatus used was essentially of the type and size described and used by Gilman and Meyers for the preparation of ethyl-

---

Gilman, Peterson and Schulze, Rec. *trav. chim.*, 47, 22 (1928); Gilman and Heck, *Bull. soc. chim.*, 45,250 (1929).

magnesium iodide,[2] except that a detachable side-arm buret was connected to the outer end of the siphon tube passing through the wall of the flask. The desired quantity of magnesium was introduced into the reaction flask and the apparatus assembled. The flask and attached condenser were then swept out with dry hydrogen while the sample of alkyl halide was being weighed. After discontinuing the flow of hydrogen, from 10 to 15 ml. of anhydrous ether was introduced from the attached 60-ml. separatory funnel. The alkyl halide, contained in a 50-ml. glass-stoppered flask, was diluted with about 20 ml. of anhydrous ether, quickly transferred to the dropping funnel, after which approximately 15 ml of ether, in two or three portions, was used to wash out any remaining sample from the bottle, and all washings rapidly transferred to the dropping funnel. This diluted the sample to a volume of 35 to 40 ml. The contents of the flask were then stirred and the alkyl halide introduced dropwise over a period of thirty-five to forty minutes. A reaction, evidenced by the boiling of the solution, usually set in after one to three minutes. After the halide was all introduced, stirring was continued for five minutes, or longer if boiling continued, and a further quantity of about 50 ml. of dry ether was then introduced through the dropping funnel, over a period of ten to fifteen minutes, so as to bring the total volume up to approximately 105 ml. Dry hydrogen gas was then bubbled through the reaction mixture for two or three minutes, after which the stirring was stopped, all openings to the reaction flask corked to exclude air, and the reaction mixture allowed to stand undisturbed for one-half hour, or until all solid matter had settled. Making due allowance for the stirring rod and any other residual solid matter, the total volume of the reaction mixture was then obtained from the graduated scale on the neck of the flask, and three aliquots of approximately 20 ml. each were forced out under hydrogen pressure through the siphon tube into the buret.

The acid titration method, as recommended by Gilman, Wilkinson, Fishel and Meyers,[3] was used for the estimation of the Grignard reagent produced, Each 20-ml. aliquot was drained from the buret into 50 ml. of water, an excess of 0.2 N sulfuric acid added and the product heated on the steam-bath to accelerate hydrolysis and to expel the ether. The resulting solution was then cooled, and the sample titrated with 0.1 N sodium hydroxide, using phenolphthalein as an indicator. From these data the amount of $Mg(OH)X$ present in the mixture was calculated and hence the yield of $RMgX$.

The magnesium (88%) copper (12%) alloy used in this investigation was in the form of turnings and was supplied by the Dow Chemical Company. Powdered copper alloy from the Eastman Kodak Company was

---

[3] Gilman, Wilkinson, Fishel and Meyers, *ibid.*, 45, 150 (1923).

also used, as was pure magnesium turnings plus copper powder ("Natur Kupfer C"). The results obtained with the powder were not greatly different from those obtained with magnesium turnings. Copper powder reduced the yield of Grignard reagent but not so markedly as when the metal was alloyed with the magnesium. In the case of four of the halides only a small excess of magnesium was used over that necessary for the formation of the Grignard reagent. In the case of cyclohexyl bromide and allyl bromide a considerable excess of magnesium was used because Gilman and McGlumphy[4] reported that the yield of Grignard reagent from allyl bromide was higher when a large excess of magnesium was used. Ethyl iodide was used both with a small and large excess of magnesium.

TABLE I

THE EFFECT OF COPPER UPON THE YIELD OF GRIGNARD REAGENTS[a]

Alkyl halide		Magnesium,	% yield of RMgX	
Name	Moles	g. atoms	From Mg	From Cu–Mg
n-Butyl bromide	0.056	0.062	92.5	78.7 ± 2 (3)
Sec.-butyl bromide	.059	.062	73.8	49.6
n-Butyl iodide	.057	.058	82.4	64.2
Ethyl iodide	.059	.062	83.4	76.1
Ethyl iodide	.058	.250	90.8	80.7
Benzyl chloride	.059	.065	94.1 ± 0 (2)	80.2 ± 2 (8)
Cyclohexyl bromide	.059	.165	82.5 ± 2 (3)	64.711 (3)
Allyl bromide	.058	.272	72.1 ± 4 (10)	6.014 (6)
Phenyl bromide	.059	.063	90.8 ± 0.5 (3)	89.1 ± 2 (3)

[a] Three analyses were made on each reaction mixture. When more than one reaction mixture was made up the numbers as well as the variation in yields are indicated in the table.

There are given in Table I the yields of Grignard reagents obtained for eight halides through their reactions with magnesium and the copper magnesium alloy. It is apparent from the data so reported that copper lowers the yield of Grignard reagent. The halides in the order of their increasing susceptibility to the effect of copper were phenyl bromide, ethyl iodide, benzyl chloride, n-butyl bromide, n-butyl iodide, cyclohexyl bromide, *sec.*-butyl bromide and allyl bromide. The formation of the Grignard reagent from the first of these was little affected by copper, while in the case of allyl bromide the yield of the reagent was lowered to 10% of the value obtained with pure magnesium.

Meisenheimer[5] ascertained the ratio of reactions I and II by comparing the amount of Grignard reagent with the total amount of halogen in the ether solution which was precipitable as silver halide. If no Wurtz reaction had occurred, the ratio of precipitable halogen to the Grignard reagent would be 1 to 1. If the Wurtz reaction had occurred, then the

---

[4] Gian and McGlumphy, Bull. *soc. chim.*, 43, 1322 (1928).

[5] Meisenheimer, *Ber.*, 61, 708 (1928).

ratio of halogen to Grignard reagent would be greater than 1 to 1 by a corresponding amount. For example, if the two reactions had occurred to an equal extent, the ratio would be 2 to 1.

There is given below after the name of each halide the amount of precipitable halogen, for one part of Grignard reagent, which was found for pure magnesium and for magnesium–copper alloy: benzyl chloride, 1.02 (Mg); 1.20 (Mg-Cu); cyclohexyl bromide 1.20 (Mg), 1.52 (Mg–Cu); n-butyl bromide 1.08 (Mg), 1.26 (Mg–Cu); *sec.*-butyl bromide 1.33 (Mg), 1.98 (Mg–Cu); n-butyl iodide 1.21 (Mg), 1.54 (Mg–Cu); ethyl iodide 1.20 (Mg) 1.27 (Mg–Cu), phenyl bromide 1.1 (Mg), 1.1 (Mg–Cu); and allyl bromide 1.35 (Mg). These figures show very definitely that copper promotes the Wurtz reaction. The ratio is without significance in the case of magnesium-copper alloy and allyl bromide because so much magnesium bromide was formed that the solubility of its etherate was exceeded,[6] and so was not found upon analysis of the ether solution.

The completeness of reaction of each alkyl halide with magnesium may also be determined from the amount of halogen in the ether solution which was precipitable as silver halide. Upon this basis from 98 to 100% of the phenyl, n-butyl, *sec.*-butyl and cyclohexyl bromide and n-butyl and ethyl iodide and from 94 to 98% of the benzyl chloride underwent reaction over both pure magnesium and the alloy. In the case of allyl bromide, from 96 to 98% of the halide underwent reaction with pure magnesium, while with magnesium–copper alloy so much magnesium bromide was formed that the solubility of its etherate was exceeded, as noted above.

No attempt has been made during this investigation to determine accurately the rates of reaction of the alkyl halide; however, there has been no evidence that the halides reacted more rapidly with the alloy than with pure magnesium. In fact, in some cases the reaction started more slowly with the alloy than with the pure magnesium.

Summary

The yields of Grignard reagents obtained by reacting eight alkyl halides with magnesium and with an alloy of magnesium and copper have been determined. The yields of the Grignard reagent were very considerably lowered, except from phenyl bromide, by the presence of the copper, which promoted the competitive Wurtz reaction.

THE REDUCTION OF AZOBENZENE, AZOXYBENZENE AND NITROSOBENZENE BY THE SYSTEM MAGNESIUM + MAGNESIUM IODIDE

BY W. E. BACHMANN

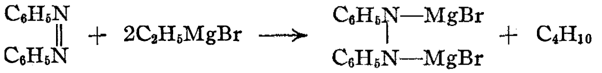
RECEIVED JANUARY 10, 1931 PUBLISHED APRIL 6, 1931

Previous papers[1] have described the addition of the MgI group to the C=O group of various classes of compounds and to the trivalent C atom of triarylmethyls, the addition taking place when these compounds are treated with a mixture of magnesium and magnesium iodide in an ether-benzene solution. According to the hypothesis which was set forth, the active reducing agent is magnesium subiodide, generated by the interaction of the metal and metal halide

$$Mg + MgI_2 \leftrightarrows 2MgI \qquad (1)$$

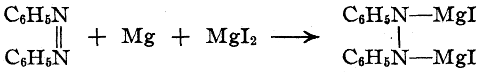
and present as such only in minute quantities at any one moment.

The behavior of the mixture, Mg + MgI_2, with azobenzene was of particular interest in view of the mechanism of the reduction of azobenzene by the Crignard reagent. Franzel and Deibel[2] found that ethylmagnesium bromide reduces azobenzene to a hydrazobenzene derivative and they formulated the reaction as follows



$$\begin{matrix} C_6H_5N \\ \| \\ C_6H_5N \end{matrix} + 2C_2H_5MgBr \longrightarrow \begin{matrix} C_6H_5N\text{—}MgBr \\ | \\ C_6H_5N\text{—}MgBr \end{matrix} + C_4H_{10} \qquad (2)$$

Addition of water gives hydrazobenzene.[3] It is observed that the reduction of the azobenzene is occasioned by the addition of the MgX group of the Grignard reagent to each of the nitrogen atoms of the N=N group. It was, therefore, to be expected that the binary system, in virtue of its ability to furnish MgX, would readily accomplish a similar reduction. Such was found to be the case. A mixture of magnesium and magnesium iodide reduces azobenzene rapidly and completely according to the following reaction



$$\begin{matrix} C_6H_5N \\ \| \\ C_6H_5N \end{matrix} + Mg + MgI_2 \longrightarrow \begin{matrix} C_6H_5N\text{—}MgI \\ | \\ C_6H_5N\text{—}MgI \end{matrix} \qquad (3)$$

I

For each gram molecule of azobenzene, a gram atom of magnesium is dissolved and a gram molecule of iodomagnesium-hydrazobenzene (I) is formed. In the process of reduction the solution displays a series of intense colors, brown, reddish-brown and brown-black; at the end of the

---

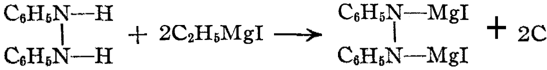
[3] See also Gilman and Pickens, THIS JOURNAL, 47, 2406 (1925); and Rheinboldt and Kirberg, J. prakt. *Chem.*, **118**, 1 (1928).

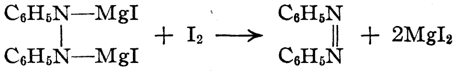
reaction the mixture is colorless. The play of colors is probably due to the formation of a complex between the iodomagnesium-hydrazobenzene and unreduced azobenzene, the complex being analogous to the quinhydrone-like compound which Schlenk and Appenrodt[4] obtained by the action of sodium or potassium on azobenzene. They found that only one atom of potassium reacted for each molecule of azobenzene and they considered their dark violet-brown product to have the composition, $C_6H_5(K)N{-}N(K)C_6H_5{\cdot}C_6H_5N{=}NC_6H_5$. Unlike sodium and potassium, the binary system is able to reduce the complex completely to the hydrazobenzene derivative. The identity of the product (I) as iodomagnesium-hydrazobenzene was established by its reactions and by its synthesis from hydrazobenzene through the action of a Grignard reagent.



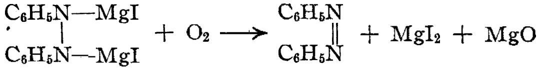
$$\begin{array}{c} C_6H_5N{-}H \\ | \\ C_6H_5N{-}H \end{array} + 2C_2H_5MgI \longrightarrow \begin{array}{c} C_6H_5N{-}MgI \\ | \\ C_6H_5N{-}MgI \end{array} + 2C_2H_6 \qquad (4)$$

The iodomagnesium-hydrazobenzene (I) is very reactive. It is instantly decomposed by water into hydrazobenzene. The yield of hydrazobenzene obtained by hydrolysis of the reaction mixture varies between 85 and 90% of that calculated according to Equation **3.** The remainder of the product consists of aniline produced by reduction beyond the hydrazobenzene stage; in agreement with this result is the fact that the amount of magnesium dissolved in the reaction is 10 to 15% greater than that required by Equation **3.**

Iodine and oxygen react readily with the iodomagnesium-hydrazobenzene; the principal product of the reactions is azobenzene.

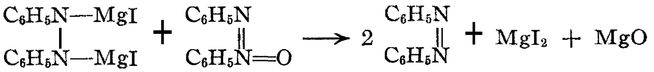


$$\begin{array}{c} C_6H_5N{-}MgI \\ | \\ C_6H_5N{-}MgI \end{array} + I_2 \longrightarrow \begin{array}{c} C_6H_5N \\ \| \\ C_6H_5N \end{array} + 2MgI_2 \qquad (5)$$



$$\begin{array}{c} C_6H_5N{-}MgI \\ | \\ C_6H_5N{-}MgI \end{array} + O_2 \longrightarrow \begin{array}{c} C_6H_5N \\ \| \\ C_6H_5N \end{array} + MgI_2 + MgO \qquad (6)$$

If an equivalent amount of azoxybenzene is added to the reduction product, the latter is oxidized and the azoxybenzene is reduced to one and the same product, azobenzene



$$\begin{array}{c} C_6H_5N{-}MgI \\ | \\ C_6H_5N{-}MgI \end{array} + \begin{array}{c} C_6H_5N \\ \| \\ C_6H_5N{=}O \end{array} \longrightarrow 2 \begin{array}{c} C_6H_5N \\ \| \\ C_6H_5N \end{array} + MgI_2 + MgO \qquad (7)$$

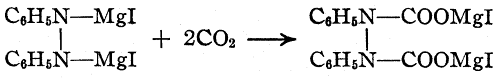
This reaction is analogous to the reaction between iodomagnesium-hydrobenzoinate and benzil, which yields benzoin as the sole product.[5]

The iodomagnesium-hydrazobenzene reacts with benzoyl chloride, both MgI groups being replaced by benzoyl groups with the formation of dibenzoyl-hydrazobenzene. It reacts with carbon dioxide in the manner of a Grignard reagent giving the iodomagnesium salt of hydrazobenzene-N,N-dicarboxylic acid.

---

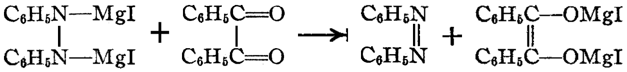
[4] Schlenk and Appenrodt, *Ber.*, 47,4851 (1914).

[5] Shankland and Gomberg, THIS JOURNAL, 52,4973 (1930).



$$\begin{array}{c} C_6H_5N\text{—}MgI \\ | \\ C_6H_5N\text{—}MgI \end{array} + 2CO_2 \longrightarrow \begin{array}{c} C_6H_5N\text{—}COOMgI \\ | \\ C_6H_5N\text{—}COOMgI \end{array} \qquad (8)$$

Benzil is able to abstract both MgI groups from the nitrogen atoms and attach them to its two C=O groups

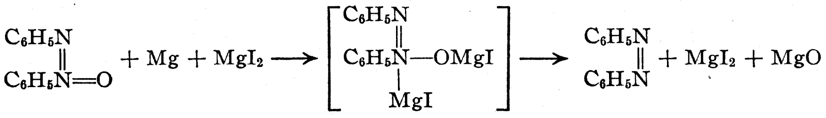


$$\begin{array}{c} C_6H_5N\text{—}MgI \\ | \\ C_6H_5N\text{—}MgI \end{array} + \begin{array}{c} C_6H_5C{=}O \\ | \\ C_6H_5C{=}O \end{array} \longrightarrow \begin{array}{c} C_6H_5N \\ \| \\ C_6H_5N \end{array} + \begin{array}{c} C_6H_5C\text{—}OMgI \\ \| \\ C_6H_5C\text{—}OMgI \end{array} \qquad (9)$$

On hydrolysis azobenzene and benzoin[6] are obtained in equivalent amounts. Benzaldehyde, however, behaves differently; it gives benzanilide as the chief product.

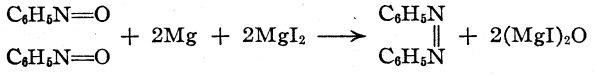
Para-substituted dimethyl-, dimethoxy- and diphenylazobenzene were reduced by the binary system; in all cases reduction occurred to a considerable extent (up to 49%) beyond the hydrazobenzene stage and an equivalent amount of the corresponding substituted aniline was found in the hydrolyzed products. The actual mechanism of this reduction to the aniline stage is unknown.

Azoxybenzene and substituted azoxybenzenes were found to react rapidly with a mixture of magnesium and magnesium iodide. If only one gram atom of metallic magnesium is employed for a gram molecule of azoxybenzene, azobenzene is obtained on hydrolysis of the reaction product. If twice that amount of reducing agent is present, reduction proceeds to iodomagnesium-hydrazobenzene. One may consider that the azoxybenzene is reduced to azobenzene (Equation 10) and that this is then reduced further according to Equation 3.



$$\begin{array}{c} C_6H_5N \\ \| \\ C_6H_5N{=}O \end{array} + Mg + MgI_2 \longrightarrow \left[\begin{array}{c} C_6H_5N \\ \| \\ C_6H_5N\text{—}OMgI \\ | \\ MgI \end{array}\right] \longrightarrow \begin{array}{c} C_6H_5N \\ \| \\ C_6H_5N \end{array} + MgI_2 + MgO \qquad (10)$$

The reaction between nitrosobenzene and a mixture of magnesium and magnesium iodide is similar to the reduction of azobenzene and azoxybenzene. The principal reaction (to the extent of 70%) consists in the reduction of nitrosobenzene to azobenzene (Equation 11) followed by the reduction of the latter compound to iodomagnesium-hydrazobenzene.



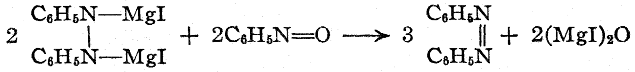
$$\begin{array}{c} C_6H_5N{=}O \\ \\ C_6H_5N{=}O \end{array} + 2Mg + 2MgI_2 \longrightarrow \begin{array}{c} C_6H_5N \\ \| \\ C_6H_5N \end{array} + 2(MgI)_2O \qquad (11)$$

When an amount of reducing agent corresponding to that given in Equation 11 is employed, azobenzene is the chief reduction product. By using an excess of reducing agent, iodomagnesium-hydrazobenzene is obtained.

Nitrosobenzene can also be reduced by iodomagnesium-hydrazobenzene; both reactants are converted to azobenzene in the reaction.

---

[6] Compare the reduction of benzil by Mg + MgI_2, Gomberg and Bachmann, This Journal, 49, 2584 (1927).



$$2\begin{matrix} C_6H_5N—MgI \\ | \\ C_6H_5N—MgI \end{matrix} + 2C_6H_5N{=}O \longrightarrow 3\begin{matrix} C_6H_5N \\ \| \\ C_6H_5N \end{matrix} + 2(MgI)_2O \qquad (12)$$

Experimental

For rapid reaction magnesium was used in the form of powder or turnings; when magnesium powder was employed, the reaction was completed in several hours. In most cases magnesium rods were used because they can be withdrawn from the solution at any time and the weight of magnesium that has reacted can be accurately determined. Best results were obtained when the reaction was carried out at room temperature. Moisture, oxygen and carbon dioxide must be excluded from the reaction mixture; this was accomplished most conveniently by carrying out the reaction in stoppered glass cylinders or heavy test-tubes of such a capacity that the solutions practically filled the tube.

Reduction of Azobenzene.—To a filtered solution of magnesium iodide, prepared from 27 g. of iodine in a mixture of 40 cc. of ether and 80 cc. of benzene, was added 18.2 g. of azobenzene and a rod of magnesium. The tube was quickly stoppered and shaken mechanically at room temperature. Frequently the reaction started in a few minutes, as was evidenced by the appearance of a dark brown color. During the reduction the solution became dark brown, reddish-brown and brown-black (like dark-oak stain) in color. The color gradually disappeared and after two days the mixture was practically colorless and contained a large amount of finely-divided grayish-white solid. The magnesium rod was withdrawn from the mixture, washed with alcohol and weighed. The loss in weight was 2.70 g., which is 111% of that calculated (2.43 g.) according to Equation 3 Numerous determinations showed that from 10–15% reduction occurred beyond the hydrazobenzene stage.

The mixture was poured into ice and water that had been saturated with carbon dioxide, and all subsequent operations were carried out in an atmosphere of carbon dioxide in order to prevent oxidation. Dilute acetic acid was used to dissolve the magnesium hydroxide which was produced on hydrolysis. After the ether–benzene solution had been washed with water, the solvents were removed by distillation under reduced pressure at 30–35° (at high temperatures hydrazobenzene is decomposed into azobenzene and aniline). The solid residue was treated with warm petroleum ether in order to remove azobenzene and aniline; the insoluble colorless residue of hydrazobenzene weighed 14.7 g. The petroleum ether filtrate was evaporated to dryness under reduced pressure and the residue was treated with a cold solution of 30% acetic acid in order to extract aniline; this acid extract yielded 1.2 g. (6%) of aniline. The residue which was insoluble in acetic acid was heated with dilute hydrochloric acid in order to convert the hydrazobenzene in it to benzidine. The azobenzene which remained weighed 0.25 g. (1%) and the benzidine (isolated as sulfate) corresponded to 1.6 g. of hydrazobenzene, The total weight of hydrazobenzene was 16.3 g. (89%) and agrees with that expected from the amount of magnesium that had reacted.

Attempts were made to reduce the product more completely to aniline by employing an excess of magnesium and magnesium iodide and allowing a long period of time for the reaction. The results were no different from those given above.

It is possible to reduce a gram molecule of azobenzene completely without using a full mole of magnesium iodide; this indicates that magnesium iodide is split off from the iodomagnesium-hdyrazobenzene and is thus made available for further reaction. The rate of reaction when smaller proportions of magnesium iodide are used is, however, greatly decreased. Using 50% of magnesium iodide, complete reduction was effected in one week (112% Mg loss); when only 25% of magnesium iodide was employed, two weeks were required for reduction (111% Mg loss).

Reaction of the Reduction Product with Benzoyl Chloride.—The colorless mixture obtained by reducing 7.28 g. of azobenzene was treated with a solution of 11 g. of benzoyl chloride in 20 cc. of benzene. The benzoyl chloride was added in small portions and the mixture was kept cold throughout the reaction. A vigorous reaction ensued and a dark reddish-brown solution resulted. After five hours the mixture was hydrolyzed and it yielded 3.3 g. of dibenzoylhydrazobenzene; m. p. 158°. The product was found to be identical with dibenzoylhydrazobenzene prepared from hydrazobenzene and benzoyl chloride.

The identical results were obtained from iodomagnesium-hydrazobenzene prepared from hydrazobenzene and ethylmagnesium iodide (Equation 4). A solution of ethylmagnesium iodide was prepared from 4.5 cc. of ethyl iodide in a mixture of 30 cc. of ether and 60 cc. of benzene and to the filtered solution solid hydrazobenzene was added in small portions until no further evolution of ethane took place (3.82 g. of hydrazobenzene). This mixture behaved in all respects like the reduction mixture from azobenzene. Addition of 5 cc. of benzoyl chloride gave 1.8 g. of dibenzoylhydrazobenzene.[7]

Reaction with Iodine.—Five grams of iodine was added in portions to the colorless reduction mixture from 3.64 g. of azobenzene. Cooling was necessary because a considerable amount of heat was developed in the reaction. At first the solution became dark-blue in color, then black-brown and finally reddish-brown. After two hours, hydrolysis gave 3.3 g. (90%) of azobenzene, 0.2 g. of hydrazobenzene and 0.1 g. of a black material. The iodomagnesium-hydrazobenzene prepared from hydrazobenzene and a Grignard reagent reacted with iodine in the same manner; the same color changes were observed and azobenzene was obtained in practically the same yield.

Reaction with Oxygen.—When a colorless solution of iodomagnesium-hydrazobenzene is exposed to the air for but an instant, the solution immediately becomes opaque blue-black and then brown-black in color. These colors, like the colors produced during the process of reduction, are due, as explained before, to the formation of quinhydrone-like complexes between the iodomagnesium-hydrazobenzene and azobenzene (the latter compound being furnished here by oxidation).

Dry air was passed into a solution of iodomagnesium-hydrazobenzene for two hours; the following color changes were observed: deep blue, greenish-brown, reddish-brown, dark brown. Hydrolysis gave a 90% yield of azobenzene and no hydrazobenzene. A similar result was obtained when air was passed into iodomagnesium-hydrazobenzene which had been prepared from hydrazobenzene.

Reaction with Carbon Dioxide.—Dry carbon dioxide was passed into the colorless reduction mixture prepared from 7.28 g. of azobenzene; the mixture was kept at 20° throughout the reaction. The grayish-white precipitate which was originally present disappeared completely after one hour and two liquid layers were obtained. After one and one-half hours of carbonation, a mixture of ice and water was added; a large amount of the salt of hydrazobenzene-N,N-dicarboxylic acid (Equation 8) precipitated in the aqueous solution. The benzene–ether solution which was removed was found to contain only 0.72 g. (10%) of product. The aqueous solution was filtered from the solid; the clear filtrate rapidly became cloudy because the salt of the acid loses carbon dioxide and gives hydrazobenzene. When the aqueous solution was acidified, the free acid was precipitated as a solid; it decomposed in a short time into carbon dioxide and hydrazobenzene. Schlenk and Appenrodt observed the same kind of reaction in the case of the sodium addition products of azobenzene.

---

[7] Compare Gilman and Pickens, THIS JOURNAL, 47,2406 (1925).

Practically identical results were obtained from iodomagnesium-hydrazobenzene which had been prepared from hydrazobenzene (3.15 g.) and ethylmagnesium iodide. Hydrolysis of the carbonated mixture gave an aqueous solution of the salt of the dicarboxylic acid; acidification of the filtered aqueous solution gave 1.76 g. of hydrazobenzene.

Reaction with **Azoxybenzene.**—Nine and one-tenth grams of azobenzene was reduced and the colorless reduction mixture was treated with 9.9 g. of azoxybenzene in portions; cooling was necessary. The mixture became dark blue, then opaque brown and finally brown-red in color. After twenty hours at room temperature, the solution was hydrolyzed; there was obtained 17 g. of azobenzene and no hydrazobenzene.

Reaction with **Benzil.**—A solution of 10.5 g. of benzil in 30 cc. of benzene was added in the course of five minutes to the iodomagnesium-hydrazobenzene from 9.1 g. of azobenzene. The dark reddish-brown solution which resulted was hydrolyzed after six hours. The solid residue of azobenzene and benzoin which remained after removal of the organic solvents was extracted in a Soxhlet extractor with petroleum ether (40–60°) until the siphoning liquid was colorless. From the extract, 5.6 g. of azobenzene was obtained. The colorless benzoin in the extraction thimble weighed 6.8 g.; by recrystallization from acetic acid it was obtained in the form of colorless needles melting at 132–133°.

Reaction with **Benzaldehyde.**—Addition of 10.6 g. of benzaldehyde in 10 cc. of benzene to the reduction product from 9.1 g. of azobenzene developed a large amount of heat (cooling necessary) and a dark reddish-brown solution resulted. After standing overnight at room temperature, the mixture was hydrolyzed; some aniline and 4.5 g. of benzanilide were obtained. After recrystallization from acetone, the benzanilide melted at 161–162°; the same melting point was observed when the compound was mixed with authentic benzanilide. Benzanilide has been found to be the product when azobenzene is heated at 200° with benzaldehyde.[8]

TABLE I

REDUCTION OF SUBSTITUTED AZOBENZENES BY $Mg + MgI_2$

Compound	G.	Mg *reacted,* %	*Substituted* hydrazobenzene	*Substituted aniline*
4,4′-Dimethylazobenzene	4.20	149	1.80	1.0
4,4′-Dimethoxyazobenzene	4.84	146	....	1.0
4,4′-Diphenylazobenzene	3.34	160	1.08	1.0

In all cases the hydrazobenzene was contaminated with some of the corresponding azobenzene. The reaction with dimethoxyazobenzene is a complex one; the product was a dark oil from which only traces of dimethylhydrazobenzene could be isolated.

In order to obtain some idea concerning the formation of *p*-toluidine (and of aniline from azobenzene), a solution of iodomagnesium-dimethylhydrazobenzene, prepared from dimethylhydrazobenzene (4.2 g.) and the Grignard reagent, was allowed to react with a mixture of magnesium and magnesium iodide. After six days of shaking at room temperature, 0.23 g. (48%) of magnesium had reacted and hydrolysis gave 2.0 g. of a mixture of dimethylhydrazobenzene and dimethylazobenzene and 1.0 g. of p-toluidine. Several formulations for the reaction suggest themselves but the correct one cannot be decided at this time.

Reduction of Azoxybenzene (One Equivalent of Magnesium).—A mixture of 3.96 g. (0.02 mole) of azoxybenzene, 0.486 g. (0.02 atom) of magnesium ribbon and 5.5 g. of magnesium iodide in ether and benzene was shaken until all of the magnesium had disappeared. The reddish-brown solution which contained a small amount of precipitate was hydrolyzed; 3.4 g. of azobenzene and no hydrazobenzene was obtained.

---

[8] Bamberger, *Ber.*, 57, 2085 (1924); Bigiavi, *Gazz. chim. ital.*, 57, 160 (1927).

Reduction of Azoxybenzene (Two Equivalents of Magnesium).—To a filtered solution of magnesium iodide, prepared from 6 g. of iodine in 20 cc. of ether and 40 cc. of benzene, was added 4.95 g. of azoxybenzene and a magnesium rod. After three days of shaking the mixture was colorless and contained a precipitate; the mixture had the appearance of the reduction mixture obtained from azobenzene; loss in magnesium, 1.20 g.; calculated, 1.21 g. Hydrolysis gave 4.2 g. (92%) of hydrazobenzene.

The product obtained by the complete reduction of azoxybenzene was identical with the reaction product obtained by reduction of azobenzene. It reacted with azoxybenzene, with iodide and with oxygen, giving azobenzene as the principal product in each case.

TABLE II

REDUCTION OF SUBSTITUTED AZOXYBENZENES BY $Mg + MgI_2$

Compound	G.	Mg reacted, %	Substituted hydrazobenzene	Substituted aniline
4,4′-Dichloroazoxybenzene	5.34	96	4.0	..
4,4′-Dimethoxyazoxybenzene	4.30	110	0.5	..
4,4′Diphenylazoxybenzene	1.75	123	.83	0.35

Reduction of Nitrosobenzene to **Hydrazobenzene.**—To a filtered solution of magnesium iodide, prepared from 36 g. of iodine in a mixture of 40 cc. of ether and 80 cc. of benzene, was added 10.7 g. of nitrosobenzene and a rod of magnesium. The nitrosobenzene dissolved and a reddish-brown solution was obtained; however, after two minutes a complex of nitrosobenzene and magnesium iodide precipitated as an oil which quickly solidified. After ten minutes a large amount of the tan-colored crystals of the complex was present.

During this time reduction had begun and after half an hour the mixture was black in color. This color gradually disappeared and at the end of the reaction the mixture was light brown in color and contained a finely divided solid. The loss in weight of the magnesium rod was 3.76 g.; calculated, 3.65 g. (Equations 11 and 3). Half a dozen similar experiments gave exactly the same loss (103% of the calculated value) of magnesium. Hydrolysis of the mixture gave 6 g. (66%) of hydrazobenzene. Although the amount of magnesium that reacted corresponded closely to that required by Equations 11 and 3, nevertheless the yield of hydrazobenzene was never more than 70% of the calculated amount, which indicates that side reactions occur. The by-products appear to be of the nature of aniline-black. No reduction of nitrosobenzene occurred when it was shaken with magnesium without the addition of magnesium iodide.

When the reaction mixture was treated with iodine or with oxygen, azobenzene was obtained in 65–70% yields.

Reduction of Nitrosobenzene to **Azobenzene.**—A mixture of 5.35 g. of nitrosobenzene, 1.216 g. of magnesium ribbon and 15 g. of magnesium iodide in 20 cc. of ether and 40 cc. of benzene was shaken until all of the magnesium had disappeared. Hydrolysis of the black mixture gave 3.26 g. (71%) of azobenzene and no hydrazobenzene (Equation 11).

It was considered that azoxybenzene might be formed prior to azobenzene. However, when just enough reducing agent was employed to convert all of the nitrosobenzene to azoxybenzene (0.608 g. of magnesium for 5.35 g. of nitrosobenzene), the product consisted of a mixture of unchanged nitrosobenzene and azobenzene (33% yield).

Reaction of the Reduction Mixture with Nitrosobenzene.—To the fully reduced product from 5.35 g. of nitrosobenzene was added 2.68 g. of nitrosobenzene. A vigorous reaction took place with evolution of heat and a dark black mixture resulted. After twenty hours the mixture was hydrolyzed, and gave 4.8 g. (70% of that calculated in Equation 12) of azobenzene.

Summary

Azobenzene is reduced by the system Mg + MgI_2 to iodomagnesium-hydrazobenzene according to the reaction $C_6H_5N{=}NC_6H_5 + Mg + MgI_2 \longrightarrow C_6H_5(MgI)N{-}N(MgI)C_6H_5$.

Azoxybenzene is reduced by the binary system to azobenzene or to the hydrazobenzene derivative according to the amount of reducing agent employed.

Substituted azobenzenes and azoxybenzenes react in the manner of the unsubstituted compounds except that in certain instances reduction proceeds to a considerable extent beyond the hydrazobenzene stage

Nitrosobenzene is reduced principally to iodomagnesium-hydrazobenzene according to the following formulation: $2C_6H_5N{=}O + 3Mg + 3MgI_2 \longrightarrow C_6H_5(MgI)N{-}N(MgI)C_6H_5 + 2(MgI)_2O$. Azobenzene is formed as an intermediate product in this reaction.

The results obtained, in agreement with those of previous studies, lend support to the hypothesis that the active reducing agent is MgX, generated by interaction of magnesium and magnesium halide.

CONDENSATIONS OF SECONDARY AMINES WITH NAPHTHOLS AND ALDEHYDES. II

BY WALLACE R. BRODE AND JOSEPH B. LITTMAN

RECEIVED JANUARY 10, 1931 PUBLISHED APRIL 6, 1931

In earlier papers by the authors a description has been given, of the preparation[1] of a few condensation products of the type which might be associated with the intermediates formed in the Claisen or Knoevenagel reactions, and the resolution of one of these condensation products *(1-(a-*1-piperidylbenzyl)-2-naphthol),[2] into its optical antipodes. The present paper describes the preparation of several more condensation products involving other aromatic and aliphatic aldehydes. A preparation is also described in which a-naphthol is used in place of 8-naphthol in these condensations.

The mechanism of the a-naphthol condensation was shown to be the same as that of the β-naphthol condensation by the preparation of the α-naphthol derivative through the interaction of benzylidene-dipiperidine and a-naphthol.

The structure of the naphthol derivative (2-(a-1-piperidylbenzyl)-1-

---

[1] Littman and Brode, THIS JOURNAL, 52, 1655 (1930).

[2] Brode and Littman, *ibid.*, 52,5056 (1930).

naphthol) was assigned by analogy from similar condensation products which have been previously prepared and analyzed.[3,4,5]

Experimental

The tertiary amines described in this paper were prepared by the following general method: 0.1 mole of naphthol (*a*- or β-) and 0.1 mole of aldehyde were dissolved in 10 cc. of absolute alcohol and to this solution 0.1 to 0.15 mole of secondary amines was added. The solution generally darkened in color and a rise in temperature was noted. On standing from two days to five months the crystalline amine separated out, which was then easily recrystallized from ligroin–alcohol or benzene–alcohol mixtures. The yields varied from 20 to 70% of the theoretical. The hydrochlorides were prepared by passing dry hydrogen chloride gas into a benzene solution of the amine.

TABLE I

PREPARATION, CONSTANTS AND ANALYSES OF AMINES

Amine (-Naphthol)	Naph- thol	Aldehyde	Amine	M. p., °C.	Analyses, % Calcd.	Found
1-(a-Di-n-propylaminobenzyl)-2-	β-	Benz-	Di-n-Pr	95	N, 4.2	4.06
1-(α-Dimethylaminoanisyl)-2-	β-	Anis-	Dimethyl[a]	132	N, 4.56	4.37
1-(α-1-Piperidylanisyl)-2-	β-	Anis-	Piperidine	134.5	Cl, 9.2	9.07
1-(α-Dimethylaminopiperonyl)-2-	β-	Piperonal	Dimethyl"	120	N, 4.36	4.34
2-(α-1-Piperidylbenzyl)-1-	a-	Benz-	Piperidine	110	Cl, 10.0	9.9

[a] An excess of dimethylamine was introduced as a gas.

The tertiary amine, 2-(α-1-piperidylbenzyl)-1-naphthol is very soluble in ether and only slightly soluble in alcohol. The alcohol solution is colored light yellow and on heating the color becomes very intense. On cooling the alcohol solution in a freezing mixture, the color disappears and on warming it reappears. This process may be repeated many times with no apparent effect on the resulting crystalline product or its melting point.

Summary

Several new condensation products formed by the interaction of secondary amines, aromatic aldehydes and β-naphthol have been prepared and described. A description is also given of the application of this type of condensation to secondary amines, aromatic aldehydes and or-naphthol.

THE SYNTHESIS OF ALPHA,BETA-UNSATURATED ETHERS

BY WALTER M. LAUER AND MARVIN A. SPIELMAN

RECEIVED JANUARY 12, 1931 PUBLISHED APRIL 6, 1931

The recent work of Swallen and Boord[1] and Dykstra, Lewis and Boord[2] has drawn attention to the possibilities of halogenated ethers in organic synthesis. The present paper deals with a synthesis of α,β-unsaturated ethers by the use of halogenated ethers in a series of four reactions as shown in the equations

$$RCH_2CHO + R'OH + HCl \longrightarrow RCH_2CH(OR')Cl + H_2O \quad (1)$$
$$RCH_2CH(OR')Cl + Br_2 \longrightarrow RCHBrCH(OR')Br + HCl \quad (2)$$
$$RCHBrCH(OR')Br + R''MgBr \longrightarrow RCHBrCH(OR')R'' + MgBr_2 \quad (3)$$
$$RCHBrCH(OR')R'' + KOH \longrightarrow RCH{=}C(OR')R'' + KCl + H_2O \quad (4)$$

The first three steps in the synthesis were developed by Boord and his co-workers, and in the present work they were carried out in substantially the manner described by these investigators. The last step represents the removal of the elements of hydrobromic acid from a β-bromo ether.

Boord comments on the unusual stability of β-bromo ethers to sodium hydroxide and states that they may be distilled from solid caustic soda without appreciable decomposition. This has been our experience, but we have found finely powdered potassium hydroxide to be an effective reagent for the elimination of hydrobromic acid. In many cases two or three distillations of a β-bromo ether from this substance are sufficient to complete the reaction. Several other reagents were tried, among which were alcoholic potash, quinoline, dimethylaniline, sodium acetate, sodium oxide, potassium carbonate, barium hydroxide, etc. The first two were partially effective, but the yields were small, due to complicating side reactions; the others were almost entirely inert.

It is interesting to note that Hibbert[3] found the same reagent, solid potassium hydroxide, to be the most suitable in the preparation of divinyl ether from β,β'-dichloroethyl ether.

Four vinyl ethers, III, V, VIII and XI, were synthesized as shown below. The α,β-dibromo ethers I, VI and IX given as starting materials were prepared as indicated in equations (1) and (2) above. The proper aldehyde, with an alcohol and gaseous hydrogen chloride, is converted to an a-chloro ether, and this on bromination yields the desired α,β-dibromo ether. By treatment with the Grignard reagent, β-bromo ethers II, IV, VII and X are obtained, and these are distilled from potassium hydroxide to produce the vinyl ethers.

$$\underset{\text{I}}{CH_2BrCH(OC_2H_5)Br} \xrightarrow{C_2H_5MgBr} \underset{\text{II}}{CH_2BrCH(OC_2H_5)C_2H_5} \xrightarrow{KOH} \underset{\text{III}}{CH_2{=}C(OC_2H_5)C_2H_5}$$

$$\xrightarrow{C_6H_5MgBr} \underset{\text{IV}}{CH_2BrCH(OC_2H_5)C_6H_5} \xrightarrow{KOH} \underset{\text{V}}{CH_2{=}C(OC_2H_5)C_6H_5}$$

$$\underset{\text{VI}}{CH_3CHBrCH(OCH_3)Br} \xrightarrow{C_6H_5MgBr} \underset{\text{VII}}{CH_3CHBrCH(OCH_3)C_6H_5} \xrightarrow{KOH} \underset{\text{VIII}}{CH_3CH{=}C(OCH_3)C_6H_5}$$

$$\underset{\text{IX}}{C_2H_5CHBrCH(OCH_3)Br} \xrightarrow{C_2H_5MgBr} \underset{\text{X}}{C_2H_5CHBrCH(OCH_3)C_2H_5} \xrightarrow{KOH} \underset{\text{XI}}{C_2H_5CH{=}C(OCH_3)C_2H_5}$$

The substituted vinyl ethers are ethereal liquids, miscible with the usual organic solvents and easily distilled without decomposition. In the presence of a trace of acid, or even semicarbazide hydrochloride, they hydrolyze to the corresponding ketones.

$$RCH{=}C(OR')R'' + H_2O \longrightarrow RCH_2COR'' + R'OH$$

This property was used as a constitution proof for those not described in the literature. The ketones were characterized as semicarbazones.

Experimental Part

A. Preparation of the Chloro Ethers. Equation (I).—The procedure followed was essentially that described by Boord. In working with propionaldehyde or butyraldehyde, however, greater care was necessary. When the aldehyde and alcohol were mixed, considerable heat was evolved, and if thorough cooling with an ice–salt bath was not effected before the influx of the hydrogen chloride, unmanageable colored liquids were obtained from which none of the desired product could be isolated.

B. Preparation of the α,β-Dibromo Ethers. Equation (2).—The α-chloro ethers were brominated without purification and without a solvent in an ice–salt bath at 0–5°. Bromine was added in small portions as fast as it was taken up. After the last had been added, the mixture was allowed to stand overnight and then distilled under diminished pressure. The average yields based on the aldehyde taken for the first reaction were about 70%.

C. Preparation of the β-Bromo Ethers. Equation (3).—The Grignard reactions were carried out by the improved procedure described by Boord in his second paper.[3]

β-Ethoxybutyl Bromide (II).—Yield, 80%; n^{25}_D 1.4427; b. p. 154–156° (Boord reports 166°).

α-Phenyl-β-bromoethyl Ethyl Ether (IV).—Yield, 66%; b. p. 129–133° at 18 mm.; n^{25}_D 1.5317.

Anal. Calcd. for $C_{10}H_{13}OBr$: Br, 34.93. Found: Br, 35.38, 35.51.

α-Phenyl-β-bromopropyl Methyl Ether (VII).—Yield, 71%; b. p. 122–124° at 14 mm.; n^{25}_D 1.5316. This compound has been synthesized by Spath and Göhring[4] by the same Grignard reaction. The violet color observed by these workers was apparent for a time, but soon faded out.

3-Bromo-4-methoxy-hexane (X).—Yield, 56%; b. p. 74–78' at 20 mm.; n^{25}_D 1.4495.

---

[4] Spath and Gohring, *Monatsh.*, 41, 319 (1920).

Anal. Calcd. for $C_7H_{15}OBr$: Br, 41.03. Found: Br, 40.23, 40.20.

D. Preparation of the **α,β-Unsaturated** Ethers, Equation (4).—In a distilling flask connected to a condenser was placed 40–60 g. of the β-bromo ether with an equal weight of finely powdered technical grade flake potassium hydroxide. A large sand-bath was placed under the flask and the temperature was raised very slowly to incipient boiling and maintained at that level for half an hour or longer. More heat was then applied and distillation was allowed to take place over a period of two hours. Suction was advantageously employed in distilling off the last of the material from the potash, which generally fused toward the end of the reaction. In the case of compounds (V) and (VXII) most of the distillation was conducted under diminished pressure to delay the fusion of the alkali and subsequent "layering out" of materials. In three of the four compounds studied, three such distillations were sufficient to remove the last of the bromine, as indicated by the Beilstein test. The products were then purified by distillation.

2-Ethoxy-butene-1 (III).—Yield, 65%; some unchanged halide was recovered, bringing the yield up to 75.6%; b. p. 85–87'; $n_D^{24.5}$ 1.4011.

And. Calcd. for $C_6H_{12}O$: OC_2H_5, 45.0. Found: OC_2H_5, 44.9, 44.4.

One-half cc. was hydrolyzed with 5 cc. of water, 0.5 g. of semicarbazide hydrochloride and enough alcohol to effect solution. The hydrolysis proceeded spontaneously. Sodium acetate was added and after half an hour of heating in a beaker of water the test-tube was cooled and the methyl ethyl ketone semicarbazone separated out. After crystallization from hot water it melted at 143–144.5". Pickard and Kenyon[5] give 135–136°, Robinson' gives 148° and Michael[7] gives 139°. A sample prepared from authentic methyl ethyl ketone melted at 143–144° and a mixed melting point showed no depression.

a-Ethoxystyrene (V).—Yield, 62%; b. p. 109–112° at 30 mm.; $n_D^{25.5}$ 1.5287. This compound has been prepared by Hoering,[8] Claisen,[9] Moureu,[10] and Tiffeneau.[11] It was hydrolyzed to acetophenone, which was identified as the semicarbazone; m. p. and mixed m. p. 198–199°. Shriner[12] gives the same figure.

a-Methoxy-p-methylstyrene (VIII).—Yield, 42%; b. p. 96–98° at 19 mm.; n_D^{26} 1.5271.

Anal. Calcd. for $C_9H_{12}O$: OCH_3, 20.9. Found: OCH_3, 20.9, 21.3.

This compound was collected by Spath and Göhring[4] as a by-product in their synthesis of ephedrine, but not in a form sufficiently pure for analysis. One cc. was hydrolyzed by warming with 50% alcohol and a drop of hydrochloric acid. The propiophenone which settled out on dilution was converted to the semicarbazone: m. p. and mixed m. p. 172–174". Shriner[12] gives 173–174°.

3-Methoxyhexene-3 (XI).—Yield, 79%; b. p. 114–115°; n_D^{25} 1.4130.

Anal. Calcd. for $C_7H_{14}O$: OCH_3, 27.2. Found: OCH_3, 27.3, 27.7.

This was hydrolyzed to ethyl propyl ketone and converted to the semicarbazone: m. p. 110–110.5". Michael[7] gives 111°. Blaise[13] gives 110°.

Summary

A method for the synthesis of α,β-unsaturated ethers is described and examples are given. This method appears to be quite general in its application.

MIXED BENZOINS.
III. THE STRUCTURE OF SOME UNSYMMETRICALLY SUBSTITUTED DESOXYBENZOINS

BY JOHANNES S. BUCK AND WALTER S. IDE

RECEIVED JANUARY 22, 1931 PUBLISHED APRIL 6, 1931

In general, the structure of a mixed benzoin, when produced in the usual manner from two aldehydes, cannot be assigned with any degree of probability. The same remark applies to the desoxy compound derived from it by the usual methods of reduction, for even were the structure of the mixed benzoin known, the desoxy compound might be derived from it via the hydrobenzoin or the isohydrobenzoin, from which compounds water can be eliminated in several ways. Thus RCOCHOHR' could give RCHOH-CHOHR' which, by elimination of a molecule of water, could give either $RCOCH_2R'$ or RCH_2COR' by the "vinyl-dehydration" of Tiffeneau. Other compounds, for example, diphenylacetaldehydes, produced by the "pinacoline-dehydration" of Tiffeneau, might also be expected to occur. The authors therefore sought for an unambiguous reaction to prove the structure of desoxy compounds and selected for this purpose the Beckmann transformation. A given mixed benzoin, on reduction, can give two desoxy compounds, each of which can, in turn, give two oximes. With a suitable reagent these oximes are converted into amides, the amide being different in each case. The amides are readily identified, either by hydrolysis or by synthesis, so that it is possible to assign a structure to both the oxime and to the parent desoxy compound. Usually a mixed benzoin gives but one desoxy compound, but this is not general.[1] In turn a given desoxy compound yields usually only one oxime, but again this is not general, the authors having in one case obtained both oximes in sufficient amounts to carry out Beckmann transformations on them.

There appears to be only one instance recorded of the application of the Beckmann transformation to a desoxy type of compound,[2] in this case produced by a Friedel-Crafts reaction and of known structure. The present authors have applied the transformation to seven desoxy compounds

---

[1] Jenkins, Buck and Bigelow, THIS JOURNAL, 52, 4495 (1930).

[2] Cain, Simonsen and Smith, *J. Chem. Soc.*, 103, 1035 (1913).

which were produced by the direct reduction of mixed benzoins, and have established the structure of these and of their oximes. The choice of the benzoins used was purely a matter of expediency, the most readily accessible ones being selected. The case of desoxydimethylaminobenzoin[1] was included in order to check the somewhat involved reasoning used in deducing its structure.

In a later paper it is hoped, after certain difficulties have been overcome, to apply the Beckmann transformation to the mixed benzoins themselves, since their structure cannot with certainty be inferred from the structure of the desoxy compounds.

Desoxy compounds of the mixed benzoins formed from the following pairs of aldehydes were investigated: (1) o-chlorobenzaldehyde and veratric aldehyde,[4] (2) o-chlorobenzaldehyde and anisaldehyde,[4] (3) *o*-chlorobenzaldehyde and *p*-dimethylaminobenzaldehyde,[3] (4) *o*-chlorobenzaldehyde and piperonal,[3] (5) benzaldehyde and anisaldehyde,[5] (6) benzaldehyde and piperonal,[3] and (7) benzaldehyde and *p*-dimethylaminobenzaldehyde.[1]

The desoxybenzoin from benzoin (1) gave 1-chlorophenylacet-3,4-dimethoxyanilide, and is hence 1-chlorobenzyl-3,4-dimethoxyphenyl ketone. Its oxime is the syn-dimethoxyphenyl derivative. The desoxy compound from benzoin *(2)* gave similarly 1-chlorophenylacetanisidide, showing that it is 1-chlorobenzyl-4-methoxyphenyl ketone and its oxime the syn-methoxyphenyl compound. From the desoxy compound of benzoin (3) 1-chlorophenylacet-4-dimethylaminoanilide was obtained and hence the desoxy compound is 1-chlorobenzyl-4-dimethylaminophenyl ketone and its oxime is the syn-dimethylaminophenyl oxime. The desoxy compound from benzoin (4) has an analogous structure, 1-chlorophenylacet-3,4-methylenedioxyanilide being formed on transformation of the oxime. The desoxy compound is therefore 1-chlorobenzyl-3,4-methylenedioxyphenyl ketone and the oxime is the syn-methylenedioxyphenyl compound.

From the desoxy compound of benzoin (5) two oximes were obtained. The syn-phenyl oxime gave 4-methoxyphenylacetanilide, while the *anti*-phenyl oxime gave benzoyl-4-methoxybenzylamine. Both these products indicate that the desoxybenzoin is 4-methoxybenzyl phenyl ketone. Tiffeneau and OrCkhoff[6] have described a compound, prepared in a different manner, to which they assign the same structure. Their compound appears to be identical with that of the present authors. As a check of the

---

[3] Buck and Ide, THIS JOURNAL, 52,220 (1930).

[4] Buck and Ide, *ibid.*, 52,4107 (1930).

[5] Previously obtained by several workers. The preparation used was that of Kinney, *ibid.*, 51,1592 (1929).

[6] Tiffeneau and Orékhoff, *Bull. soc. chim.*, [4] 37,430, 1410 (1925).

method, benzyl-4-methoxyphenyl ketone was prepared by a Friedel–Craft reaction. From it only one oxime was obtained, and this was transformed into phenylacetanisidide, showing that the oxime had the *syn*-methoxyphenyl structure and confirming the method. As a further check, the last possible isomeric amide, 4-methoxybenzoylbenzylamine was prepared and found to differ from the other three amides obtained in the transformations. This series is shown in full below, to illustrate the reactions and the principles involved in this work.

Tiffeneau and Lévy[7] describe phenyl-3,4-methylenedioxybenzyl ketone, obtained by distilling the oxide of α-phenyl-β-3,4-methylenedioxyethylene. They give the melting point as 71–72°. The desoxy compound obtained by the present authors melts at 86° and its oxime, by the Beckmann transformation, gives phenylacet-3,4-methylenedioxyanilide, showing that the oxime is the anti-benzyl compound and that the desoxy compound is the isomer of Tiffeneau and Lévy's ketone and is benzyl-3,4-methylenedioxyphenyl ketone.

The structure of β-desoxy-*p*-dimethylaminobenzoin was earlier deduced by rather involved reasoning[2,8] and it was desirable to check this. The oxime gave phenylacet-4-dimethylaminoanilide and hence the β-desoxy compound is benzyl-4-dimethylaminophenyl ketone, as previously stated, and the oxime is the anti-benzyl oxime.

The yields of the desoxy compounds are frequently mediocre. It is quite possible that the isomeric desoxy compound and the diphenylacetaldehyde were present in some cases, but no serious attempt to isolate these was made, for the present purpose.

A few of the amides encountered hydrolyzed under rather drastic treatment. The acid fragment was readily isolated, but the basic fragment was degraded by the reagent used. This is to be expected with amines such as dimethyl-*p*-phenylenediamine.[9] For this reason the structure of the amide was checked synthetically in all cases. For practical purposes the identification of the acid fragment is sufficient. The majority of the amides resisted hydrolysis even by powerful reagents.

The authors have avoided assigning definite names to the mixed benzoins (*cf.* Buck and Ide[3]) on account of the ambiguity in their structure. It is hoped to clear up this point soon.

The structures of the desoxy compounds and of their oximes have been deduced on the assumption that the transformation takes place directly, between the vicinal groups of the oximes, and that no transposition of groups, such as that suggested by Meisenheimer[10] for the benzil oximes,

takes place. The amides actually obtained could not have been produced had a transposition of groups occurred. Further strong evidence in favor of the authors' assumption, is afforded by the fact that the oximes of several desoxy compounds whose structures have been established by other methods (v. s.) gave without exception the amides to be expected on the basis of a straight transformation between the vicinal groups.

TABLE I

KETONES

No.	Phenyl ketones	Formula	From benzoin	Yield, %
(A)[4]	1-Chlorobenzyl-3,4-dimethoxy-	$ClC_6H_4CH_2COC_6H_3(OMe)_2$	(1)	..
(B)[4]	1-Chlorobenzyl-4-methoxy-	$ClC_6H_4CH_2COC_6H_4OMe$	(2)	..
(C)	1-Chlorobenzyl-4-dimethylamino-	$ClC_6H_4CH_2COC_6H_4NMe_2$	(3)	44
(D)	1-Chlorobenzyl-3,4-methylenedioxy-	$ClC_6H_4CH_2COC_6H_3O_2CH_2$	(4)	96
(E)[6]	4-Methoxybenzyl	$MeOC_6H_4CH_2COC_6H_5$	(5)	87
(F)	Benzyl-4-methoxy-	$C_6H_5CH_2COC_6H_4OMe$	...	..
(G)	Benzyl-3,4-methylenedioxy-	$C_6H_5CH_2COC_6H_3O_2CH_2$	(6)	64
(H)[1]	Benzyl-4-dimethylamino-	$C_6H_5CH_2COC_6H_4NMe_2$	(7)	..

The ketones (with the exception of F) were prepared by reducing the benzoin by boiling with tin and concd. hydrochloric acid, in alcoholic solution, for six or more hours (Buck and Ide, Refs. 3 and 4). Ketone F was prepared by a Friedel–Crafts reaction on phenylacetyl chloride and anisole. Ketones A, B, E and H have been described elsewhere, A and B without structures assigned. Ketone E is reduced catalytically to a compound melting at 128.5°, probably the same as Tiffeneau and Orékhoff's compound of m. p. 134–135°.[6] By analogy, it is the hydrobenzoin. It forms silky, white leaves, giving an intense golden-brown color with concd. sulfuric acid (cf. (6) where the color is given as red). Anal. Calcd. for $C_{15}H_{16}O_3$: C, 73.73; H, 6.61. Found: C, 73.86; H, 6.77.

TABLE II (*Concluded*)

Two methods were used for preparing the oximes. [1] The ketone, in alcoholic solution, was allowed to stand with an excess of hydroxylamine acetate (from the hydrochloride and potassium acetate) and finally warmed for two hours and the mixture then diluted with water. [2] The ketone, in pyridine solution, was warmed on the bath for three hours with hydroxylamine hydrochloride (excess) and the mixture then diluted with water. In either case the product was recrystallized from alcohol until pure.

Oxime E-1 has been described by Tiffeneau and Orékhoff,[6] form undetermined.

Oxime H has been described by Jenkins, Buck and Bigelow,[1] form undetermined.

(I)	4-Methoxybenzoylbenzylamine	$C_6H_5CH_2NHCOC_6H_4OMe$	...

The amides were synthesized by one of the following two methods, the one used being determined by circumstances: (1) the Schotten–Baumann reaction, (2) heating the acid and amine together in molecular proportions, at 180–200° for two hours.

The Beckmann reaction was carried out in one or both of two ways, (1) by means of benzenesulfone chloride and sodium hydroxide solution, after the manner of a Schotten–Baumann reaction, and (2) by the action of phosphorus pentachloride on the oxime in absolute ether. The first method is convenient, rapid and gives good yields.

Amides A, C and D were hydrolyzed by strong acids, giving o-chlorophenylacetic acid.

TABLE III (*Concluded*)

The solubilities of the compounds described are not distinctive. The amides are moderately soluble in alcohol, and rather soluble in benzene, chloroform, etc. The oximes are frequently very soluble in absolute alcohol, but separate readily on the addition of a little water. In every instance the compounds were recrystallized from alcohol until pure. The melting points given are corrected. The identification of the amides obtained in the Beckmann reaction was always carried out by comparison and mixed melting point determinations with a synthetic specimen. The analyses are all microanalyses (Pregl).

Summary

The Beckmann transformation has been used to determine the structures of certain unsymmetrically substituted desoxybenzoins, and to assign configurations to the oximes derived from them. Seven desoxy compounds were examined. **A** number of new desoxy compounds, oximes and amides are described. The results support the view that the transformation takes place between the vicinal groups of the oximes.

REACTIONS OF SOME ORGANIC LEAD COMPOUNDS[1]

BY CHARLES D. HURD AND PAUL R. AUSTIN

RECEIVED JANUARY 22, 1931 PUBLISHED APRIL 6, 1931

Many cases exist to show that in the reaction of mineral acids with aryl-alkyl-metal compounds, the aryl group is more readily severed than the alkyl group. Such, for example, is the case with diphenyldiethyllead,[2] triphenylalkyllead[3] (where alkyl represents methyl, ethyl or cyclohexyl), phenylmethylmercury,[4] triphenylbenzyltin[5] and others. On the basis of such evidence, arguments have been advanced that the preferential removal of aryl signifies that aryl groups possess a greater electron attraction than alkyl groups. Although electron attraction is probably the determining factor in compounds like ArHgR or Ar_2PbR_2, with such a compound as Ar_3PbR it might be said that the greater supply of Ar groups is the determining factor. In fact, Calingaert[6] has stated: "It is also worth mentioning that, in (lead) compounds containing different organic radicals, the halogen exerts a very decided selective action, reacting almost invariably with one of the groups of which there is the larger number."

Phenyltriethyllead, therefore, presents an interesting case. With the preponderance of ethyl groups, it might be expected that ethyl, rather than phenyl, should be removed first. With electron attraction as the determining factor the reverse might be expected. Actually, it has been found that hydrochloric acid reacts to cause preferential scission of phenyl to yield benzene and triethyllead chloride. Benzene was identified as *m*-dinitrobenzene. With nitric acid and phenyltriethyllead, the reaction product is diethyllead dinitrate, $Et_2Pb(NO_3)_2$. This dinitrate, hitherto unprepared, was also made by the action of nitric acid on tetraethyllead.

These reactions are best carried out in the presence of chloroform. When undiluted, they are difficult to control. Diethyllead dinitrate is a water-soluble salt which was found to be about 79% ionized in tenth molar solution. Conditions were determined for preparing triethyllead nitrate from tetraethyllead. This nitrate rapidly reacts further to yield the dinitrate. Further interaction apparently yields lead nitrate rather than such a substance as ethyllead trinitrate.

Pyrolysis of Lead Compounds.—It is known that in the pyrolysis of

---

[1] This investigation was made possible by the help of Mr. Thomas Midgley, Jr., and Mr. E. W. Webb of the Ethyl Gasoline Corporation, which is gratefully acknowledged. Original manuscript received July 30, 1930.

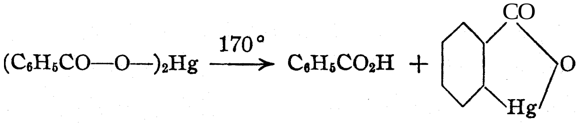
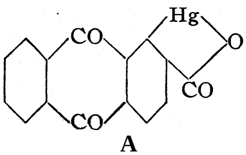
mercuric benzoate,[7] benzoic acid is eliminated and a carbon-to-mercury union is established



Mercuric 1,2-anthraquinonedicarboxylate[8] has been found to behave similarly, giving the anhydro hydroxymercuri compound, A, when heated at 235°. Since a C—Hg linkage was established in these reactions, it was of interest to see if a carbon-to-lead linkage could be established by an analogous process, namely, by the pyrolysis of lead tetrabenzoate. We prepared the latter by interaction of lead tetraacetate and benzoic acid, a reaction which has recently been described by Criegee.[9]



A

The pyrolysis of lead tetrabenzoate was always accompanied by a mild explosion, Possibly this could have been avoided by the use of an inert medium, but this was not tried. Although benzoic acid was detached it is not exactly clear how this occurs for no evidence was found for tetravalent lead in the residue. This residue was completely soluble in dilute sodium hydroxide solution and no lead dioxide was formed thereby. Lead dibenzoate was the only lead compound identified. Had such a compound as $\left(C_6H_4\overset{CO_2}{\diagup\!\!\!\diagdown}\right)_2Pb$ been found, (1) the action of bromine on the residue should have yielded o-bromobenzoic acid, but no positive evidence for this could be obtained; (2) sodium hydroxide solution should have yielded ortho $(HO)_2Pb(C_6H_4CO_2Na)_2$ which would have behaved quite differently from the Pb^{++} ions actually found.

Lead acetate and acetic acid, but no other compounds, were noted when lead tetraacetate was decomposed at 190°.

Experimental Part

Triethyllead chloride was prepared from tetraethyllead[10] and concd. hydrochloric acid by the method of Browne and Reid.[11] It, in turn, was added in portions to an ether solution of phenylmagnesium bromide. Phenyltriethyllead was thus prepared by the method of Griittner and Grüttner.[12] They recorded its boiling point as 136° at 13 mm.

[10] A generous supply of this material was donated by the Ethyl Gasoline Corporation.

[11] Browne and Reid, THIS JOURNAL, 49, 836 (1927). Gilman and Robinson, *ibid.*, 52, 1975 (1930) describe a preparation using tetraethyllead, ether and hydrogen chloride.

[12] Griittner and Griittner, *Ber.*, 51, 1296 (1918).

Tetraethyllead and Nitric Acid.—One hundred grams of tetraethyllead and 350 cc. of chloroform were placed in a 3-necked flask and 28 cc. of concd. nitric acid was added drop by drop into the boiling solution. Then it was refluxed for one and one-half hours. At the start of the reflux period a heavy liquid layer, presumably a mixture of triethyl- and diethyllead nitrates, appeared. This gradually became solid as the reaction progressed. The solid was filtered while hot. About 50 g. of impure diethyllead dinitrate was collected on the filter. It was identified by conversion into diethyllead dichloride by dissolving it in methanol and adding concd. hydrochloric acid. The mixture was filtered from lead chloride and the filtrate concentrated. The diethyllead dichloride which precipitated was washed with ether, dried and analyzed.

Anal. Calcd. for $(C_2H_5)_2PbCl_2$: Pb, 61.5; Cl, 21.1. Found: Pb, 61.3; Cl, 20.8.

The filtrate, on cooling, gave a small precipitation of a salt analyzing 60–61% of lead which was evidently triethyllead nitrate for the most part. The calcd. Pb in $(C_2H_5)_3PbNO_3$ is 58.1%, and in $(C_2H_5)_2Pb(NO_3)_2$ is 53.2%. Some lead nitrate was also in it. The same substance was found to precipitate at the beginning of the reaction if it was chilled.

Phenyltriethyllead and Nitric Acid.—Three cc. of nitric acid was added to a solution of 8 g. of phenyltriethyllead in 100 cc. of chloroform. A liquid layer formed. The solution was refluxed for fifteen minutes, filtered hot and the filtrate cooled. The 1.3 g. of crystalline diethyllead dinitrate which appeared was collected. Another 0.9 g. was obtained by extracting the residue from the first filtration. These crystals were soluble in water and the solution gave no test for lead ion with potassium dichromate solution.

Anal. Calcd. for $(C_2H_5)_2Pb(NO_3)_2$: Pb, 53.2. Calcd. for $(C_6H_5)(C_2H_5)Pb(NO_3)_2$: Pb, 47.3. Found: Pb, 53.1, 52.9.

Fractionation of the chloroform solution gave a fraction which contained benzene. Thus, nitration of this fraction yielded m-dinitrobenzene which melted at 88°. A mixed melting point determination with an authentic specimen of m. p. 90°, was 89°.

Conversion of the dinitrate into the dichloride was effected in the manner previously described with the dinitrate from tetraethyllead.

Reaction without Diluents.—Small yields of diethyllead dinitrate which analyzed 53.0% of lead were obtained when 0.9 cc. of nitric acid (sp. gr. 1.4) was dropped onto 2 g. of phenyltriethyllead at room temperature. Far better yields were obtained when solvents were employed, and of these chloroform appeared to give better results than benzene or ether.

Dissociation of Diethyllead Dinitrate.—The apparent molecular weight of this salt was determined by the freezing point method, using water as the solvent. In two experiments, these findings were 150.9 and 150.0, whereas the true molecular weight of $(C_2H_5)_2Pb(NO_3)_2$ is 389.

Data. Subs., 0.8085, 0.4581: H_2O, 20 and 20 g.; moles of the salt per 1000 g. of H_2O, 0.104, 0.059; depression of the freezing point, 0.498°, 0.284°.

From these data, calculation of the percentage ionization of diethyllead dinitrate into three ions gave values of 78.8 and 79.5%, respectively.

Phenyltriethyllead and Hydrochloric Acid.—One hundred cc. of chloroform and 12.7 g. of phenyltriethyllead (b. p. (10 mm.) 128–137°) were put in a reaction flask and 4 cc. of concd. hydrochloric acid was added. The mixture was refluxed for twenty minutes, after which it was carefully fractionated. The last fraction contained benzene. On nitration with nitric and sulfuric acids, it yielded crystals of m-dinitrobenzene of melting point 88° and mixed m. p. 89° with a known specimen.

The non-volatile residue solidified. It was recrystallized once from alcohol, dried and analyzed for lead and chlorine. The data imply slight contamination with either diethyllead dichloride or phenyldiethyllead chloride, but they show that the salt represents triethyllead chloride for the most part.

Anal. Calcd. for $(C_2H_5)_3PbCl$: Pb, 62.8; Cl, 10.77. Calcd. for $(C_6H_5)(C_2H_5)_2PbCl$: Pb, 54.8; Cl, 9.4. Found: Pb, 61.7; Cl, 10.69, 10.71.

In another similar reaction of phenyltriethyllead (in chloroform) and hydrochloric acid, a small quantity of material separated from the hot chloroform solution. It was collected on a filter, washed, dried and analyzed. It appeared to be largely diethyllead dichloride.

Anal. Found: Pb, 59.8; Cl, 20.5.

Preparation of Lead **Tetrabenzoate.**—This compound was synthesized in essentially the manner suggested by Criegee,[13] but the following details were found to be helpful. A one-liter Claisen flask was arranged for vacuum distillation and a thermometer was placed so that the bulb dipped into the reaction mixture. Five hundred grams of benzoic acid was melted in the flask and then 155 g. of lead tetraacetate was added. Larger quantities could be used if desired. The vacuum of a water pump was used and the heating carried out so that the temperature of the mixture did not exceed 120°. The distillation temperature was from 60–80°. Most of the time the pressure was gradually dropping from 170 to 80 mm., but finally the value was 60 mm. During the course of the distillation, which required one and one-half hours, a yellow precipitate of lead tetrabenzoate separated in the molten benzoic acid. At the conclusion, most of the benzoic acid layer was decanted. This facilitated the separation of the lead tetrabenzoate from benzoic acid. For purification, the lead salt was washed with warm methanol and then with benzene. About 140 g. of the compound was obtained. The product from crystallization from benzene or even from washing with benzene appeared to retain benzene of crystallization.

Colson's observation[14] that lead tetra-salts are decomposed by alcohol was confirmed with lead tetrabenzoate. Thus, when it was boiled with methanol for a short time it went into solution to form the dibenzoate, which crystallized readily on cooling and apparently with methanol of crystallization. After drying for a week in a vacuum desiccator over phosphorus pentoxide, this alcohol was removed and the lead dibenzoate melted at 118–119°. A melting point value of 119–120° was found for lead dibenzoate which was synthesized from lead nitrate and sodium benzoate after similar crystallization from methanol and vacuum drying over phosphorus pentoxide. A mixed melting point of these two samples was 118–119°. These melting points were taken on a Maquenne block. When the usual capillary tube method was used, this lead dibenzoate melted at 107–115° with decomposition.

Anal. Subs., 0.4033, 0.4011: cc. of 0.02957 M ammonium molybdate, 30.2, 30.1. Calcd. for $(C_6H_5CO_2)_2Pb$: Pb, 46.1. Found: Pb, 45.9, 46.0.

Curiously, if any of these samples of lead dibenzoate were recrystallized from ethylene dichloride, the melting point was raised about twenty-five degrees. Thus, the value of the 118–119" material was changed to 145–147° (Maquenne block) by this process.

Pyrolysis of Lead **Tetrabenzoate.**—The pyrolysis was carried out by placing the compound in a 200-cc. round-bottomed flask which was fitted with a long air condenser. The flask was heated slowly with an oil-bath. The decomposition always took place with a mild explosion and was complete in a short time. In four experiments with 10–20 g. samples, the oil-bath temperature when vigorous decomposition occurred was 130, 148, 155 and 170". The temperature of decomposition seemed to depend somewhat on the rate of heating and somewhat on the benzene which adhered to the compound.

---

[13] Criegee, *Ann.*, 481, 284 (1930).

[14] Colson, *Compt. rend.*, 136, 676, 1664 (1903).

Dense white clouds were evolved during the pyrolyses and sublimates of benzoic acid collected on the cooler parts of the flask. The residue was a sticky black *gum.* soluble in methanol. By slow evaporation and by recrystallization from dilute methanol, lead dibenzoate alone was isolated. A small sample of the residue dissolved almost completely in aqueous sodium hydroxide solution and gave no lead dioxide. Acidification of the alkaline solution with acetic acid, followed by potassium chromate solution, gave a yellow precipitate of lead chromate, indicative of Pb^{++} ion.

The pyrolytic residue was dissolved in chloroform and was apparently held in solution by the small amount of gummy impurity. After a few minutes it precipitated. From a 17-g. run, there was 14 g. of this light gray powder. Some of it was twice recrystallized from ethylene dichloride; m. p. 141–142°. A mixed melting point with lead dibenzoate of melting point 145–147" (from ethylene dichloride) was 143–144° (Maquenne block).

The chloroform filtrate from the first solution of the product was evaporated, leaving a gum. This was treated with hot ligroin (65–110°) and the hydrocarbon decanted and evaporated. This left about **0.3** g. of an oily solid which was shown to be benzoic acid. After crystallization from water and alcohol, it melted at 119–120°.

Three grams of the product from the pyrolysis was dissolved in 100 cc. of ethylene dichloride and treated with bromine (in chloroform) for about one and one-half hours. The excess bromine was evaporated and the solution filtered. Two grams of lead bromide was obtained. The filtrate was given an alkaline wash, the layers separated, and the alkaline solution was poured into cold dilute hydrochloric acid. The precipitate which formed was filtered and recrystallized from water. The first fraction, obtained by cooling slowly to room temperature, melted at 130–132" but there was not enough of this to recrystallize or characterize. After cooling in ice, a fraction of 118–119° was obtained; weight 0.1 g. The third fraction of 0.05 g. precipitated on standing overnight; m. p. 119–120'. The second and third fractions were unmistakably benzoic acid rather than a bromobenzoic acid which might have been formed had there been a C–Pb bond for the bromine to sever.

Pyrolysis of Lead Tetraacetate.—Twenty grams of lead tetraacetate was heated on an oil-bath in a 200-cc. flask which was fitted with a reflux condenser. At a bath temperature of 190°, vigorous decomposition set in. A small portion of the product, after removal from the flask, was found to dissolve completely in water. This gave tests for lead ion (bivalent) with dilute sulfuric acid and with potassium chromate solution.

By ether extracting the contents of the flask, a liquid was obtained on evaporation of the ether which was evidently acetic acid. The residue from the extraction was dissolved in water and filtered. The filter held a trace of black precipitate which was presumably lead dioxide. Almost a quantitative yield of lead diacetate was found in the filtrate. It was twice recrystallized from water, dried for twelve hours at 105°, and then crystallized from absolute alcohol; m. p. 183–187". An authentic specimen of lead acetate, twice recrystallized from absolute alcohol, melted at 187–189°. A mixed melting point determination was 184–186° (capillary tube).

Summary

Phenyltriethyllead reacts with hydrochloric acid to yield benzene and triethyllead chloride. Further reaction gives the more insoluble dichloride. Both phenyltriethyllead and tetraethyllead react readily with nitric acid to produce diethyllead dinitrate, a salt which reacts metathetically in methanol with hydrochloric acid to give the dichloride. In 0.1 *M* solution, the dinitrate is apparently 79% ionized,

On pyrolysis, lead tetrabenzoate and lead tetraacetate give rise to benzoic acid and lead dibenzoate and acetic acid and lead diacetate, respectively.

STUDIES OF ORGANIC LEAD COMPOUNDS.
I. ACTION OF ACIDS ON LEAD ARYLS

BY PAUL R. AUSTIN[1]

RECEIVED JANUARY 26, 1931 PUBLISHED APRIL 6, 1931

In the study of the severing action of mineral acids or halogens on mixed alkyl-aryl or mixed aryl lead compounds, there appear to be two factors which determine the group that is removed. Almost invariably one of the groups of which there is the largest number is removed first.[2] As has been shown in a previous paper,[3] the electron attraction of the group in question is an even more determining factor, superseding the effect of the predominance of one of the groups, as is seen from the following example

$$(C_2H_5)_3PbC_6H_5 + HCl \longrightarrow (C_2H_5)_3PbCl + C_6H_6$$

In general, aromatic groups are replaced before aliphatic[4] and in the aromatic series (in contrast to the aliphatic) the heaviest group is replaced first.[5]

In these replacement reactions it is usually possible to replace one or two groups as desired. The removal of three groups to leave a single lead–carbon linkage in the molecule has never been accomplished. The reactions of a compound in which both the electron attraction and predominance of groups worked together should, therefore, prove to be interesting. Phenyltri-o-tolyllead was selected as being such a compound; the three *o*-tolyl groups have a greater electron attraction than the phenyl group.

Actually, the reactions of phenyltri-o-tolyllead show the strong tendency of organo-lead compounds to retain at least two lead-carbon linkages. Hydrobromic acid removed either one or two o-tolyl groups of phenyltri-*o*-tolyllead according to the concentration of the hydrobromic acid used. Nitric acid exerted a similar selective action: phenyltri-o-tolyllead in chloroform solution yielded phenyl-o-tolyllead dinitrate when treated with nitric acid. Even when the phenyltri-o-tolyllead was added to boiling concentrated nitric acid, phenyl-o-tolyllead dinitrate and di-o-tolyllead dinitrate were produced, but no single lead–carbon linkage was established.

[5] Krause and Schlöttig, *ibid.*, 58, 427 (1925).

The production of a mixture of products from the latter reaction is not without precedent. Triphenyl-*p*-phenetyllead yields an analogous mixture of products when treated with silver nitrate.[6]

In connection with the above study several interesting reactions were encountered. Tetra-o-tolyllead (which cannot be prepared directly from the Grignard reagent and lead chloride) was prepared by heating tri-o-tolyllead in xylene for twenty-four hours. The reaction is similar to the action of heat on triphenyllead.[7]

Attempts to prepare tri-o-tolyllead bromide by the action of bromine on tri-o-tolyllead at low temperatures were unsuccessful, probably due to the insolubility of the tri-o-tolyllead. The action of bromine on tri-*o*-tolyllead at room temperature yielded di-o-tolyllead dibromide.

The action of hydrobromic acid on tri-o-tolyllead yielded the tri-o-tolyllead bromide desired for the synthesis of phenyltri-o-tolyllead. This is a new type of synthesis of triaryl lead halides and should prove to be useful in other similar cases. The reaction also takes place in the aliphatic series,[8] but is not of importance as a method of synthesis of trialkyl lead halides.

Since the iodimetric method for the determination of lead in organo-lead compounds[9] did not appear to be suitable for this study and a volumetric method was desirable, the molybdate method for lead was adapted to the analysis of aryl lead compounds.

Experimental Part

Analytical.—A method for the analysis of lead in aryl lead compounds which has given satisfactory results has been worked out as follows. The compound was first decomposed with nitric and sulfuric acid as described by Gilman and Robinson.[10] After the lead sulfate stood for an hour with aqueous alcohol mixture, the solution was decanted through a filter and the residue was washed five times by decantation using 10-cc. portions of 1% sulfuric acid. Boiling ammonium acetate solution (15–20 cc.) was then poured through the filter paper into the beaker containing the precipitate. The filter paper was washed with boiling water containing ammonium acetate, the solution was diluted to 100 cc. and titrated hot with standard ammonium molybdate, using tannic acid as the indicator.[11] Inasmuch as a definite concentration of ammonium molybdate must be present to give the color reaction with the indicator, a blank determination should be made. The ammonium molybdate should be restandardized occasionally. This method gave satisfactory results with known tri-o-tolyllead and so was used in all of the analyses given in this paper. Analyses for bromine in the organo-lead salts were made as described by Grüttner.[12]

[12] Grüttner, Ber., **51**, 1301 (1918).

Tri-*o*-tolyllead.—This compound has been previously prepared by Krause and Reissaus[13] and their directions were followed with some modification. To one mole of o-tolylmagnesium bromide in 400 cc. of ether, 1500 cc. of benzene and 150 g. of lead chloride were added and the whole was refluxed and stirred for five and one-half hours. The mixture was cooled and decomposed with iced ammonium chloride solution and then filtered with suction. Tri-*o*-tolyllead was extracted from the dried sludge with hot toluene. The benzene–ether layer separated from the water in the above filtrate was distilled and yielded an additional amount of product. The total yield of tri-*o*-tolyllead was 87 g. or 51% of the theoretical amount based on the o-bromotoluene used.

Tetra-*o*-tolyllead.—The preparation of this compound was carried out by refluxing 5 g. of tri-*o*-tolyllead in 130 cc. of xylene for twenty-four hours. A black precipitate of metallic lead was filtered, and refluxing again for nineteen hours did not induce further precipitation of lead. The solution was filtered again to remove a small amount of yellowish-brown precipitate and the xylene was evaporated. Recrystallization of the residue from acetone yielded 1 g. of original material (insoluble in hot acetone) and 2 g. of tetra-*o*-tolyllead. The compound was recrystallized from acetone or alcohol and melted at 201–202°.

Anal. Calcd. for $(C_7H_7)_4Pb$: Pb, 36.26. Found: Pb, 36.10, 36.07.

Phenyltri-*o*-tolyllead.—This compound was prepared by the general method described by Krause and Schmitz.[14] Eighteen grams (0.032 mole) of tri-o-tolyllead bromide was added in small portions to 0.2 mole of phenylmagnesium bromide contained in 300 cc. of ether and the mixture was stirred and refluxed for three hours. The mixture was decomposed with iced ammonium chloride solution and filtered to remove some crude phenyltri-o-tolyllead. The ether was separated and evaporated and the residue was added to the crude phenyltri-o-tolyllead obtained by filtration. The combined crude products were recrystallized from acetone or benzene, which yielded 16 g. of phenyltri-o-tolyllead. The pure compound melted at 161–162°.

Anal. Calcd. for $(C_7H_7)_3(C_6H_5)Pb$: Pb, 37.17. Found: Pb, 37.10, 37.13.

Aryl Lead Salts.—The properties of these compounds are given in Table I. The experimental conditions of the reactions varied and are recorded for each salt.

TABLE I

ARYL SALTS OF LEAD

Aryl lead salts	Yield, %	M. p., °C.	Formula	Lead, % Calcd.	Lead, % Found	Bromine, % Calcd.	Bromine, % Found
Tri-*o*-tolyl bromide	64	129–130	$(C_7H_7)_3PbBr$	36.98	36.85 36.92	14.26	14.23 14.32

[a] H_2O.

Tri-*o*-tolyllead Bromide.—This compound was prepared by placing 8 g. of tri-*o*-tolyllead, 150 cc. of chloroform and 9 cc. of 40% hydrobromic acid in a 200-cc. round-

---

[13] Krause and Reissaus, Ber., 55, 901 (1922).

[14] Krause and Schmitz, *ibid.*, 52, 2152 (1919).

bottomed flask and shaking on a mechanical shaker for two to three hours. The mixture was filtered to remove any unreacted material and lead bromide and the chloroform separated and evaporated. The residue was recrystallized from alcohol. The product of two such reactions usually yielded 4 g. of unreacted material and 6 g. of tri-o-tolyllead bromide.

Di-o-tolyllead **Dibromide.**—(A) Five grams of tri-o-tolyllead, 150 cc. of chloroform and 10 cc. of 40% hydrobromic acid were shaken in a mechanical shaker for two hours. A clear solution resulted. The residue obtained by evaporation of the chloroform was recrystallized from alcohol. This yielded 2 g. of a mixture of tri-o-tolyllead bromide and di-o-tolyllead dibromide. Consecutive recrystallizations from aqueous alcohol and from ligroin yielded one g. of the di-o-tolyllead dibromide.

(B) Five grams of tri-o-tolyllead was dissolved and suspended in 200 cc. of chloroform. A 10% solution of bromine in chloroform was then added dropwise with stirring until the bromine color no longer disappeared. The solution was filtered to remove lead bromide and was then evaporated. Recrystallization from alcohol yielded 2 g. of di-o-tolyllead dibromide.

Phenyldi-o-tolyllead Bromide.—Six grams of phenyltri-o-tolyllead, 100 cc. of chloroform and 6 cc. of 40% hydrobromic acid were refluxed and stirred for forty-five minutes. The chloroform was separated and evaporated and the residue extracted first with a mixture of hot ligroin and absolute alcohol and then with hot alcohol. This yielded 5.5 g. of phenyldi-o-tolyllead bromide which was recrystallized from alcohol.

Phenyl-o-tolyllead **Dibromide.**—To a solution of 3.5 g. of phenyltri-o-tolyllead in 100 cc. of chloroform, 10 cc. of 40% hydrobromic acid was added and the mixture was refluxed and stirred rapidly for ninety minutes. Another 10 cc. of 40% hydrobromic acid was then added and the reaction continued for ninety minutes longer. The chloroform was separated and evaporated and the residue was recrystallized from aqueous alcohol, which yielded 1.5 g. of phenyl-o-tolyllead dibromide.

A very small amount of an unidentified by-product was obtained from this reaction. The compound is less soluble than the phenyl-o-tolyllead dibromide. It was recrystallized twice from alcohol and melted at 232° with decomposition. That the compound was not phenyllead tribromide was shown by analysis.

Anal. Calcd. for $(C_6H_5)PbBr_3$: Br, 45.75. Found: Br, 29.86.

Phenyl-o-tolyllead Dinitrate **Dihydrate.**—Three grams of phenyltri-o-tolyllead was dissolved in 100 cc. of petroleum ether (b. p. 65–110°) (chloroform was used in some reactions) and was stirred and refluxed for one hour during the slow addition of 7 cc. of nitric acid (sp. gr. 1.42). The insoluble product was filtered and weighed 2.0 g. It was recrystallized from water acidified with nitric acid.

Two grams of the above lead compound was dissolved in water and added to an aqueous solution of 3 g. of sodium bromide. The precipitate was filtered and recrystallized from aqueous alcohol, yield, 1.5 g. After three recrystallizations from aqueous alcohol the compound was pure and it was shown to be phenyl-o-tolyllead dibromide by a melting point and mixed melting point determination. About 0.2 g. of a substance which melted at 220–225° with decomposition was obtained as a by-product. This was less soluble than the main product and was undoubtedly identical with the by-product obtained above in the reaction of phenyltri-o-tolyllead and hydrobromic acid.

A more vigorous reaction was tried by adding 5 g. of phenyltri-o-tolyllead to 40 cc. of boiling nitric acid (sp. gr. 1.42). After the addition, the solution was cooled and filtered on a sintered glass funnel. Two such runs yielded 9 g. of crude product. This was recrystallized three times from water acidified with nitric acid, but the substance was not analytically pure. Three grams of the dinitrate was converted to the bromide as above; yield, 1.3 g. Repeated recrystallization from aqueous alcohol yielded two products. The larger and more soluble fraction was shown to be **phenyl-*o*-tolyl** lead dibromide by a melting point and mixed melting point. The smaller less soluble fraction was not obtained entirely pure after five recrystallizations. It melted at 144–145° and a mixed melting point with di-o-tolyllead dibromide indicated its identity with that substance. The di-o-tolyllead dibromide isolated from this reaction turned purple on exposure to light, a phenomenon not observed with the pure compound.

The author wishes to express his appreciation to Professor C. S. Marvel for his many helpful suggestions.

Summary

1. The strong tendency of organo-lead compounds to retain at least two lead-carbon linkages has been further demonstrated by the action of nitric and hydrobromic acids on phenyltri-o-tolyllead.

2. A new method for the preparation of certain triaryl lead halides has been described.

3. A new volumetric method for the determination of lead in aryl lead compounds has been developed.

THE REACTIONS OF SOME CARBONYL COMPOUNDS WITH PHENYLHYDRAZINE

BY L. CHAS. RAIFORD AND WILBUR T. DADDOW

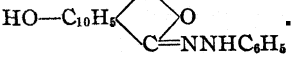
RECEIVED JANUARY 26, 1931 PUBLISHED APRIL 6, 1931

The interaction of phenylhydrazine with a carbonyl group joined directly to carbon and hydrogen (aldehydic) or to carbon and carbon (ketonic) is well known; but instances of this reaction are rare when the radical is situated between other elements. It is true that hydrazones corresponding to the last-named group of carbonyl compounds are known, but they are usually prepared by some method other than the direct[1] one indicated above.

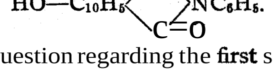
The carbonyl radical in formanilide is bound directly to hydrogen and to nitrogen. A compound said to represent the hydrazone theoretically derivable from formanilide was prepared by Zwingenberger and Walther[2]

---

[1] The structure assigned by Anselm and Zuckmayer [Ber., 32, 3294 (1899)] to the hydrazone obtained by direct action of phenylhydrazine on hydroxynaphthalic anhydride is,



. In the same paper the anilide is represented by the symmetrical structure,



Reasons for these differences are not given, which raises a question regarding the first structure.

[2] Zwingenberger and Walther, J. prakt. *Chem.*, [2] 57,223 (1898).

by heating methenyldiphenylamidine with an excess of phenylhydrazine. They recorded a melting point of 90–91°. Worrall[3] heated equimolecular proportions of phenylhydrazine and thiodiacetoacetylanilide and obtained a product melting at 126–127°. He recorded it as the hydrazone of formanilide. In the present work in an attempt to use the direct method, formylphenylhydrazine, m. p. 143–144°,[4] was obtained by heating a mixture of formanilide, phenylhydrazine and acetic acid.[5] The same product was obtained when formanilide was substituted by 4-bromo-, 2-, 3-, and 4-nitroformanilides, and by o- and *p*-formotoluidides, which indicates that the reaction is probably general. In each case the corresponding aniline was recovered.

A compound in which the carbonyl radical is joined directly to two nitrogen atoms is diphenylurea. Its behavior toward phenylhydrazine was next studied. When an alcoholic solution of equimolecular proportions of these compounds was heated for two days in an open vessel no new product could be detected. Repetition of the experiment in the presence of acetic acid failed to cause any change. After the mixture had been heated for thirty days, only starting material could be isolated. To test the possibility of reaction under different conditions, a mixture of diphenylurea with 1.2 molecular proportions of phenylhydrazine was heated in a sealed tube at 80–90° for seventy days. This gave 1,4-diphenylsemicarbazide; m. p. 176°. The use of an alcoholic solution of the reactants in another experiment gave almost the theoretical yield of the same product. It was identified by a mixed melting point determination with the semicarbazide prepared by the interaction of phenylhydrazine and phenyl isocyanate.[6]

It is known that certain sulfur compounds are more reactive than their oxygen analogs. Thus, Tiemann[7] found that coumarin, which contains a carbonyl radical, does not react with phenylhydrazine, while thiocoumarin does so to give the corresponding hydrazone. In the present study an attempt was made to prepare a phenylhydrazone from diphenylthiourea by refluxing an alcoholic solution of the latter with phenylhydrazine. The crystalline solid that separated on cooling melted at 178°. Aniline was isolated from the filtrate and identified by conversion into acetanilide. The other product was found by mixed melting point determination and other properties to be identical with 1,4-diphenylthiosemicarbazide,[8] m. p.

---

[3] Worrall, THIS JOURNAL, 42, 1058 (1920).

[4] Just [*Ber.*, 19, 1201 (1886)] reported 145° for a product obtained by heating formamide and phenylhydrazine.

[5] Not obtained in the absence of the acid.

[6] Kuhn [*Ber.*, 17, 2884 (1884)] reported 170° as the melting point.

[7] Tiemann, *ibid.*, 19, 1666 (1886); Meyer and Jacobson, "Lehrbuch der organischen Chemie," Veit, Leipzig, 1902, Bd. II, Th. I, p. 676.

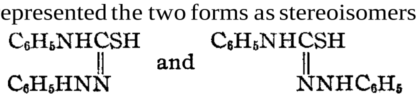
[8] This compound was first isolated by Fischer [*Ann.*, 190, 122 (1878)], who obtained it by mixing equimolecular proportions of phenyl mustard oil and phenylhydrazine in

178–179°, prepared by the action of phenylhydrazine on phenyl mustard oil. It was further identified by conversion into a mercury salt,[9] which was readily decomposed by hydrogen sulfide. Apparently this action of phenylhydrazine on thioureas is general, as indicated in Table I.

When a solution of phenylhydrazine and a thiourea is heated in the presence of a desulfurizing agent such as lead oxide, a guanidine derivative is formed. L. Marckwald[10] boiled an alcoholic solution of equimolecular proportions of thiocarbanilide and phenylhydrazine with an excess of lead oxide until desulfurization was complete. The product melted at 138–139°, and was assigned the structure required by the hydrazone of diphenylurea, $(C_6H_5NH)_2C{=}NNHC_6H_5$ (I). The same structure was assigned by Wessel[11] to a product that melted at 204°, which he obtained by heating at 120° an equimolecular mixture of carbodiphenylimide and phenylhydrazine, and which he named phenylhydrazone carbodiphenylamine or hydrazone base. W. Marckwald and Wolff[12] also used this structure for a product that melted at 160°, and which was obtained by boiling an alcoholic solution of either of the stereoisomeric diphenylthiosemicarbazides mentioned above with aniline and lead oxide until desulfurization was complete. Their product could also be represented by formula (11),  $\genfrac{}{}{0pt}{}{C_6H_5N}{C_6H_5NH}\!\!>\!C{-}NHNHC_6H_5$, which indicates a hydrazine rather than a hydrazone. The choice between these formulas involves both the method of preparation and the properties of the compounds.

Though these guanidine derivatives can be prepared from the thioureas in one operation, as indicated above, it was found in the present work that Busch's[13] method, which involves the preparation of the carbodiphenylimide in the pure form and subsequent treatment of this with phenylhydrazine, gives the highest yield. Incidentally, this proves that the imide is the intermediate product in Marckwald's method. The behavior

"not too dilute" alcoholic solution. He reported a melting point of 177°. W. Marckwald [*Ber.*, 25, 3106 (1892)] found that at a lower temperature the reaction gave a labile form, m. p. 139°, which may be isomerized by heat or treatment with acid into a stable form, m. p. 176°. He represented the two forms as stereoisomers



$$\begin{array}{c} C_6H_5NHCSH \\ \| \\ C_6H_5HNN \end{array} \quad \text{and} \quad \begin{array}{c} C_6H_5NHCSH \\ \| \\ NNHC_6H_5 \end{array}$$

(labile) (stable)

[9] Though the product here in question was obtained in but one form, the fact that it gave a mercury salt may possibly be regarded as support for Marckwald's hydrosulfide structure. *Anal.* Subs., 0.1471: HgS, 0.0487. Calcd. for $(C_{13}H_{13}N_3S)_2Hg$: Hg, 29.15. Found: Hg, 28.50.

[11] Wessel, *Ber.*, 21, 2272 (1888).

[12] W. Marckwald and Wolff, *ibid.*, 25, 3116 (1892).

[13] Busch, *ibid.*, 38, 858 (1905).

of the imide toward other reagents shows that the normal reaction involves addition at one double bond, and tends to support Formula II for the product obtained when it adds phenylhydrazine. Thus, Weith[14] found that carbodiphenylimide may add one molecular proportion of hydrogen chloride. Lengfeld and Stieglitz[15] showed' that this product reacts with sodium ethylate to give the ethyl ether of isodiphenylurea, which they obtained, also, by direct addition of alcohol to the diimide at an elevated temperature lander pressure. Formula I would require addition at both double bonds,

If the guanidine derivatives under consideration are represented by Formula I they would be hydrazones and should not reduce Fehling's solution.[16] They do reduce it slightly at the boiling point. Again, if these products are hydrazones, oxidizing agents should convert them into tetrazones, as observed by Pechmann and Runge[17] and the molecular weights of the products should be practically double those of the starting materials. The compounds here under consideration were oxidized by mercuric oxide to new substances, but molecular weight determinations showed no difference between starting material and product, which is in accordance with the behavior expected if the starting material is represented by Formula II. Here the loss of hydrogen should occur from adjacent hydrogen atoms in the same molecule to give an azo compound. Azo compounds were obtained.

Experimental Part

Sym.-di-(2,5-dibromophenyl)-thiourea.—Dyson, George and Hunter[18] recorded 154° as the melting point of the thiourea obtained by the action of thiocarbonyl chloride on the required dibromoaniline. In the present work the urea was first prepared by boiling an alcoholic solution of the aniline, carbon disulfide and sodium hydroxide for fourteen hours. Crystallization from benzene gave colorless needles; m. p. 191°. A second portion prepared according to Fry's[19] directions melted at 191°, as did a third sample obtained by the action of thiocarbonyl chloride, mentioned above.

Anal. Subs., 0.1718: 6.30 cc. of 0.1 N HCl. Subs., 0.2054: AgBr, 0.2828. Calcd. for $C_{13}H_8N_2Br_4S$: N, 5.14; Br, 58.82. Found: N, 5.14; Br, 58.60.

Sym.-di-(2,4-dibromophenyl)-thiourea.—To a solution of 8 g. of pyridine and 9.3 g. of 2,4-dibromoaniline, prepared as directed by Chattaway and Clemo,[20] in 100 cc. of carbon disulfide, there was added a solution of 6.4 g. of iodine in 50 cc. of carbon disulfide. After two hours, when the color of iodine had disappeared, the mixture was dis-

Preparation of Thiosemicarbazides.—With the exceptions noted below, the general method here used was as follows: **10** g. of the required urea was suspended in alcohol, a slight excess of phenylhydrazine was added, the mixture was boiled under a reflux condenser for about six hours, and then poured into water. The method was first tested by the preparation of derivatives from phenyl-, m- and *p*-tolyl, and β-naphthylureas, which had previously been obtained by the interaction of the required amine and mustard oil. after which a number of new ones were studied. In most instances the products were readily purified by crystallization from alcohol, from which they separated as colorless needles. Physical constants and analytical data are given in Table I.

[a] The composition was also checked by analysis for bromine. *Anal.* Subs., **0.1534:** AgBr, **0.1429.** Calcd. for $C_{13}H_{11}N_3Br_2S$: Br, **39.90.** Found: Br, **39.65.**

[b] Composition checked for halogen content. Anal. Subs., **0.1559:** AgBr, **0.1454.** Calcd. for $C_{13}H_{11}N_3Br_2S$: Br, **39.90.** Found: Br, **39.69.**

[c] Obtained previously by interaction of phenylhydrazine and o-tolyl mustard oil by Dixon [*J.* Chem. *Soc.*, *57*, **258 (1890)**], who reported a melting point of **162–163°.** In the present work a solution of **10** g. of the required thiourea and **5** g. of phenylhydrazine in **250 cc.** of benzene was evaporated at its boiling point to a volume of about **25 cc.** and allowed to cool.

[d] Reported by Bose and Ray-Chaudhury [*J. Ind.* Chem. *Soc.*, **4, 261 (1927)**], who prepared it by the action of m-tolyl mustard oil on phenylhydrazine. Here prepared by the method given above for the ortho isomeride.

[e] Checked by analysis because the product obtained by Dixon [J. Chem. *Soc.*, 61, **1019 (1892)**] through the action of phenylhydrazine on a-naphthyl mustard oil and supposed to be identical with this one, was recorded as melting at **183°.**

[f] Kjeldahl method was modified as directed by Milbauer [*Z.* anal. Chem.. **42, 728 (1903)**] in order to avoid loss of nitrogen.

Preparation of **Carbodiphenylimides.**—A mixture of **20** g. of the thiourea, **30** g. of lead oxide and **500 cc.** of benzene was refluxed until a filtered portion no longer darkened a fresh portion of oxide, the whole filtered, the solvent distilled off until about **40–50** cc. remained, and the residue allowed to stand. The product was then purified in a suitable way. Data for the new ones thus obtained are given in Table II.

Preparation of Diphenylanilguanidines.—Ten grams of the required **carbodiphenylimide** was dissolved in about **250** cc. of benzene, the necessary amount of phenylhydrazine added, the liquid evaporated to about **25 cc.** and allowed to stand. The resulting

TABLE II

CARBODIIMIDES

Name	Formula	M p , °C.	Nitrogen, % Calcd	Nitrogen, % Found
Carbodi-(m-tolyl)	$C_{15}H_{14}N_2$	118–119[a]	12.61	12.72
Carbodi-(2-bromophenyl)	$C_{13}H_8N_2Br_2$	98–100	7.95	7.83
Carbodi-(4-bromophenyl)	$C_{13}H_8N_2Br_2$	144[b]	7.95	7.91
Carbodi-(2,4-dibromophenyl)	$C_{13}H_6N_2Br_4$	156–157[c]	5.49	5.48
Carbodi-(2,5-dibromophenyl)	$C_{13}H_6N_2Br_4$	172–173[d]	..	..

[a] The residue left after evaporation of the solvent used in the method of preparation described above did not solidify on standing. Most of it boiled at 218° under **24** mm., and this distillate solidified within twenty-four hours.

[b] Ingold [*J. Chem. Soc.*, 125, 101 (1924)] obtained by a different method a product having the composition of this one and recorded it as a yellow viscous liquid boiling at 202" and 10 mm. The product here in question has not been reported, and is probably a polymer of Ingold's compound. Unsubstituted carbodiphenylimide was obtained by Weith [*Ber.*, 7, 10 (1874)] in both the oily and the solid forms, and Miller and Plochl [*Ber.*, 28, 1007 (1895)] argue that the latter is a polymer of the former.

[c] Obtained as colorless needles from alcohol.

[d] Attempts to crystallize from benzene gave small compact globules that were crystalline in structure. Bromine content agrees with the formula given. *Anal.* Subs., 0.1985: AgBr, 0.2913. Calcd. for $C_{13}H_6N_2Br_4$: Br, 62.74. Found: Br, 62.46.

solid was purified in a suitable way.[21] Data for these derivatives are given in Table III.[22]

TABLE III

ANILGUANIDINES[e]

Name	Formula	M. p., °C.	Nitrogen, % Calcd.	Nitrogen, % Found

[a] Colorless prisms from benzene. [b] Faintly colored prisms from benzene. [c] Colorless, fine needles from benzene. [d] Four recrystallizations from benzene failed to give a product with constant melting point. [e] All these products become colored more or less rapidly when exposed to air.

Preparation of the Azo Compounds.—The method was tested by starting with the unsubstituted diphenylanilguanidine isolated by Marckwald and Wolff. Five grams of the compound was dissolved in about 10 cc. of hot alcohol, an excess of mercuric oxide

---

[21] During crystallization these products often become colored, due probably to oxidation. To prevent this change Marckwald and Wolff[12] passed hydrogen sulfide into the crystallizing mixture. In the present work such treatment was avoided, because tests showed that when it was used the final product was contaminated with sulfur.

[22] It is of interest to note that no guanidine derivative was obtained from a diphenylimide which contained two bromine atoms in a single phenyl nucleus. This failure does not seem to be explainable in terms of steric hindrance. It will be studied further.

added, the mixture boiled for five to ten minutes, filtered and the azo compound isolated from the filtrate in a suitable way. The product showed the properties recorded in the literature. To show that it was not a tetrazone the molecular weight was determined.[23]

(a) 0.0297 g. of substance dissolved in 0.6172 g. camphor, A = 6.7"

$$\text{Molecular weight} = \frac{(40{,}000)\ (0.0297)}{(0.6172)\ (6.7)} = 287$$

(b) 0.0281 g. of substance dissolved in 0.6878 g. camphor, A = 5.5"

$$\text{Molecular weight} = \frac{(40{,}000)\ (0.0281)}{(0.6878)\ (5.5)} = 297$$

Calcd. for $C_{19}H_{16}N_4$: mol. wt., 300. Found: 287. 297.

Other compounds indicated in Table IV were obtained in the same way.

Table IV

[a] Pale red needles from alcohol. [b] Brilliant red needles from alcohol. [c] Crystallization from alcohol gave brilliant red needles that soften at about 129" if heated slowly. [d] Obtained as dull red needles when the hot saturated alcoholic solution was diluted with hot water until precipitation began, and then allowed to cool. [e] Red crystalline material from the alcoholic filtrate of the reaction mixture.

Summary and Conclusions

1. The carbonyl radical in formanilide does not condense with phenylhydrazine to give a hydrazone under the conditions studied. The products are aniline and formylphenylhydrazine. Substitution products of formanilide react similarly.
2. Diphenylurea reacts with phenylhydrazine to give a semicarbazide and eliminates aniline. The corresponding thiourea behaves in the same way.
3. Several new carbodiphenylimides have been prepared and studied. With the exception of the 2,4- and 2,5-dibromo compounds, the imides added phenylhydrazine to give the corresponding anilguanidines. These failures are not explainable on the theory of steric hindrance.
4. The evidence indicates that these guanidine derivatives are not hydrazones.
5. Further work is in progress.

THE REACTION BETWEEN BARBITAL (DIETHYLBARBITURIC ACID) AND PHOSPHORUS PENTACHLORIDE

BY ARTHUR W. DOX[1]

RECEIVED JANUARY 28, 1931 PUBLISHED APRIL 6, 1931

The 5,5-dialkylbarbituric acids, of which barbital is the oldest and most familiar example, are surprisingly inert chemically despite their powerful physiological action as hypnotics. Barbital is one of the least reactive members of the series, presumably because of a molecular stability conferred by its paired ethyl groups. It is resistant to most oxidizing and reducing agents, to high temperatures, and is not easily hydrolyzed. Aside from its imide hydrogen it may be said to possess no functionally reactive groupings. Consequently very few derivatives have been prepared from it. These few comprise desoxyveronal,[2] a xanthydrol condensation product,[3] the Grignard reaction products,[4] and several N-alkyl derivatives[5] These represent practically all the derivatives that have been prepared directly from a 5,5-dialkylbarbituric acid without breaking open the pyrimidine ring.

In view of the fact that other pyrimidones have been converted into corresponding chloropyrimidines by means of phosphorus oxychloride and pentachloride, it seemed reasonable to expect that barbital would undergo the same reaction. Our purpose was to replace the three oxygens by six chlorines, two of which would then split off as hydrogen chloride, leaving a tetrachloropyrimidine derivative with paired ethyls in the 5-position; and then to replace the four chlorines by hydrogen and obtain the structural base, *viz.*, 5,5-diethyldihydropyrimidine. The first of the above reactions was successfully accomplished and the tetrachloro derivative obtained beautifully crystalline. The yield, however, was small, due to a side reaction of an intermediate chlorination product. Removal of the four chlorines to obtain the structural base has thus far been unsuccessful because of the ease with which the tetrachloro derivative is hydrolyzed by water alone into a nitrile. An unexpected reaction occurs here. Hydrogen chloride is split off quantitatively, but the pyrimidine ring then breaks down into diethylmalononitrile and presumably water and carbon dioxide. In the presence of zinc dust there is formed also a diethyldichloropyrimidine by replacement of two chlorines by hydrogens. This substance is much

more stable and may be steam distilled without decomposition. It is also resistant to further reduction, so that our attempts thus far to replace the two remaining chlorines by hydrogen have not been successful.

Experimental

In the first attempts to chlorinate barbital, phosphorus oxychloride was used. The parent barbituric acid had previously been converted into trichloropyrimidine.[6] by heating for one hour in a sealed tube at 130–140° with phosphorus oxychloride. Under these conditions barbital failed to react. Even when the temperature was raised to 175–180° and the heating prolonged six hours, there was very little evidence of reaction. The barbital was recovered almost quantitatively and identified by its melting point. The only indication of a slight reaction was a terpene-like odor of the steam distillate obtained after decomposition of the phosphorus oxychloride by pouring the reaction mixture on ice.

2,4,6-Trichloro-5-*sec.*-butylpyrimidine.—The stability of the dialkylbarbituric acids. as illustrated by barbital, toward phosphorus oxychloride is in striking contrast to the readiness with which a monoalkylbarbituric acid reacts. A tube containing 5 g. of *sec.*-butylbarbituric acid and 15 cc. of phosphorus oxychloride was heated at 175–180° simultaneously with the barbital in the preceding experiment. The reaction mixture was poured on ice and after decomposition of the excess phosphorus oxychloride the residual oil was extracted with ether. Evaporation of the solvent then left a white crystalline mass which after recrystallization from alcohol melted at 40°. The yield was 5.157 g. from 5 g. of *sec.*-butylbarbituric acid, or 79% of the theoretical.

Anal. Calcd. for $C_8H_9N_2Cl_3$: N, 11.69; Cl, 44.47. Found: N, 11.65, 11.53; Cl, 44.53.

As pointed out by Behrend,[7] in the analogous reaction with methyluracil, each oxygen atom is evidently replaced by two chlorines, then one chlorine from each pair is split out with an adjacent hydrogen as hydrogen chloride, leaving three double bonds in the ring.

A lower homolog, 2,4,6-trichloro-5-ethylpyrimidine, has been prepared by v. Merkatz[8] from 5-ethylbarbituric acid and phosphorus oxychloride.

Reaction with Barbital

In subsequent experiments with barbital, phosphorus pentachloride was used in place of phosphorus oxychloride because of its greater reactivity. Even here the reaction appears to reach an equilibrium, so that phosphorus pentachloride and unreacted barbital are still present although the mixture may have been heated for two or three days after the evolution of hydrogen chloride had ceased. The phosphorus pentachloride exchanges 2Cl for each O of the barbital, and the resulting phosphorus oxychloride can for the most part be removed readily by distillation. It is unlikely that complete chlorination of the barbital molecule occurs before the splitting out of hydrogen chloride begins. If the reaction proceeds stepwise and in a definite sequence, replacement of oxygen being followed by removal of hydrogen chloride, there would be four intermediate products between Formulas II and VI. It is obvious that one of the carbons must retain both its chlorines, since there are three pairs of chlorines but only two adjacent hydrogens. The final product would be a tetrachloro derivative with two

---

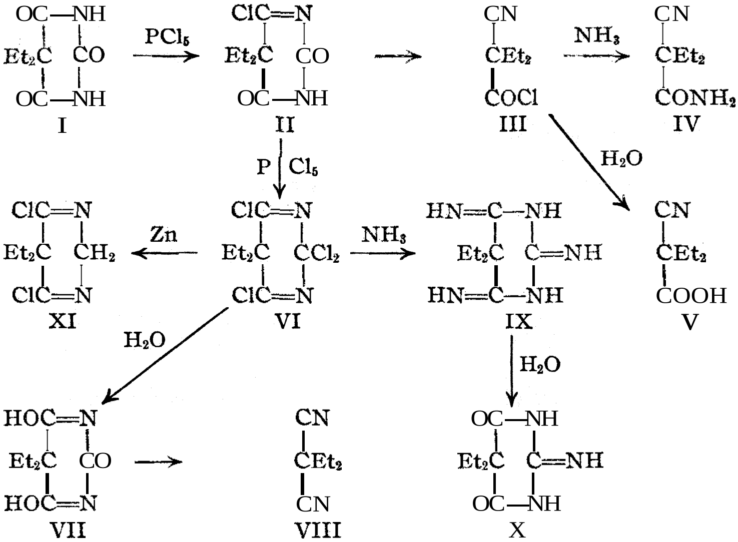
[8] v. Merkatz, Ber., 52,869 (1919).

double bonds, instead of a trichloro derivative with three double bonds as illustrated by the *sec.*-butyl compound above.



Theoretical proportions for this reaction would be $3PCl_5$ to 1 barbital. Actually this represents an excess of phosphorus pentachloride, for the reason that the reaction does not proceed entirely in this manner. Another and entirely different reaction occurs simultaneously, yielding a product which retains one of the barbital oxygens. This will be discussed presently.

In the case of barbituric acid or its monoalkyl derivatives only the first of these reactions seems to occur. The reaction mixture may be poured on ice to decompose the remaining phosphorus chlorides, and a good yield of the chlorinated pyrimidine thus obtained. With barbital, however, a viscous product remains which reacts slowly with water and has the characteristic odor of organic acid chlorides. In the first experiments where the reaction mixture, after hydrolysis of the phosphorus chlorides, was extracted with ether and the tetrachloropyrimidine derivative crystallized by evaporation of the solvent, a viscous mother liquor remained. Distillation of this with steam gave an oily product with a strong camphoraceous odor. The oil solidified in crystals, melting at 44°, which were identified as diethylmalononitrile, while extraction of the aqueous layer with ether gave a crystalline substance which was identified as diethylcyanoacetic acid. These obviously were secondary products formed during the steam distillation. In subsequent experiments steam distillation was therefore avoided.

A number of chlorinations were made, using barbital and phosphorus pentachloride. In several of these a small quantity of phosphorus oxychloride was added to moisten the mixture but no advantage appeared to be gained by so doing. The following experiment was performed on a somewhat larger scale and illustrates the typical reaction.

An intimate mixture of 96 g. of barbital and 376 g. of phosphorus pentachloride was placed in a 1-liter distilling flask connected with a downward condenser and receiver, the latter provided with an outlet tube leading through dry calcium chloride and terminating over a quantity of water contained in a flask. The mixture was heated by immersing the distilling flask in an oil-bath maintained at 115–120°. The mass slowly sintered while a vigorous evolution of hydrogen chloride occurred. The hydrogen chloride was absorbed by the water beneath the end of the outlet tube. After six hours' heating the mass had become liquid and the evolution of gas had practically ceased. On cooling overnight the excess phosphorus pentachloride formed a crystalline crust on the walls of the flask. Titration of an aliquot of the hydrogen chloride collected indicated the equivalent of 40.8 g. compared to a theoretical value of 38.1 g., hence the escaping vapors had carried over some of the phosphorus oxychloride. The apparatus was then connected to a water pump and the bath gradually warmed. At first more hydrogen chloride came off at 65 mm. and bath temperature of 55–60°. At 80° and 80 mm. distillation of the phosphorus oxychloride began. At 110° and 80 mm. the distillation was practically complete and the sublimation of phosphorus pentachloride began. The phosphorus oxychloride thus collected weighed 45.5 g. This does not represent the entire yield since no attempt was made at quantitative recovery by providing adequate cooling. Atmospheric pressure was then restored and the bath temperature raised to 135° for four hours to insure as complete a reaction as possible. The reaction mixture was again cooled overnight, and the viscous amber-colored liquid was filtered through dry asbestos to remove the phosphorus pentachloride that had separated. The filtrate was collected directly in a Claisen distilling flask.

Distillation of this filtrate gave a further yield of phosphorus oxychloride. Between 50 and 55° at 65 mm. 25 g. was collected, and a further sublimation of phosphorus pentachloride occurred. Distillation was then continued at 5–6 mm. pressure, 20.6 g. of colorless liquid passing over between 60 and 80°. Although the bath temperature was raised to 150°, no more distillate was obtained. The bath was then removed and the flask carefully heated over a free flame. Practically no further distillate was thus obtained, but a rise of mercury in the manometer from 5 to 15 mm. indicated an incipient decomposition, hence the distillation was discontinued.

Diethylcyanoacetyl Chloride (Formula III).—The distillate thus obtained had the characteristic odor of organic acid chlorides, and a test portion treated with water slowly decomposed with liberation of acid. Owing to the difficulty of removing traces of phosphorus chlorides the product was not analyzed, but was converted into crystalline derivatives for identification.

Diethylcyanoacetamide (Formula IV).—The above distillate was dissolved in 300 cc. of benzene and saturated with dry ammonia. A copious separation of ammonium chloride was filtered off and washed with ether. Evaporation of the combined mother liquor and washings left a white crystalline residue which on recrystallization from hot water gave long needles (5 cm.) melting at 121°.

Anal. Calcd. for $C_7H_{12}ON_2$: N, 20.0. Found: N, 19.81.

Diethylcyanoacetic Acid (Formula V).—Another portion of the distillate was distilled with steam and the distillate extracted with ether. Evaporation of the solvent and recrystallization of the residue by dissolving in benzene and adding petroleum ether gave a crystalline product, very soluble in water, alcohol and benzene, strongly acid and melting at 68°.[9]

Anal. Calcd. for $C_7H_{11}O_2N$: N, 10.07. Found: N, 9.93. Mol. wt. by titration, 143; calcd., 141.

2,2,4,6-Tetrachloro-5,5-diethyldihydropyrimidine (Formula VI).[10]—The undistilled

---

[9] The melting point of diethylcyanoacetic acid is given by Hesse (*Am. Chem. J.*, 18, 748 (1896), as 57°, and by Hessler, THIS JOURNAL, 38, 939 (1916), as 61°.

[10] The difference in conjugated structure between this substance and the 2,4,5,6-tetrachloropyrimidine prepared by Ciamician and Magnaghi, [*Ber.*, 18, 3444 (1885)] from alloxan and by Emery, [*Ber.*, 34, 4178 (1901)] from dialuric acid will be seen by a glance at the formula.

residue from the diethylcyanoacetyl chloride was orange-red in color and quite viscous. On two days' standing it deposited a mass of crystals which were then collected on a large frit filter and washed with a little petroleum ether, then with methyl alcohol which removed the sticky mother liquor. The alcohol washings were collected separately and discarded. White rhombic crystals remained which melted at 127° and showed no change in melting point after recrystallization from ethyl alcohol.

Anal. Calcd. for $C_8H_{10}N_2Cl_4$: Cl, 51.45; N, 10.14. Found: Cl, 51.14; N, 10.19.

The yield in the first crop was 14.2 g. and a second crop of 9.3 g. was obtained by allowing the filtrate, diluted with petroleum ether, to stand for two days. The mother liquor was further diluted with petroleum ether (10 vols.) and treated with dry ammonia, avoiding an excess. After removal of the ammonium chloride by filtration, small amounts of both diethylcyanoacetamide and the tetrachloropyrimidine were obtained by evaporation of the solvent.

Diethylmalononitrile (Formula VIII).—Steam distillation of the final mother liquor gave an oily product which presently solidified and had a strong camphoraceous odor. This came over (about 1 g.) in the first few cc. of distillate and was collected separately. It melted at 44° and was quite volatile.

Anal. Calcd. for $C_7H_{10}N_2$: N, 22.95. Found: N, 23.0.

It is obviously a product formed in the steam distillation, since in no case was it otherwise obtained or its odor detected. Further distillation with steam yielded about 1 g. of the tetrachloropyrimidine, m. p. 127°, which solidified completely in the condenser.

The residue in the distilling flask consisted of a slightly turbid aqueous solution and a brown gummy mass. When clarified with charcoal and evaporated, the aqueous solution yielded about 1 g. of barbital crystals, identified by melting point and taste.

5,5-Diethylmalonylguanidine (Formula X).—The precipitate of ammonium chloride from the ammonia treatment of the second mother liquor from the tetrachloropyrimidine was gummy and evidently contained other reaction products. Extraction of the ammonium chloride with water left a brown gummy mass which dried overnight to a porous brittle mass. Treatment of this with ether dissolved all but a white crystalline powder, insoluble in water and in ether, very slightly soluble in alcohol. By crystallizing from a large volume (1.5 liters) of hot alcohol it was obtained in colorless needles which did not melt when heated to 270°. The substance was readily soluble, however, in dilute acids and alkalies and was reprecipitated by neutralizing the solution.

Anal. Calcd. for $C_8H_{13}O_2N_3$: C, 52.46; H, 7.10; N, 22.95. Found: C, 52.6, 52.7; H, 6.7, 7.1; N, 23.0, 23.3.

The yield was 2.3 g. This substance has been prepared by Fischer and Dilthey[11] from ethyl diethylmalonate and guanidine.

Evaporation of the ether used in the above extraction gave a further separation of barbital. In fact, small quantities of barbital were frequently encountered at various stages of the process of working up the reaction products, especially in mother liquors that had been given a final treatment with water or in residues from steam distillation. It is possible that its presence indicates a regeneration of barbital by hydrolysis of the tetrachloropyrimidine or partially chlorinated intermediate products. On the other hand, it is equally probable that the chlorination is not strictly quantitative and that some of the original substance remains unaltered despite the excess of phosphorus pentachloride used.

A yellowish-brown amorphous residue finally remained from which we were unable to obtain any definitely crystalline substance. On the basis of the total amount of tetrachloro derivative actually isolated (24.5 g.), and the crude diethylcyanoacetyl

---

[11] Fischer and Dilthey, *Ann.*, 334,352 (1904).

chloride (**20.6** g.) from which the corresponding amide and acid were prepared, these substances evidently constitute the main reaction products. They are formed in nearly equal quantities under the conditions of our experiments and together account for approximately 46% of the barbital used. In neither case, however, was the recovery quantitative, as was shown by the further isolation of their derivatives from mother liquors.

The formation of a nitrile acid chloride (diethylcyanoacetyl chloride) by the action of phosphorus pentachloride on a cyclic urea such as barbital was at first rather puzzling because no such reaction had been recorded as occurring in the chlorination of numerous purine and pyrimidine derivatives. An interesting parallel, however, was found in the work of Bredt and Iwanoff,[12] who obtained a nitrile acid chloride from phosphorus pentachloride and camphoric imide. The same pyridone ring is present in both glutaric and camphoric imide, but only the latter undergoes this reaction. Now barbital and camphoric imide not only have an imide grouping in common, but both contain also a paired alkyl grouping and in that respect differ from their parent substances which yield only a stable chlorinated ring. The mechanism of the reaction in the case of barbital is not as simple as that proposed by Bredt and Iwanoff for the camphoric imide reaction, since the ring has to break at two places. In the barbital reaction their hypothesis could be applied to the formation of the nitrile grouping, but the formation of acid chloride requires a cleavage by hydrogen chloride. The products would then be diethylcyanoacetyl chloride and carbamyl chloride. The latter boils at 61–62° and would pass off with the hydrogen chloride and phosphorus oxychloride in the first distillate. It may be assumed that the nitrile acid chloride is formed from an intermediate chlorination product, e. g., Formula 11, where one of the malonyl carbonyls is still present.

4,6-Dichloro-5,5-diethyldihydropyrimidine (Formula XI).[13]—The tetrachloro derivative, melting at 127°, is readily hydrolyzed by simply refluxing with water. For example, after boiling 0.0694 g. of the substance for two and one-half hours with 25 cc. of water the solution was titrated with *N* sodium hydroxide and methyl red. The titer was 9.94 cc., corresponding to 0.0363 g. of hydrogen chloride, or 98.9% of the value 0.0367 g. calculated for the liberation of 4 hydrogen chloride. During the refluxing a volatile substance solidified in the condenser tube. This had a strong camphoraceous odor and melted at 44°. It is diethylmalononitrile, the substance described above as a product of the steam distillation of the crude chlorination products. The formation of this nitrile, containing the paired ethyl groupings of the original barbital, establishes the fact that the tetrachloro derivative from which it was obtained also has this structure and that no alkyl migration occurred during the chlorination.

Refluxing with zinc dust and water, however, removed two chlorines and gave a product which was readily isolated by steam distillation. It had a camphoraceous odor, but melted at 117°. This substance is considerably more stable than the tetrachloro derivative. No hydrogen chloride was liberated from it by two and one-half hours' refluxing with water. Like the nitrile, it tends to sublime in the condenser tube. The same product was obtained by reduction of the tetrachloro derivative with zinc dust and alcohol and with zinc dust and acetic acid.

Anal. Calcd. for $C_8H_{12}N_2Cl_2$: N, 13.52; Cl, 34.30. Found: N, 13.40; Cl, 33.78.

When the residue from the distillation was made alkaline with sodium hydroxide and distilled further, the distillate was practically neutral and left no residue on evaporation. No evidence was therefore obtained of a further reduction product.

---

[12] Bredt and Iwanoff, Ber., **58**, 56 (1925).

[13] The isomeric formula with both chlorines in the 2-position is less in conformity with the properties of the substance.

The hydrolysis of the tetrachloro derivative into diethylmalononitrile is rather a curious reaction. As already stated, hydrogen chloride is liberated quantitatively. It may be supposed that this hydrolysis results first in the formation of an unstable intermediate product, a 5,5-diethyl-2-keto-4,6-dihydroxydihydropyrimidine (Formula VII), which then breaks up into one molecule each of diethylmalononitrile. water and carbon dioxide. This hypothetical intermediate is simply an enolic tautomer of barbital. No oxygen ethers or other derivatives of it are known. It is possible, however, that the ring breaks open after the first stage of hydrolysis involving only the more reactive chlorines in the 2-position. There would then be formed, by hydrolysis and loss of carbon dioxide, a diimine $Et_2C(CCl{=}NH)_2$ which would promptly lose two molecules of hydrogen chloride and form the dinitrile. The former reaction, where all four chlorines are removed by hydrolysis and an enolic barbital is formed, appeals more strongly to the writer in view of the fact that barbital itself appears to yield small quantities of the nitrile under conditions of simple hydrolysis. In a parallel experiment the same quantity of barbital in the same concentration was refluxed for the same length of time with four equivalents of hydrogen chloride. A very minute quantity of needle-shaped crystals sublimed in the condenser and these had a distinct camphor odor, but the yield was altogether too small for a melting point determination. Here we have the suggestion of an enol–keto equilibrium in the case of barbital.

2,4,6-Triimino-5,5-diethylhexahydropyrimidine (Formula IX).[14]—As was to be expected, the tetrachloro derivative in an inert solvent reacts with dry ammonia. A solution of 1 g. in 50 cc. of absolute alcohol was saturated with dry ammonia, tightly stoppered and allowed to stand at room temperature for several days. In about twenty-four hours a separation of transparent granular crystals began. These continued to grow during the next two days, accompanied by the formation of fern-like crystals of ammonium chloride, until they had attained a diameter of about 5 mm. After filtering and washing with cold water to remove the ammonium chloride the yield was 0.585 g. Evaporation of the mother liquor gave a further yield. The substance is soluble in water and gives a copious precipitate with silver nitrate, hence is the hydrochloric acid salt of a base. It contains alcohol of crystallization, and the transparent crystals effloresce in the oven at 100°. This triimino derivative is rather a strong base since it separates as a mono-hydrochloride salt in the presence of a large excess of ammonia.

Anal. Calcd. for $C_8H_{15}N_5 \cdot HCl$: Cl, 16.32; N, 32.18. Found: Cl, 16.8, 16.2; N, 30.4.

The base has been described[15] as a condensation product of diethylmalononitrile and guanidine. Although the hydrochloric acid salt is moderately stable to dilute acids, the free base is rather easily hydrolyzed. A sample of the hydrochloride salt was treated with the exact equivalent of 0.1 N sodium hydroxide and evaporated on the steam-bath. The odor of ammonia was soon recognized and an insoluble residue was finally obtained which had the properties of diethylmalonylguanidine (Formula X). The 2-imino group is evidently more firmly bound than the 4- and 6-imino groups. Further hydrolysis by dilute sulfuric acid yielded barbital.

Summary

Barbital reacts with phosphorus pentachloride at 115–120° with formation chiefly of diethylcyanoacetyl chloride and 2,2,4,6-tetrachloro-5,5-diethyldihydropyrimidine. The former is a cleavage product of an intermediate partially chlorinated pyrimidine, the reaction being somewhat

---

[14] Possibly the tautomeric 4,6-diamino derivative.

[15] German Patent 165,692 (1905).

analogous to the formation of a nitrile acid chloride from camphoric imide, observed by Bredt and Iwanoff. It was identified by conversion into the amide and the free acid.

The tetrachlorodiethyldihydropyrimidine readily undergoes hydrolysis to diethylmalononitrile. It is suggested that this reaction occurs by way of an enolic tautomer of barbital.

Reduction of the tetrachloro derivative with zinc dust yields a stable dichlorodiethyldihydropyrimidine which does not easily undergo further reduction.

STUDIES IN THE DIPHENYL ETHER SERIES. III. DERIVATIVES OF THE LOCAL ANESTHETIC TYPE[1]

BY C. M. SUTER AND ELMER OBERG

RECEIVED JANUARY 29, 1931 PUBLISHED APRIL 6, 1931

The purpose of this work was to study some derivatives of diphenyl ether which differ from the commonly used esters of *p*-aminobenzoic acid mainly in that the amino and ester groups are not attached to the same benzene ring. By a comparison of the local anesthetic action of these compounds with isomers containing both groups in the same ring it is hoped some conclusions may be drawn concerning the mutual effect of these two atomic complexes. The derivatives here reported upon are esters of 4-(4-aminophenoxy)-benzoic acid.

There are several methods which might be used in synthesizing the 4-(4-nitrophenoxy)-benzoic acid necessary for preparing the desired esters. It has been previously[2] obtained in small amounts by the action of the dipotassium salt of p-hydroxybenzoic acid upon p-chloronitrobenzene. Since the potassium salt of *p*-hydroxybenzaldehyde undergoes this type of reaction very readily, giving an aldehyde which may be oxidized to the desired 4-(4-nitrophenoxy)-benzoic acid, this latter method was used instead of the original one. When this work was practically completed, another feasible method was found in the acetylation of 4-nitrodiphenyl ether and the subsequent oxidation of the 4-(4-nitrophenoxy)-acetophenone.

The 4-(4-nitrophenoxy)-benzoic acid was converted into the acid chloride by the use of thionyl chloride. This was reacted with ethyl, n-butyl and β-diethylaminoethyl alcohols to give the nitro esters, which were catalytically reduced[3] to the desired compounds.

[3] Adams, Cohen and Rees, THIS JOURNAL, 49, 1093 (1927).

Preliminary experiments[4] indicate that the ethyl and butyl ester hydrochlorides show a slight local anesthetic action although they are too insoluble in water to be tested adequately. The β-diethylaminoethyl ester monohydrochloride has an activity approximately equal to that of borocaine or procaine, but it is considerably more toxic than these. Although its solubility in water is too small to give the 2% solution generally used, addition of the amount of hydrochloric acid necessary to form the dihydrochloride renders it sufficiently soluble.

Throughout the experimental work, Fischer short-stemmed thermometers were used in obtaining the melting points.

Experimental

4-(4-Nitrophenoxy)-benzaldehyde.—A solution of 45 g. of potassium hydroxide in 25 cc. of hot water was added with stirring to 97 g. of crude p-hydroxybenzaldehyde in 200 cc. of absolute ethyl alcohol. By cooling in ice there was obtained 116 g. or 91% of the theoretical of the potassium salt. The material so obtained was dark red in color but was satisfactory for the following reaction.

To 200 g. (1.27 moles) of *p*-chloronitrobenzene kept at 165–170° was added in small portions with stirring during one hour 93 g. (0.58 mole) of the dry potassium salt. The mixture was then maintained at 190–200° for six hours, cooled and steam distilled to remove the excess *p*-chloronitrobenzene. One crystallization from dilute acetic acid gave 106 g., 75% of the theoretical, of a brownish product which, after treatment with bone-black in alcohol, was obtained as colorless needles melting at 104–105°.

Anal. Calcd. for $C_{13}H_9O_4N$: N, 5.76. Found: N, 5.60, 5.62.

4-(2-Nitrophenoxy)-benzaldehyde.—This was prepared similarly to the preceding by the reaction of the potassium salt of p-hydroxybenzaldehyde with *o*-chloronitrobenzene. It was obtained as a white powder melting at 84–85°.

Anal. Calcd. for $C_{13}H_9O_4N$: N, 5.76. Found: N, 5.90, 5.84.

4-(4-Nitrophenoxy)-acetophenone.[5]—To a solution of 10.8 g. (0.05 mole) of 4-nitrodiphenyl ether and 13.3 g. (0.1 mole) of anhydrous aluminum chloride in 100 cc. of carbon disulfide was added during ten minutes 5 g. (0.06 mole) of acetyl chloride. After refluxing the mixture for fifteen minutes, the solvent was removed by distillation and the residue heated for half an hour longer on the steam-bath. Water was added and the product crystallized from 95% alcohol. The yield was 7 g., 55% of the theoretical, of a colorless product melting at 80–81°.

Anal. Calcd. for $C_{14}H_{11}O_4N$: N, 5.45. Found: N, 5.49, 5.38.

4-(4-Nitrophenoxy)-benzoic Acid.—A mixture of 60 g. of sodium dichromate in 100 cc. of water and 49 g. of the crude aldehyde was warmed until the aldehyde melted; then 43 cc. of concentrated sulfuric acid was added to the stirred mixture during half an hour. After an hour, the mixture was cooled, diluted with water and the insoluble residue extracted several times with hot dilute sodium hydroxide solution. Acidifying this alkaline solution gave 41 g., 79% of the theoretical, of the acid melting at 235–236°. Haeussermann and Bauer[2] report 236–237° for the acid prepared in a different way.

---

[4] Our thanks are due Mr. Leonard Fosdick of the Northwestern Dental School for this report.

[5] Dilthey, Bach, Grütering and Hausdorfer, J. prakt. *Chem.*, 117, 361 (1927).

The same acid was obtained in 76% yield by oxidation of **4-(4-nitrophenoxy)**-acetophenone with bleaching powder by warming in water solution. This indicates the structure of this compound to be that assigned to it.

4-(4-Nitrophenoxy)-benzoyl Chloride.—A mixture of 10 g. of the acid and 50 g. of thionyl chloride was refluxed for an hour, the excess thionyl chloride distilled off and the residue extracted several times with petroleum ether (60–90°). There was obtained 9 g., 84% of the theoretical, of a slightly colored product which upon recrystallizing again from the same solvent gave long colorless needles which melted at 79–80'. It is slightly soluble in ether and readily soluble in benzene.

Anal. Calcd. for $C_{13}H_8O_4NCl$: N. 5.04. Found: N, 5.00, 5.05.

The amide was obtained by passing ammonia into a benzene solution of the acid chloride. It melts at 167–168".

Anal. Calcd. for $C_{13}H_{10}O_4N_2$: N, 10.86. Found: N, 10.94, 10.93.

Ethyl **4-(4-Nitrophenoxy)-benzoate.**—A solution of 24 g. of the acid chloride in 125 cc. of absolute ethyl alcohol was warmed on the steam-bath for an hour. Upon cooling, the ester separated as a white powder in nearly quantitative yield. Upon recrystallizing from alcohol, it melted at 74–75°.

Anal. Calcd. for $C_{15}H_{13}O_5N$: N, 4.88. Found: N, 4.74, 4.94.

Ethyl **4-(4-Aminophenoxy)-benzoate.**—A solution of 17.3 g. (0.06 mole) of the nitro ester in 230 cc. of 95% alcohol was reduced with hydrogen in the presence of 0.2 g. of platinum oxide[a] catalyst. Upon removing the solvent, a viscous, slightly colored oil remained which did not crystallize. The hydrochloride was obtained as a white powder by passing hydrogen chloride through a benzene solution of the amine. It had no definite melting point but decomposed at about 165'. It is very slightly soluble in water.

Anal. Calcd. for $C_{15}H_{16}O_3NCl$: N, 4.77. Found: N, 4.76, 4.63.

The acetyl derivative separated from 95% alcohol as colorless crystals melting at 122–123°.

Anal. Calcd. for $C_{17}H_{17}O_4N$: N, 4.68. Found: N, 4.70, 4.53.

Butyl 4-(4-Nitrophenoxy)-benzoate.—This was obtained from **4-(4-nitrophenoxy)-benzoyl** chloride and n-butyl alcohol as a thick yellow oil which distilled at 250–255' at 5 mm.

Anal. Calcd. for $C_{17}H_{17}O_5N$: N, 4.44. Found: N, 4.50, 4.58.

Butyl **4-(4-Aminophenoxy)-benzoate.**—This was obtained similarly to the ethyl homolog by reduction of the nitro ester. It was obtained as a jelly-like material which did not crystallize. It was converted into the hydrochloride, which is practically insoluble in water and upon heating decomposes at 155–160°.

Anal. Calcd. for $C_{17}H_{20}O_3NCl$: N, 4.35. Found: N, 4.35, 4.38.

The acetyl derivative separated from 95% alcohol as a white flocculent material which melted at 98–99'.

Anal. Calcd. for $C_{19}H_{21}O_4N$: N, 4.29. Found: N, 4.33, 4.41.

β-Diethylaminoethyl 4-(4-Nitrophenoxy)-benzoate Hydrochloride.—A solution of 17 g. of the acid chloride in 100 cc. of benzene was treated with 6 g. (0.05 mole) of β-diethylaminoethyl alcohol in 15 cc. of benzene. The mixture was heated on the steam-bath for an hour, cooled and filtered. There was obtained 18 g. or 90% of the theoretical of material which decomposed at 100–110'.

Anal. Calcd. for $C_{19}H_{23}O_5N_2Cl$: N, 7.00. Found: N, 7.05, 7.08.

β-Diethylaminoethyl 4-(4-Aminophenoxy)-benzoate Hydrochloride.—This was obtained, by reduction of the nitro compound described in the preceding preparation, as a jelly-like material which is insoluble in ether and benzene, but dissolves in warm water and separates upon cooling in an amorphous condition.

Anal. Calcd. for $C_{19}H_{25}O_3N_2Cl$: N, 7.68. Found: N, 7.33, 7.36.

Summary

A number of local anesthetic type derivatives of diphenyl ether have been prepared in which the carboxy and amino groups are not attached to the same benzene ring.

Although these derivatives show considerable anesthetic action, they are too toxic to be of practical value.

THE OXIMES OF ORTHO HYDROXY BENZOPHENONE

BY E. P. KOHLER AND W. F. BRUCE

RECEIVED JANUARY 30, 1931 PUBLISHED APRIL 6, 1931

The oximes of o-hydroxy benzophenone have acquired a certain importance in connection with the interpretation of the Beckmann rearrangement. One of the two possible oximes was first made by Cohn,[1] who described a product melting at 134°. Meisenheimer and Meis[2] recently repeated the work under somewhat different conditions, but likewise obtained only a single oxime (135°). Like o-chloro benzophenone and o-bromo benzophenone, therefore, o-hydroxy benzophenone appeared to be capable of forming but one oxime that was sufficiently stable for isolation, and it seemed probable that the known oximes of these three ketones-had the same configuration.

Since alkalies convert the known oximes of o-chloro and o-bromo benzophenone into a cyclicc ompound—phenyl indoxazene—Meisenheimer and Meis concluded that these were probably *syn* oximes. They subsequently verified[3] this conclusion beyond all doubt by preparing the much more reactive dinitro o-chloro benzophenone oxime and showing that it forms the corresponding indoxazene under conditions under which isomerization of the oxime need not be feared. The configuration of these three oximes can therefore be regarded as established by their relation to cyclic compounds. When they were subjected to a Beckmann rearrangement, all three gave products which were in accord with Meisenheimer's interpretation of this rearrangement.

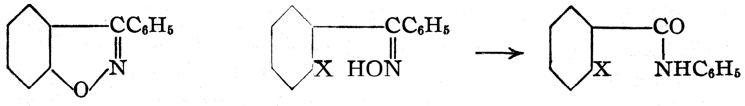
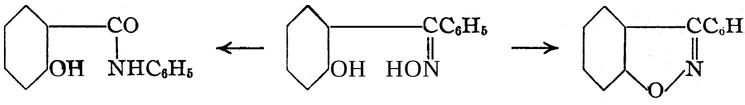
[2] Meisenheimer and Meis, Ber., 57, 289 (1924).

[3] Meisenheimer, Zimmermann and v. Kummer, Ann., 446, 208 (1926).



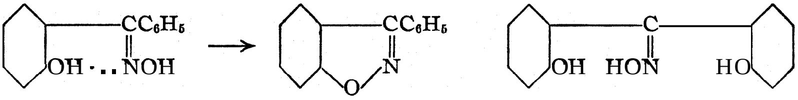
II I III

By analogy with these halogen compounds, the known oxime of o-hydroxy benzophenone would be expected to yield salicylanilide on rearrangement and phenyl indoxazene on dehydration. Meisenheimer and Meis found that it is readily rearranged by phosphorus pentachloride and that the principal product is salicylanilide, but they also found that it resisted all their efforts to convert it into the cyclic compound.



IV V II

In order to account for this unexpected resistance to dehydration, they resorted to the same auxiliary hypothesis that Meisenheimer had adopted to explain why the y-dioxime of benzil, which according to Meisenheimer's interpretation is the *amphi* form, loses water more readily than any of its isomers.[4] Accordingly, they assumed that for the elimination of water, the interplay of residual valences was decisive, and they predicted that the indoxazene derivative would be readily formed from the *anti* form.



VI II VII

This prediction lost much of its probability when Auwers and Jordan[5] showed that it was impossible to transform the oxime of *o,o'*-dihydroxy benzophenone (VII) into an indoxazene derivative. As a matter of fact the prediction is wrong; we have prepared both of the oximes of o-hydroxy benzophenone, and have found that neither of them can be dehydrated. It is impossible, therefore, to establish the configuration of these oximes by relating them to phenyl indoxazene.

Surprisingly enough, in view of the fact that isomeric oximes of ortho substituted benzophenones have so seldom been obtained,[6] both of the oximes of o-hydroxy benzophenone are relatively stable substances. They differ little in solubility and melting point but they are readily distinguished by their crystalline form, the h-oxime (143°) crystallizing from benzene

---

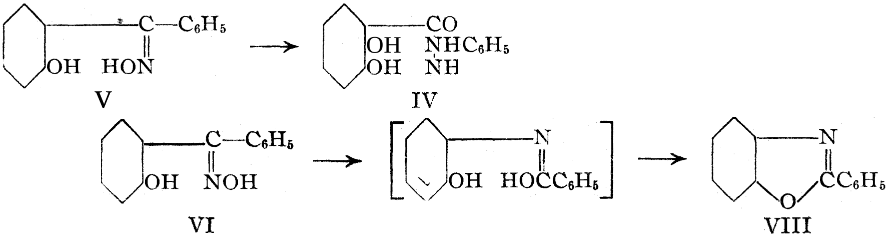
[5] Auwers and Jordan, *ibid.*, 58, 26 (1925).

[6] *(a)* A. W. Smith, *ibid.*, 24,4057 (1891); (b) A. Hantzsch, *ibid.*, 25,2164 (1892); (c) Auwers and Myenburg, *ibid.*, 24, 2383 (1891); 29, 1264 (1896); (d) Auwers and Jordan, *ibid.*, 57, 800 (1924).

in plates while the n form (141°) appears in needles. Neither passes into the other in boiling solvents or at the melting point. At higher temperatures the h-form sublimes unchanged, while the n-form is changed to its isomer, but even at 185–200° the process is exceedingly slow.

Although both oximes can be obtained in alkaline solutions of hydroxylamine, and Cohn, as well as Meisenheirner and Meis, doubtless had mixtures of the two, the needles must be regarded as the "alkali-stable" form because boiling alkalies slowly convert the plates into this form, Formic acid, on the other hand, changes the n- to the h-form; this may, therefore, be regarded as the "acid-stable" oxime, but the term is misleading because formic acid also very readily brings about a Beckmann rearrangement.

With phosphorus pentachloride in ether each oxime yields a single rearrangement product, the n-oxime being converted into salicylanilide and the h-oxime into 2-phenyl benzoxazole (VIII). As usual the process is accompanied by side reactions but no salicylanilide is formed from the h-oxime and no phenyl benzoxazole from the isomer. Since Meisenheimer's interpretation of the Beckmann rearrangement has proved to be correct in every case in which an oxime has been obtained from a cyclic compound, we regard the n-form as the syn and the h-form as the *anti* oxime.



From the foregoing account it is evident that the isomeric oximes of o-hydroxy benzophenone do not furnish any independent evidence with respect to the proper interpretation of the Beckmann rearrangement. Their behavior, however, serves to dispel some of the doubts raised by Auwers and Seyfried[7] concerning the use of this rearrangement for determining configurations. These authors point out that not infrequently a single oxime gives two rearrangement products and that while, as is generally assumed, these products may be due to isomerization of part of the oxime, antecedent to rearrangement, this is not certain because they may also be due to different modes of rearrangement of the same oxime. In the absence of evidence to the contrary, this is doubtless true. We have found, however, that in the case of the n-oxime, which is exceedingly sensitive to acids, it is possible to get a single rearrangement product by operating with phosphorus pentachloride in absolute ether, at a low temperature; and we also found that while formic acid very readily transforms this oxime into the

[7] Auwers and Seyfried. Ann., 484, 178 (1930).

rearrangement product of its isomer, it is possible to isolate the h-oxime as an intermediate in the process. We therefore believe that even when but one isomer is known, the Beckmann rearrangement is useful if it is employed with sufficient care.

Experimental Part

Both of the oximes of o-hydroxy benzophenone can be obtained directly from the ketone by treating it with hydroxylamine in an alkaline medium. The result of this treatment depends mainly, at any rate, upon the temperature. At the ordinary temperature the product is almost pure *h*-**oxime,** which crystallizes in plates. In boiling solutions the product is a mixture in which the quantity of n-oxime increases with the time that the solution is boiled. From mixtures which are composed mainly of either isomer it is comparatively easy to get pure substances by recrystallization from benzene and petroleum ether, but it is not feasible to separate mixtures containing considerable quantities of both components in this manner.

The h-oxime is most readily obtained by operating at the ordinary temperature. Thus 0.5 g. of the ketone was added to 4 cc. of 40% aqueous potassium hydroxide. The ketone dissolved with the characteristic yellow coloration and a yellow solid soon precipitated from the solution. To this mixture was added 0.5 g. of hydroxylamine hydrochloride. The temperature rose, the yellow solid soon dissolved and the intense yellow color disappeared within fifteen minutes. The solution was then acidified with hydrochloric acid; it deposited a white precipitate which was collected on a funnel, washed with a little 50% methyl alcohol and dried. The crude product weighed 0.45 g. and melted at 128–130°. Recrystallization from benzene and a little petroleum ether gave 0.35 g. of pure oxime, crystallizing in thin plates and melting at 142–143°. The pure oxime crystallizes well from dilute methyl alcohol in large thick plates but it is very difficult to separate a mixture of the oximes by crystallization from this solvent.

Anal. Calcd. for $C_{13}H_{11}O_2N$: C, 73.2; H, 5.1. Found: C, 72.9; H, 5.2.

The *n-oxime* is probably obtained most readily by heating the h-oxime with strong alkalies. Thus a solution of 0.5 g. of the h-oxime in 20 cc. of 20% aqueous sodium hydroxide was boiled vigorously for two hours, during which it became slightly yellow (possibly because some of the hydroxy ketone was regenerated). On acidification the solution deposited a solid contaminated with a small quantity of red oil. Recrystallization from benzene and petroleum ether yielded 0.3 g. of a pure product crystallizing in needles and melting at 141–142°. A mixture of the two forms melted at 115–120°.

Anal. Calcd. for $C_{13}H_{11}O_2N$: C, 73.2; H, 5.1; N, 6.6. Found: C, 73.5; H, 5.4; N, 7.0.

Separation of Mixtures.—To a solution of 5 g. of o-hydroxy benzophenone and 5 g. of hydroxylamine hydrochloride in 50 cc. of methyl alcohol was added a solution of 8 g. of potassium hydroxide in 8 cc. of water. The mixture was boiled for two hours, then poured into 150 cc. of water. A slight gummy precipitate was removed by filtration, and then the clear filtrate was partially neutralized with 3 cc. of glacial acetic acid; it deposited 1.34 g. of a colorless solid which was collected on a filter, washed and dried. One recrystallization of this first crop from 4 cc. of benzene gave the pure h-oxime melting at 143°.

From the filtrate from the first fraction 1 cc. of glacial acetic acid precipitated 1.08 g. of a pale yellow solid which melted at 128–135° and which proved to be a mixture of the two isomers, separable most readily by a repetition of the operation. Final acidification with 3 cc. of glacial acetic and 3 cc. of concentrated hydrochloric acids resulted in

0.8 g. of a colorless precipitate which after one recrystallization from benzene and petroleum ether was pure n-oxime.

The Action of Alkalies on the **Oximes.—It** has been shown that the isomerization of the h-oxime by alkalies is accompanied by secondary reactions that lead to the development of color. The n-oxime appears to be much more stable in boiling alkalies, for when a solution of **0.5** g. of the substance in **20** cc. of **20%** aqueous sodium hydroxide was boiled for two hours it remained colorless and **0.45** g. of the pure oxime was recovered when the solution was acidified.

The Action of Heat on the **Oximes.—A small** quantity (**0.24** g.) of the h-oxime was heated under **25** mm. to 175–180° for half an hour during which most of it (0.15 g.) sublimed to the upper part of the flask. The sublimate was unchanged oxime. The residue was dissolved in a little methyl alcohol in which the dehydration product, phenyl indoxazene, is sparingly soluble, but nothing except unchanged h-oxime could be detected in the solution. Two-tenths of a gram of the n-oxime was heated in a similar manner to 180–200° and a part of the material sublimed in plates. Solid residue and sublimate dissolved completely in **2** cc. of methyl alcohol and inoculation of this solution with phenyl indoxazene had no effect. The solution, on cautious dilution with water, deposited **0.15** g. of the h-oxime, and further dilution gave **0.05** g. more or less pure material (137–140°). At elevated temperatures, therefore, the n-oxime does not undergo dehydration but is changed to the k-isomer.

The Action of Phosphorus Pentachloride on the **Oximes.—To** a solution of **1** g. of the n-oxime in **30** cc. of absolute ether was added **1.9** g. of phosphorus pentachloride. The cloudy solution was allowed to remain at 20° for fifteen minutes, then mixed with **20** g. of ice. The ethereal layer was washed with hydrochloric acid and with water, dried and evaporated. It left a gummy residue which was completely soluble in alkalies, therefore contained no phenyl benzoxazole. From the alkaline solution carbon dioxide precipitated **0.45** g. of salicylanilide melting at **132–133°.**

In a similar manner **1** g. of the h-oxime was treated with **1.5** g. of phosphorus pentachloride. The washed and dried ethereal solution on evaporation left a gummy residue of which all but **0.42** g. was soluble in alkali. The insoluble portion was identified as 2-phenyl benzoxazole melting at 102–103°. From the alkaline solution carbon dioxide precipitated a solid which after recrystallization melted at 164–167°. Only a small amount of this substance was obtained in fairly pure state; it had the properties of *o*-aminophenol, a cleavage product of the compound resulting from the initial rearrangement.

The Action of Hydrogen Chloride on the **Oximes.—Attempts** to dehydrate one or other of the oximes with dry hydrogen chloride met with no success. From ethereal solutions of h-oxime dry hydrogen chloride precipitated a yellow hydrochloride that melted at **118–120°** when freshly prepared but which rapidly deteriorated when kept in a vacuum desiccator. When an alcoholic solution of this chloride was immediately diluted with water, the h-form was recovered, practically quantitatively, and when the chloride was dissolved in chloroform, hydrogen chloride was given off and again the h-form was recovered. But when the chloride was heated to 140–145° it decomposed freely, and moisture condensed on the cool part of the tube. From the residue alkali extracted *o*-hydroxy benzophenone and left 2-phenyl benzoxazole, which was identified by a mixed melting point.

The n-form likewise gave a solid hydrochloride. This melted at **132–134'** and regenerated the n-oxime when it was dissolved in hot chloroform or when its solution in alcohol was diluted with water. When it was heated to **145°** this oxime likewise gave 2-phenyl benzoxazole. Under these conditions, therefore, neither of the oximes can be dehydrated.

The Action of Formic Acid on the Oximes.—Preliminary experiments showed that neither cold concentrated sulfuric nor glacial acetic acid has any action on the oximes. We therefore turned to formic acid, which is known[6d] to be much more effective. Both oximes gave, along with a small quantity of yellow oil which was doubtless the hydroxy ketone due to hydrolysis, mainly phenyl benzoxazole. This result was to be expected in the case of the h-oxime because the oxazole derivative is obtained from the normal Reckmann rearrangement product of this oxime. But in the case of the n-oxime the formation of this product involves either an abnormal rearrangement or a combination of isomerization and rearrangement.

In order to decide between these alternatives we repeated the experiment with the n-oxime with much greater care. To this end a solution of 0.25 g. of the oxime in 2 cc. of formic acid (sp. gr. 1.20) was heated without delay to 100° for five minutes. The yellow solution was then cooled and diluted with 10 cc. of water. A gummy yellow precipitate separated. Excess of sodium carbonate was added and the mixture was left to itself for several hours, during which the precipitate became solid and nearly white. It was collected on a sintered glass filter and digested for fifteen to twenty minutes with sodium bicarbonate solution. After this had been sucked off, a clean receiver was placed under the filter and the solid was stirred with 5 cc. of 10% sodium hydroxide. A partial solution occurred. The insoluble part was washed with alkali, water and dilute methyl alcohol (about 50%), and dried. It weighed 0.05 g. and melted at 97–100°. The mixed melting point with 2-phenyl benzoxazole gave no depression.

To the faintly turbid alkaline filtrate was added drop by drop with shaking 5% acetic acid until a more pronounced permanent turbidity just became evident. The solution stood overnight and the small brown plates which formed were filtered off. They weighed 0.04 g. and melted at 134–137°. On crystallization from benzene and petroleum ether a solid melting at 140–141° was secured. The mixed melting point with the plate form oxime was 141–143°, and with the needle form 110–115°. It is important not to add more than the specified amount of acid in precipitating this portion since a slight excess will precipitate the n-form also, and separation of a mixture of the isomers by crystallization is practically impossible unless one form is very largely in excess.

Acidification of the faintly alkaline filtrate gave 0.12 g. of white unchanged *n*-oxime melting at 138–140°, mixed melting point with the original n-oxime, 139–141° This procedure was carried out twice with the same result.

Summary

The stereoisomeric oximes of o-hydroxy benzophenone have been prepared. Neither of them can be dehydrated to a cyclic compound. Their behavior, therefore, contributes no independent evidence with respect to the proper interpretation of the Beckmann rearrangement, but indicates that this rearrangement is reliable when it is employed with sufficient care.

STEREOCHEMISTRY OF DIPHENYL COMPOUNDS. THE PREPARATION AND RESOLUTION OF 3,5,3′,5′-TETRAMETHYL-2,2′-DIFLUORO-6,6′-DIAMINODIPHENYL. XIV[1]

BY E. C. KLEIDERER[2] AND ROGER ADAMS

RECEIVED FEBRUARY 2, 1931 PUBLISHED APRIL 6, 1931

The interpretation of the degree of resistance to free rotation of the rings in 2,2′,6,6′-substituted diphenyls through x-ray values representing the size of the groups, was discussed in detail in an earlier paper.[3] Since that time these values have been applied to various new diphenyl compounds and have fitted in better with the experimental facts than might have been anticipated. However, sufficient data have not as yet been collected so that generalizations might be drawn which would make possible the prediction of the properties of any new derivatives in a quantitative way.

It was pointed out that any diphenyl molecule which showed interference between the 2,2′ and 6,6′ substituting groups of only a few hundredths of an Å. would probably racemize readily, a property not shown by most of the molecules studied up to this time. It may thus be seen that in 2,2′-difluoro-6,6′-diaminodiphenyl such conditions should exist. On each side of the molecule the interference would be only 0.05 Å.: C–F, 1.39 Å. + C–NH_2, 1.56 Å. = 2.95Å. – 2.90Å. (vertical distance between the 2,2′ carbon atoms) = 0.05 Å. In this investigation a homolog of this compound has been described and its ease of racemization determined. The properties are exactly those which were predicted.

The compound synthesized was 3,5,3′,5′-tetramethyl-2,2′-difluoro-6,6′-diaminodiphenyl (V). It was readily resolved through the dicamphorsulfonate salt. The active amines had surprisingly low rotations compared to most of the other optically active diphenyls previously studied; $[\alpha]^{20}_{D}$ $-4.1°$ and $[\alpha]^{20}_{D}$ $+3.2°$. The former undoubtedly is the maximum rotation for the active compound as it was obtained from the pure, less soluble salt.

The active forms racemized with the greatest ease. By boiling in ethyl alcohol, the I-form was half racemized in one hour and completely racemized in two hours; in glacial acetic acid it was entirely racemized in half an hour; even in boiling methyl alcohol the racemization was complete in four hours.

To synthesize this compound the following series of reactions was carried out: 3,5-dimethyl-2-aminobenzene ⟶ 3,5-dimethyl-2-amino-6-nitro-

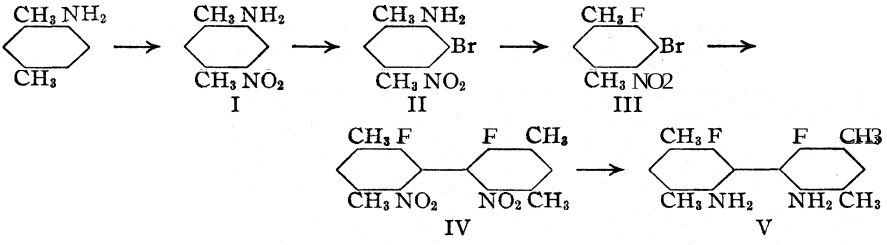
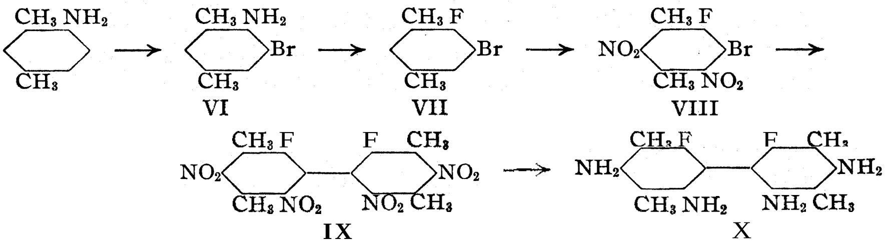
[2] This communication is a portion of a thesis submitted by E. C. Kleiderer in partial fulfilment of the requirements for the Degree of Doctor of Philosophy in Chemistry at the University of Illinois.

[3] Stanley and Adams, THIS JOURNAL, 52,1200 (1930).

benzene (I) → 3,5-dimethyl-2-amino-6-nitro-1-bromobenzene (II) → 3,5-dimethyl-2-fluoro-6-nitro-1-bromobenzene (111) → 3,5,3′,5′-tetramethyl-2,2′-difluoro-6,6′-dinitrodiphenyl (IV) → 3,5,3′,5′-tetramethyl-2,2′-difluoro-6,6′-diaminodiphenyl (V).



In the experimental part is also described the preparation of 3,5,3′,5′-tetramethyl-2,2′-difluoro-4,4′,6,6′-tetraaminodiphenyl, as follows: 3,5-dimethyl-2-aminobenzene → 3,5-dimethyl-2-amino-1-bromobenzene (VI) → 3,5-dimethyl-2-fluoro-1-bromobenzene (VII) → 3,5-dimethyl-2-fluoro-4,6-dinitro-1-bromobenzene (VIII) → 3,5,3′,5′-tetramethyl-2,2′-difluoro-4,6,4′,6′-tetranitrodiphenyl (IX) → 3,5,3′,5′-tetramethyl-2,2′-difluoro-4,6,4′,6′-tetraaminodiphenyl (X).



This compound was synthesized before the corresponding diamino derivative but, in attempting resolution, crystalline salts could not be isolated using d-tartaric acid, d-camphorsulfonic acid, or *d*-bromocamphorsulfonic acid.

Experimental

3,5-Dimethyl-2-amino-6-nitrobenzene (I).—In a 600-cc. beaker, 20 g. of *m*-xylidine was dissolved in 200 g. of concentrated sulfuric acid. The mixture was then cooled to 5° and not allowed to rise above 15°. To this was slowly added with stirring 16.5 g. of concentrated nitric acid (sp. gr. 1.42). After all of the nitric acid had been added, the mixture was stirred for thirty minutes longer. It was then poured onto ice, when the amine sulfate precipitated. This was filtered off and made alkaline with 10% sodium carbonate solution. The free amine was purified by crystallization from 50% alcohol–water mixture. A small amount of an insoluble by-product always resulted which may have been a dinitro compound. The mononitro compound formed deep orange needles melting at 123–124° and the yield was 23 g. (84%).

---

[4] Noelting and Collin, *Ber.*, 17, 265 (1884).

3,5-Dimethyl-2-amino-6-nitro-1-bromobenzene (II).[5]—In a 1-liter round-bottomed flask, 10 g. of 3,5-dimethyl-2-amino-6-nitrobenzene was dissolved in 100 g. of glacial acetic acid. To this was added, with stirring, 9.5 g. of bromine dissolved in 50 cc. of glacial acetic acid. During the addition, the hydrobromide of the brominated amine crystallized out in white needles. The crystals were filtered off and made alkaline with a 10% sodium carbonate solution and the base thus obtained was used directly for further experimentation.

3,5-Dimethyl-6-nitro-1-bromobenzene-2-diazoniumborofluoride.—In a 300-cc. beaker was placed 25 cc. of concentrated hydrochloric acid. In this was suspended 10 g. of 3,5-dimethyl-2-amino-6-nitro-1-bromobenzene, and the mixture cooled to 0°. A solution of saturated sodium nitrite was added until there remained a slight excess of free nitrous acid as determined by potassium iodide–starch test papers. The solution was filtered from any sodium chloride and to the filtrate was added 27.6 g. of a solution of hydroborofluoric acid, made by mixing 20 g. of 48% hydrofluoric acid and 7.6 g. of boric acid. Upon the addition of the acid, the borofluoride precipitated in white needles. It was filtered off and washed with more hydroborofluoric acid. The yield was 9 g. (67%). The decomposition point of the compound was 195°.

3,5-Dimethyl-2-fluoro-6-nitro-1-bromobenzene (III).—In a small Pyrex test-tube, connected by a wide glass delivery tube to a 500-cc. distilling flask cooled in ice, was placed 3 g. of the 3,5-dimethyl-6-nitro-1-bromobenzene-2-diazoniumborofluoride. The compound was heated with a Méker burner and as soon as it commenced to decompose, the system was placed under reduced pressure and heating continued. The compound became very black and charred but a quantity of the fluorine derivative distilled over. Heating was continued until no more material could be distilled, when the test-tube was emptied of the carbon and refilled with 3 g. more of the borofluoride. It was found that the yield increased when small quantities of the borofluoride were decomposed at a time. Additional fluorine compound could be obtained by reheating the carbon residue obtained from previous decompositions. The fluorine compound was purified by mixing with water and steam distilling and then crystallizing from low-boiling petroleum ether. It formed yellow needles, melting at 49–51". The yield was 17 g. from 50 g. of borofluoride (45%).

Anal. Calcd. for $C_8H_7O_2BrFN$: Br, 32.22. Found: Br, 31.85.

3,5,3′,5′-Tetramethyl-2,2′-difluoro-6,6′-dinitrodiphenyl (IV).—In a 200-cc., round-bottomed, 3-necked flask containing a stirrer and an air-cooled reflux condenser were placed 10 g. of 3,5-dimethyl-2-fluoro-6-nitro-1-bromobenzene and 20 cc. of dry nitrobenzene. The flask was heated in a metal bath for five hours to 200° and vigorously stirred. During this time 20 g. of powdered copper bronze was added in small amounts. The mixture was filtered and the solid was washed with acetone. The filtrates were steam distilled and the diphenyl compound remained as a residue. This was washed with alcohol to remove any remaining nitrobenzene and was crystallized from 50% acetone–water mixture. The compound formed white plates melting at 234–236° (corr.). The yield was 5 g. (75%).

Anal. Calcd. for $C_{16}H_{14}O_4F_2N_2$: N, 8.33. Found: Kjeldahl ($TiCl_3$), N, 8.48.

3,5,3′,5′-Tetramethyl-2,2′-difluoro-6,6′-diaminodiphenyl (V).—In a 400-cc. beaker was placed 200 cc. of glacial acetic acid, 20 cc. of concentrated hydrochloric acid and 8 g. of 3,5,3′,5′-tetramethyl-2,2′-difluoro-6,6′-dinitrodiphenyl. This mixture was heated to boiling and to it was added 6 g. of zinc dust. The reduction was allowed to proceed at the boiling point for ten minutes. The mixture was then made alkaline by pouring it into an ice-cold solution of 10% sodium hydroxide. The diamine was filtered off

---

and recrystallized from a 50% alcohol–water mixture. It formed fine white needles, melting at 154–155° (corr.). The yield was 4.5 g. (68%).

Anal. Calcd. for $C_{16}H_{18}F_2N_2$: N, 10.14. Found: N, 9.88.

Resolution of **3,5,3′,5′-Tetramethyl-2,2′-difluoro-6,6′-diaminodiphenyl.**—To a solution of 8.6 g. of the diamine in 130 cc. of anhydrous ethyl acetate was added 15 g. of d-camphorsulfonic acid dissolved in 200 cc. of anhydrous ethyl acetate. The solution was boiled for several minutes, when the salt precipitated out. After cooling and filtering the salt, it was found that all but 2.5 g. of the salt had precipitated. The salt was dissolved in a mixture of 170 cc. of anhydrous ethyl acetate and 28 cc. of absolute ethyl alcohol by heating and the solution was then allowed to stand for six hours. At the end of this time 7 g. of crystals had separated, which were filtered off and washed with anhydrous ethyl acetate and dried. This was shown to be essentially pure I-salt by comparison of the rotation with that of recrystallized material, m. p. 171–173°.

Rotation. 0.1500 g. made up to 15 cc. with absolute alcohol at 20° gave α_D \$0.52"; 1 = 2; $[\alpha]^{20}_{D}$ +26.0°. Recrystallizing from 100 cc. of anhydrous ethyl acetate and 20 cc. of absolute alcohol gave 5 g. of crystals.

Rotation. 0.1500 g. made up to 15 cc. with absolute alcohol at 20° gave α_D +0.52°; l = 2, $[\alpha]^{20}_{D}$ +26.0°.

Anal. Calcd. for $C_{16}H_{18}F_2N_2 \cdot 2C_{10}H_{15}O(SO_3H)$: S, 8.65. Found: S, 8.40.

The mother liquor from the first crop of crystals was evaporated to 125 cc., 50 cc. more of anhydrous ethyl acetate was added, and the solution allowed to stand overnight at room temperature. A crop of 6.7 g. of crystals came down which consisted of a mixture of the less and more soluble salts. The mother liquor from the second crop of crystals was evaporated to 75 cc. and 75 cc. more of anhydrous ethyl acetate was added. On standing overnight, a crop of 4.5 g. of crystals came down which was filtered off and washed with a small amount of anhydrous ethyl acetate, m. p. 125–130°.

Rotation. 0.1500 g. made up to 15 cc. with absolute alcohol at 20° gave α_D +0.60°; l = 2, $[\alpha]^{20}_{D}$ 30.0°. The salt was recrystallized from 100 cc. of anhydrous ethyl acetate.

Rotation. 0.1500 g. made up to 15 cc. with absolute alcohol at 20° gave a, \$0.65"; 1 = 2, $[\alpha]^{20}_{D}$ +32.5°. The salt was again recrystallized from anhydrous ethyl acetate.

Rotation. 0.1500 g. made up to 15 cc. with absolute ethyl alcohol at 20° gave α_D \$0.65"; *1* = 2, $[\alpha]^{20}_{D}$ \$32.5'.

Anal. Calcd. for $C_{16}H_{15}F_2N_2 \cdot 2C_{10}H_{15}O(SO_3H)$: S, 8.65. Found: S, 8.45.

***l*-3,5,3′,5′-Tetramethyl-2,2′-difluoro-6,6′-diaminodiphenyl.**—To the less soluble salt dissolved in water at 0° was added a solution of 10% sodium carbonate. The active amine, which separated in fine white needles, melted at 150–152° (corr.).

Rotation. 0.4352 g. made up to 15 cc. in acetone at 20° gave a, –0.24"; l = 2, $[\alpha]^{20}_{D}$ –4.1".

It was recrystallized from 50% acetone–water mixture by dissolving in cold solvent and evaporating, with stirring, under diminished pressure in the cold until the amine just commenced to crystallize. The melting point was 151–152" (corr.).

Rotation. 0.4000 g. made up to 15 cc. in acetone at 20° gave a, –0.22'; 1 = 2, $[\alpha]^{20}_{D}$ –4.1°.

Anal. Calcd. for $C_{16}H_{18}F_2N_2$: N, 10.14. Found: N, 10.49.

***d*-3,5,3′,5′-Tetramethyl-2,2′-difluoro-6,6′-diaminodiphenyl.**—The d-form was obtained in a manner similar to the 1-form and melted as obtained directly from the salt at 150–151" (corr.).

Rotation. 0.4000 g. made up to 15 cc. in acetone at 20° gave a, +0.16°; *1* = 2, $[\alpha]^{20}_{D}$ +3.0°. The active amine was recrystallized using the procedure for the ***l*-form** and melted at 150–151° (corr.).

Rotation. 0.4000 g. made up to 15 cc. in acetone at 20° gave a, +0.17°; l = 2, $[\alpha]^{20}_{D}$ + 3.2'. Another crystallization gave no change in rotation.

Anal. Calcd. for $C_{16}H_{18}F_2N_2$: N, 10.14. Found: N, 10.60.

Racemization Experiments

1. The rotation was taken on the *l*-amine in absolute alcohol.

Rotation. 0.4000 g. made up to 15 cc. with absolute alcohol at 20° gave a, −0.21°; l = 2, $[\alpha]^{20}_{D}$ −4.0°. The solution was refluxed for thirty minutes and the rotation taken; it was found to be $[\alpha]^{20}_{D}$ −1.5'; after one hour $[a]^{20}_{D}$ −1.4° and at the end of two hours $[\alpha]^{20}_{D}$ 0°.

2. The rotation was taken on the 1-amine in glacial acetic acid.

Rotation. 0.2000 g. made up to 15 cc. with glacial acetic acid at 20° gave a, −0.16°; I = 2, $[\alpha]^{20}_{D}$ −6.0'. After refluxing for fifteen minutes, the rotation was $[\alpha]^{20}_{D}$ −2.6° and in thirty minutes, $[\alpha]^{20}_{D}$ 0°.

3. The rotation was taken on the 1-amine in methyl alcohol

Rotation. 0.4000 g. made up to 15 cc. with methyl alcohol at 20° gave a,, −0.22°; l = 2, $[\alpha]^{20}_{D}$ −4.1°. After refluxing, the following readings were obtained: one hour, $[\alpha]^{20}_{D}$ −2.5°; two hours, $[\alpha]^{20}_{D}$ −1.7'; three hours, $[\alpha]^{20}_{D}$ −0.09'; four hours, $[\alpha]^{20}_{D}$ −0.0'.

3,5-Dimethyl-1-bromobenzene-2-diazoniumborofluoride.—In a 300-cc. beaker was placed 20 cc. of concentrated hydrochloric acid. In this was suspended 5 g. of 3,5-dimethyl-2-amino-1-bromobenzene[6] and the mixture cooled to 0°. The amine was diazotized by addition of a saturated solution of sodium nitrite in slight excess as shown by potassium iodide starch test papers. The diazonium solution was filtered from any sodium chloride and to the filtrate was added 27.6 g. of a solution of hydroborofluoric acid, made by mixing 20 g. of 48% hydrofluoric acid and 7.6 g. of boric acid. Upon addition of the acid, the borofluoride precipitated in white needles. These were filtered off and washed with more hydroborofluoric acid. The yield was 4.5 g. (60%). The decomposition point was 161°.

3,5-Dimethyl-2-fluoro-1-bromobenzene (VII).—A quantity of diazonium borofluoride was placed in a 500-cc. distilling flask set for distillation. The flask was placed in a metal bath and heated to 170°, when decomposition occurred. The borontrifluoride was run through a dilute solution of sodium hydroxide. Water was added to the heated product and the fluorine derivative steam distilled. The yield was quantitative. The 3,5-dimethyl-2-fluoro-1-bromobenzene was purified by distillation: b. p. 87–89" at 11 mm., n^{20}_{D} 1.3100, d^{20}_{20} 1.452.

Anal. Calcd. for C_8H_8BrF: Br, 39.40. Found: Br, 39.85.

3,5-Dimethyl-2-fluoro-4,6-dinitro-1-bromobenzene (VIII).—In a cooled 100-cc. beaker was placed 25 cc. of cold fuming nitric acid (sp. gr. 1.60), and the mixture cooled to 0°. To this was added slowly 3.6 g. of 3,5-dimethyl-2-fluoro-1-bromobenzene. The mixture was allowed to stand for three minutes and was then poured onto ice. A very light yellow substance precipitated, which on purification from 70% alcohol–water mixture melted at 86–87°. The yield was 4.6 g. (88%).

Anal. Calcd. for $C_8H_6O_4BrFN_2$: Br, 27.30. Found: Br, 27.27.

3,5,3',5'-Tetramethyl-2,2'-difluoro-4,6,4',6'-tetranitrodiphenyl (IX).—In a 200-cc. 3-necked, round-bottomed flask, containing a stirrer and a reflux air condenser, was placed 30 cc. of dry nitrobenzene The flask was heated for five hours to 190°, and the contents vigorously stirred. During this time 10 g. of 3,5-dimethyl-2-fluoro-4,6-

---

[6] Wheeler and Thomas, THIS JOURNAL, **50**, 2286 (1928). See also Schiemann, Ber., **60**, 1186 (1927).

dinitro-1-bromobenzene and 10 g. of powdered copper bronze were added in small portions. The mixture was then filtered and the solid washed with acetone. The filtrate was steam distilled and the diphenyl compound was left as a residue. This was washed with alcohol to remove the remaining traces of nitrobenzene and was recrystallized from a 50% acetone–water mixture. It formed long white needles melting at 202–204° (corr.). The yield was 5 g. (69%).

Anal. Calcd. for $C_{16}H_{12}O_8F_2N_4$: N, 13.13. Found: Kjeldahl ($TiCl_3$), N, 12.90.

3,5,3′,5′-Tetramethyl-2,2′-difluoro-4,6,4′,6′-tetraaminodiphenyl (X).—In a 200-cc. beaker, 3.8 g. of the tetranitro compound was dissolved in 30 cc. of boiling acetic acid and 5 cc. of concentrated hydrochloric acid. To the hot solution 3 g. of powdered zinc was added with stirring and then 2 g. of powdered stannous chloride. The solution was allowed to boil for ten minutes and then cooled. Ammonium hydroxide was added to precipitate the zinc and tin salts and free amine. The solid was filtered and extracted with acetone, which dissolved the amine from the mixture. The amine was purified by crystallization from acetone–water mixture. It formed yellow crystals melting at 250–253°. The yield was 2 g. (74%).

Anal. Calcd. for $C_{16}H_{20}F_2N_4$: N, 18.30. Found: Kjeldahl N, 18.02.

Attempts to Prepare Suitable Salts of **3,5,3′,5′-Tetramethyl-2,2′-difluoro-4,6,4′,6′-tetraaminodiphenyl.**—Attempts were made to prepare salts of the tetraamine with *d*-camphorsulfonic acid, d-bromocamphorsulfonic acid and d-tartaric acid. The following solvents were tried: water, acetone, chloroform, petroleum ether, alcohol, ethyl acetate. pyridine and methyl alcohol. In no case did a crystalline salt result. The salts were either too soluble or, when thrown out of solution with some solvent, such as petroleum ether, came out as gummy precipitates. Both di- and tetra-salts were tried for the three acids.

Summary

1. The preparation of 3,5,3′,5′-tetramethyl-2,2′-difluoro-6,6′-diaminodiphenyl is described. The compound was resolved through the dicamphorsulfonate salt.

2. The active forms racemized readily by heating in a neutral solvent such as ethyl or methyl alcohol or more rapidly in glacial acetic acid.

THE EFFECTS OF ACTIVATED AND NON-ACTIVATED MAGNESIUM-COPPER ALLOY ON THE YIELDS OF SOME ORGANOMAGNESIUM HALIDES

BY HENRY GILMAN AND E. A. ZOELLNER

RECEIVED FEBRUARY 2, 1931 PUBLISHED APRIL 6, 1931

Introduction

Activated magnesium-copper alloys containing 12.75[1] and 14.5%[2] of copper are apparently the best known catalysts for initiating reactions between RX compounds and magnesium in ether.[3] It has always been recommended that a small quantity of the catalyst be used to start the reaction, and that subsequently the reaction with the major part of the RX compound be carried out with ordinary magnesium. However, in studies on the preparation of the di-Grignard reagent from *p*-dibromobenzene,[4] it was observed that the highest yield of terephthalic acid (obtained subsequent to carbonation) resulted when a large excess of the activated alloy was used. This and the peculiar effects of the activated alloy and of varying quantities of iodine on the preparation and the yields of phenylmagnesium chloride[5] and other RMgX compounds was the basis for the statement: "Related unusual results with other RX compounds using varying quantities of iodine and alloy will be reported later."[5] We are now reporting some of these results from an as yet uncompleted study. The following paper on the capture of free radicals describes some additional experiments[6] concerned with the effects of an excess of iodine on the yields of some RMgX compounds.

The results here reported indicate that an equivalent of the alloy, either as such or after activation with iodine, decreases the yields of some typical Grignard reagents. The decrease is generally greater with the activated alloy. However, an excess of either the activated or non-activated alloy appears to increase the yield in some cases to those values obtainable when ordinary magnesium turnings or powder is used. For all practical purposes these variations in yield with the use of the alloy are without essential significance because only a very small quantity (usually 0.2 g.) of the activated alloy is used to initiate the reaction. This is established by experiments in which **0.19** to **0.51** g. of activated 12.75% alloy was used at first, the reaction with RX compound being

[2] Gilman and Heck, *Bull. soc. chim.*, 45, 250 (1929).

[3] References to some of the applications by others of the activated alloy are: Hurd and Webb, THIS JOURNAL, 49, 546 (1927); Shepard, Winslow and Johnson, *ibid.*, 52, 2089 (1930).

[4] Gilman, Beaber and Jones, *Rec. trav. chim.*, 48, 597 (1929).

[5] Gilman and St. John, *ibid.*, 49, 717 (1930).

then completed with 1.1 atoms of ordinary magnesium turnings. With 0.19 g. of the activated alloy and n-butyl bromide the yield was 1–4% below normal, and the drop increased to 7% when 0.51 g. of activated alloy was used; with 0.25 g. of activated alloy and benzyl chloride, the yield was decreased 0–3%; and with 0.19 or 0.48 g. of activated alloy and bromobenzene the yield was unaffected.

The depression of the yield is probably not due to a reaction between the alloy and RMgX compound already formed, because in one experiment 1.5 g. of the 12.75% alloy when refluxed for ten minutes with preformed n-butylmagnesium bromide did not lower the yield within experimental error. The drop in yield when more than the recommended quantity of activated alloy is used may be due in part to the iodine or magnesium iodide contained therein, because the following paper shows that iodine or magnesium iodide when used in more than a very small amount or less than a full equivalent also lowers the yield of some Grignard reagents. It appears that a very small, and yet effective, quantity of either iodine or the activated alloy is without essential effect on the yield.

Experimental Part

The apparatus and general technique was that used in related studies.[6] The powdered alloy, as such or activated, was covered with 5 cc. of ether; then 20 drops of the pure RX compound and a crystal of iodine (always used with the non-activated alloy) was added. The mixture was heated for ten minutes by means of a water-bath at 45°. Then the remainder of the halide (a total of 0.05 mole) mixed with 25 cc. of ether, was added over a period of thirty minutes with stirring. After all of the halide had been added, the reaction mixture was stirred for an additional ten minutes.

TABLE I

YIELDS OF RMgX COMPOUNDS FROM UNACTIVATED AND ACTIVATED ALLOYS

Halide (0.5 mole)	Unactivated alloy G.[a]	Unactivated alloy % Yield, RMgX[b]	Activated alloy G.[c]	Activated alloy % Yield, RMgX[b]	Ordinary Mg turnings. % Yield RMgX[d]

[a] One equivalent or 0.05 mole of the alloy is 1.38 g.

[b] Each percentage yield listed is an average of at least two analyses made from one preparation.

---

[6] Gilman, Zoellner and Dickey, THIS JOURNAL, 51, 1676 (1929).

[c] The alloy used here was re-activated. In a few experiments carried out **with** activated alloy which was exposed to a somewhat humid atmosphere for twenty-five minutes after activation and then used directly without re-activation, the yields of *n*-butylmagnesium bromide from *2.0* g. of such alloy were **43.9** and 45%, and bromobenzene did not react. One equivalent of the activated alloy is *1.67* g.

[d] These percentages are taken from the studies described in Ref. 6, wherein ordinary magnesium *turnings* were used. They are, therefore, not comparable **with** the results obtained with the powdered alloy. This finds support in an experiment carried out during the present studies where the yield of phenylmagnesium bromide prepared from **1.33** g. of 100-mesh ordinary magnesium was 97.3%. See, also, Gilman and Fothergill, *Iowa State Coll. J. of Sci.*, *4*, *351* (1930), for the effect of an excess of fine magnesium on the yields of some Grignard reagents. The smaller drop in yield with an excess of the alloy may be due, in part, to the essential presence of an excess of fine magnesium.

[e] The percentages in parentheses are those obtained **with** the 12.75% copper-magnesium alloy of 30–80 mesh. In all other cases the alloy used contained 11.25% copper, and was of *60–200* mesh.

[f] With 6 g. of 12.75% copper–magnesium alloy of 30–80 mesh the yield of benzylmagnesium chloride was practically equal to that obtained with turnings of ordinary magnesium.

Summary

When equivalent quantities of copper–magnesium alloy are used alone, either in the activated or non-activated condition, the yields of some Grignard reagents are lowered. However, small, but effective, quantities of the activated alloy appear to have no significant effect on the yield. The other more commonly used catalyst, iodine, apparently has the same general effect as the alloy on the yields of some Grignard reagents (see following paper).

THE PREPARATION OF ORGANOMAGNESIUM HALIDES IN THE PRESENCE OF MAGNESIUM IODIDE. STUDIES ON THE CAPTURE OF FREE RADICALS

BY HENRY GILMAN AND E. A. ZOELLNER

RECEIVED FEBRUARY 2, 1931 PUBLISHED APRIL 6, 1931

Introduction

One of the current interpretations of the preparation of Grignard reagents involves the prior or intermediate formation of free radicals, after the following representation.

$$\mathrm{RX} + \mathrm{Mg} \longrightarrow \mathrm{R—} + \mathrm{—MgX} \tag{I}$$
$$\mathrm{R—} + \mathrm{—MgX} \longrightarrow \mathrm{RMgX} \tag{II}$$

There are several kinds of evidence for the intermediate formation of free radicals (R—) in accordance with Reaction I. The side reactions that invariably accompany the preparation of RMgX compounds, from RX compounds and magnesium, are best explained by the coupling, disproportionation and rearrangement reactions of the free radicals.[1] Furthermore, there is direct experimental evidence in support of Reaction II, inasmuch as it has been shown[2] that triarylmethyls, like $(C_6H_5)_3C—$, will combine with the hypothetical —MgX or its equivalent (the binary system, Mg + MgX_2, of Gomberg) to give triphenylmethylmagnesium halide, $(C_6H_5)_3CMgX$.

However, because triarylmethyls are, in a sense, a special class of free radicals, it was felt that a more complete case for Reaction II would be had if another type of free radical, as yet not isolated, were captured incidental to the formation of RMgX compounds. For this purpose, a study was first made of the reaction between *tert.*-butyl chloride and magnesium in either. Under ordinary conditions it is very difficult to get a satisfactory yield of *tert.*-butylmagnesium chloride[3] because of the marked tendency of the hypothetical intermediate *tert.*-butyl radicals to undergo coupling and, particularly, disproportionation to isobutane and isobutylene.

One way of capturing the *tert.*-butyl radicals is to have present, during the reaction between *tert.*-butyl chloride and magnesium, the —MgX (or the binary system, Mg + MgX_2). A procedure of this kind was successful in contributing to the improvement of the yield of triphenylmethylmagnesium chloride;[4] and, as already stated,[2] the independent systems, R— and —MgX, have been combined to give triphenylmethylmagnesium halides. When, however, this principle was employed in the preparation of *tert.*-butylmagnesium chloride we either did not capture the intermediate *tert.*-butyl radical, or having captured it we did not hold it for long because the yields of *tert.*-butylmagnesium chloride were, in general, actually reduced. In short, the binary system (Mg + MgI_2) did not make it possible to obtain a yield of *tert.*-butylmagnesium halide in excess of that obtained under optimal conditions when none of the binary system was purposefully added; but a trace of iodine (or of MgI_2 or (Mg + MgI_2)) or a full equivalent of the binary system did give a yield equal to that obtained when no magnesium iodide was added, and intermediate quantities depressed the yield—the greatest lowering being observed with about 0.25 equivalent of the binary system per equivalent of RX compound. This depression of yield very probably occurs in the early stages of the formation of the RMgX compound, inasmuch as magnesium or magnesium iodide or a combination of the two is without essential effect on the *tert.*-butylmagnesium chloride after it is once formed. Apparently the same sort of a depression, but to a less marked extent,

occurs with n-butylmagnesium bromide. It would be unwise to generalize from these two illustrations because of the frequently observed distinct differences between apparently related organomagnesium halides.

From the preliminary report now made, it follows that the generally used catalyst (iodine) has a deleterious effect on the yield unless used in very small quantities or in very large quantities. A like phenomenon is reported in the preceding paper,[5] when another more recent catalyst, the activated magnesium–copper alloys, is used. Fortunately, these effects are of no apparent serious moment from a practical viewpoint because the catalysts are almost always used in very small quantities merely to initiate reaction between a part of the RX compound and magnesium. In this connection it is interesting to recall that the time required to prepare phenylmagnesium chloride in ether solution decreases in a regular manner with the increase of iodine.[6]

Experimental Part

The apparatus and general technique was that used in related studies.' In the n-butylmagnesium bromide experiments the 30–80 mesh magnesium was first covered with 16 cc. of ether; then the selected quantity of iodine was added; when the iodine color disappeared, 20 drops of the n-butyl bromide was added directly without a solvent; the mixture was then refluxed for ten minutes; and, finally, the remainder of the halide (totaling 0.05 mole) in 21 cc. of ether was added with stirring at a uniform rate over one hour.

A variation of this procedure was used with the *tert.*-butylmagnesium chloride experiments. Because preliminary experiments showed that erratic results generally followed the addition of the chloride to the magnesium and magnesium iodide in ether, a part of the selected quantity of iodine was added subsequent to the formation of the major portion of magnesium iodide and subsequent to the addition of 20 drops of the chloride. In this manner the reaction between the *tert.*-butyl chloride and magnesium set in smoothly and there was no difficulty in getting concordant results. With each halide the quantity of fine magnesium used was one atom equivalent for each atom equivalent of iodine, in addition to one atom per mole of n-butyl bromide and three atoms per mole of *tert.*-butyl chloride.

The results of the experiments are contained in Table I. The average values are those of at least two preparations from each of which at least two aliquots were removed for titration, The agreements were of an uncommonly high order when one considers the great sensitivity of an RMgX compound like *tert.*-butylmagnesium chloride.

[5] Gilman and Zoellner, THIS JOURNAL, 53, 1581 (1931).

[6] Gilman and St. John, Rec. *trav. chim.*, 49, 717 (1930).

[7] Gilman, Zoellner and Dickey, THIS JOURNAL, 51, 1576 (1929).

A like degree of duplicability of results with *tert.*-butylmagnesium iodide prepared in the presence of magnesium iodide was not observed in a few preliminary experiments. Here the yields of RMgI compound in two independent preparations using 0.08 g. or 0.0125 atom equivalent of iodine were 57.0 and 52.3%; and with 6.35 g. or 1.0 atom equivalent of iodine, the yields were 55.1 and 58.4%. These experiments with the iodide were carried out because of the possibility of magnesium iodide reacting with *tert.*-butyl chloride or *tert.*-butylmagnesium chloride to give *tert.*-butylmagnesium iodide.

TABLE I

EFFECT OF IODINE ON YIELD OF *n*-BUTYLMAGNESIUM BROMIDE AND *Tert.*-BUTYLMAGNESIUM CHLORIDE

Iodine			
G.	Atom equivalent	Av. % yield of n-C_4H_9MgBr	Av. % yield of $(CH_3)_3CMgCl$
None	None	**95.9"**	**83.3**
0.08	**0.0125**	**96.5"**	**83.6**
16	.025	..	**77.1**
.32	**.05**	**95.6**	**72.2**
.64	.1	**93.5**	**65.5'**
1 28	.2	**92.6**	**64.9**
1.90	.3[c]	**96.0**	**64.8**
2.54	.4	**94.9**	**71.8**
3.81	.6	**95.1**	**76.2**
6.35	1.0	**96.4**	**79.7**

[a] With **0.04** g. or **0.0063** equivalent of iodine the yield was **99%.** This unusually high value was checked. Further work is in progress on the effect of very small quantities of iodine on the yields of some other RMgX compounds.

[b] The low yield by titration was confirmed in a carbonation experiment with this relative quantity of iodine and with the **0.08** g. of iodine experiment which gave the 83.6% of Grignard reagent. It is interesting to note that this very high yield of RMgCl makes it possible to obtain trimethylacetic acid from it by carbonation in a **75%** yield.

[c] In the experiments using **0.3** or more atom equivalent of iodine, it was necessary to cover the magnesium with **35** cc. and not **16** cc. of ether. This, however, is without apparent effect on the relative yields because there was no change in yield when some of the preparations using less than **0.3** atom equivalent of iodine were carried out with 35 cc. instead of **16** cc. of ether.

Summary

In studies concerned with the capture of free radicals formed during the preparation of organomagnesium halides it has been shown that the quantity of iodine used to catalyze the formation of *tert.*-butylmagnesium chloride has a significant effect on the yield. There is no appreciable lowering of yield with a very small amount or a full atom equivalent of iodine. Another catalyst, the magnesium–copper alloy which is used with more refractory RX compounds, also appears to have a corresponding effect on the yields of other RMgX compounds.

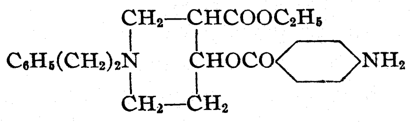
N-METHYL-N-PHENYLALKYL-AMINO-ALKYL BENZOATES AND PARA-AMINOBENZOATES

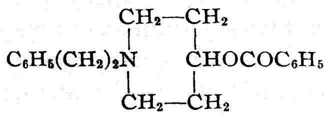
BY ARTHUR C. COPE AND S. M. MCELVAIN

RECEIVED FEBRUARY 2, 1931 PUBLISHED APRIL 6, 1931

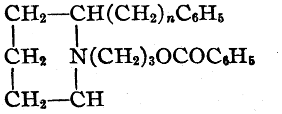
All of the pharmacological data resulting from studies of the various types of local anesthetics which have been prepared in this Laboratory have shown very definitely that unusually powerful local anesthetic action is associated with those compounds containing a phenylalkyl group attached to the basic nitrogen atom. For example, 1-phenylethyl-3-carbethoxy-4-piperidyl *p*-aminobenzoate[1] (I) and 1-phenylethyl-4-piperidyl benzoate[2] (II) show, respectively, about two and seven times the power of cocaine for mucous membrane anesthesia.



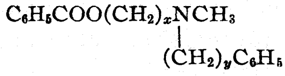
I



II



III



$C_6H_5COO(CH_2)_xNCH_3$ / $(CH_2)_yC_6H_5$

IV

Compounds of type III in which *n* is 1 or 2, were found[3] to be extraordinarily potent anesthetics, producing in 2% solution anesthesia of the rabbit's cornea that lasted from five to six days. When, however, the phenylalkyl substituent of the piperidine ring was shifted from the 2-position to the 4-position, there was a considerable diminution of the anesthetic action. This latter observation suggested that for maximum anesthetic effect the optimum number of carbon atoms in the chain between the phenyl group and the nitrogen atom would be less than five.

For this reason it seemed desirable to prepare and submit for pharmacological study a series of compounds of the procaine type in which various phenylalkyl groups would be attached to the nitrogen atom. This paper gives the preparation and a brief pharmacological report of a series of N-methyl-N-phenylalkyl-aminoalkyl benzoates (IV) in which x is 2 and 3 and y is varied from 1 to 4.

These compounds were prepared by condensing β-chloroethyl and γ-chloropropyl benzoates with the N-methylphenylalkylamines, which were

[3] Bailey and McElvain, *ibid.*, 52, 1633 (1930).

obtained from the hydrolysis of the N-methyl-N-phenylalkyl p-toluenesulfonamides. The benzoates were isolated as the hydrochlorides.

When an attempt was made to evaluate these benzoate hydrochlorides pharmacologically it was found that they produced an excessive amount of irritation in the rabbit's eye; consequently their anesthetic effect was so uncertain that any comparison on the basis of this property would have no particular meaning. For this reason the corresponding p-aminobenzoates were prepared in the hope that the increased basicity of the molecule would eliminate this undesirable property of the benzoates.[4] The *p*-aminobenzoates were obtained by the reduction of the corresponding *p*-nitrobenzoates. On account of the difficulties encountered in the purification of these *p*-aminobenzoates some were isolated as the monohydrochlorides and others as the dihydrochlorides.

Experimental Part

All boiling and melting points herein given are corrected.

Phenylalkylamines.—Benzylamine was prepared from benzyl chloride and hexamethylenetetramine according to the procedure of Delépine.[5] β-Phenylethylamine, γ-phenylpropylamine and δ-phenylbutylamine were prepared by the catalytic reduction of the corresponding cyanides by the method described by Carothers and Jones.[6]

N-Methylphenylalkylamines.—These amines were prepared from the phenylalkylamines by the method of Carothers, Bickford and Hurwitz.[7] This method involves the preparation of the N-phenylalkyl p-toluenesulfonamides, the methylation of these sulfonamides with methyl iodide to the N-methyl-N-phenylalkyl p-toluenesulfonamides and the hydrolysis of these latter compounds to the N-methylphenylalkylamines. The N-methylbenzylamine and N-methyl-β-phenylethylamine and the intermediate sulfonamides from which the amines were obtained have been described by these authors. The intermediate sulfonamides obtained in the preparation of N-methyl-γ-phenylpropylamine and N-methyl-δ-phenylbutylamine are new compounds and are summarized in Table I. There was one modification of the procedure necessary for the purification of the N-methyl-N-phenylalkyl p-toluenesulfonamides that should be noted. It was found that the N-methyl sulfonamides as obtained from the methylation reaction when the phenylalkyl group was phenylpropyl and phenylbutyl could not be caused to crystallize as they did when the phenylalkyl group was benzyl and phenylethyl. If, however, these oily sulfonamides were distilled under diminished pressure, the distillate solidified and could be recrystallized as easily as the lower homologs.

3	53.26	53.27	8.58	8.51	126.2–126.8	17.76	17.73

[a] The following melting points have been reported in the literature for this hydrochloride: 152–154" [Johnson and Guest, *Am. Chem. J.*, **42**, 340 (1909)]; 154–156" [Decker and Becker, *Ber.*, **45**, 2408 (1912)]; 156–157° [Decker and Becker, *Ann.*, **395**, 367 (1913)]; 155–157° [Hamilton and Robinson, *J. Chem. Soc.*, **109**, 1034 (1916)].

[b] This compound has been prepared [v. Braun, *Ber.*, **43**, 3216 (1910)] by the action of cyanogen bromide on N,N-dimethyl-γ-phenylpropylamine and was found to boil at 110° (17 mm.).

N-Methyl-N-phenylalkylaminoalkyl Benzoate Hydrochlorides.—Each of the secondary amines described in the preceding section was condensed with β-chloroethyl and γ-chloropropyl benzoates according to a method previously described.[8] The benzoates obtained were isolated as the hydrochlorides, which were formed by passing dry hydrogen chloride into an ether solution of the amino ester. These hydrochlorides were purified by recrystallization from the solvents indicated in Table III. The N-methyl-N-phenylalkyl-aminoethyl benzoates required additional purification by treatment with benzoyl chloride in the presence of sodium hydroxide in

---

[8] McElvain, THIS JOURNAL, **49**, 2837 (1927).

order to remove unreacted secondary amine. The yields of pure hydrochlorides were 50–75% of the theoretical. The data for these compounds are summarized in Table III.

β-Chloroethyl and **γ-Chloropropyl *p*-Nitrobenzoates.**—These esters were prepared by heating ethylene chlorohydrin and trimethylene chlorohydrin with *p*-nitrobenzoyl chloride. The chloroethyl ester after purification melts at 55–56°.[9] The chloropropyl ester does not appear to have been described in the literature It boils at 168.5–169.5° (2 mm.), is a liquid at ordinary temperatures, d^{25}_{25} 1.3222, n^{25}_{D} 1.54736, M_D calcd., 57.91, found, 58.44. *Anal.* Calcd., Cl, 14.55. Found: Cl, 14.74

N-Methyl-N-phenylalkyl-aminoalkyl *p*-Nitrobenzoate Hydrochlorides.—While good yields of these hydrochlorides were obtained from the condensation of the chloro esters with N-methylbenzyl, β-phenylethyl, and δ-phenylbutylamines, the products of similar condensations with N-methyl-γ-phenylpropylamine could not be purified. Consequently the N-methyl-y-phenylpropylamine was condensed with ethylene and trimethylene chlorohydrins, and the tertiary amino alcohols thus produced were esterified with p-nitrobenzoyl chloride. This procedure gave the hydrochlorides of the *p*-nitrobenzoates of these amino alcohols in about 90% yields. The amino alcohols are described below.

TABLE III

N-METHYL-N-PHENYLALKYLAMINO-ALKYL BENZOATE HYDROCHLORIDES

$C_6H_5COO(CH_2)_xNCH_3$ / $C_6H_5(CH_2)_y$

x	y	Formula	M. p., °C.	Recryst. solvent	% Cl Calcd.	% Cl Found
2	1	$C_{17}H_{20}O_2NCl$	145.6–146.4	Ether + EtOH	11.60	11.72
2	2	$C_{18}H_{22}O_2NCl$	134.2–134.8 (Softens at 114)	EtOH	11.09	11.14
2	3	$C_{19}H_{24}O_2NCl$	106.3–107.1	*n*-BuOH	10.62	10.68
2	4	$C_{20}H_{26}O_2NCl$	106.9–107.5	*n*-BuOH	10.20	10.29
3	1	$C_{18}H_{22}O_2NCl$	145.4–146.3	EtOH	11.09	11.06
3	2	$C_{19}H_{24}O_2NCl$	128.8–129.4	EtOH	10.62	10.64
3	3	$C_{20}H_{26}O_2NCl$	117.5–118.3	*n*-BuOH	10.20	10.27
3	4	$C_{21}H_{28}O_2NCl$	124.7–125.7	*n*-BuOH	9.80	9.85

As in the case of the benzoates the condensation was more complete with y-chloropropyl p-nitrobenzoate than with β-chloroethyl *p*-nitrobenzoate, making purification of the product by treatment with benzoyl chloride as well as by recrystallization necessary in the latter case. The yields of purified products were 45–70% of the theoretical.

N-Methyl-N-y-phenylpropylaminoethanol.—Fen *g.* (0.1 mole) of N-methyl-γ-phenylpropylamine and 4.05 g. (0.05 mole) of ethylene chlorohydrin were condensed by heating for four hours at 100–120°. On diluting the reaction mixture with ether a yield of 9.35 g of **N-methyl-y-phenylpropylamine** hydrochloride was obtained after filtering and drying. The ether solution of the tertiary amino alcohol was dried over

N-Methyl-N-phenylalkylaminoalkyl *p*-Aminobenzoate Hydrochlorides.—Those paminobenzoates which are tabulated in Table V as the monohydrochlorides were prepared by the catalytic reduction of the corresponding *p*-nitrobenzoates by a procedure previously described.[4] The other p-aminobenzoates shown in Table V could not be obtained crystalline from the catalytic reduction either as the monohydrochlorides or as the dihydrochlorides. It was possible, however, to obtain these aminobenzoates as crystalline dihydrochlorides from the reduction of the nitrobenzoates with iron. The procedure consisted simply of stirring the hydrochloride of the *p*-nitrobenzoate into a paste made from ten times its weight of iron powder, water, and a small amount of dilute hydrochloric acid until the heat of reaction subsided, extracting the free base with benzene, and precipitating the dihydrochloride from this benzene solution with dry hydrogen chloride. It was not possible to obtain an analytically pure

hydrochloride of N-methyl-N-6-phenylbutylaminoethyl *p*-aminobenzoate from either of the reduction procedures. The yields of the monohydrochlorides after purification from the catalytic reduction were 60–70% and of the dihydrochlorides from the iron reduction 50–95% of those theoretically possible. The hydrochlorides of the p-aminobenzoates are summarized in Table V.

Pharmacological Report

The N-methyl-N-phenylalkylamino-alkyl benzoates and *p*-aminobenzoates are being studied pharmacologically by Mr. Charles L. Rose of The Lilly Research Laboratories, Indianapolis, Indiana. The preliminary pharmacological observations are summarized in Table VI. The corneal anesthesia values were determined by application of a solution of the anesthetic to the rabbit's cornea and noting the duration of anesthesia. In this determination a 2% solution of the benzoate hydrochlorides was used in each case, but with the p-aminobenzoates a 1% solution of the monohydrochloride was used on account of the low solubility of certain members of this series. The monohydrochlorides of those p-aminobenzoates which are listed in Table V as the dihydrochlorides were obtained by dissolving the latter salt in water and titrating off one of the

[a] For those compounds in which AR is phenyl a 2% solution was used and for those in which AR is p-aminophenyl a 1% solution was used. [b] The doses producing the values in this column were 0.1 cc. of a 1% solution.

halogen acid molecules with standard alkali. On account of the uncertain corneal anesthesia values obtained with the benzoate hydrochlorides, the infiltration anesthesia values for these compounds as determined from intracutaneous injection into the guinea pig are included in Table VI. The toxicities as determined by subcutaneous injection into white mice and by intravenous injection into white rats are reported as minimum lethal doses in milligrams per kilogram body weight. The anesthetic and toxicity values for cocaine and procaine are included in the table for comparison.

Discussion of the Pharmacological Data.—As pointed out above, the excessive amount of irritation which was caused in the case of each of the benzoate hydrochlorides when applied to the rabbit's cornea does not allow for very much, if any, significance to be attached to these values in the above table. This undesirable property which was so pronounced in the benzoate series is entirely absent in the p-aminobenzoate series.

There is some indication from the data in Table VI that maximum anesthetic effect is associated with certain intermediate sizes of the phenylalkyl groups in some of the more closely related groups of compounds. For example, with the aminopropyl benzoates (AR is phenyl and x is 3) the maximum infiltration anesthetic effect is shown by the phenylpropyl group (where y is 3), and in the p-aminobenzoate group where x is 2 the maximum corneal anesthesia value is found where the nitrogen substituent is a phenylethyl group. Unfortunately for any generalization a similar relationship does not exist in the infiltration anesthesia values for the aminoethyl benzoates (AR is phenyl, x is 2) or in the corneal anesthesia values for the aminopropyl p-arninobenzoates (AR is p-aminophenyl, x is 3).

The extremely low toxicities of the N-methyl-N-phenyl-alkyl benzoates are worthy of note. As a group they are much less toxic than procaine both subcutaneously and intravenously. The corresponding p-aminobenzoates show a decidedly different and most unusual toxic effect. Their intravenous toxicities are rather low as a group, certain ones approaching the toxicity of procaine. The subcutaneous toxicities, however, are considerably' higher than would be expected from the intravenous values. An outstanding case is the N-methyl-N-benzylaminoethyl *p*-aminobenzoate. This compound is about 80% as toxic as procaine intravenously but is over twice as toxic subcutaneously. It is quite probable that this unusual behavior is due to the very rapid absorption of the p-aminobenzoates when they are injected subcutaneously.

Summary

A series of local anesthetics of the formula, $ARCOO(CH_2)_xN(CH_3)(CH_2)_yC_6H_5$, in which AR is phenyl and p-aminophenyl, x is 2 and 3, and y is varied from 1 to 4 has been prepared and described.

A brief report of the preliminary pharmacological study of these compounds together with a discussion of some relationships between their structure and pharmacological action is given.

PREPARATION OF DICHLOROACETIC ACID

BY HOWARD WATERS DOUGHTY AND GERHARD JULIUS DERGE[1]

RECEIVED FEBRUARY 3, 1931 PUBLISHED APRIL 6, 1931

In **1925** Doughty and Black[e] described the preparation of dichloroacetic acid by the reaction of copper powder with trichloroacetic acid or aniline trichloroacetate, in benzene. They obtained yields of aniline dichloroacetate, from which they prepared dichloroacetic acid, up to 75% of the theoretical. Other experimenters have used this method with varying success, and the irregularity of yield, as reported privately to the senior author, has led to a reëxamination of the procedure by the present authors. We first repeated the procedure of Doughty and Black and found that when insufficient hydrogen chloride is used for complete saturation in precipitating the copper chlorides and aniline hydrochloride, a complex substance containing copper and aniline is formed, which is unsatisfactory to work with. We did, however, obtain yields from 50 to **70%** of the theoretical, without making especial effort for maximum yield.

The reaction of trichloroacetic acid in aqueous solution on various metals has been studied to some extent in this Laboratory, and in **1929** Doughty and Lacoss[3] showed that the reaction between trichloroacetic acid and zinc in water proceeds quantitatively according to the equation

$$2CCl_3COOH + 2Zn = (CCl_2HCOO)_2Zn + ZnCl_2$$

and it has also been found* that cadmium, iron and copper act similarly with trichloroacetic acid in aqueous solution, while with magnesium and aluminum considerable quantities of hydrogen are formed and the reaction is evidently more complicated. In view of the difficulties which have been reported in obtaining consistent yields by the method of Doughty and Black, we decided to investigate the reaction in aqueous solution and, if practicable, develop a procedure for the preparation of dichloroacetic acid, though earlier attempts in this direction have given low yields. It seemed possible that the hydrolysis of trichloroacetic acid to chloroform and

---

[1] The work here reported is in partial fulfilment of the requirement for "Honors in Chemistry" by Gerhard J. Derge. The work has been checked by Howard W. Jones, to whom we wish to express our thanks.

[2] Doughty and Black, THIS JOURNAL, 47,1091 (1925).

[3] Doughty and Lacoss, *ibid.*, 51,852 (1929).

[4] Unpublished work by H. W. Doughty.

carbon dioxide might be the cause of the low yield, and that proper control of temperature might give better results. We therefore made a preliminary study of the hydrolysis of trichloroacetic acid as affected by temperature.

Hydrolysis of Trichloroacetic Acid.—At room temperature hydrolysis is very slow. A 1.007 molar solution of trichloroacetic acid in water was prepared on February 13. On May 10 it was found to be 0.9856 molar. Other determinations were made at approximately 60 and at 100°. The temperature control at 60° was within two or three degrees, and at the higher temperature the solution was simply boiled with return condenser, portions being removed from time to time for analysis. The velocity constants were calculated as for a first order reaction, as the water concentration remains constant, using the equation $k = (1/t) \log [a/(a-x)]$, where t is elapsed time in minutes, a is the original concentration of trichloroacetic acid, x is the moles of chloroform per liter produced, and therefore $a - x$ is the concentration of trichloroacetic acid at time t.

TABLE I

HYDROLYSIS OF TRICHLOROACETIC ACID AT 100°

t	Concentration of CCLCOOEI + HCI	Concentration of HCl	$(a - x) =$ Concentration of CCl_3COOH	k
0	0.9656 = a	0.0000	0.9656	
30	.7490	.0105	.7385	0.0039
90	.4669	.0190	.4479	.0037
330	.0774	.0341	.0433	.0040

Apparently there was some hydrolysis of the trichloromethyl group, either of the trichloroacetic acid or the resultant chloroform, as indicated by the hydrochloric acid found. Correction was made for this by subtracting the concentration of hydrochloric acid from the total acid found.

TABLE II

HYDROLYSIS OF TRICHLOROACETIC ACID AT 60°

t	Concentration of $CCl_3COOH + HCl$	Concentration of HCl	$(a - x) =$ Concentration of CCl_3COOH	k
0	0.9469	0.000	0.9469	
90	.9332	.0040	.9292	0.000091
240	.9101	.0087	.9014	.000088

From these results the temperature coefficient of the hydrolysis is found to be $k_{(t+10)}/k_t = 2.576$. Evidently the loss by hydrolysis would be relatively small if the temperature is kept at about 60° during the reaction of trichloroacetic acid with copper. The following procedure was accordingly adopted.

Preparation of Dichloroacetic Acid.—A solution of 55 g. (one-third mole) of trichloroacetic acid in 450 cc. of water is placed in a one-liter flask, which is provided with a mechanical stirrer and thermometer. The stirring is started at once, 35 g. of copper powder (approximately 0.5 gram atomic weight) is added, and the temperature raised to 60°. (As stated in previous communications, we have found the so-called "dark copper bronze" powder used by decorators to be very satisfactory for use in this connection.) The reaction is quite strongly exothermic, and the heating may be discontinued after the desired temperature, 60°, is reached. After stirring for about one hour and a half, the solution is heated to boiling for about one hour, during which the solid portion of the mixture changes in color from a dirty green to white, due to the action of the excess of copper on the cupric chloride, precipitating cuprous chloride. This reaction always occurs to some extent, and unless an excess of copper is used over the amount calculated in terms of the corresponding reaction with zinc, trichloroacetic acid is found in the product. After the precipitate has become white and shows no excess copper, the mixture is cooled to allow maximum separation of cuprous chloride. It is then filtered and washed with small amounts of cold water. The filtrate is now saturated with hydrogen sulfide until the precipitation of copper sulfides is complete. The precipitate is removed by filtering with suction, washed, and the filtrate, which should be colorless or slightly yellow, is distilled under diminished pressure. The portion which boils above 50° at 20 mm. is fractionated at 20 mm. Dichloroacetic acid boils at 102° (20 mm.). The whole dilute solution of dichloroacetic acid is distilled under diminished pressure, as otherwise the yield is not satisfactory. This appears to be due to the presence of the hydrochloric acid formed during the precipitation of the copper sulfides, as experiment has shown that at 100° the hydrolysis of dichloroacetic acid is not more than 10% in twenty-four hours. The yield by this procedure is about 80%.

To check the purity of the product, the acid thus prepared was analyzed by titration with sodium hydroxide, and 2.1006 mg. moles of dichloracetic acid required 2.0848 mg. moles of sodium hydroxide, indicating 99.25% purity. The density of the acid was found, by pycnometer, to be d_{22}^{22} 1.5594. Perkin[5] gives d_4^4 1.5843 and d_{25}^{25} 1.5604, and Doughty and Black[2] found d_{20}^{20} 1.5666 and d_4^{20} 1.5634.

The melting point of our acid was between 5 and 6°. The melting point of dichloroacetic acid as given in successive issues of Beilstein is variously recorded as −4, −10.8, +10.8° and finally as reported by Kendall,[6] −4.1° and +9.7° according to the rate of cooling and the degree of undercooling. Under ordinary conditions, therefore, the melting point of this acid cannot be regarded as a criterion of purity.

Summary

A simple and convenient method is described for the preparation of dichloroacetic acid by the reaction of copper with trichloroacetic acid in aqueous solution.

The hydrolysis of trichloroacetic acid has been studied at 60° and at 100° and the temperature coefficient found to be *2.576.*

NEW SOURCES OF INULIN[1]

BY E. YANOVSKY AND R. M. KINGSBURY

RECEIVED FEBRUARY 3, 1931 PUBLISHED APRIL 6, 1931

In spite of the fact that inulin was discovered 125 years ago[2] and that voluminous literature has appeared since that time,[3] both the chemical nature of inulin and its physiological significance are but little understood.

Inulin, prepared originally from elecampane (*Inula helenium*), has been since detected in a great many plants, mostly of the family *Compositae*. For actual preparation of quantities of inulin, only a few plants have been used, among which dahlia (Dahlia *variabilis*), Jerusalem artichoke (*Helianthus tuberosus*), chicory (*Cichorium intybus*) and dandelion (*Taraxacum officinale*) are by far the most important. Dean[4] prepared inulin from burdock roots (*Lappa minor*) and the roots of goldenrod (*Solidago*).

Although the similarity of inulin prepared from different sources was evident, the identity of products of different origin was averred by some investigators and denied by others. The question was finally settled by Tanret,[5] who fractionated the inulin from the Jerusalem artichoke into five—as he believed—distinct compounds, varying in their molecular complexity, specific rotation (−17 to −39°), and the degree of solubility in water and dilute alcohol. Some doubt may be felt as to the existence of Tanret's compounds as definite chemical individuals; the existence, however, of a series of complex anhydrides of levulose—by whatever name we may call them—was established beyond doubt. Dean[4] suggested that the name inulin be limited to the fraction of specific rotation between −33 and −40°, and that the compounds of lower levorotatory power and higher solubility be called levulins. This suggestion, however, does not seem to constitute an improvement over Tanret's classification, since it is apparent that a compound whose specific rotation varies 7° cannot be called a chemical individual. For the time being, until the chemistry of the group

[3] No attempt will be made in this article to review the literature on the subject. The reader is referred to Dragendorff's "Materialien zu einer Monographie des Inulins," 1870; and articles by Kiliani, *Ann.*, 205, 145 (1880); Willaman, *J. Biol. Chem.*, 51, 275 (1922); Harding, Sugar. 636 1923; and others, who quote extensively the literature on the subject.

[4] Dean, *Am. Chem.* J., 32, 69 (1904).

[5] Tanret, *Bull. soc. chim.*, 9, 200, 227, 622 (1893); also Colin, *Rev. Gen. Bot.*, 31, 75, 179, 229, 277 (1919).

is better known, we may speak of the inulin group or inulin compounds as comprising all complex anhydrides of levulose.

In view of the fact that the practical sources of inulin are limited in number, we thought it would be advisable to call the attention of investigators in this line to some new sources of inulin, found in the course of systematic investigation of carbohydrates of uncultivated plants indigenous to the United States.

Inulin from Camas Roots.—Camas roots—*Quamasia quamash* (Pursh) Coville (*Camassia esculenta* Lindl.)[6]—were extensively and to a certain extent still are used for food by the North American Indians. The roots were cooked in stone-lined pits in the ground to a sweet, molasses-like sirup, or were roasted and ground into flour. Camas can be found in large quantities in Colorado, Utah, Idaho, Montana, Washington, Oregon and California. It is used as an ornamental plant in France.[7]

Results of analyses of camas roots received from different parts of the country are given in Table I.[8]

[8] We wish to acknowledge our indebtedness for furnishing us with roots to Professor H. St. John, at the time with State College of Washington, Pullman, Wash., and to the following members of the U. S. Forest Service: R. H. Rutledge, Regional Forester, Ogden, Utah; S. W. Stoddard, Supervisor, Targhee National Forest, St. Anthony, Idaho; E. N. Kavanagh, Asst. Regional Forester, Portland, Ore.; G. D. Brown, Supervisor, Fremont National Forest, Lakeview, Ore.; Evan W. Kelley, Regional Forester, Missoula, Mont.; and K. D. Flock, Chief of Party, G-Surveys, Monarch, Mont.

An extract of camas root prepared for sugar analysis showed a rotation of –2.75′ V. in a 2-dm. tube. After hydrolysis, the rotation was –6.7°. The rotation of other solutions taken from different samples of roots was as follows

Before hydrolysis........ ...	–2.0°	–2.6"	–2.4°	–2.4°
After hydrolysis...... . .	–5.6°	–6.1°	–6.5°	–6.5"

When it is taken into consideration that the specific rotation of inulin is about –35° and the specific rotation of levulose is –92°, the figures given above indicate that most (if not all) of the "non-reducing sugar" in camas roots is present in the form of inulin. Both the root and its extract give a positive Seliwanoff's reaction.

Owing to the presence of pectin-like gum in camas roots, the usual extraction of inulin with water is inconvenient, and the following method was used.

Two hundred grams of bulbs, put through a meat chopper, was extracted by heating with 1 liter of 50% alcohol and a little calcium carbonate. It was then made up to 2 liters with 95% alcohol and filtered. Eighteen hundred cubic centimeters of the filtrate was evaporated to about 400 cc. The solution was treated with neutral lead acetate and, after filtering, deleaded either with hydrogen sulfide or sodium carbonate. It was then evaporated to a thin sirup, and several volumes of 95% alcohol was added. After a few hours the alcohol was poured off the precipitated gummy material and some absolute alcohol added. After the gum had hardened it was dried in vacuo at about 70°. The spongy material obtained was easily ground to a white powder. The yield was 30–31 g. Various preparations of the material thus obtained had a specific rotation of –23.0 to –29.0°; 80 to 90% of it was non-reducing sugar (inulin); 2 to 3% reducing sugar was present, and the rest was mostly moisture and ash. On dissolving the inulin in a very small amount of water and reprecipitating it with a large volume of alcohol, a product of specific rotation of –33.0′ was obtained. It had no trace of reducing sugar. The inulin thus obtained was *soluble* in *cold water and 60% alcohol.* The latter dissolves about 5% inulin at room temperature. It resembled somewhat the inulin from asphodel, described by Colin and Neyron de Méons,[9] although the asphodel inulin had a considerably lower specific rotation.

Inulin from Allium nuttallii S. Wats.—This variety of wild onion was used for food by various Indian tribes. The Cheyennes boiled it with meat.[10] A sample received from Nebraska (April, 1930) showed the following content of reducing and non-reducing sugars.

[9] Colin and Neyron de Méons, *Compt.* rend., 185, 1604 (1927).

[10] Grinnell, "The Cheyenne Indians." 1923, Vol. II, p. 171.

	%	On dry basis. %
Moisture	69.8	..
Reducing sugar	1.7	5.6
Non-reducing sugar	18.1	59.9

A solution of sugars prepared from the bulbs had a rotation of —5.5' V. in a 2-dm. tube. On hydrolysis the rotation changed to —12.5'. Seliwanoff's reaction was positive.

Two hundred grams of bulbs, put through a meat chopper, was extracted with about 2 liters of cold water. After filtering and washing the pulp, the solution was treated with neutral lead acetate. The excess of lead was removed with hydrogen sulfide. Excess hydrogen sulfide was removed by a stream of air. The solution was filtered with decolorizing carbon and evaporated in vacuo to a thin, colorless sirup. Several volumes of 95% alcohol was added. The amorphous precipitate was dried in vacuo. The yield was 25 g. of white powder. Without further purification the specific rotation was $[\alpha]^{20}_{\mathrm{D}}$ —31'. The inulin thus obtained was soluble in cold water and 70% alcohol (5% solution).

Both camas roots and wild onions belong to the family of *Liliaceae,* which has been little investigated for its inulin contents.[11]

The third source of inulin we came across—*Balsamorrhiza sagittata* (Pursh) Nutt—belongs to the family *Compositae,* known to contain many inulin-bearing plants. Although, at certain stages of growth, balsam root apparently contains a great deal of inulin,[12] it cannot be considered a very good practical source of inulin on account of the heavy bark and the woody structure of the root itself. The root, however, has been used for food and medicinal purposes by the Indians.[13]

The decorticated root had the following content of reducing and non-reducing sugars

Source and date recd.	Moisture, %	Reducing sugar (calcd. as dextrose)		Non-reducing sugar (calcd. as sucrose)	
			On dry basis		On dry basis
Utah, July, 1929	7.0	10 6	11.4	9.3	10.1
Wyoming, August, 1929	9.0	12.4	13.6	9.0	9.9
Utah, May, 1930	8.8	2.1	2.3	6.2	6.8

A solution of sugars prepared from the root had the optical rotation —1.2' V. in a 2-dm. tube. After hydrolysis the rotation was —3.3'.

---

[11] Chevastelon [Dissertation, Paris, 1894, quoted through four-page abstract, J. *Pharm. Chim.*, 2, 83 (1895)] prepared from garlic inulin of sp. rot. −39°, very soluble in cold water and 70% alcohol. Similar preparations were made from hyacinth and other representatives of the Lily family.

[12] Inulin crystals were found by V. A. Pease, Associate Microscopist, Bureau of Chemistry and Soils, and George L. Keenan, Microanalyst, Food and Drug Administration, U. S. Department of Agriculture, in the course of histological and microchemical study of this plant (unpublished records).

[13] Yanovsky, THIS JOURNAL, 52, 3446 (1930).

Seliwanoff's reaction was positive. One hundred grams of powdered root was treated in the way described for *Allium nuttallii.* The inulin obtained was redissolved in water and reprecipitated with alcohol. The yield was 3.2 g. The specific rotation was –27.7°. The product was soluble in water, but less soluble in dilute alcohol than the inulin from camas or wild onions; 40% alcohol dissolved 5% of inulin.

Summary

1. Three new sources of inulin are described, two plants of the family of *Liliaceae* and one of the *Compositae.*
2. The specific rotation of inulin from these sources ranged from –28 to –33°. All products were soluble in water and dilute alcohol.
3. In the light of this work and that of Chevastelon, it appears that there is no correlation between the specific rotation and the solubility of inulin.
4. No claim is made that any of the products described was a definite chemical individual.

IDENTIFICATION OF ALCOHOLS. PARA-NITROPHENYL URETHANS

BY R. L. SHRINER AND RICHARD F. B. COX

RECEIVED FEBRUARY 7, 1931 PUBLISHED APRIL 6, 1931

The common reagents used for the preparation of solid derivatives of the alcohols are 3,5-dinitrobenzoyl chloride, phenyl isocyanate and α-naphthyl isocyanate. Since the melting points of many of these derivatives of the common aliphatic alcohols are rather low, which makes them difficult to purify, and since the differences in the melting points of certain pairs of compounds are rather small, it was thought that a series of higher-melting derivatives would be of value. The present communication presents the data obtained on p-nitrophenyl urethans of the common aliphatic alcohols. Table I summarizes the properties of the new derivatives and also lists the melting points of the 3,5-dinitrobenzoates, phenyl urethans and α-naphthyl urethans for comparison.

From the above table it is evident that the *p*-nitrophenyl urethans possess a few advantages over the other derivatives. The general melting point range is higher, which makes them easier to recrystallize. In two instances the melting point difference does not permit absolute identification, namely, n-propyl and isopropyl alcohols and hexyl and heptyl alcohols.

Para-nitrophenyl urethans may be prepared by the reaction between an alcohol and either *p*-nitrophenyl isocyanate or *p*-nitrophenylcarbamyl

TABLE I

MELTING POINTS OF ALCOHOL DERIVATIVES

chloride. Swartz[4] prepared *p*-nitrophenyl isocyanate by heating *p*-nitrophenylcarbamyl chloride which was obtained by the action of phosphorus pentachloride on ethyl *p*-nitrophenylcarbamate. The latter was made by the rearrangement of N-bromo-p-nitrobenzamide with sodium ethylate.[5]

Vittenet[6] prepared these reagents by the action of phosgene on *p*-nitraniline. Since the latter method makes use of readily available and inexpensive starting materials, a study was made of this procedure. Also, *p*-nitrophenylcarbamyl chloride was easier to prepare than the isocyanate and hence its preparation and use were studied.

When phosgene was passed into fused p-nitraniline similarly to the procedure used for phenyl isocyanate,[7] considerable charring and tar formation took place. Vittenet[6] refluxed together a toluene solution of p-nitraniline and a benzene solution of phosgene and succeeded in preparing *p*-nitrophenyl isocyanate in small amounts. As soon as phosgene is run into a solution of *p*-nitraniline in toluene, a precipitate of *p*-nitraniline hydrochloride separates.

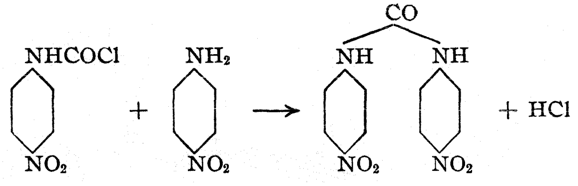
This reaction consumes half the p-nitraniline and also makes the reaction difficult to carry out because the undissolved p-nitraniline hydrochloride does not react with the phosgene. If a large amount of p-nitraniline is present in excess, a second reaction occurs as follows



The reaction mixture therefore contains all these substances and makes it difficult to obtain a pure reagent. Hence the best conditions call for a constant excess of phosgene to prevent the formation of substituted ureas, a temperature sufficiently high to prevent the precipitation of *p*-nitraniline hydrochloride and a good solvent for p-nitraniline. It was found that ethyl acetate was not only a good solvent for phosgene[S] but also a much better solvent for p-nitraniline than benzene or toluene, and therefore more suitable for the preparation of larger amounts of the reagent.

Although Swartz[4,5] reports that *p*-nitrophenylcarbamyl chloride decomposes at 56° to the isocyanate, the material obtained by the above procedure was always the acid chloride. Evidently the dissociation did not occur in ethyl acetate solution in the presence of phosgene and the hydrogen chloride produced in the reaction.

Experimental Part

Preparation of ***p*-Nitrophenylcarbamyl** Chloride.—The apparatus was set up as shown in Fig. 1. This arrangement permits the phosgene reaction to be carried out conveniently and without danger providing a good hood and exhaust fan are available.

Five hundred cubic centimeters of ethyl acetate was placed in the 5-liter round-bottomed Pyrex flask. Phosgene was bubbled slowly through the ethyl acetate until it was saturated. A solution of 150 g. of 9-nitraniline in 1500 cc. of ethyl acetate was run in slowly from the tap funnel over a period of from two and one-half to three hours. The addition of p-nitraniline must be at such a rate that the precipitate of p-nitraniline hydrochloride which is formed at first is allowed to dissolve and not accumulate. The mixture may be warmed if necessary. A steady stream of phosgene must be kept passing through the solution, and toward the end of the reaction the solution must be boiled gently to break up the p-nitraniline hydrochloride, as it dissolves quite slowly.

After the addition of the last of the p-nitraniline the stream of phosgene was continued for five minutes and then shut off. The flame under the flask was then turned up and the ethyl acetate distilled. The brown residue was treated with 800 cc. of hot carbon tetrachloride and the insoluble residue (the disubstituted urea) removed by filtration. About two-thirds of the carbon tetrachloride was distilled and the solution cooled. The *p*-nitrophenylcarbamyl chloride crystallizes and is filtered. By concentration of the mother liquor a further crop may be obtained. The product may be re-

---

[8] Baskerville and Cohen, *Ind. Eng. Chem.*, **13**, 333 (1921).

crystallized again from carbon tetrachloride and yields light yellow needles, melting at 57°. The yield of crude product after one recrystallization was 210 g. (96.5% of the theoretical).

Anal. Subs., 0.2001: 20.0 cc. of 0.10 N HCl. Calcd. for $C_7H_5O_3N_2Cl$: N, 13.97. Found: N, 14.00.

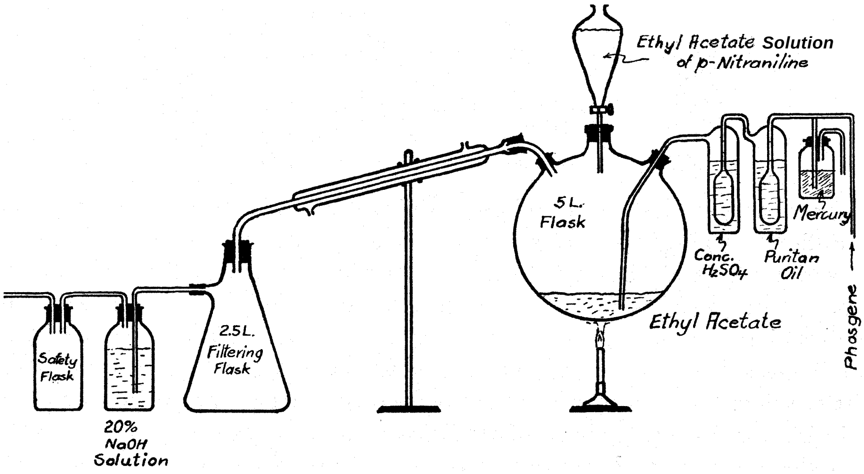


Fig. 1.

Preparation of **p-Nitrophenyl Urethans.**—It was found that the best method for making the urethans was to prepare a benzene solution of p-nitrophenylcarbamyl chloride and add a slight excess of the pure alcohol. The reaction usually takes place spontaneously with evolution of heat and is over in about five minutes. The benzene is distilled and an excess of cold carbon tetrachloride added together with a little norit. The solution is then filtered. This procedure removed any *sym.*-di-[*p*-nitrophenyl]-urea which may be formed by traces of water in the alcohol. Evaporation of the carbon tetrachloride to a small volume and cooling yields crystals of the urethan. The p-nitrophenyl urethans with their melting points and analyses are given in Table II.

THE SYNTHESIS OF SIMPLE AND OF SUBSTITUTED 2-ALKYLCINNAMIC ALCOHOLS, INCLUDING A MONOMOLECULAR CUBEBIN

BY MARSTON TAYLOR BOGERT AND GARFIELD POWELL[1]

RECEIVED FEBRUARY 11, 1931 PUBLISHED APRIL 6, 1931

Introductory

The appearance of the recent articles by Gomberg and Bachmann[2] and by Shankland and Gomberg,[3] lead us to publish some closely related work, carried out in 1929, reported at the Annual Convention of the American Manufacturers of Toilet Articles, New York, last April, and published last spring as part of the Dissertation submitted by the junior author for the Ph.D. degree at Columbia University.

The problem of reducing unsaturated aldehydes to the corresponding unsaturated alcohols has occupied the attention of organic chemists for many years and is a subject of considerable practical importance to the perfume industry.

Iron and acetic acid have been used on aldehydes[4] or on their diacetates,[5] but the methods are tedious and the yields unsatisfactory.

The reducing action of aliphatic Grignard reagents on aldehydes and ketones has been known for many years. Marshall's experiments: supported by the work of Meisenheimer[7] and of Shankland and Gomberg,[3]

---

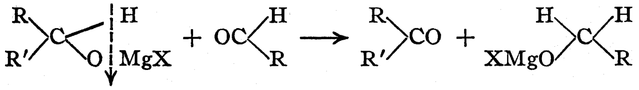
make it clear that is not the Grignard reagent itself which functions as the reducing agent in such cases, but the addition product formed by the reagent with the aldehyde, RCH(OMgX)R′, which is then oxidized by the excess of aldehyde, the latter being compensatingly reduced



Liittringhaus[8] patented a process of reducing aldehydes to alcohols by the action of ethyl alcohol in the presence of activated magnesium, the alcohol being oxidized simultaneously to aldehyde, and claimed the successful reduction of citronellal, geranial (citral) and cinnamic aldehydes to the corresponding alcohols.

Meerwein and Schmidt[9] discovered that $Al(OR)_3$, or ROMgX, in the presence of some free ROH, acting on aldehydes at moderate temperatures, gave 80 to 90% yields of the corresponding alcohols, the aldehyde and alcohol groups exchanging partners, the equilibrium being kept moving to the right by the removal of the aldehydic by-product as fast as it formed

$$RCHO + R'CH_2OH \rightleftharpoons RCH_2OH + R'CHO$$

Among the alcohols they secured in this way from their aldehydes, were geraniol and hydroxycitronellol.

Ponndorf,[10] by the use of a similar method, successfully prepared cinnamic alcohol, geraniol and nerol, carveol and other alcohols, from the corresponding aldehyde or ketone. As pointed out by Gibson and Simonsen,[11] dl-piperitol can thus be prepared readily from dl-piperitone.

Inasmuch as a compensating oxidation and reduction seems to be involved in the change, it has been likened[9] to the Cannizzaro Reaction.

The noteworthy fact remains, however, that when $Al(OR)_3$ acts upon mixtures of aldehydes and alcohols, the products are the same as when ROMgX is the catalyst, although aluminum does not form organic complexes of exactly the same type as magnesium.

Child and Adkins[12] carried out an interesting series of experiments, using aluminum ethoxide as catalyst to convert aldehydes into esters, $2RCHO \longrightarrow RCOOCH_2R$.

Adams and his co-workers[13] obtained an excellent yield of cinnamic alcohol by reducing cinnamic aldehyde with hydrogen in the presence of their platinum oxide–platinum black catalyst. Our experience with this method, however, has been that the conditions determining a satisfactory

yield are highly specific, small variations in the proportions of the catalyst mixture, or changes in its activity, affecting the results profoundly, so that considerable experimentation would have been necessary to ascertain the optimum conditions in the case of each aldehyde.

For the reduction of certain cinnamic aldehydes we had on hand, the method of Meerwein and Schmidt proved entirely satisfactory and in this way 2-ethyl and 2-isoamyl cinnamic alcohol, 2-methyl-3-*p*-tolylallyl alcohol and 2-piperonylidene-ethanol, were prepared. The products were practically free from unchanged initial aldehydes, for simple fractional distillation under diminished pressure sufficed to give a pure alcohol, without any previous special chemical treatment for the removal of aldehydes.

The 2-piperonylidene-ethanol prepared by this method was not identical with the product obtained by Pauly, Schmidt and Böhme[5c] by reduction of the same aldehyde with iron and acetic acid, and to which they assigned the same formula. The reason for this discrepancy is under investigation and the results will be published later.

Natural cubebin was at one time assumed to be the 2-piperonylidene-ethanol, but recent researches, especially those of Mameli,[14] make it clear that its formula is much more complicated and, in support of this, the 2-piperonylidene-ethanol obtained by Pauly, Schmidt and Bohme, and the one prepared by us, are totally different from natural cubebin.

In general, these unsaturated alcohols decolorized a carbon tetrachloride solution of bromine much more rapidly than the corresponding unsaturated aldehydes, the color being discharged promptly until near the saturation point.[15]

Their boiling points were generally higher than those of the corresponding saturated or unsaturated aldehydes, saturated alcohols or propanes. Their odors were of the cinnamic alcohol type.

Experimental

2-Ethylcinnamyl Alcohol, $C_6H_5CH{=}C(C_2H_5)CH_2OH$.—A solution of 5.5 g. of dry hydrogen chloride in 100 cc. of absolute alcohol was prepared in a flask provided with a reflux condenser which carried a calcium chloride guard tube, and to this solution there was added 4 g. of clean magnesium ribbon. The reaction was completed by refluxing the mixture until all the metal was dissolved (one hour or longer). The air in the apparatus was then displaced by a current of dry nitrogen and, while this gas was kept passing through the refluxing mixture, 30 cc. of a-ethylcinnamic aldehyde was added through the condenser. The water in the condenser was not changed during this reaction and upon its completion had become sufficiently heated by the refluxing condensate so that the calcium chloride tube was removed and 40 cc. of alcohol was carried out in this way by the stream of nitrogen gas. After refluxing for about seven hours, the mixture was cooled, thrown into excess of water, the whole acidified with acetic acid, ether added, the

mass filtered from a small amount of resinous impurities, the ether layer separated, washed with sodium carbonate solution, to remove all acetic acid, then with water, dried and the solvent removed. The residue was fractioned under reduced pressure in an atmosphere of nitrogen and 22 cc. of a nearly colorless oil was collected at 127–137° (mostly at 137°) at 8 mm., leaving a viscous residue in the flask. When the fraction collected was redistilled (in nitrogen), practically all passed over at 131–132° (corr.) at 9 mm., as a colorless oil.

Anal. Calcd. for $C_{11}H_{14}O$: C, 81.42; H, 8.70. Found: C, 81.28; H, 8.86.

In this preparation, chloromagnesium ethylate was found to be far superior to aluminum ethylate. Meerwein and Schmidt[9] record a similar experience in the production of cinnamic alcohol from the aldehyde.

The viscous by-product remaining in our flask after taking off the fraction of b. p. 127–137° (8 mm.) yielded, with incipient decomposition, a fraction boiling at about 200° (4 mm.), containing 79.39% of carbon and 8.92% of hydrogen, but which was not investigated further.

The alcohol instantly decolorized carbon tetrachloride solutions of bromine, with no observable evolution of hydrogen bromide, whereas the corresponding unsaturated aldehydes take from seconds to minutes to discharge the color of such bromine solutions. The odor was weak but agreeable, similar in type to that of cinnamic alcohol itself. The alcohol was easily reduced to the corresponding 2-ethylhydrocinnamyl alcohol (2-ethyl-3-phenylpropyl alcohol) and 2-ethyl-3-phenylpropane (3-methyl-4-phenylbutane), by hydrogen in the presence of palladium (Skita method). It discharged the color of a dilute aqueous potassium permanganate solution when shaken with it.

p-Nitrobenzoate.—This was prepared from *p*-nitrobenzoyl chloride and the alcohol in the presence of pyridine; m. p. 110–111° (corr.).

Anal. Calcd. for $C_{18}H_{17}O_4N$: H, 5.5. Found: H, 5.68. Through an accident, the carbon determination was lost, and there remained insufficient material for purification and another combustion.

A **phenylurethan** also was produced by heating equal moles of the alcohol and phenyl isocyanate together in a sealed tube for six hours at 100°. By the addition of petroleum ether (b. p. 40–60") to the reaction product, crystals were obtained, m. p. 63–64° (corr.), whose melting point was unchanged by recrystallization from 75% alcohol.

2-*n*-Amylcinnamyl alcohol, $C_6H_5CH{=}C(C_5H_{11})CH_2OH$, was prepared similarly. The refluxing was continued for eleven and one-half hours, and the crude product separated as before and distilled in nitrogen, gave a main fraction, b. p. 144–165' (6 mm.). This was redistilled and the fraction, b. p. 141–143' (5 mm.) was a colorless oil of faint odor recalling that of cinnamic alcohol; yield, 50%.

Anal. Calcd. for $C_{14}H_{20}O$: C, 82.29; H, 9.88. Found: C, 82.15; H, 10.0.

The properties of this alcohol, so far as tested, were the same as those of the corresponding 2-ethyl derivative.

Phenylurethan.—A mixture of the alcohol with a slight excess of phenyl isocyanate was heated in a sealed tube for two and one-quarter hours at 100°. The excess of isocyanate was removed from the product by heating at 100° and reducing the pressure to 16 mm. Addition of petroleum ether to the residue precipitated a solid, which crystallized from dilute alcohol in colorless crystals, m. p. 61–62° (uncorr.).

2-Methyl-3-p-tolylallyl alcohol, $p\text{-}CH_3C_6H_4CH{=}C(CH_3)CH_2OH$, from 3.5 g. of magnesium, 5 g. of hydrogen chloride in 225 cc. of absolute alcohol, and 25 cc. of 2-methyl-3-p-tolylacrolein, refluxed for seven and one-half hours in an atmosphere of nitrogen, was worked up as in the case of the other alcohols and finally distilled. The portion coming over below 160" at 10 mm. on rectification gave a fraction, b. p. 142–143° (11 mm.), as a colorless oil, whose odor and other properties resembled those already described; yield, 60%.

Anal. Calcd. for $C_{11}H_{14}O$: C, 81.42; H, 8.70. Found: C, 81.39; H, 8.97.

2-Piperonylidene-ethanol (Monomolecular "Cubebin") was prepared from 4 g. of magnesium, 5 5 g. of dry hydrogen chloride in 225 cc. of absolute alcohol, and 23 g. of piperonylidene-acetaldehyde (m. p. 83–84"; b. p. 162–163" (5 mm.)). After refluxing for four hours (in nitrogen), the crude product was separated and distilled at 5 mm. pressure. Above 200°. considerable decomposition was evident. The distillate collected below this point yielded, on rectification, a fraction, b. p. 167–168° (5 mm.), which gave colorless crystals from benzene or alcohol, m. p. 78–78.8° (corr.).

Anal. Calcd. for $C_{10}H_{10}O_3$: C, 67.39; H, 5.66. Found: C, 67.17; H, 5.95. Molecular weight (in camphor): Calcd., 178. Found: 173.

The yield before final purification was only about 20% (4 g.), but this was raised to approximately 30% when aluminum ethylate was used in place of the chloromagnesium ethylate.

Its reactions were similar to those of the other alcohols described in this paper. It decolorized instantly a carbon tetrachloride solution of bromine, or an aqueous permanganate solution. Reduced catalytically, the odor of dihydrosafrole was pronounced, one mole of hydrogen being absorbed in about ten minutes.

Benzoate.—The alcohol was condensed with benzoyl chloride in the presence of pyridine, and the purified product formed fine long colorless needles, m. p. 96–97' (corr.), which decolorized bromine solutions less rapidly than the alcohol itself.

Anal. Calcd. for $C_{17}H_{14}O_4$: C, 72.31; H, 5.0. Found: C, 72.21; H, 5.22.

Phenyl **Urethan.**—A mixture of the alcohol with an excess of phenyl isocyanate was heated in a sealed tube for four hours at 100°. As the tube cooled, the contents solidified. The crude product was dissolved in benzene, reprecipitated by the addition of petroleum ether and the precipitate then crystallized from a mixture of these two solvents. Small colorless needles were obtained, m. p. 96–97" (uncorr.).

Anal. Calcd. for $C_{17}H_{15}O_4N$: C, 68.66; H, 5.1. Found: C, 68.98; H, 5.11.

Summary

1. The 2-alkylated cinnamic aldehydes are very satisfactorily reduced to the corresponding cinnamic alcohols by the use of chlorornagnesium ethylate or aluminum ethylate.
2. The monomolecular "cubebin" prepared in this way differs from that recorded in the literature, which was obtained by reduction with iron and acetic acid.

NEW YORK, N. Y.

COMMUNICATIONS TO THE EDITOR

THE ABSORPTION OF WATER VAPOR BY COTTON CELLULOSE

sir:

In a paper by L. M. Pidgeon and O. Maass entitled "The Adsorption of Water by Wood" [THIS JOURNAL, 52, 1053 (1930)], figures are given for the adsorption of water vapor by purified cotton cellulose. The method of measurement was one that was selected by the authors after a consideration of the possible sources of error, since, they say, "Little of the work which has been done is entirely free from objection , . . . and . . . . in even the most careful determinations of the adsorption by cotton cellulose the amount of adsorption was measured indirectly."

The absorption of water vapor by cotton has formed the subject of systematic investigations extending over eight years by my colleagues, the late Dr. A. M. Williams and Dr. A. R. Urquhart. The methods used were submitted to critical examination, and the results of the investigation, which derive from observations on some hundreds of samples of cotton, are contained in the *Shirley Institute Memoirs*, and are being published in a series of communications to the "Journal of the Textile Institute," nine of which have so far appeared since 1924. A complete absorption and desorption isotherm for pure cotton cellulose at 25° is given in one of these communications [J. *Text. Inst., 15,* T433 (1924), or *Shirley Institute Memoirs,* 3, 197 (1924)], the latter of these two references being quoted by Pidgeon and Maass in their paper.

Since these authors have omitted to do so, and since the *Shirley Institute Memoirs* do not possess the wide circulation among scientific readers enjoyed by the *Journal of the American Chemical Society,* it seems desirable to call the attention of your readers to the fact that, at high relative humidities, there are gross discrepancies between the results of Pidgeon and Maass and those of Urquhart and Williams. Only one isotherm is given by Pidgeon and Maass, namely, at 23°, but this can be compared with the isotherm obtained by Urquhart and Williams at 25°, since it is clear from the work of both laboratories that this small difference of temperature can have no significant effect on the moisture absorption at a given relative humidity. The value obtained by Urquhart and Williams exceeds that given by Pidgeon and Maass by 11% at saturation, by 4% at 90% relative humidity, and by 2% at 80% relative humidity.

It is to be hoped that an attempt will be made to discover the source of the discrepancy, which must lie either in the technique of measurement or in the samples of "pure cotton cellulose." In this connection, it must be pointed out that the chemical attack of cotton cellulose by bleaching or otherwise, which increases its solubility in sodium hydroxide solutions, or reduces its so-called "a-cellulose" content, does not increase its moisture absorption at constant humidity, as Pidgeon and Maass would appear to expect on theoretical considerations, but has the opposite effect.

From the purely scientific aspect, the absolute values of the absorption may appear of less importance, as any errors of technique affecting all measurements would not necessarily invalidate conclusions drawn from the comparative behavior of different materials. Absolute values of the moisture absorption of cotton are, however, of the highest commercial and technical importance, since cotton is bought and sold on an agreed average moisture content, which can be defined from the absorption isotherm when the average conditions with respect to humidity and temperature are known. From this point of view alone it seems advisable to place on record the fact that the low figures of Pidgeon and Maass at high humidities—which will certainly surprise many technical workers experienced in the cotton processing industries—are much below those of other workers who have also devoted themselves to a long and critical examination of the subject.

THE SUPERPOSITION OF ELECTRON CHARGES IN MOLECULES AND a-PARTICLES

Sir:

In their paper on the hydrogen molecule, Heitler and London[1] went to great length to stress the fact that the valence forces were not the ordinary coulomb forces, but were due to an exchange phenomenon involving the pair of electrons. Recent work by Slater,[2] Zener,[3] Bartlett[4] and others, raises the question as to whether Heitler and London have not overemphasized the importance of the exchange phenomenon. When we consider the exchange phenomenon we find that it has little objective significance; it may be described as a resonance effect in wave functions. On the other hand, the work of Slater and the others referred to above makes it clear that the bonding force between atoms is due to the overlapping or superposition of electron charge, the electron charge being treated as a distributed charge, whose density is proportion to $\psi\bar{\psi}$. In atoms with more than one valence electron, where the charge distribution is not spherically symmetrical, there is the possibility of a considerable

[1] Heitler and London, Z. *Physik*, 44, 455 (1927).

[2] Slater, Phys. Rev., 36, 57 (1930).

[3] Zener, *ibid.*, 36, 51 (1930).

[4] Bartlett, *ibid.*, 36, 1096 (1930).

bonding force, without the exchange phenomenon. When the exchange phenomenon is taken into account, a redistribution of charge is obtained with an increase in banding energy, but this increase is in some cases a small fraction of the total energy. It seems entirely probable that the "residual affinity" which has been invented to explain compounds such as B_2H_6 may be a result of overlapping of charge, without the exchange phenomenon.

It is perhaps not realized by chemists how revolutionary the idea of superposition of electron charges is, and how completely it removes the old difficulties with electrical charges and coulomb forces. The combination of two protons and two electrons in a stable arrangement is an impossibility; if the two electrons are superposed the repulsive forces between electrons disappear and a stable configuration is possible.

Of course, the complete superposition of charge does not occur ordinarily but one may wonder if it is not approached in the a-particle. The idea of the tetrahedral structure of the a-particle has suggested itself to many, and Latimer[6] has recently developed the idea in formulating a lattice structure for the nucleus. It is evident that a pair of electrons surrounded by four protons is subject to extraordinary forces and the superposition of the two electron charges might be nearly complete. The solution of this problem seems to lie within the present possibilities of wave mechanics, and the result would be of great interest.

ZIRCONIUM. III. THE REACTION BETWEEN AMMONIA AND METHYL ALCOHOLIC SOLUTIONS OF ZIRCONIUM SULFATE

Sir:

The fact that solutions of zirconium salts yield, upon the addition of ammonium hydroxide. a white gelatinous precipitate of zirconium hydroxide quite insoluble in water or in an excess of the precipitant has been known since the days of Berzelius. The results of recent work in this Laboratory tend to show, however, that under special conditions a compound other than the hydroxide may be precipitated by ammonium hydroxide if the zirconium sulfate be dissolved in methyl alcohol.

A methyl alcoholic solution of zirconium sulfate was treated with ammonium hydroxide or ammonia gas. Under ordinary conditions only the hydroxide would have been precipitated. If the solution be quite fresh, that is, if it has been prepared for only a matter of two or three minutes,

---

[5] Latimer, THIS JOURNAL, 53, 981 (1931).

a white precipitate is obtained which is, strangely enough, quite soluble in water or in an excess of the precipitant. If the solution be allowed to stand for from five to ten minutes, only the hydroxide is precipitated. It was thought possible that the alcohol, employed as a solvent, either went into a direct-chemical reaction, or prevented hydrolysis from taking place as would have been the case if water had been employed as a solvent and to this end it was decided to carry out the experiments with a fresh water solution of zirconium sulfate in which hydrolysis had not taken place to any great extent. A solution of the age of three minutes yielded only the hydroxide upon precipitation with ammonia, and it was thought to be possibly too old. To this end the entire procedure of the preparation of the solution and precipitation by ammonia was reduced to ten seconds, then to five, but even in these cases only the hydroxide was obtained. It was considered that the amount of hydrolysis which could take place in five seconds would be very slight, and certainly would have had no great influence upon the reaction. Consequently it was considered that the presence of methyl alcohol was necessary for the reaction. Naturally this consideration does not account for the fact that old methyl alcoholic solutions yield only the hydroxide, and this will be discussed later.

A water solution of the precipitate was treated with the following reagents: ammonium hydroxide, ammonium carbonate, citric acid, and oxalic acid, all of which give characteristic precipitates with the zirconium ion. In no case was any reaction observed. When the solution was treated with barium chloride, however, a precipitate of barium sulfate was filtered off, and the filtrate resulting from this reaction readily gave precipitates with ammonium hydroxide and the other reagents mentioned above. When the usual analytical precautions were taken it was found that the precipitate lost **87.52%** by weight on ignition over a Fisher burner for forty-five minutes. Since the sample turned black during the course of ignition it was suspected that organic matter was present in the compound.

The fact that only fresh methyl alcoholic solutions of zirconium sulfate yield the soluble precipitate tends to indicate that some intermediate, and probably very complex, compound is formed between methyl alcohol and zirconium sulfate. Under ordinary conditions this compound probably decomposes very readily, but if the solution be used when fresh and treated with ammonium hydroxide, the ammonia enters the compound and forms a complex with zirconium in the anion. These conclusions, while not necessarily final, are supported by the evidence given above.

It is interesting to note that this phenomenon appears to take place with certain other elements such as aluminum and zinc, while such substances as magnesium and iron give no such reaction.

Work is now going on to the thorough study of these phenomena. Since the results are rather novel, however, this preliminary report has been prepared with the hope in mind that it might prove of some interest to those working with zirconium, especially since the complete research will not appear for some months.

THE ORTHO-PARA-HYDROGEN CONVERSION AT SURFACES

Sir:

Bonhoeffer and Harteck [*Z. physik.* Chem., **4B, 113** (1929)] found that nickel possessed a negligible activity for the reconversion of para-hydrogen to the ortho-para mixture even at room temperatures. Still less might one expect it to function as an agent for para-hydrogen formation at liquid-air temperatures. The data of Benton and White [THIS JOURNAL, 52,2325 (1930)] showed adsorption of hydrogen on nickel even at $-110°$ in an activated form [Taylor, THIS JOURNAL, 53,585 (1931)]. We have, therefore, carried out experiments on para-hydrogen formation with a very active nickel (10% nickel on kieselguhr) showing specific adsorptions for hydrogen of a much higher order of magnitude than the material employed by Benton and White. With this material we have shown it possible to produce the equilibrium concentration of 50% para-hydrogen at liquid-air temperatures as readily as on charcoal. That the surface activity was the important factor was readily shown by experiments with small fragments of nickel wire. With such, there was no measurable para-hydrogen formation.

We have extended these measurements to oxide surfaces since it has been found in adsorption studies [Garner and Kingman, Nature, **126**,352 (1930); Taylor and Williamson, THIS JOURNAL, **53**,813 (1931)] that below 0° there is no evidence of an activating adsorption of hydrogen but marked adsorption of molecular hydrogen. Our results on para-hydrogen conversion confirm this. Neither with an active zinc oxide nor with the more active hydrogenation agent zinc-chromium oxide is there any para-hydrogen formed at liquid-air temperatures even after fourteen hours' contact. On the contrary, in the temperature region where, on these surfaces, activated adsorption of hydrogen sets in, namely from 0° upwards, there is an immediate activity in the reconversion of the 50% para-hydrogen to the normal 1:3 mixture. The relative activities in this respect are exactly parallel with the influence of composition on the velocity of activated adsorption. Thus, with zinc-chromium oxide, the reconversion is complete in fifteen minutes' contact time at room temperature. With the less active zinc oxide it is barely perceptible in the same time at the same temperature and is not quite complete at 100° with the same time of contact. We are extending further this interesting method of determining the nature of hydrogen adsorbed on surfaces.

THE ALLOMERIZATION OF CHLOROPHYLL

Sir:

When an alcoholic solution of chlorophyll is allowed to stand, a process known as allomerization takes place.[1] Allomerized chlorophyll *a* differs from the original material in that the product of hot alkaline hydrolysis is a mixture of unstable chlorins instead of the normal product chlorin *e*. The same unstable chlorins are obtained from unallomerized chlorophyll or the magnesium-free compounds (phaeophytin *a* or methyl phaeophorbide *a*) by saponification with alcoholic alkali at room temperature or below. It has recently been established[2] that the essential change in both allomerization and low temperature saponification ("phase test" hydrolysis) is the dehydrogenation of the grouping —CHOHCO— to —COCO—. The fate of the two hydrogen atoms was, however, uncertain. We have now been able to show by very simple experiments that the hydrogen atoms are removed by the oxygen of the air. If allomerization or "phase test" saponification is carried out in a modified Warburg apparatus,[3] the absorption of oxygen is easily measured. The amount absorbed corresponds to the removal of two hydrogen atoms with the formation of hydrogen peroxide.

The dehydrogenation of chlorophyll *a* or the magnesium-free compounds in the *a* or b series may also be brought about by the use of potassium molybdicyanide in acetone–pyridine solution. Two equivalents of reagent are required per mole. Dehydrogenated chlorophyll *a* thus prepared is identical with allomerized chlorophyll (the ultraviolet absorption spectrum is a satisfactory method of distinguishing the dehydro compound from the original material). After removal of the magnesium from allomerized chlorophyll or chlorophyll dehydrogenated with molybdicyanide, the absorption spectrum in the visible and the ultraviolet is identical in both cases and indistinguishable from that of methyl dehydrophaeophorbide. This latter substance we have prepared in quantity by the action of molybdicyanide on methyl phaeophorbide *a*; it yields the unstable chlorins on hot alkaline hydrolysis.

[2] Conant, Hyde, Moyer and Dietz, THIS JOURNAL, 53, 359 (1931).

[3] Hyde and Scherp, *ibid.*, 52, 3359 (1930).

From the facts given above, it is clear that allomerization is dehydrogenation brought about by the oxygen of the air. It is interesting that the dehydrogenation of a very easily oxidized group in chlorophyll is without pronounced effect on the color, although marked changes in color, as a rule, accompany the oxidation of a colored substance. The unusual behavior of chlorophyll in this respect is due to the fact that the chromophoric group is not the most easily oxidized group. A theory of photosynthesis has been recently suggested[4] which is based on the presence of this easily dehydrogenated group in chlorophyll.

NEW BOOKS

Fundamentals of Chemistry. By CARL WILLIAM GRAY, CLAUDE W. SANDIFUR and HOWARD J. HANNA. Revised and enlarged edition. Houghton Mifflin Company, 2 Park St., Boston, Massachusetts, 1929. xiv + 650 pp. 201 figs. 13 × 19.5 cm. Price $1.80.

This book is a revised and enlarged edition of a high school text, first published in 1924.[1] The order of presentation of the subject matter, used in the first edition, remains one of the original features of the book. This unusual order is characterized in part by the introduction of metals in Chapter III, metallic oxides and ores in Chapter VI, and the introduction of carbon as the third element considered. A new chapter on the structure of matter has been introduced before the chapter on ionization, obviating one criticism of the first edition. These two chapters now constitute a good elementary presentation of the electron concept, which, however, is not afterward utilized even in discussing such topics as the periodic classification and storage batteries, and only a limited use is made of this concept in the chapter on oxidation and reduction which has been added in this edition.

Other new chapters are entitled "The Atmosphere," "Paints, Varnishes and Lacquers," and "Chemistry in Agriculture." These titles indicate that the method of treatment and the subject matter are those conventionally associated with courses for school students not in the college preparatory group. However, it cannot be said that the fundamental generalizations have suffered. The illustrative material and the order of treatment constitute the chief differences from the conventional text.

[4] Conant, Dietz and Kamerling, *Science*, 73, 268 (1931).

[1] Reviewed in THIS JOURNAL, 47, 592 (1925).

Preparatory school teachers, seeking this type of textbook, will find this volume well worth consideration. It is, in general, logically and clearly written, well illustrated and attractively arranged for student use, with outline summaries, questions and exercises at the close of each chapter.

C. R. HOOVER

Inorganic Chemistry for Colleges. A Textbook for Students of Second Year Chemistry. By WILLIAM FOSTER, Ph.D., Professor of Chemistry in Princeton University. Second Printing, 1930. D. Van Nostrand Company, Inc., 8 Warren Street, New York, 1929. viii + 837 pp. 212 figs. 14 × 22 cm. Price, $3.90.

A second printing a year after its publication indicates that this book has been well received. It is designed for students who have passed chemistry for entrance to college. The words, "A Textbook for Students of Second Year Chemistry," appear on the title page. While this book presupposes an elementary knowledge of the common elements, the descriptive side of chemistry has not been neglected; nor have the many applications of the science been slighted. The essential difference between this book and the average elementary college textbook lies in the more comprehensive treatment of fundamental laws and theories.

The book is divided into four parts, namely: Part I, (112 pages) is given to fundamentals, such as the laws of chemical combination, symbols, formulas, equations, the gas laws, the kinetic theory, the internal structure of crystals. Then an important and logical departure from the usual order of topics as found in other textbooks of this character: in Chapter IV, nearly 20 pages, the radioactive elements are studied in some detail in order to lay an experimental foundation for the study of atomic structure, which is considered in the following chapter on the classification of the elements.

Part II (386 pages), the non-metals, includes the usual descriptive matter, with separate chapters on solution; molecular and atomic weights; energy and chemical change; chemical equilibrium; the ionic theory and some of its applications; acids, bases and salts; oxidation and reduction from an electronic standpoint; colloid chemistry. While carbon is discussed in this part, organic compounds proper are left for Part IV.

Part III is devoted to the metals, the periodic classification being closely followed. A chapter on electrochemistry is placed between the tin and arsenic groups in the discussion of the metals.

Part IV (71 pages) called the supplementary part, is devoted entirely to organic compounds. The closing chapter is on The Food of Plants and of Animals. At the end of this section there is a good set of 144 problems with answers to most of them, which illustrate the principles taken up in the entire book.

At the end of each chapter a set of exercises is given and references for supplementary reading. The appendix contains the usual tables, also a four place table of logarithms, and the book closes with a bibliography of over one hundred titles.

HERMAN SCHLUNDT

General Chemistry. By HARRY N. HOLMES, Professor of Chemistry in Oberlin College, Revised edition. The Macmillan Company, 60 Fifth Ave., New York, 1930. x + 654 pp. 167 figs. 15 × 22.5 cm. Price, $3.50.

The revised edition of "General Chemistry" is a decided improvement over the first edition.

The author has succeeded in arranging the presentation of facts and theories in such a way that the student will never become "fed up" on one type of material. He has also included a good description of the various chemical processes that have become of great industrial importance and there is no better way of stimulating the interest of a Liberal Arts College student in chemistry than that of showing its relation to his own happiness and well-being.

His method of presenting the oxides of nitrogen before nitric acid is rather unusual. In fact his nitrogen question is rather confused but with this exception the book is very well written and should appeal to the teacher of General Chemistry.

It is not too hard for the student who has not had any previous training in chemistry and yet the introduction of considerable material in fine print makes it possible to arrange a course so that the student entering college with a good High School course in chemistry will find plenty to keep him busy.

This edition as well as the earlier edition will especially appeal to some teachers because the author has the courage to write equations at the beginning of the book. Teaching chemistry without equations is like trying to teach a language without a vocabulary. Equations should be introduced as soon as the first element is discussed.

The placing of Carbon and its oxides in Chapter IX and Sodium and Sodium Hydroxide Bases in Chapter XV is a help but leaving Equilibrium until Chapter XXIII is a decided weakness. Equilibrium conditions are encountered with the preparation of oxygen and it is regrettable that the author did not have the same courage with respect to equilibrium as he showed in writing equations.

The Periodic Table showing the Atomic Numbers in red is a particularly good feature.

It is a good text and the student will find it understandable as well as very interesting.

JOHN B. ZINN

Laboratory Manual of General Chemistry. By HARRY N. HOLMES, Professor of Chemistry in Oberlin College. Third edition. The Macmillan Company, 60 Fifth Ave., New York, 1930. x + 163 pp. 34 figs. 14.5 X 22.5 cm.

This laboratory manual is of the interleaved type. The subject matter is that usually found in a laboratory manual of first year college chemistry. The material is well arranged and the experiments are sufficient in number so that it is possible for the individual instructor to adapt the book to almost any type of laboratory course. Some of the experiments, marked with an asterisk, are rather difficult and well suited to those students who have had some previous training in chemistry.

In preliminary exercises, the time spent on the balance seems rather ill advised, but the chapter on Colloids would be a decided addition to any laboratory manual. The chapter on solutions is also very good and the set-up for the determination of the molecular weight of water on page 44 would keep the best student interested. The experiment using the Law of Du-Long and Petit is something different and a good addition.

The preparation of atomic models with toothpicks, chewing gum and soft wax seems rather childish. The chapter on equilibrium is very good but rather late in the course.

The book is especially well adapted to mixed classes made up of those who have had some training in chemistry and those who are studying chemistry for the first time.

On the whole it is a very good manual and is well worthy of the careful consideration of all teachers of General Chemistry.

JOHN B. ZINN

Chemistry in Daily Life. By SAMUEL GLASSTONE, D.Sc., Ph.D., F.I.C., Lecturer in Chemistry at the University of Sheffield. E. P. Dutton and Company, Inc., 286–302 Fourth Avenue, New York, 1929. vi + 250 pp. 21 figs. 13 × 19.5 cm. Price $2.25.

This book can be described as a textbook for the general reader. The author is content to chronicle in simple language the wonderful accomplishments of chemistry without attempting to present them as sensationally romantic. The content of the book can be judged by listing a few chapter headings: "The Beginnings of Chemistry"; "The Structure of Matter"; "Electricity and the Atom"; "Air and its Gases"; "Carbon and its Oxides"; "Our Daily Food; "Chemistry of Digestion"; "Catalysts and Enzymes"; and "Medicines and Perfumes." In short, the twenty chapters of the book cover the usual range of subjects included in popular chemistry, but they also include topics sometimes omitted.

The book is very sparsely illustrated, and, compared with some of our American school text and popular books on chemistry, would appear to be dry reading, but the clarity and simplicity of its style and the wide variety of general information presented compensate for this. In the opinion of the reviewer, it is a good reference book for the elementary student and of interest to the graduate who wishes to review his general knowledge of chemistry.

C. R. HOOVER

A Laboratory Manual of General Chemistry. By WILLIAM J. HALE, Director, Organic Chemical Research, Dow Chemical Company. Revised by William G. Smeaton, Professor of General and Physical Chemistry, University of Michigan. Revised edition. The Macmillan Company, 60 Fifth Avenue, New York, 1930. x + 530 pp. Illustrated. 13 × 20 cm. Price, $2.50.

"Eleven reprintings since this manual was first published in 1917 testify to its merit." It provides a series of experiments which can be coordinated with any standard textbook in general chemistry. The amount of experimental work given in the book is far more than can be covered in the first year course in general chemistry. The authors recognize this in the closing sentence of the preface: "By judicious selection from the experimental material offered, an instructor can organize a practical course of elementary general chemistry to meet any reasonable requirement."

After a chapter on general directions, Chapters II to XVII contain experiments on the common elements with one chapter on ionization and applications of the ionic theory. In this section of the manual a good balance is maintained between qualitative and quantitative experiments, but the latter are rarely required to be performed in duplicate. Chapter XVIII gives a systematic scheme for the identification of negative radicals. Chapters XIX to XXVI outline experiments on the metals. The final chapter contains notes on the procedure in qualitative analysis with a diagrammatic scheme for the identification of the common cations. The appendix contains seven very useful reference tables.

A notebook is not required as most of the pages are printed on but one side. This feature conserves the student's time for doing some thinking, which is demanded for intelligent performance of the experiments.

HERMAN SCHLUNDT

Principles of Chemistry. An Introductory Textbook of Inorganic, Organic and Physiological Chemistry for Nurses and Students of Home Economics and Applied Chemistry. With Laboratory Experiments. By JOSEPH H. ROE, Ph.D., Professor of Chemistry, George Washington University Medical School. Second edition. The C. V. Mosby Company, 3523–3525 Pine Boulevard, St. Louis, Mo., 1929. 427 pp. 13.5 × 20.5 cm. Price, $2.50.

This book is designed to meet the requirements of the short course in chemistry generally offered to nurses in training. There are 28 chapters of text, each followed by review questions,-in Part I, and 35 appropriately selected laboratory exercises in Part II. The book presents elementary chemical theory, very brief reference to elements other than oxygen, hydrogen nitrogen and carbon; few chemical formulas; and a simplified discussion of structural organic chemistry. Special emphasis is placed on the application of chemistry to life processes by the introduction of chapters on blood, internal secretions, digestion and metabolism.

Anyone who has attempted to teach the rudiments of chemistry to prospective nurses, undergoing the strenuous practical training of the average hospital course, realizes the need for making such a chemistry course as concise and practical as possible. The author has succeeded well in this endeavor.

It is not perhaps in accord with accepted educational methods of nurses' training to attempt to do more than the author has done to stimulate curiosity, originality and individual responsibility, but it seems that the average graduate nurse might well acquire more of these attributes in some part of her professional education.

C. R. HOOVER

Qualitative Analyse mit Hilfe von Tüpfelreaktionen. Theoretische Grundlagen und praktische Ausführung. (Spot Reactions in Qualitive Analysis. Theory and Their Practical Applications.) By DR. FRITZ FEIGL, Lecturer at the University of Vienna. Akademische Verlagsgesellschaft m. b. H., Schlossgasse 9, Leipzig C 1, Germany, 1931. xii + 387 pp. 12 figs. 2 colored plates. 16 × 24 cm. Price, unbound, M. 26.40; bound, M. 28.

Although the methods of qualitative inorganic analysis have not changed very much during the last century, the system is still far from being perfect. Therefore, any attempt to improve the situation must be welcomed by anyone interested in this field. Dr. Feigl has established his name in analytical chemistry by the discovery of a great number of qualitative and partly quantitative reactions for the detection and determination of various inorganic ions. A summary of his work (and that of others) and the fundamental principles on which it is based are given in this book, which is a valuable contribution to qualitative analysis and which discloses a field for systematic search of new organic reagents specific for metal ions and anions. This part of Feigl's work seems to be of more fundamental importance than the development of spot reactions on *a* spot plate or on filter paper, since the latter procedure does not introduce a new principle, although it must be admitted that this micro method has proved to be useful in cases where only small amounts of material are available. The theoretical part of the book dealing mostly on the properties of complex compounds (Werner) is well worth reading; this is especially true of Chapters 7 and 8 dealing with the specific action of organic compounds as a result of the presence of characteristic groups and on the influence of various organic groups on the solubility of complex compounds. In the practical part

(270 pages) various spot reactions for metal ions and anions are described and their applications to a systematic analysis and to purity tests are given. This part covers the literature fairly completely although the diethyl dithiocarbamate test for copper (Callan and Henderson, 1929), dinitroresorcinol for iron, copper and cobalt (Nichols and Cooper, 1923, 1925), thioglycolic acid for iron (Lyons, 1927), cysteine for cobalt (Michaelis and Yamagashi, 1928), aurintricarboxylic acid for aluminum, curcumin for beryllium and others might have been mentioned.

Without hesitation, Feigl's book can be recommended to anyone who is interested in the development of qualitative inorganic analysis. However, the reviewer wishes to point out that the book gives the impression that the results of the spot analysis may be favorably compared with those of micro-crystal reactions. But it should not be overlooked that the observation of the crystal form and a study of the crystal properties enables one to conclude with absolute certainty whether or not a certain constituent is present, whereas the simple color spot tests, useful as they may be, will never reach this degree of reliability and perfection.

I. M. KOLTHOFF

Elements of Chemical Engineering. BY WALTER L. BADGER, Professor of Chemical Engineering, and WARREN L. MCCABE, Assistant Professor of Chemical Engineering, University of Michigan. McGraw-Hill Book Co., Inc., 370 Seventh Ave., New York, 1931. xvii + 625 pp. Illustrated. 15.5 × 23.5 cm. Price, $5.00.

The recognition of chemical engineering as a distinct branch of engineering with its own peculiar body of facts and principles has been rapid since the widespread acceptance of the idea of the fundamental unit operations as its nucleus The well-known book by Walker, Lewis and McAdams was the pioneer in breaking away from the traditional type of text. The latter was essentially either a collection of facts and illustrations taken from trade catalogs or *a* description, accompanied by flow sheets and chemical reactions, of processes used in industry, many of which were obsolete. This book represented the first serious attempt to treat chemical engineering wholly from the standpoint of unit operations and to apply, in a comprehensive manner, fundamental principles of mathematics, physics, chemistry and economics to develop adequate quantitative theories of these basic operations.

The new text by Badger and McCabe covers nearly the same ground as the older book, but in a manner that is better suited to the needs of the beginner. All of the essential mathematical theory of the unit operations is included, but the approach to it is by an easier grade. The fundamental ideas upon which the mathematical development is based are more clearly explained and illustrated. It is the more elementary of the two texts, not in the sense that the more difficult theory has been omitted, but only that it has not been extended to so many different cases and more pains have been taken to present the underlying principles in a logical and orderly fashion so that they are more readily grasped by minds unaccustomed to thinking in abstract terms.

Practically all of the important unit operations of chemical engineering are covered, one chapter being devoted to each. An excellent balance is maintained between the theory of each operation and the practical art. The most important of the tools available to the chemical engineer in the practice of his art are well described with the aid of a large number of illustrations, which are clearly one of the outstanding features of the book. These are all line drawings, especially made for the book and have been admirably executed to show clearly the essential features of construction and to explain the principle of operation. The fact that there are somewhat more than half as many figures as there are pages in the book is convincing evidence of the extent to which visual aid to instruction has been utilized.

We venture to predict that this book will be widely adopted as the standard text for beginning students in chemical engineering and even for some more advanced courses. But one should not infer from this that its appeal is only to the student. On the contrary, its general excellence in both the theoretical and practical side of the subject is such that no one who has any contact with the technical side of chemical industry can afford to be without it.

BARNETT F. DODGE

Veröffentlichungen des wissenschaftlichen Zentral-laboratoriums der Photographischen Abteilung—AGFA. (Publications from the Scientific Laboratories of the Photographic Division—AGFA.) Vol. I. Issued by the I. G. Farbenindustrie Aktiengesellschaft. Verlag von S. Hirzel, Königstrasse 2, Leipzig C 1, Germany, 1930. vii + 155 pp. Illustrated. 94 figs. 17.5 × 24.5 cm. Price, RM. 10.

This first volume of a series to be issued by the I. G. Farbenindustrie Aktiengesellschaft contains a number of fairly elementary articles of interest to the spectroscopist, the photo-chemist, the color photographer, the Rontgenologist and the tone-film engineer, all treated from the standpoint of photographic technique. Articles by Eggert, Arens and others, on the theory of the latent image, the laws of blackening of the photographic emulsion and color sensitometry, are followed by a brief discussion of infra-red photography by Dieterle. Then come pages devoted to the use and control of photographic film in the talking movies. The next articles deal with x-ray problems, the first discussed being that of taking stereoscopic x-ray photographs, while the Agfa-Rontgen film dosimeter and its use constitute another.

The balance of the volume is taken up with a discussion of experiments on the thermal and other physical properties of cellulose and its derivatives, as of interest in photography; and with certain problems of half-tone reproduction. While as to unity of material the volume is a typical "Contributions from the ———Laboratory," it is well written and illustrated and nicely printed. A well selected bibliography accompanies each article.

GEORGE R. HARRISON

Chemical Calculations. By ERNEST L. DINSMORE, A.B., Chairman of the Chemistry Department, Boys High School, Brooklyn, New York. Globe Book Company, New York. vi + 182 pp. 7 figures. 12.5 × 19 cm.

The fourteen chapters of this book provide a "wealth of material in chemical calculations." In Chapters I to X inclusive the problems are arranged by types in the order in which the corresponding subject matter occurs in standard elementary texts on chemistry. Each chapter is introduced by some theoretical matter, definitions of chemical terms employed, and by the solution of one or more typical problems. A few study questions generally precede the numerical problems. Chapter XI comprises miscellaneous problems covering all the different types previously presented. Chapter XII includes 272 problems grouped under the chapter headings of the average textbook. These will be of special service in connection with review work, and will be helpful to teachers in the preparation of examination papers. Chapters XIII and XIV consist of 54 problems selected mainly from recent examination questions of the College Entrance Examination Board. No answers are given.

Some of the exercises in Chapter X, Solutions, deal with normal and molar concentration but problems based on Raoult's laws have been omitted. And there are no exercises on electrolysis—Faraday's laws—ionization constants, solubility product, P_H values, and calculations based upon oxidation–reduction reactions.

HERMAN SCHLUNDT

Reactions and Symbols of Carbon Compounds. A Textbook of Organic Chemistry. By T. CLINTON TAYLOR, Ph.D., Associate Professor of Chemistry, Columbia University. The Century Company, 353 Fourth Avenue, New York, 1930. x + 704 pp. 14.5 X 22 cm. Price, $4.00.

It should be stated at the outset that this is not "just another organic text." Professor Taylor has gone further than any other author your reviewer is aware of in presenting a course in theoretical organic chemistry on the basis of experiment. Despite the obvious difficulty of the undertaking, he has managed, in the main, to accomplish what he aimed to do. Students who really learn a considerable part of the material presented will know what reagents are actually employed to achieve certain ends, something, alas, which those brought up on the more conventional texts are liable to have altogether too little appreciation of.

The most glaring discrepancies in the book, and it must be admitted there are several, are evidently due to too hasty proof-reading. At least three proper names are misspelled, and other errors of spelling are easily discoverable. Too many formulas are incomplete, or actually wrong; for example, that for thymol indicates it to be an aldehyde, and nerolin is said to be an ethyl ether. Furthermore, the statement appears that "no acid chlorides (of oxalic acid) are known,') and this despite the fact that each set of the decennial indices to Chemical *Abstracts* presents numerous references to oxalyl chloride, which has been known for over fifteen years at least. The author, regrettably, consistently utilizes the term "symbol" where "formula" is the conventional designation, and offers no explanation for this eccentricity; also there are too many instances of the use of a term not yet explained, sometimes never explained, such as olefin, to cite a rather notable example. Sometimes where a preferable name, such as glycerol or pinacol, is mentioned by the author, he will subsequently content himself to use the older or less desirable nomenclature, which if we ever hope to arrive at a general usage of the preferable term is at least unfortunate. The modern interpretation of the Beckmann rearrangement is not given, and the formula for strychnine is, unhappily, not that on which Robinson's recent work has put the stamp of approval. The book is rather difficult reading at times because of the author's use of parenthetical expressions and references injected into the text; but, more particularly, footnotes are employed to an excessive extent, in one sentence characters appear referring the reader to three separate footnotes One extraordinary instance of lack of balance is evident; carbohydrates and rather closely related substances are given 82 pages out of 687 of actual text; whereas proteins are disposed of in **13.** One may be excused for riding an important hobby to the limit, but to back a favorite 6–1 is rather overdoing it.

It is always easy to find faults in anything and one should not infer from the foregoing that this text lacks attractive features. Those who have sought, too frequently in vain, for a good structural formula for mercurochrome, will be glad to find one included here. Electronic equations constitute a noteworthy feature of this text and **are** consistently and remarkably successfully employed.

When Professor Taylor's book appears in its next edition, more carefully proof-read, it will furnish a unique and thoroughly worth-while presentation of organic chemistry for college students.

G. ALBERT HILL
