RECALCULATIONS OF THE FIRST DISSOCIATION CONSTANT OF PHOSPHORIC ACID IN AQUEOUS SOLUTION AT 18°, AND INCIDENTAL DETERMINATION OF THE ACTIVITY COEFFICIENTS OF THE UNDISSOCIATED ACID MOLECULES

BY JOSEPH W. H. LUGG

RECEIVED JULY 1, 1930 PUBLISHED JANUARY 12, 1931

In 1907 Noyes and Eastman[1] measured the formula conductivities of phosphoric acid in aqueous solutions of low concentration at 18°, and in 1909 Abbott and Bray[2] used these data in conjunction with their own determination of the equivalent conductivity at infinite dilution of $H^+ + H_2PO_4^-$ ions, in calculations of the first stoichiometric dissociation constant. It appears that no reliable conductivity measurements of dilute phosphoric acid solutions have been made since then.

Sherrill and Noyes[3] in 1926 recalculated the first constant from Noyes and Eastman's data and by way of correcting for inter-ionic electrical effects they made use of the fact noted by MacInnes,[4] namely, that mobilities of certain monatomic univalent ions (K^C, Na^C, Cl^-, etc.), up to about 0.1 N concentration, are independent of the oppositely charged ions associated with them provided these latter are monatomic and univalent.

In their recalculations of the original data, Sendroy and Hastings[5] did not correct for inter-ionic attraction forces. They calculated the ionic strengths of the solutions from the original phosphoric acid molarities instead of from the equivalent ion concentrations.

Onsager's[6] admirable development of the Debye–Hückel theory[7] furnishes means for correcting the measured conductivities of the phosphoric acid solutions for inter-ionic attraction forces. For completely dissociated

uni-univalent electrolytes in aqueous solution at 18°, Onsager's limiting equation is

$$A = A, - (35.7 + 0.159\Lambda_\infty)\sqrt{2c} \qquad (1)$$

where A is the equivalent conductivity at concentration c and **A,** is the equivalent conductivity at infinite dilution. Practically all modern evidence weighs in favor of the contention that strong electrolytes such as NaCl, KCl, LiCl, HCI, KOH, etc., and many of higher valence type, are completely dissociated in aqueous solution, even up to molar concentration. To conductivity data for the uni-univalent electrolytes, Debye and Hiickel[8] have applied equations of the form

$$A = \Lambda_\infty - a\sqrt{2c} + b2c \qquad (2)$$

determining the constants *a* and b for each electrolyte by the method of least squares. It may be concluded from Onsager's paper that a negative value for b connotes incomplete dissociation.

The *a* values agree excellently with the Onsager theoretical coefficients, so the assumption that an equation of the form of (2) would apply to solutions containing only H^+ and $H_2PO_4^-$ ions necessarily in equal concentration is well founded. With the value of A, at 18° known, *a* could be calculated from Equation 1, and b may be assigned the rough value +40, from a consideration of the positive Debye–Hiickel coefficients.

Determination of A, ($H^+ + H_2PO_4^-$) at 18°

The quantity μ which occurs frequently in this paper is not quite the same as the "ionic strength" as defined by Lewis and Randall,[9] but is defined in the identity, $\mu \equiv {}^1/_2\Sigma(Cz^2)$, where C is the concentration of an ion in moles per liter, and z is its valence. "μ" defined in this way has greater significance in the Onsager and Debye–Hiickel equations.

In arriving at a value for Λ_∞ ($H^+ + H_2PO_4^-$), the conductivity data of Abbott and Bray[2] for the salt NaH_2PO_4 were employed, but were first corrected for dissociation of the $H_2PO_4^-$ ions. The corrections were considerably smaller than those calculated by Abbott and Bray. A generalized equation for the second stoichiometric dissociation constant of phosphoric acid and rough values for the mobilities of the ions H^+, $H_2PO_4^-$ and $HPO_4^=$, used in calculating the corrections to be applied to A NaH_2PO_4 as measured, appear below

$$pK_2 = 7.16 - \frac{2\sqrt{\mu}}{1 + 1.5\sqrt{\mu}} \qquad (3)$$

$\Lambda_\infty H^+ = 314$; $\Lambda_\infty H_2PO_4^- = 27$; $\Lambda_\infty {}^1/_2HPO_4^= = 53$. Decreases in these values with increase in μ are calculable from the Onsager equations.

Equation **3** has been deduced by the author from his own data for the

second constant[10] and from the data in W. Mansfield Clark's 1928 edition of "The Determination of Hydrogen Ions." From these sources it is found that in presence of most salts, $p\overline{K}_2$ (*i. e.*, $pK_2 + p\gamma_{\mathrm{H}^+}$) $= 7.16 - 1.5\sqrt{\mu}/1 + a\sqrt{\mu})$ at 18°, where p signifies negative common logarithm, γ_{H^+} is the activity coefficient of H^+ ion, and a is a constant determined by the ionic environment. Replacing $p\gamma_{\mathrm{H}^+}$ from Equation 12 of this paper, one obtains for pK_2 at 18°, the approximate equation $pK_2 = 7.16 - 2\sqrt{\mu}/(1 + a\sqrt{\mu})$. The most likely value for a in NaH_2PO_4 solutions seems to be about 1.5, but the uncertainty will not materially affect the calculations.

Where d is the degree of dissociation of the $H_2PO_4^-$ ion, calculated with the help of Equation **3,** we have

$$\Lambda_{\text{corr.}}\ \mathrm{NaH_2PO_4} = \Lambda\mathrm{NaH_2PO_4} - d\Lambda\mathrm{H^+} - 2d\Lambda{}^1/{}_2\mathrm{HPO_4^=} + d\Lambda\mathrm{H_2PO_4^-}$$

Table I contains the data of Abbott and Bray for NaH_2PO_4 conductivity; corrections to be applied for secondary dissociation of the H_2PO_4 ions; corrected values of ΛNaH_2PO_4; values of μ; and values of $\sqrt{\mu}$.

TABLE I

EQUIVALENT CONDUCTIVITY OF NaH_2PO_4 AT 18°

Molarity of NaH_2PO_4	Approx. $\sqrt{\mu}$	Molar conductivity (measured), ΛNaH_2PO_4	Corrn.	Corr. molar or equivalent conductivity, $\Lambda_{\text{corr.}}$ NaH_2PO_4
0	0			70.1[a]
0.001	0.032	71.68 ?	−3.8	67.9

.100	.316	54.43	− .3	54.1
.200	.447	49.74	− .2	49.5

[a] **Extrapolated.**

Corrected values of Λ were plotted against corresponding values of $\sqrt{\mu}$, and the curve drawn was extrapolated from the points for lowest concentrations almost linearly with $\sqrt{\mu}$ to the point, $\sqrt{\mu} = 0$, $\Lambda_{\text{corr.}} = 70.1$. Slopes of tangents to the curve at low $\sqrt{\mu}$ values corresponded very well with the slope of the theoretical limiting straight line, $\Lambda = 70.1 - (35.7 + 0.159 \times 70.1)\sqrt{2\mu}$, divergences being in the direction expected for a completely dissociated salt.

For Λ_∞NaCl, the value 108.9 determined by Debye and Hückel[8] from the data of Kohlrausch and Maltby was accepted. A value 379.3 for Λ_∞HCl was obtained from the data of Goodwin and Haskell[11] by extra-

---

[10] Not **yet published.**

[11] Goodwin and **Haskell,** *Phys.* ***Rev.*,19,369** (1904).

polating to $\sqrt{\mu} = 0$ a curve connecting A with $\sqrt{\mu}$, just as in the case of NaH_2PO_4.

These values of Λ_∞ for the three electrolytes, NaH_2PO_4, NaCl and HCl, are for 18°, and A, $(H^+ + H_2PO_4^-)$ at 18° is readily obtained from 379.3 + 70.1 − 108.9, giving 340.5.

Thus the equation one would expect to apply to aqueous solutions at 18° containing only H^+ and $H_2PO_4^-$ ions is

$$A = A, \; -(35.7 + 0.159 \times 340.5)\sqrt{2e} + 40 \times 2e, \text{ that is}$$

$$A = A, \; - 127.1 \sqrt{e} + 80e \qquad (4)$$

where e is the equivalent ion concentration and A refers to a dilution $1/e$.

Although the second term ($80e$) is not negligible, it is obviously small compared with the first ($127.1 \sqrt{e}$) up to e = 0.04, so the uncertainty attached to the coefficient 80 will be found scarcely to affect the calculations below that value of e.

Calculation of the First Stoichiometric Dissociation Constant.—In aqueous solution phosphoric acid dissociates as follows

$$H_3PO_4 \rightleftharpoons H^+ + H_2PO_4^-; \quad H_2PO_4^- \rightleftharpoons H^+ + HPO_4^=; \quad HPO_4^= \rightleftharpoons H^+ + PO_4^{\equiv}$$

For any but almost infinitely dilute solutions of the free acid, the magnitudes of the three dissociation constants are such as to allow the production of only H^+ and $H_2PO_4^-$ ions in any appreciable quantity. OH^- ion concentrations, of course, are negligibly small in consequence of the hydrogen ionization of the acid. Thus the conductivity of phosphoric acid solutions down to a molarity of, say, 0.0001 may be considered due entirely to the presence of H^+ and $H_2PO_4^-$ ions in equal concentration. Hence where A is the molar conductivity at molarity c of a solution of phosphoric acid at 18°, and d is the degree of the first dissociation, we have, neglecting viscosity changes which are small enough at low concentrations

$$\Lambda/d = A, \; (H^+ + H_2PO_4^-) - A\sqrt{dc} + Bdc \qquad (5)$$

where A is 127.1 and B is 80. Transposition, squaring of both sides and subsequent rearrangement lead to

$$(B^2c^2)d^4 + (2B\Lambda_\infty - A^2c)d^3 - (2B\Lambda c - \Lambda_\infty^2)d^2 - (2\Lambda\Lambda_\infty)d + \Lambda^2 = 0 \qquad (6)$$

Certain roots of this biquadratic in d would have to be excluded and it must be recalled that only the positive extraction of $\sqrt{dc}$ in Equation 5 is to be used.

Defining $A_{,,,,}$ in the relation $\Lambda_{corr.}/\Lambda_\infty = d$, and substituting in Equation 5, one obtains

$$A_{,,,,.} = A + Ad\sqrt{dc} - Bd^2c \qquad (7)$$

and $A_{,,,,}$ is A corrected for inter-ionic attraction forces. From Equation 7 $A_{,,,}$ may be obtained by a series of successive approximations and then d may be calculated from the definition. Two such approximations were found sufficient to give values of $\Lambda_{corr.}$ unaltered in the first decimal place by successive approximations, and values of d appearing in

Table II were derived from these instead of from laborious solution of Equation 6.

By the law of mass action we have for the first stoichiometric dissociation constant, square brackets signifying molarities

$$K_1 = \frac{[H^+][H_2PO_4^-]}{[H_3PO_4]} = \frac{dcdc}{(1-d)c} = \frac{d^2c}{(1-d)} \tag{8}$$

In logarithmic form, where p signifies negative common logarithm, Equation 8 becomes

$$pK_1 = p[H^+] + p[H_2PO_4] - p[H_3PO_4] = 2pd + pc - p(1 - d) \tag{9}$$

Table II contains in the order of the columns, the data of Noyes and Eastman, corrections to A, $\Lambda_{corr.}$, d, μ, $\sqrt{\mu}$, K_1 and pK_1.

[a] Extr.

The Constant at Infinite Dilution. Activity Coefficients of H_3PO_4.—By definition and the mass law, the first activity dissociation constant of phosphoric acid K'_1 is given in Equation 10 and is an exact constant. α_X signifies activity of X, and $\alpha_X = \gamma_X[X]$, where γ_X is the activity coefficient, expresses its relation to the molarity. The chosen standard state in which $\gamma_X = 1$ (*i. e.*, $\alpha_X = [X]$) for H^+, $H_2PO_4^-$, and H_3PO_4, is infinite dilution in each case.

$$K'_1 = \frac{\alpha_{H^+} \times \alpha_{H_2PO_4^-}}{\alpha_{H_3PO_4}} \tag{10}$$

Hence replacing α_X by $\gamma_X[X]$ and expressing in logarithmic form

$$pK'_1 = p[H^+] + p[H_2PO_4] - p[H_3PO_4] + p\gamma_{H^+} + p\gamma_{H_2PO_5} - p\gamma_{H_3PO_4}$$

Substitution from Equation **9** followed by rearrangement, gives

$$pK_1 = pK'_1 - p\gamma_{H^+} - p\gamma_{H_2PO_4^-} + p\gamma_{H_3PO_4} \tag{11}$$

For variation of the activity coefficient of an ion with μ, the Debye-Hückel[12] equation has been found to apply admirably up to $\mu = 0.5$ or more

$$p\gamma_i = \frac{0.5\, z_i^2 \sqrt{\mu}}{1 + 3.3 \times 10^7 a_i \sqrt{\mu}} \tag{12}$$

---

[12] Debye-Hückel, *Physik. Z.*, *24*, 185 (1923).

where z_i is the valence of the ion and a_i is the mean limit of approach of ions to ions of kind "i."[13] In place of 3.3 X $10^7 a_i$ one may use the coefficients a for H^+ and b for $H_2PO_4^-$ ions, in solutions containing H^+ and $H_2PO_4^-$ ions. Then $-p\gamma_{H^+} - p\gamma_{H_2PO_4^-}$ may be put in the form

$$\frac{-0.5\sqrt{\mu}}{1 + a\sqrt{\mu}} + \frac{-0.5\sqrt{\mu}}{1 + b\sqrt{\mu}}$$

and provided a and b be of the same order of magnitude the expression may be reduced for practical purposes to

$$-\frac{\sqrt{\mu}}{1 + a\sqrt{\mu}}$$

where a now has some mean value. The expression approaches $-\sqrt{\mu}$ as $\sqrt{\mu} \longrightarrow 0$.

Debye and McAulay[14] have investigated variation of the activity coefficient of a non-electrolyte in presence of an electrolyte, and have deduced a theoretical equation which may be expressed

$$p\gamma_{\text{non-elect.}} = -S\mu \qquad (13)$$

where S is a constant depending upon the mean effective ionic radius, among other things. Experimentally, it has been shown by these authors and by Randall and Failey[15] that the variation depends almost entirely upon the concentration of electrolyte and scarcely at all upon the concentration of non-electrolyte up to moderate concentrations, and is, moreover, in agreement with the general equation. One may therefore replace $p\gamma_{H_3PO_4}$ in Equation 11 by $-S\mu$, where S is a constant. Equation 11 becomes

$$pK_1 = pK_1' - \frac{\sqrt{\mu}}{1 + a\sqrt{\mu}} - S\mu \qquad (14)$$

$dpK_1/d\sqrt{\mu} = -1/(1 + a\sqrt{\mu})^2 - 2S\sqrt{\mu}$, giving slopes of tangents to the curve of Equation 14 and showing that the slope is -1 when $\sqrt{\mu} = 0$.

Values of pK_1 appearing in Table II were plotted against corresponding values of $\sqrt{\mu}$, but practically no weight was placed upon the point corresponding with lowest phosphoric acid concentration, because A, and A„„ cannot be known exactly and for this point it requires an error of but ±0.1 in either to effect an error of ± 0.01 in pK_1. **A** smooth curve was drawn with tangential slopes continually approaching -1 as $\sqrt{\mu}$ decreased to zero.[16] pK_1 at $\sqrt{\mu} = 0$ (*i. e.*, pK_1') was found to be 2.09. The values obtained by Sherrill and Noyes and by Sendroy and Hastings, are 2.08 and 2.11, respectively.

---

[13] The additional "salting out term," $(-C\mu)$, deduced by Hückel [*Physik.* Z., 26,931 (1925)], where Cis small and positive, may well be omitted here since its effects would be inappreciable up to $\sqrt{\mu} = 0.2$. A very small increase in the value of a_i compensates for the omission up to much higher values of $\sqrt{\mu}$.

[14] Debye and McAulay, *ibid.*, 26, 22 (1925).

[15] Randall and Failey, *Chem.* Reviews, 4, 271 (1927).

[16] When S is positive, Equation 14 permits such a smooth extrapolation only provided that $S > a$. The condition is satisfied in this case.

In Fig. 1 are shown the curve connecting pK_1 with $\sqrt{\mu}$ and passing through the point $pK_1 = 2.09$, $\sqrt{\mu} = 0$, the limiting straight line $pK_1 = 2.09 - \sqrt{\mu}$, and a curve $pK_1 = 2.09 - \sqrt{\mu}/(1 + 1.0\sqrt{\mu})$. The choice of a value 1.0 for a in Equation 14 is suggested from an examination of scattered data for different electrolytes, and it is considered unlikely to be in error by more than +0.5 or −0.3. From the divergence of the two curves in the figure, S in Equation 14 is readily calculated to be 1.8 An error of ±0.3 in the chosen value for a, would result in an error of about ±0.2 in the calculated value of *S*. With the assumed value 1.0 for a, therefore, the equation connecting pK_1 for pure phosphoric acid in dilute aqueous solution at 18°, with μ calculated from the H^+ and $H_2PO_4^-$ ions, is

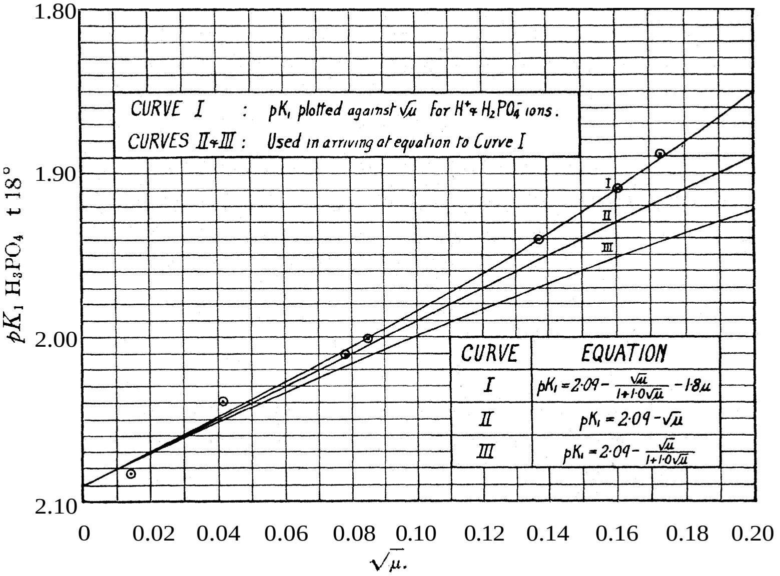

Fig. 1.

$$pK_1 = 2.09 - \frac{}{1 + 1.0\sqrt{\mu}} - 1.8\mu \tag{15}$$

making the equation for the activity coefficient of undissociated phosphoric acid in presence of H^+ and $H_2PO_4^-$ ions in aqueous solution at 18°.

$$p\gamma_{H_3PO_4} = -1.8\mu \tag{16}$$

In conclusion the author wishes to acknowledge his indebtedness to Dr. S. W. Pennycuick of the Adelaide University for reading the manuscript and suggesting alterations, and making the necessary arrangements for publication.

Summary

1. From data in the literature it has been found that Λ_∞ NaH_2PO_4 is 70.1 at 18°, and from this and the values 108.9 and 379.3 for A, NaCl and

Λ_∞HCl, respectively, Λ_∞ ($H^+ + H_2PO_4^-$) has been calculated to be 340.5 at that same temperature.

2. Values for the first stoichiometric dissociation constant of phosphoric acid alone in aqueous solution at 18° have been calculated from the data of Noyes and Eastman. pK_1' (*i. e.*, pK_1 at infinite dilution) has been assigned the value 2.09. An equation well fitting the data is $pK_1 = 2.09 - \sqrt{\mu}/(1 + 1.0\sqrt{\mu}) - 1.8\mu$.

3. An approximate equation for the activity coefficient of the undissociated fraction in pure dilute aqueous solutions of phosphoric acid at 18° is $p\gamma_{H_3PO_4} = -1.8\mu$, where μ is calculated from the equivalent ion concentration.

[Contribution from the Department of Chemistry, Yale University]

THE TEMPERATURE COEFFICIENT OF DISSOCIATION OF ACETIC ACID IN POTASSIUM AND SODIUM CHLORIDE SOLUTIONS[1]

By Herbert S. Harned and George M. Murphy

Received July 15, 1930 Published January 12, 1931

It has been shown by Harned and Robinson, and Harned and Owen[2] that the ionization constant, hydrogen- or hydroxide-ion concentrations, and ionic activity coefficients of weak acids and bases may be determined from measurements of cells without liquid junction. Their measurements were all made at 25°. Since it is a matter of considerable importance to study the effect of temperature on the dissociation of a weak electrolyte both in a pure solvent and in salt solutions, the present study was undertaken. To this end accurate measurements of the cells

$$H_2 \mid HCl\ (0.01),\ MCl\ (m) \mid AgCl \mid Ag, \text{ and} \qquad (I)$$
$$H_2 \mid HAc\ (0.2),\ MCl\ (m) \mid AgCl \mid Ag \qquad (II)$$

at 20, 25 and 30° have been made, in which HAc is acetic acid, and MCl sodium and potassium chlorides.

Experimental Procedure and Results

The cells employed were of the usual H-type, and were equipped with a three-way stopcock through which the hydrogen entered the cell. By the proper manipulation of this stopcock, the cell could easily be transferred from a thermostat maintained at one temperature to one at another temperature without danger of the hydrogen electrode coming into contact with air. Equilibrium in the cell was considered established when

In Table I are given the observed electromotive forces of the cells designated at 20, 25, and 30°.

The frequently employed equation

$$E_t = E_{25}\,(1 + a_{25}\,(t - 25) + b_{25}\,(t - 25)^2) \qquad (1)$$

is sufficient to express the electromotive force as a function of t. The constants a_{25} and b_{25} are given in the fifth and sixth columns of the table.

The Activity Coefficients and Partial Heat Content **of** Hydrochloric Acid in the Chloride Solutions.—The activity coefficient of the acid in the salt solutions may be computed from the well-known equation

$$\ln \gamma = \frac{E_0 - E}{2RT} F \ln \gamma_0 - \ln \frac{\sqrt{0.01(0.01 + m)}}{0.01} \qquad (2)$$

where E is the electromotive force of the cell containing salt, E_0 that of the cell containing acid only, and γ_0, the activity coefficient of the acid of 0.01 M concentration at a temperature T.

According to the computations of Randall and Young,[3] the activity coefficient of ±0.01 M acid at the freezing point of the solution differs by 0.2% from that at 25°. Fortunately, sufficient heat data are available to estimate the variation of γ_0 with the temperature in the neighborhood of 25°. The variation of the activity with the temperature is given by

$$\frac{\mathrm{d} \ln a}{\mathrm{d}T} = -\frac{\bar{L}}{RT^2} \qquad (3)$$

where $\bar{L}$ is the partial heat content relative to o at zero concentration of solute. The variation of $\bar{L}$ with temperature may be represented by the equation

$$\bar{L} = \bar{L}_{25} + (\bar{C}_p - \bar{C}_p^{\circ})\,(T - 298.1) \qquad (4)$$

where $\bar{C}_p$ and $\bar{C}_p^{\circ}$ are the partial molal heat capacities of the solute at concentrations m and o, respectively, and $\bar{L}_{25}$ is the relative partial heat content at 25°. Substituting this expression in Equation 3 and performing the integration, it is found that

$$\log \frac{a_{25}}{a_t} = -\bar{L}_{25}y + \Delta C_p z \qquad (5)$$

where

$$y = \frac{298.1 - T}{2.303 \times 298.1 \times RT} \qquad (6)$$

and

$$z = 298.1y - \frac{1}{R} \log \frac{298.1}{T} \qquad (7)$$

Values of y and z have been computed and tabulated by Lewis and Randall.[4] Since

$$\log a = 2 \log a, = 2 \log my \qquad (8)$$

---

[3] Randall and Young. THIS JOURNAL, 50,989 (1928).

[4] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., New York, 1923, pp. 613–616.

we readily find that

$$\log \frac{\gamma_{25}}{\gamma} = -\frac{1}{2}(\bar{L}_{25}y - \Delta C_p Z) \qquad (9)$$

The value of $\bar{L}_{25}$ for 0.01 M hydrochloric acid has been computed by Harned[5] from the electromotive force measurements of Ellis, and Noyes and Ellis[6] and is 78.9 calories. The values of C_p and C_p° have been determined calorimetically by Randall and Ramage[7] and are: $\bar{C}_p^\circ = -41$; $\bar{C}_p = -41 + 14m^{1/2} = -39.6$, whence $\Delta\bar{C}_p = 1.4$ cal. Substituting these values in (9) and performing the calculation, we find that the value of the ratios, γ_{25}/γ_{20} and γ_{30}/γ_{25} is 0.999, corresponding to a variation of about 0.1% for a change in temperature of 5°. Since only a 0.2% variation is obtained in going from the freezing point of the acid at 25° and 0.1% for 5° change, it appears that γ is changing most rapidly in the neighborhood of 25° provided that the method of extrapolation from the freezing point data is accurate. Since the change in γ_0 with the temperature at the concentration in question is so small, and because of the uncertainty in the heat data, we have taken γ_0 to be the same at 20, 25 and 30°. The value used was 0.902,[8] which upon substitution in Equation 2 gives

$$\log \gamma = \frac{2520}{T}(E^\circ - E) - 0.04479 - \log \frac{\sqrt{0.01(0.01 + m)}}{0.01} \qquad (10)$$

The activity coefficients given in Table II were computed by this equation from the electromotive forces in the first half of Table I.

The data in the table show that γ decreases slightly with the increase of temperature and that this decrease becomes greater at higher salt concentrations. Such a decrease of y is to be expected.

If we substitute the value for the free energy of the cell reaction derivable from Equation 1 in the Gibbs–Helmholtz equation

$$\frac{d(-\Delta E/T)}{dT} = \frac{\Delta H}{T^2} \qquad (11)$$

we obtain

$$-\Delta H_{25} = \Delta F_{25}(1 - 298a_{25}) \qquad (12)$$ [9]

by means of which the heat content of the cell reaction at all salt concentrations may be computed. By subtracting the values of $(-\Delta H)_{25}$ at a given salt concentration, M, from the value at zero salt concentration, we obtain the heat content change corresponding to the transfer

$$\text{HCl } (0.01), [\text{MCl}(m)] = \text{HCl } (0.01)$$

or the partial heat content of the acid in the salt solution relative to its value at zero salt concentration.[10] The values of $(-\Delta\overline{H}_{25})$ are given in the fifth column of Table II, and are plotted in Fig. 1 along with values

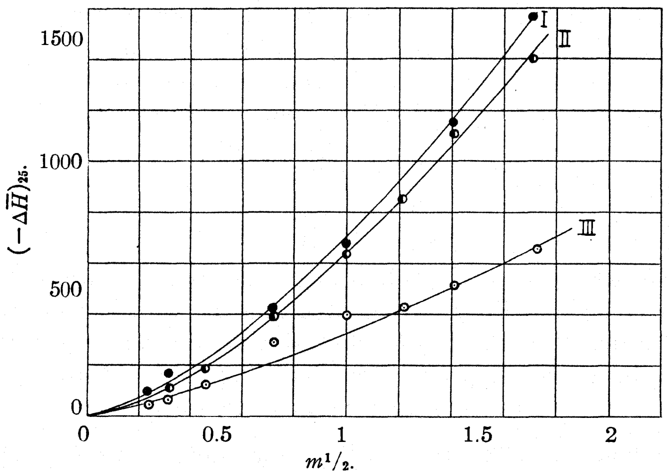

Fig. 1.—The relative partial heat content of hydrochloric acid in potassium and sodium chloride solutions. ●, HCl; ◐, HCl in NaCl; ⊙, HCl in KCl.

---

[10] Harned, THIS JOURNAL, 42, 1808 (1920).

for the partial heat content of the pure aqueous acid solution relative to 0.01 M. These latter were taken from the results computed by Harned from the data of Ellis, and of Noyes and Ellis.[5,11] The results appear reasonable and agree in magnitude at least with the less accurate results obtained by Harned.[10] In fact, great accuracy is not to be expected since an error of 0.01 mv. in the temperature coefficient of the cell causes an error of 130 calories in the partial heat content.

The Dissociation of Acetic Acid in Sodium and Potassium Chloride Solutions and its Temperature Coefficient.—From the electromotive forces of cells given in Table I, we may readily obtain those of the cells

$$\text{Ag} \mid \text{AgCl} \mid \text{HCl}\ (0.01) \mid \text{H}_2 \mid \text{HAc}\ (0.2),\ \text{MCl}\ (m) \mid \text{AgCl} \mid \text{Ag}$$

The electromotive forces of the latter are given by

$$E = E_1 - E_0 = 0.00019844\ T \log \frac{(0.902)^2\ (0.01)^2}{\gamma_{\text{H}}\gamma_{\text{Cl}} m_{\text{H}} m} \tag{13}$$

It is important to note that $\gamma_{\text{H}}\ \gamma_{\text{Cl}}$ is the activity coefficient of hydrochloric acid in a solution containing both the weak acid and the salt. Harned and Owen[2] have carefully analyzed Equation **13.** If the values of $\gamma_{\text{H}}^{\circ}\ \gamma_{\text{Cl}}^{\circ}$ obtainable from Table II are substituted in (13), an "apparent" hydrogen-ion concentration, m'_{H}, is obtained because these values of $\gamma_{\text{H}}^{\circ}\ \gamma_{\text{Cl}}^{\circ}$ are obtained in pure aqueous salt solutions and do not equal similar values obtained in the presence of undissociated acetic acid. By introducing $\gamma_{\text{H}}^{\circ}\ \gamma_{\text{Cl}}^{\circ}$ for $\gamma_{\text{H}}\ \gamma_{\text{Cl}}$ in Equation **13,** we obtain

$$\log m'_{\text{H}} = -\frac{E}{0.00019844T} - 4.09858 - 2 \log \gamma_{\text{HCl}}^{\circ} - \log m \tag{14}$$

Further, from Equation 17 of Harned and Owen's study, we find that the relation between the real and apparent hydrogen-ion concentration at a given-temperature is

$$SM = \log \frac{m'_{\text{H}}}{m_{\text{H}}} \tag{15}$$

where S is a constant which corrects for the effect of the undissociated acetic acid molecule, and M is the concentration of the acetic acid. They found that S equals 0.047 and, consequently, SM equals 0.0094. By combining (14) and (15), we obtain

$$\log m_{\text{H}} = -\frac{E}{0.00019844T} - 4.09858 - 2 \log \gamma_{\text{HCl}}^{\circ} - \log m - 0.0094 \tag{16}$$

by which the values of m_{H} contained in Table III were computed in the manner described by Harned and Robinson. In making this step, we have assumed that SM is the same at 20, 25 and 30°. This assumption involves no error greater than the experimental, since M is not high and since the temperature range under consideration is only ten degrees.

2	.002009	.002039	,002065	2	.002104	,002134	.002160
3	.001718	.001746	.001765	3	.001772	.001802	,001830

Our next step is to obtain values for the dissociation constant of the acetic acid at 20, 25 and 30°. Conductance data at temperatures other than 25° are unreliable although they indicate little change of the dissociation constant with temperature in the neighborhood of 25°. We have very good evidence to show that this is the case. The dissociation constant, K, is given thermodynamically by

$$K = \frac{\gamma_{HAc}}{\gamma_H \gamma_{Ac}} \frac{m_H^2}{0.2 - m_H} = \gamma_A^2 K_c \qquad (17)$$

Taking the logarithm, we obtain

$$\log K = \log Kc + 2\log \gamma_A \qquad (18)$$

But we know that in dilute and moderately concentrated solutions the variation of γ_A with the ionic strength is given by

$$2\log \gamma_A = -\sqrt{\mu} + B\mu \qquad (19)$$

Substituting in (18) and transposing,

$$\log K - B\mu = \log Kc - \sqrt{\mu} \qquad (20)$$

is obtained. Thus if we plot ($\log K_c - \sqrt{\mu}$), computed from the data in Table III, against μ, straight lines should be obtained in the more dilute solutions. Further, when $\mu = 0$, the right-hand member of Equation 20 equals log K. The plots of these quantities at the three temperatures are shown in Fig. 2. The plots are all drawn to the point at $\mu = 0$ corresponding 1.75×10^{-5} for K found by Harned and Owen. It is clear that the data at all three temperatures fall closely on these lines. We feel justified for the present in employing 1.75×10^{-5} for the dissociation constant at all three temperatures.

In Table IV are given the values of γ_A or $\sqrt{\gamma_H\gamma_{AC}/\gamma_{HAC}}$ in the solution of the two chlorides computed by Equation 17 from the values of m_H given in Table III.

It is apparent from these results that the activity coefficient of acetic acid decreases slightly with rising temperature at the higher ionic strengths. This is similar to the behavior of hydrochloric acid in the same salt solu-

TABLE IV

THE ACTIVITY COEFFICIENT OF ACETIC ACID IN THE SALT SOLUTIONS

MCl = KCl				MCl = NaCl

tions. Further, this temperature effect is somewhat greater the higher the salt concentration. Finally, at a given ionic strength the activity coefficient is greater in potassium than in sodium chloride solutions, a fact observed by Harned and Robinson.[2] Indeed, at 25°, our electromotive force measurements closely check those of Harned and Robinson.

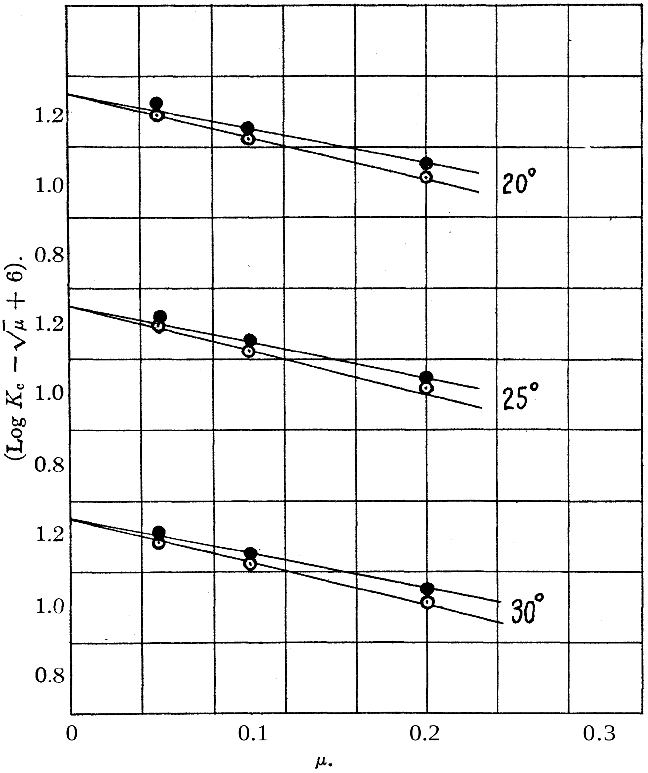

Fig. 2.—Graphical extrapolation to determine the dissociation constant of acetic acid at 20, 25 and 30°. O, KCl; ●, NaCl.

Calculation of the Electrical Heat Content Decrease.—We have made no calculations of the heat content decreases of the cell reaction from the electromotive force of the cells containing acetic acid. The only difference from the previous calculations would be that the hydrochloric acid is transferred from the salt solution containing some acetic acid. Moreover, since there is no convenient reference state upon which the calculations can be based, we cannot readily obtain the partial molal heat content.

It is a matter of some interest, however, to compute the excess or electrical partial heat content of hydrochloric acid from the results which we have so far derived.

According to theory, the partial free energy of an electrolyte may **be** divided into two parts as follows

$$\Delta\bar{F} = \Delta\bar{F}_c + \Delta\bar{F}_e \tag{21}$$

where

$$\left.\begin{aligned}\Delta\bar{F}_c &= RT \ln m, \text{ and}\\ \Delta\bar{F}_e &= RT \ln \gamma\end{aligned}\right\} \tag{22}$$

$\Delta\bar{F}_c$ is the contribution to the free energy due to the change in concentration, $\Delta\bar{F}_e$ is the contribution to the partial free energy caused by the electrostatic forces, and is denoted "the electrical free energy" or the excess free energy caused by the ionic atmosphere. Since γ is unity when m equals zero, $\Delta\bar{F}_e$ equals zero when m equals zero.

$\Delta\bar{F}_e$ may be computed readily, but we are more interested at present in the corresponding values of $\Delta\bar{H}_e$, or the excess heat content. The Gibbs–Helmholtz equation is

$$\frac{\mathrm{d}(\Delta\bar{F}_e/T)}{\mathrm{d}T} = \frac{\mathrm{d}(R \ln \gamma)}{\mathrm{d}T} = -\frac{\Delta\bar{H}_e}{T^2} \tag{23}$$

whence

$$(-\Delta\bar{H}_e) = 2.303RT^2\frac{\mathrm{d}\log\gamma}{\mathrm{d}T} = 2.303\,\frac{RT^2}{\gamma}\,\frac{\mathrm{d}\gamma}{\mathrm{d}T} = 2.303\,RT^2 A_{25} \tag{24}$$

The values of $\mathrm{d}\gamma/\mathrm{d}T$ have been determined in the following manner. The temperature variation of γ was computed by an empirical equation similar to Equation 1. The values of a_{25} thus obtained were plotted and

TABLE V

THE EXCESS HEAT CONTENT DECREASE OF HYDROCHLORIC ACID IN POTASSIUM AND SODIUM CHLORIDE SOLUTIONS AT 25° IN CALORIES

	KCl		NaCl	
M	$(-\Delta\bar{H}_e)_{25}$	10^5A_{25}	$(-\Delta\bar{H}_e)_{25}$	10^5A_{25}
0.05	+40.6	−10.0	99.6	− 24.5
.1	65.0	− 16.0	143.1	− 35.2

.5	160.0	− 41.8	335.1	− 82.4
1	243.1	− 59.8	490.8	−120.7
1.5	297.6	− 73.2	618.9	−152.2
2	342.3	− 84.2	701.4	−172.5
3	406.6	−100.0	827.5	−203.5

a smooth curve drawn through the points. From this curve A_{25} could be computed with considerable accuracy. The values of A_{25} and the decrease in the excess partial heat content, $-\Delta\overline{H}_e$, of the acid in the salt solutions computed by Equation 24 are given in Table V. In Fig. 3 these values of $(-\Delta\overline{H}_e)_{25}$ are plotted against $m^{1/2}$, and it is seen that the points fall on straight fines. Similar calculations for acetic acid were made but since at present the results appear to have no particular value, they have not been included.

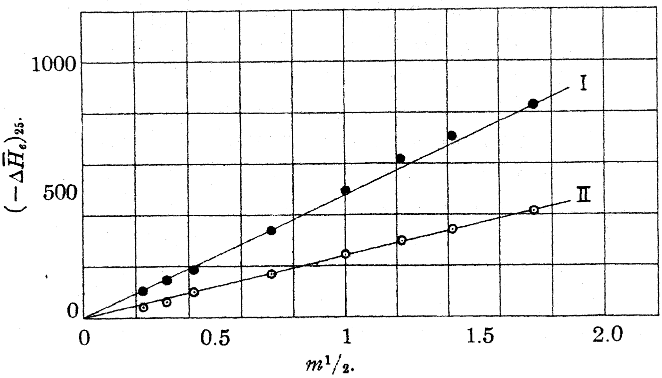

Fig. 3.—The excess relative heat content of hydrochloric acid in potassium and sodium chloride solutions. ●, HCl in NaCl; ○, HCl in KCl.

Summary

1. Measurements of the cells

H_2 | HCl (0.01), MCl (m) | AgCl | Ag, and
H_2 | HAc (0.2), MCl (m) | AgCl | Ag

have been obtained at 20, 25 and 30°. Potassium and sodium chlorides were the salts employed.

2. The activity coefficients of hydrochloric acid in the salt solutions at the three temperatures have been computed.

3. The hydrogen-ion concentrations of the acetic acid salt solutions have been computed.

4. The dissociation constant of acetic acid was found to vary very little if at all through the temperature range of from 20 to 30°.

5. The ionic activity coefficient of acetic acid in sodium and potassium chloride solutions at the three temperatures were computed.

6. The excess or electrical contribution to partial molal heat content of hydrochloric acid in the chloride solutions was computed and found as a first approximation to be proportional to the square root of the total molality.

THE VELOCITY OF DECOMPOSITION OF THE CARBONATO-TETRAMMINE-COBALTIC ION AND ITS DEPENDENCE ON THE HYDROGEN-ION CONCENTRATION

BY KAI JULIUS PEDERSEN

RECEIVED JULY 16, 1930 PUBLISHED JANUARY 12, 1931

During the last few years new light has been thrown on the field of hydrogen- and hydroxyl-ion catalysis. The recent progress is to a great extent due to the work of Bronsted and his collaborators.[1] Bronsted's views on catalysis are intimately connected with his theory of acids and bases.[2] According to this theory, any substance, whether it is a neutral molecule or an ion, is called an acid, if it has a tendency to split off protons, and a base, if it tends to add on protons. Thus if $A \rightleftharpoons B + H^+$, A is an acid and B the corresponding base. In Bronsted's theory of general acid and basic catalysis, catalytic effects are attributed not only to the hydrogen ion and to the hydroxyl ion, but to all substances which are sufficiently strong acids and bases according to the new definition. The magnitude of the catalytic effect increases with increasing acid or basic strength of the catalyst. The existence of general acid or basic catalysis has been experimentally established in a number of cases.[1] However, this fact does not exclude the possibility of cases of specific hydrogen or hydroxyl ion catalysis where only hydrogen or hydroxyl ions but not acids or bases in general are catalysts. The reaction

$$[Co(NH_3)_4(H_2O)(NO_3)]^{++} + H_2O \longrightarrow [Co(NH_3)_4(H_2O)_2]^{+++} + NO_3^-$$

examined by Bronsted[3] may be considered as being a case of specific hydroxyl-ion catalysis.

Let us consider the scheme[3a]

$$R + HA \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} RH^+ + A^- \qquad (1)$$

$$RH^+ \xrightarrow{k_2} \qquad (2)$$

k_1, k_{-1} and k_2 are velocity constants. We consider the two special limiting cases

(a) $k_2 \gg k_1 \times c_{HA}$, $k_2 \gg k_{-1} \times c_{A^-}$. Reaction 1 from left to right determines the velocity of the total reaction. Practically all the molecules RH^+ react according to (2) before they get time to react with A^- and form $R + HA$ again. We have general acid catalysis.

(b) $k_{-1} \times c_{A^-} \gg k_1 \times c_{HA} \gg k_2$. Equilibrium 1 is maintained all

[3] *J.* **N. Bronsted,** *Z. physik. Chem.*, 122, *383* (1926).

[3a] Cf. **Skrabal** *Trans. Faraday Soc.*, *24*, 687 (1928).

the time. The concentration of RH+ is small compared with that of R c_{RH^+} and consequently the velocities are only dependent on the hydrogen-ion concentration, when the salt effect is neglected. In this case we have *specific hydrogen-ion catalysis.*

These are special limiting cases. Reactions where both the velocities of (1) as well as that of (2) affect the velocity of the total reaction are quite possible, although their existence has not yet been experimentally established.

The present work was started as a contribution to the study of these different kinds of catalysis.

Carbonato–tetrammine–cobaltic salts have been prepared by S. M. Jörgensen.[4] He found that they split off carbon dioxide almost instantaneously with cold dilute hydrochloric acid. With very dilute acid (< 1 N) only diaquo-tetrammine salt is obtained

$$[\text{Co}(\text{NH}_3)_4\text{CO}_3]^+ + 2\text{H}^+ + \text{H}_2\text{O} \longrightarrow [\text{Co}(\text{NH}_3)_4(\text{H}_2\text{O})_2]^{+++} + \text{CO}_2 \qquad (3)$$

With more concentrated hydrochloric acid some chloro-ayuo-tetrammine salt is also formed.

In the present work the kinetics of Reaction **3** have been studied at 25° and at different hydrogen-ion concentrations. The experiments fall into 4 series: (1) in glycolate buffer solutions with the total salt concentration 0.11 N. (The hydrogen-ion concentration was here varied within the ratio of 1 to 10); (2) in glycolate buffers with the salt concentration 0.21 N; **(3)** in acetate buffers with the salt concentration 0.98 N; (4) in acetate buffers with the salt concentration 0.11 N.

It will be shown that the velocity may be expressed as the sum of two velocities, one being independent of the hydrogen-ion concentration, the other being proportional to the hydrogen-ion concentration:

$$\frac{\text{d}x}{\text{d}t} = (k_0' + k_1' \times c_{\text{H}^+})(c-x) \qquad (4)$$

where c is the initial concentration and $c - x$ the concentration at the time t of the carbonato-tetrammine-cobaltic salt; k_0' and k_1' are constants.

This simple relationship only holds when the carbon dioxide pressure is small or the hydrogen-ion concentration comparatively great. However, the following treatment will be based on Equation 4, and we shall see how well the experiments agree with it.

The Apparatus

The rate of Reaction **3** was followed by measuring the pressure of the carbon dioxide above the solution during the reaction. For this purpose a modification of Bronsted's shaking apparatus[5] was used. In its original form it could be used only in a narrow temperature interval, namely at and a little below room temperature, because a part

---

[5] Brönsted and King, THIS JOURNAL, 47,2523 (1925).

of the apparatus is above the water of the thermostat. Above room temperature water distils from the solution in the flask to the top of the apparatus, and the condensed water is apt to run down into the glass spring.

In its new form the apparatus is completely under water except one end of the pressure gage (Fig. 1). The reaction flask A with a capacity of 200 cc. is connected with the mercury manometer C through the elastic glass capillary B, which allows a horizontal shaking of the flask A to prevent supersaturation. The apparatus is made in two separate parts. One piece is the part which is in the thermostat, ending in the horizontal tube which goes through the wall of the thermostat. The second piece is the tube C which is originally open at the top. The two pieces are put in their positions and fused together. Mercury is poured into C through the opening at the top. The apparatus is evacuated to a low pressure simultaneously through C and the tap D. C is sealed off above the spherical part, and the apparatus is ready for use. F is an arrangement to hold and, when desired, to drop a small platinum bucket into the solution in the flask A. It consists of a ground slip-on stopper which has inside a little glass rod ending in a platinum hook. Before the start of an experiment the bucket containing the substance for the reaction is suspended on the hook. When the stopper is turned through 180° the bucket is released and drops into the flask When an experiment was to be done so much water was removed from the thermostat through the tap G that the opening of the flask A was above the surface. The buffer solution (in each experiment 100 cc.) was poured into the flask. The bucket with the carbonato-tetrammine-cobaltic salt (about 0.001 mole in each experiment) was suspended on the hook The apparatus was closed by means of the ground slip-on stopper E, and the water which had been removed from the thermostat was poured back The shaker was started, and the apparatus was evacuated through the tap D. The reaction was started when the substance was dropped into the solution. In all the experiments the temperature was kept constant at 84.95 ± 0.01°.

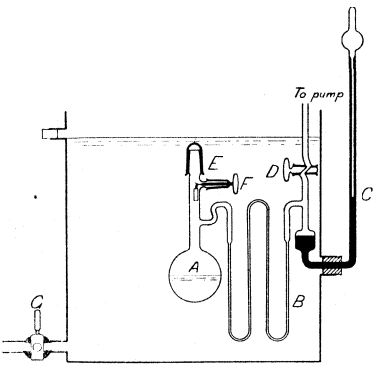

Fig. 1.

Calculation of the Velocity Constants.—We use the following symbols.

The stoichiometrical initial concentrations of the buffer solution	
Acid HA (glycolic or acetic acid)	*a* molar
Sodium salt NaA (glycolate or acetate)	b molar
Initial concentration of carbonato-tetrammine ion	c molar
Its concentration at the time *t*	$c - x$ molar
Concentration dissociation constant of the acid of the buffer solution	K
Activity dissociation constant of the same	K_0

Ratio between the concentrations of undissociated acid (glycolic or acetic) and ion (glycolate or acetate) at the time *t*

$$h = \frac{c_{\mathrm{HA}}}{c_{\mathrm{A}^-}} = \frac{c_{\mathrm{H}^+}}{K}$$

At the time $t = 0$ we set $h = h_0$, at the time $t = \infty$ we set $h = h_\infty$. $^1/_2\ (h_0 + h_\infty) = h_m$.

The equilibrium constant for the reaction

$$[\mathrm{Co(NH_3)_4(H_2O)_2}]^{+++} + A^- \rightleftarrows [\mathrm{Co(NH_3)_4(H_2O)(OH)}]^{++} + \mathrm{HA} \qquad \mathrm{L}$$

We now rewrite Equation 4 as follows

$$\frac{dx}{dt} = (k_0' + k_1' \times c_{\mathrm{H}^+})(c - x) = (k_0' + k_1' \times K \times h)(c - x) \tag{5}$$

Both k_1' and K vary with the salt concentration, but in a series of experiments where the total salt concentration is kept constant while h varies, k_1', K and accordingly also the product $k_1' \times K$ may be considered as constants. We must, however, take into account that the composition of the buffer solution, expressed by h and determining c_{H^+}, alters during the reaction according to (3). Further, the reaction product $[\mathrm{Co(NH_3)_4(H_2O)_2}]^{+++}$ is a weak acid which has also some effect on h. We have

$$h = \frac{a - hK - 2x + \frac{L}{L + h}x}{b + hK + 2x - \frac{L}{L + h}x}$$

Using the abbreviations

$$A = \frac{a - h_0K}{2 - \frac{(h_0 - h_\infty)K}{c} - \frac{L}{L + h_m}} \tag{6}$$

$$B = \frac{b + h_0K}{2 - \frac{(h_0 - h_\infty)K}{c} - \frac{L}{L + h_m}} \tag{7}$$

we have to a sufficient approximation $h = (A - x)/(B + x)$. In particular $h_0 = A/B$ and $h_\infty = (A - c)/(B + c)$. In order to calculate A and B we must know approximate values of K, L, h_0 and h_∞.

We can now write the differential Equation 5 in the following form

$$\frac{dx}{dt} = \left(k_0' + k_1'K\frac{A - x}{B + x}\right)(c - x)$$

Integrating and noting that $x = 0$ when $t = 0$ we get

$$kt = \log\frac{c}{c - x} - \frac{1 + h_\infty}{1 - f}\log\frac{fB + A}{fB + A - (1 - f)x} \tag{8}$$

where $k = k_0 + K\,k_1h_\infty$, $k_0 = 0.4343\,k_0'$, $k_1 = 0.4343\,k_1'$ and $f = k_0/Kk_1$.

The difference between the manometer readings p_∞ at the time $t = \infty$ and p at the time t is called $P = p_\infty - p$. P is proportional to $c - x$. $P = \varphi\,(c - x)$. We find the constant φ according to $\varphi = P_0/c$. Formula 8 is now transformed into

$$kt = \log\frac{P_0}{P} - \left(1 + \frac{f + h_\infty}{1 - f}\right)\log\frac{\frac{f + h_\infty}{1 - f}(B + c)\varphi + P_0}{\frac{f + h_\infty}{1 - f}(B + c)\varphi + P} \equiv \psi\,(P) \tag{9}$$

The second term of $\psi\,(P)$ expresses the effect of the change in hydrogen-ion concentration during the reaction. Generally this term is small compared with $\log P_0/P$.

The ratio f being unknown, we provisionally plot $\log\,(P_0/P)$ against t for a whole series of experiments with constant total salt concentration but with varying h,. In this way we find an approximate value for k for each experiment. We now plot these approximate values against h,. The points fall fairly well on a straight line determining according to the equation $k = k_0 + K \times k_1 \times h_\infty$ approximate values of k_0 and $K \times k_1$. From these we find an approximate value of f which we use in (9). We now plot $\psi(P)$, calculated by means of the approximate value for f against t, and find better values for k_0, $K \times k_1$ and f. By successive repetitions we continue until a repetition gives the same values again.

For the calculation of A and B, (6) and (7), it is necessary to know K and L. Fortunately they enter the expressions only in small correction terms; consequently only rough values of K and L are necessary. The activity dissociation constants found by conductivity at 25° are for glycolic acid[6] $K_0 = 1.54 \times 10^{-4}$ and for acetic acid $K_0 = 1.81 \times 10^{-5}$ (recalculated from the measurements of Kendall[7] by C. W. Davies).[8] With sufficient approximation except for the 1 N acetate, we may use the formula $-\log K = -\log K_0 - \sqrt{\mu} + \mu$, where μ is the ionic strength. We thus get for the glycolate buffer, salt concentration 0.11 N, $K = 2.6 \times 10^{-4}$, and at the salt concentration 0.21 N, $K = 3 \times 10^{-4}$. For the acetate buffer, salt concentration 0.11 N, we get $K = 3.0\ X\ 10^{-5}$. Bronsted and Volqvartz[9] have determined the acid dissociation constant of the diaquo-tetrammine-cobaltic ion

$$[Co(NH_3)_4(H_2O)_2]^{+++} \rightleftharpoons [Co(NH_3)_4(H_2O)(OH)]^{++} + H^+$$

They find at 15°, $-\log K_{Aq.} = 5.21 + 2\sqrt{\mu} - \mu$. From this and their measurement at 20° $\sqrt{\mu} = 0.29$, $-\log K_{Aq.} = 5.52$, we find by extrapolation to 25°, $-\log K_{Aq} = 4.87 + \sqrt{\mu} - P$. By combining this with the K values for glycolic and acetic acid, we find rough values for L.

Glycolate buffers, salt concentration 0.11 N, L = 0.015
Glycolate buffers, salt concentration 0.21 N, L = 0.010
Acetate buffers, salt concentration 0.11 N, L = 0.13

In the acetate buffers with the salt concentration 0.98 N, the change in hydrogen-ion concentration during the reaction is so small that it is sufficient to use $A = a/2$ and $B = b/2$.

Preparation and Purification of the Substances

Carbonato–tetrammine–cobaltic sulfate $[Co(NH_3)_4CO_3]_2SO_4 \cdot 3H_2O$ was prepared by the method of S. M. Jörgensen.[10] It was recrystallized from water and again dissolved and precipitated with alcohol. For some of the experiments the nitrate $[Co(NH_3)_4CO_3]NO_3 \cdot 0.5H_2O$ was used. My thanks are due to Professor Bronsted for a pure preparation of this salt.

The glycolic acid was purified through the barium salt, which was recrystallized twice from water. To a warm solution of the pure barium glycolate was added a small excess of 4 *N* sulfuric acid. When there is no excess of sulfuric acid the barium sulfate forms a colloidal solution. However, a small excess of the acid makes it easy to filter the barium sulfate from the solution. Afterward all the sulfuric acid could be removed by a little barium glycolate and a new filtration. The filtrate gave a hardly visible reaction with barium ions. The concentration of glycolic acid was determined by titration.

Acetic acid (Merck "Zur Analyse") was used without purification.

The buffer solutions were prepared from the solutions of the acids and sodium hydroxide solution, made of sodium hydroxide Merck "puriss. e natrio." The various glycolate buffer solutions were prepared from a standard solution by adding various amounts of hydrochloric acid and diluting.

The Experimental Data

The experimental results are given in Tables I–IV and Figs. 2–4. Experiments 1–10 and 14–16 were done with carbonato-tetrammine-cobaltic sulfate, while the nitrate was used for Experiments 11–13. In Figs. 2–3 are plotted the values of ψ (P) for each reading against the time *t* in minutes. In the experiments on glycolate (Nos. 1–10, Tables I–II, Fig. 2) the points fall well on a straight line for the greatest part of each reaction. However, at the end the velocity is always smaller than that corresponding to the

straight line. This drop in velocity is the more pronounced the smaller the hydrogen-ion concentration. The small lines crossing the curves in each experiment show where the reaction is half completed. Owing to this drop in velocity it was always necessary to wait for several days for the infinity reading. In Tables I–II are given the k values determined by the slopes of the straight lines. By plotting k against h_∞ we find k_0 and $K \times k_1$ for each of the two series of experiments. At the bottom of each table are given the values of k_0 and $K \times k_1$ determined in this way.

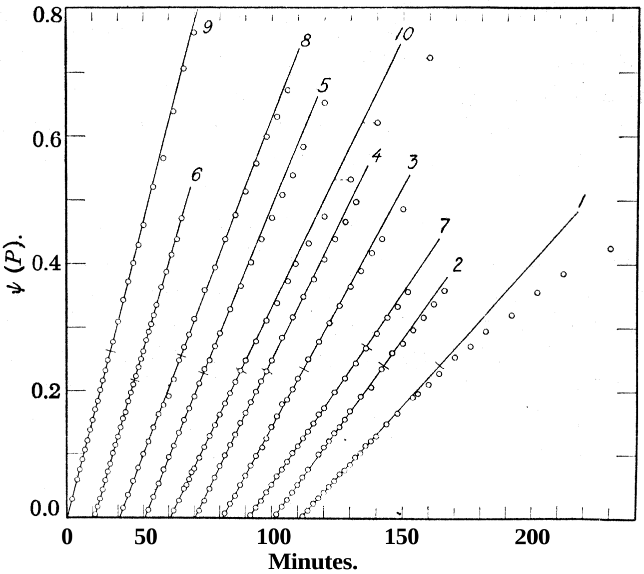

Fig. 2.—The rate of decomposition of the carbonato-tetrammine-cobaltic ion in glycolate buffer solution (Tables I–II).

The last column of the tables gives k calculated from these values. There is a good agreement between k (found) and k (calcd.). All the experiments in glycolate buffer solutions gave practically the same amount of carbon dioxide per equivalent of carbonato salt. Therefore, the reaction may be considered as being practically complete.

In the acetate buffer solutions with the salt concentration 0.11 *N* (Nos. 14–16, Table IV and Fig. 3), the drop in velocity is so great that no straight line can be drawn. The drop is especially great in Expt. 16. Here the hydrogen-ion concentration is about the same as in Expt. 14, but some carbon dioxide was in the apparatus at the start of the experiment. In order to compare the experiments with those in glycolate at the same salt con-

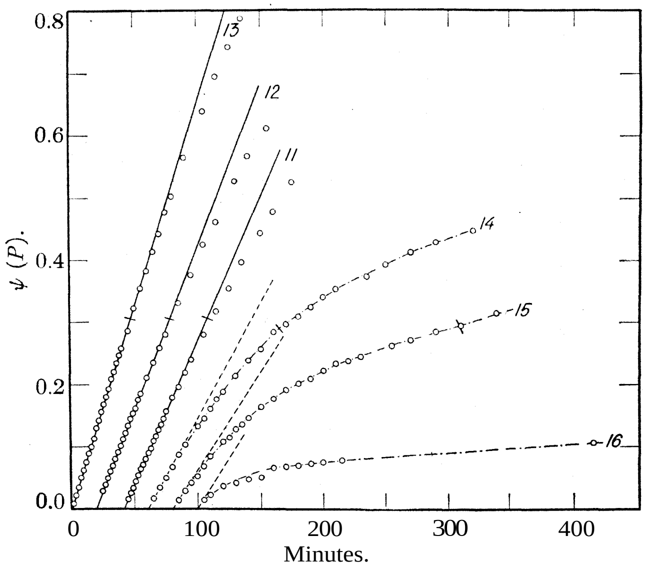

Fig. 3.—The rate of decomposition of the carbonato-tetrammine-cobaltic ion in acetate buffer solutions (Tables III–IV).

centration, where Equation 4 holds, we write the velocity constant k = 0.00265 + 45.6 K_0h_∞. We introduce the activity dissociation constant for acetic acid instead of that for glycolic acid and calculate k values for the different values of *h*,. In this way we get the k (calcd.) given in the seventh column of Table IVa. The dotted lines in Fig. **3** are drawn with the slopes k (calcd.). They fit quite well as tangents for $t = 0$. The total amount of carbon dioxide evolved in these experiments is a little smaller per equivalent carbonato salt than in the glycolate buffers. Owing to the low hydrogen-ion concentration a little carbon dioxide will be bound as bicarbonate in the solution. However, as will be shown in the following calculation, this is far from being enough to explain the decrease. Consequently, it would seem that the reaction is balanced. In order to show this we try to calculate the equilibrium constant.

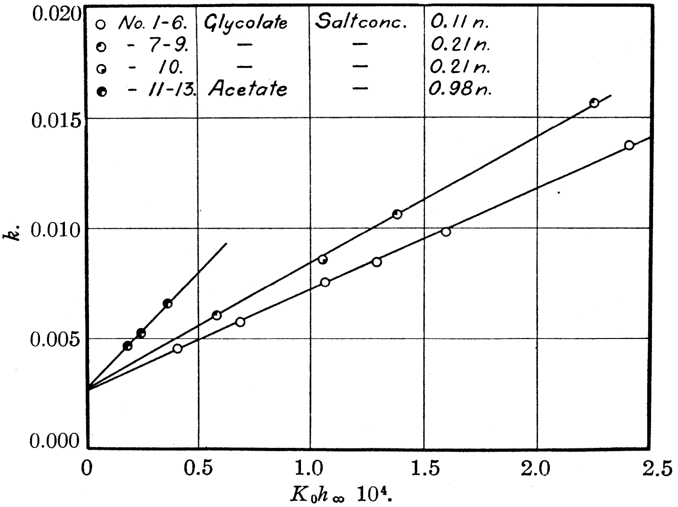

Fig. 4.—The dependence between the velocity constant and the hydrogen-ion concentration.

We denote by p_{CO_2} the carbon dioxide pressure in cm. of mercury. $p_{HCO_3^-}$ and p_{Co} are the additional pressures which would have been measured if the carbon dioxide were completely liberated from the bicarbonate and the complex cobaltic salt, respectively. Our first object is to calculate $p_{Co(t = \infty)}$. We have

$$p_{Co(t = \infty)} = p_{CO_2(t = 0)} + p_{HCO_3^-(t = 0)} + p_{Co(t = 0)} - p_{CO_2(t = \infty)} - p_{HCO_3^-(t = \infty)} \quad (10)$$

In Experiments 14 and 15, $p_{CO_2(t = 0)} = 0$ and $p_{CO_2(t = \infty)} = P_0$. In 16, where carbon dioxide is present at the start, $p_{CO_2(t = 0)}$ and $p_{CO_2(t = \infty)}$ are found by subtracting from the readings at $t = 0$ and $t = \infty$ the reading at $t = 0$ in Expt. 14, which was done in the same apparatus and with the same composition of the solution as in Expt. 16. $p_{Co(t = 0)} = \varphi c$. For

φ is used the value found in the glycolate experiments; in Expts. 14 and 16, $\varphi = 736$; in Expt. 15, which was done in another apparatus, $\varphi = 761$. It remains to calculate $p_{HCO_3^-}$ at the times 0 and ∞. The apparent first dissociation constant of carbonic acid is at 25° 3.12×10^{-7}, found by conductivity by Wilke.[11] The ratio between the constants of carbonic acid and acetic acid is $3.12 \times 10^{-7}/1.81 \times 10^{-5} = 0.0172$. Consequently we have

$$c_{HCO_3^-} = \frac{0.0172}{h}(c_{CO_2} + c_{H_2CO_3}),\ \textit{or}$$

$$p_{HCO_3^-} = \frac{0.0172}{h}\varphi\,(c_{CO_2} + c_{H_2CO_3})$$

$$c_{CO_2} + c_{H_2CO_3} = 0.759\,\frac{p_{CO_2} \times 273}{76 \times 22.4 \times 298}$$

0.759 is the Bunsen absorption coefficient for carbon dioxide in water.[12] We thus get

$$p_{HCO_3^-} = \frac{0.0172 \times 273 \times 0.759}{76 \times 22.4 \times 298}\,\frac{\varphi \times p_{CO_2}}{h} = 7.03 \times 10^{-6}\,\frac{\varphi\, p_{CO_2}}{h}$$

Finally, we find $p_{Co(t=\infty)}$ by Equation 10. The p values are given in Table IVb. We now calculate the degree of decomposition a of the carbonato salt at equilibrium for the three experiments.

$$1 - \alpha = \frac{p_{Co(t=\infty)}}{p_{Co(t=0)}}$$

a is given in the eighth column of Table IVb. In the ninth column is given the equilibrium constant expressed by

$$M = \frac{\alpha \times p_{CO_2(t=\infty)}}{(1-\alpha) \times h^2_\infty}$$

The values are constant within the limits of the experimental error. This is seen from the last column, where we have calculated α using the value $M = 4.0 \times 10^2$. In spite of the good constancy, too much weight must not be laid on this result. It is difficult to understand the great drop in velocity without assuming that the equilibrium is reached through two consecutive balanced reactions. If there is an appreciable amount of the intermediate substance present at equilibrium, the above calculation is not unobjectionable. Another objection is that possibly a formation of acetato complexes

$$[Co(NH_3)_4(H_2O)_2]^{+++} + CH_3COO^- \rightleftharpoons [Co(NH_3)_4(H_2O)(CH_3COO)]^{++} + H_2O$$

may take place. However, rough colorimetric test-tube experiments with different acetate solutions up to 1 N acetate left for several days did not support the assumption that acetato complexes were formed.

In the experiments in the more concentrated acetate buffers (salt concentration 0.98 N) the decomposition was found to be practically complete,

[11] **Wilke,** Z. anorg. Chem., 119,365 (1921).

[12] **Chr.** Bohr, *Wied.* Ann., 68,504 (1899).

and the simple equation (4) was found to hold for the greater part of the reaction (Table III and Fig. **3,** Expts. 11–13).

Discussion

We first consider the experiments where the fundamental equation (4) holds for a considerable part of the reaction (Expts. 1–13). By means of the equation $k = k_0 + k_1Kh_\infty$, we found for each series of experiments by plotting k against h_∞ the constants k_0 and $K \times k_1$. In order to facilitate a comparison of the experiments in acetate and glycolate buffers we write the equation in the form $k = k_0 + (k_1F) \times (K_0h_\infty)$. K_0 is the activity dissociation constant and F a factor expressing the salt effect on K. $F = f_{HA}/f_{H^+}f_{A^-}$, where f_{HA}, f_{H^+} and f_{A^-} are activity coefficients. While K varies with the salt concentration and is not known with sufficient accuracy, K_0 is constant and known with good accuracy. In Fig. 4 k is plotted against K_0h_∞. For each of the three series of experiments the points fall on a straight line. The slopes determine k_1F, their intercepts on the ordinate axis k_0. It is seen that all three series give almost the same value of k_0 while k_1F increases with increasing salt concentration. At the bottom of Tables I–III the equations of the straight lines are given.

No general acid catalysis was found. It is true that an increase in the concentrations of the buffer substances causes an increase in velocity (compare Expts. 1–6 with 7–9). But the same increase is produced by adding sodium chloride to the same total salt concentration (Expt. 10). Consequently the increase may be explained as neutral salt effect. Neither is it possible to detect any general acid catalysis by a comparison with each other of the data of any of the two series (Expts. 1–6 and 7–9). If we did assume an effect of the undissociated glycolic acid, we should have

$$\begin{aligned} k &= k_0 + (k_1F)(K_0h_\infty) + k_{HA} \times c_{HA} \\ &= k_0 + \left[(k_1F) + \frac{k_{HA}}{K_0}c_{A^-}\right] K_0h_\infty \end{aligned}$$

Consequently we should get no straight lines in Fig. 4 for the experiments in glycolate, where the concentration of glycolate is varied. If we assume that the values found for k_1F are constant within each series within an accuracy of 2%, we have

(Expts. 1 and 6) $$1.02\left(k_1F + \frac{k_{HA}}{K_0}0.04\right) > k_1F + \frac{k_{HA}}{K_0}0.10$$

that is, $k_{AH} < 5 \times 10^{-5}\, k_1F$

(Expts. 7 and 9) $$1.02\left(k_1F + \frac{k_{HA}}{K_0}0.10\right) > k_1F + \frac{k_{HA}}{K_0}0.20$$

that is, $k_{AH} < 3 \times 10^{-5}\, k_1F$

In order to find how great an effect of the undissociated glycolic acid we should reasonably expect if there were general acid catalysis, we use a method of calculation put forward by Brönsted.[13] In reactions with

---

[13] **J. N. Bronsted,** *Trans. Faraday* Soc., *24, 639 (1928).*

general acid catalysis the part of the reaction which is independent of the acid concentration, the so-called "spontaneous" reaction, may be considered as a catalysis of the acid H_2O. Bronsted gives the following formula for a very rough calculation of the effect of an acid if the effects of two other acids (*e.* g., H_3O^+ and H_2O) are known. The dissociation constants are denoted by K_a, K_b and K_c, the corresponding catalytic coefficients by k_a, k_b and k_c.

$$\log \frac{k_a}{k_b} \Big/ \log \frac{k_c}{k_b} = \log \frac{K_a}{K_b} \Big/ \log \frac{K_c}{K_b}$$

Acid (a), glycolic acid; $K_a = 1.5 \times 10^{-4}$; $k_a = k_{HA}$
Acid (b), H_3O^+; $K_b = 56$; k_b is roughly $k_1F = 5 \times 10$
Acid (c), H_2O; $K_c = (1.05 \times 10^{-14})/56 = 1.9 \times 10^{-16}$; $k_c = 0.0027/56 = 5 \times 10^{-5}$

We find $k_{HA} = 1.3 \times 10^{-2} \times k_1F$. This value is some hundred times greater than the greatest value $k_{HA} = 3 \times 10^{-5}\ k_1F$ which is reconcilable with the experiments.

As a result of this we may say that the rate of reaction is determined only by the hydrogen-ion concentration and a salt effect. The reaction may be considered as the sum of two simultaneous reactions, one being independent of the hydrogen-ion concentration, the other being catalyzed by hydrogen ions. The salt effect is in agreement with Bronsted's theory of kinetic salt effect,[14] according to which a reaction between an ion and an uncharged molecule in dilute solution is almost independent of the salt concentration, while an addition of salt accelerates a reaction between two ions with charges of the same sign and retards a reaction between ions of opposite sign. Consequently k_0 should be only slightly salt sensitive, while k_1 should increase with the salt concentration. Also the factor F should increase with increasing salt concentration In agreement we found almost the same k_0 at all salt concentrations, while k_1F showed a great increase with increasing salt concentration (Fig. 4).

As seen from Figs. 2 and 3 the simple formula (4) holds the better the greater the hydrogen-ion concentration and the smaller the carbon dioxide pressure. In Expts. 14 and 15 and especially 16, where extra carbon dioxide has been added, it fails completely. The reaction is balanced, but the drop in velocity is much greater than can be explained from the assumption that the velocity is determined by a single balanced reaction. A probable explanation seems to be the assumption of consecutive balanced reactions. However, we shall here refrain from suggesting a mechanism owing to the complicated nature of the calculations necessary to test it.

In conclusion the author wishes to thank the Carlsberg Foundation for a grant which has defrayed the expenses of the apparatus, and to express his great indebtedness to Professor Bjerrum for helpful criticism and valuable suggestions.

---

Summary

The kinetics of the decomposition of the carbonato-tetrammine-cobaltic ion

$$[Co(NH_3)_4CO_3]^+ + 2H^+ + H_2O \rightleftharpoons [Co(NH_3)_4(H_2O)_2]^{+++} + CO_2$$

have been studied in glycolate and acetate buffer solutions at 25° and at different salt concentrations.

In the glycolate buffers the decomposition was practically complete. In some acetate buffers it could be shown that the reaction is balanced.

When the carbon dioxide pressure is low and the hydrogen-ion concentration not too small, the velocity may be expressed as the sum of two terms, one being independent of the hydrogen-ion concentration, the other being proportional to the hydrogen-ion concentration. No general acid catalysis was found.

SOLUBILITIES IN HYDROGEN FLUORIDE

BY P. A. BOND AND V. M. STOWE

RECEIVED JULY 28, 1930 PUBLISHED JANUARY 12, 1931

Solubility relations in non-aqueous inorganic systems have received attention in this Laboratory during several years. Sulfur monochloride, liquid nitrogen tetroxide, thionyl chloride and liquid sulfur dioxide have been employed as solvents.

As one branch of the general problem of solubilities in non-aqueous inorganic systems, the authors set out to develop a technique for the use of liquid anhydrous hydrogen fluoride as a solvent, and to determine some solubilities in this medium. Liquid hydrogen fluoride was chosen for this investigation because of its unusual properties.

The anomalous boiling point of liquid hydrogen fluoride indicates that it is an associated liquid. The anomaly is apparent if one compares the boiling points of the series HI (–35.7°), HBr (–68.7°), HCl (–83.1°) and HF (+19.0°). Water and ammonia show similar anomalous boiling points when compared with the appropriate series. The vapor pressure data of Simons[1] were examined by the use of Hildebrand's modification of the Trouton rule.[2] The value of the "constant" so determined is about the average of those for normal liquids.

The chemical relationships for hydrogen fluoride indicated that it would prove to be a good solvent. Polar liquids such as ammonia, water and,

---

[1] J. Simons, THIS JOURNAL, 46, 2179 (1924).

[2] Hildebrand, "Solubility," The Chemical Catalog Co., Inc., New York, 1924, p. 89.

to a less extent, alcohol, frequently form addition compounds with solutes. This appeared to be true also in the case of hydrofluoric acid.

Finally, the qualitative results of Gore[3] and Franklin[4] indicated that hydrogen fluoride is a vigorous reagent and a good solvent. The authors believe, however, that many of the solubilities in hydrogen fluoride previously reported were preceded by chemical reaction.

Recent publication by Cadenbach[5] is quite in line with this statement. His results, while qualitative, or where quantitative, expressed in terms of molar solutions, are in quite close agreement with the results shown below.

Preparation of Hydrogen Fluoride

The liquid anhydrous hydrogen fluoride was prepared essentially according to the method of Gore,[3] *i. e.*, by the distillation of dry potassium hydrogen fluoride, KHF_2. For the preliminary work Baker and Adamson "C. P." potassium bifluoride was fused, electrolyzed by a direct current of 18 volts until arcing was no longer seen at the carbon pole, and the product was distilled from a platinum still described below. Later the potassium fluoride resulting from this distillation was treated with aqueous hydrogen fluoride, evaporated, fused and electrolyzed as above.

The acid salt is reported to be non-hygroscopic. However, electrolysis of the fused salt as carried out served to remove any trace of water which might have been present. The salt was then always preserved in a desiccator. The fused salt was poured into a clean platinum still which had been carefully dried. The still was then suspended by a nichrome wire so that the condensing tube was engaged. Heat was applied by means of a specially designed electric heating unit which supplied the heat in a ring about the still, and which could be moved up and down the still as desired. In this way the heat was applied above the acid salt and any frothing was checked by contact with the hot part of the still above. A light red heat was used. After three hours most of the acid had been distilled off from the salt. The vapor passed through a platinum tube 40 cm. long. This was surrounded by a water jacket which served to cool the gas to room temperature. The platinum tube was sealed with sulfur onto a spiral monel metal tube about three meters long and about 8 mm. in diameter. In the spiral, which was packed in an ice and salt freezing mixture, the hydrogen fluoride was condensed to a liquid. The liquid was collected directly in the solubility apparatus, which was sealed onto the still each time with ceresin wax, thus exposing only a very small amount of wax and that to the vapor only. Air pressure was equalized through a drying tube. The hydrogen fluoride obtained was clear, limpid and colorless. It carried less than 0.2% of non-volatile solid as shown by seven determinations made on amounts of hydrogen fluoride ranging from approximately 8 to 14 g.

Procedure for Determining Solubility.—The "bomb," or solubility apparatus, which was specially designed for this work, comprised the upper chamber (A, see Fig. 1) and the lower chamber (B). The piece (E) served as a partition and also formed the seat of the valve as shown. (E) was held in place by the union (D). Soft gaskets of 24 carat gold maintained an air-

[4] Franklin, *Z. anorg. Chem.*, *46*, 2 (1905).

[5] Karl Fredenhagen and Gustav Cadenbach, *Z. physik. Chem.*, Abt. A, *146*, 245 (1930).

tight joint. The valve stem was packed with ceresin wax or amorphous sulfur.

To operate the device it was assembled as shown. The plug (C) was removed and suction applied to form a moderate vacuum, The valve (E) **was** then closed tightly and the suction line was disconnected, leaving a vacuum in chamber (B). Dry air was blown through the chamber **(A).** The salt was next introduced into **(A),** and the solubility device was sealed onto the hydrogen fluoride delivery tube and the plug (C) was immediately inserted. This bore a gasket of wax or, at the higher temperatures, of 24 carat gold.

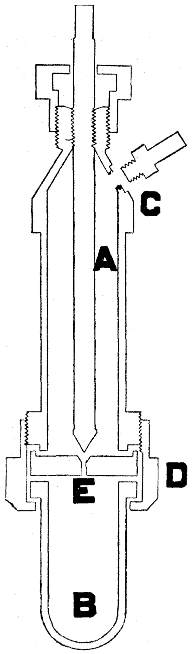

Fig. 1.—"Bomb," or solubility device.

The bomb was immediately placed in a constant temperature bath and shaken for two hours.

When time had been allowed for equilibrium to become established, the bomb was gently shaken in such a manner as to wash all the undissolved salt down into the corner of chamber **(A)** between the side and the bottom. The valve (N) was slowly opened two complete revolutions, then closed. The bomb was now removed from the thermostat. The plug (C) was removed, and the chamber **(A)** was washed out with concentrated hydrochloric acid followed by water, then dried by alcohol, ether and compressed air. The bomb and contents were now weighed on a large balance. The contents of B were washed into a platinum dish and evaporated. The bomb, platinum dish and contents were weighed. From these values the weight of the hydrogen fluoride and of the salt dissolved could be obtained by difference.

The bomb was made of monel metal. The absence of action on this material was shown by the failure to obtain tests for copper or nickel.

Potassium Iodide.—The salt was Mallinckrodt's "c. p." grade. It was screened with wire gauze to yield crystals between 12 and 20 mesh.

On treatment with liquid hydrogen fluoride in an open platinum crucible the solid apparently dissolved. However, when the solution was evaporated and the residue dissolved in water it was found that complete solvolysis had taken place. Only a slight turbidity resulted on treatment with silver nitrate, while a heavy precipitate followed the addition of calcium chloride solution to another portion of the solution. These tests indicate the absence of iodides and the presence of a fluoride. Gore[3] states that this salt is soluble but the present work shows that a reaction has taken place.

Chromium Fluoride.—The salt used was J. T. Baker Co.'s "C. P." grade. Concordant results could not be obtained with this salt even after weeks of experimentation, for unknown reasons. The material is plainly soluble.

Lithium Fluoride.—This salt was found to be quite soluble in liquid hydrogen fluoride. It reacts with the hydrogen fluoride as shown by the equation

$$\mathrm{LiF} + \mathrm{HF} = \mathrm{LiHF_2}$$

This is a good analogy to the reaction of lithium oxide with water

$$Li_2O + H_2O = 2LiOH$$

Not only so, but the solubilities of the two compounds in the respective solvents are of the same order.

Solubility data for the salt lithium fluoride are given for several temperatures in Table I.

TABLE I

SOLUBILITY DATA FOR LITHIUM FLUORIDE

Temp., °C.	Weight of HF	Wt. of Li_2SO_4	$\frac{\text{Moles LiF}}{\text{Moles HF}}$
0	12.347	1.421	0.043
0	4.229	0.4838	.043
10	7.510	.6661	.033
10	10.341	1.144	.041
20	5.214	0 6069	.044
30	4 399	.5386	.046
30	4.908	.5520	.042
30	7.138	.8084	.042
40	5.913	.7386	.046
40	10.460	1.215	.043

Calcium Fluoride.—Native fluorspar was screened to yield crystals of about 1 mm. diameter. These were then carefully hand picked, washed with hydrofluoric acid and dried, and cloudy crystals were rejected. No action occurred after four hours. The solubility was less than 0.01% at 0°.

Zinc Fluoride.—The salt was of the stock previously prepared in this Laboratory by the action of hydrofluoric acid upon pure zinc carbonate; solubility: less than 0.01% from —20 to +25°.

Magnesium Fluoride.—Magnesium fluoride was prepared by the method of C. Poulenc,[6] and that of F. Roder reported by Mellor.[7] Five grams of magnesium chloride and four grams each of sodium chloride and sodium fluoride were fused in a crucible and then cooled slowly. The resulting crystals were digested with water and well washed; solubility: less than 0.01% at 0°.

Discussion

A critical study of previous work on the physical and chemical properties of anhydrous liquid hydrogen fluoride suggests that the material is highly polar, and therefore should prove to be a good solvent for polar salts. The present work shows that for the fluorides of several elements of the first two groups of the periodic table the liquid is quite comparable to water.

It is desired to point out very clearly, however. that comparisons are to be made only between corresponding compounds. Thus lithium fluoride although insoluble in water is soluble in hydrogen fluoride. This compares to the solubility of lithium oxide in water. When solubilities are thus compared, considerable correspondence between the two solvents can be traced for the salts tested. When so compared, however, the solubilities in

---

[6] C. Poulenc, *Ann. chim. phys.*, [7] 2, 5 (1894).

[7] Mellor, "Comprehensive Treatise on Inorganic and Theoretical Chemistry," Vol. IV, p. 296.

hydrogen fluoride appear to be somewhat less than corresponding salts in water. Thus calcium and magnesium fluorides are less soluble in hydrogen fluoride than are the oxides in water, etc. Chromium fluoride seems to be an exception to this conclusion.

Summary

1. The solubility of lithium hydrogen fluoride between 0 and 40° has been established, and zinc fluoride, magnesium fluoride and calcium fluoride have been shown to be very insoluble. Potassium iodide has been found to react with liquid hydrogen fluoride. Chromium fluoride was found quite soluble but to an undetermined extent. These solubilities refer to liquid hydrogen fluoride as a solvent.

2. Comparison of these results indicates a fair similarity in the solvent action of water and hydrogen fluoride for the salts tried.

A METHOD FOR THE DETERMINATION OF CRITICAL TEMPERATURES AND THE CRITICAL TEMPERATURE OF HYDROGEN FLUORIDE

BY P. A. BOND AND DELLA A. WILLIAMS

RECEIVED JULY 28, 1930 PUBLISHED JANUARY 12, 1931

Accurate determination of the critical temperature by the usual method is difficult for several reasons. In the first place, glass is a poor conductor of heat and slight differences in bath temperature are not readily transmitted to the substance through the necessarily thick walls. Also for the same reason one end of the tube may be of slightly different temperature than the other. The gas above the critical temperature is very dense, diffusion is relatively slow and equalization of conditions in the tube does not readily take place. Some substances such as hydrogen fluoride attack glass and some such as nitrogen peroxide are so intensely colored at the critical temperature that observation is exceedingly difficult. The liability of tubes exploding under high pressures has also been a real difficulty where greater pressures are encountered. The method noted below permits the determination to be made without danger to the operator and under conditions of greater accuracy than those obtainable when the glass tube is used. Monel metal was used in the determinations because of its resistance to the action of hydrofluoric acid. Other metals could be used in the construction if desired.

Description of Apparatus

The critical temperature apparatus was composed of a constant temperature oven (Z), an assay balance (Y) and a critical temperature tube (D) (see Fig. 1). The critical temperature oven (Z) had an insulation of asbestos between the inner transite compartment (X) and the outer wooden box. The cover to the box was similarly insulated with asbestos. The heat was supplied by a resistance coil of nichrome wire (H). Circulation of the air inside was obtained by the use of the fan (A_1) propelled by the motor (A), the speed of which was regulated by a bank of lamps. After the oven had been heated for four hours and the heat and fan then turned off, a drop of but half a degree per minute was recorded. The readings were obtained from the thermometers E and E_1; one was placed in the corner of the oven and the other directly above the critical temperature tube.

The balance (Y) had the pan rests taken off, and a hole drilled through the base. At one end of the balance beam a platinum wire (F), size 50, was attached. The wire extended to the tube (D) and was of such length that the tube rested at an angle of about 20 degrees to the horizontal.

The critical temperature tube (see Fig. *2)* was 153 mm. long, 10 mm. diameter, with a wall 1 mm. in thickness. It was supported on steel knife edges (S) which rested on the polished surface of the support (C). The pointer (R), carrying the slide (V), was used to regulate the sensitiveness of the balanced system. A gold washer (U) was used to prevent leakage around the screw (T).

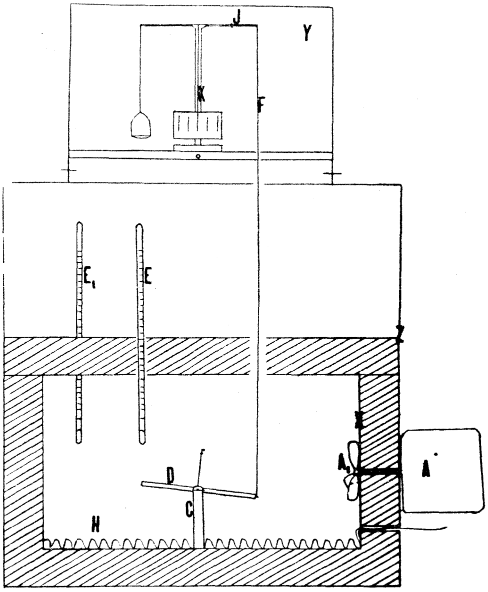

Fig. 1.

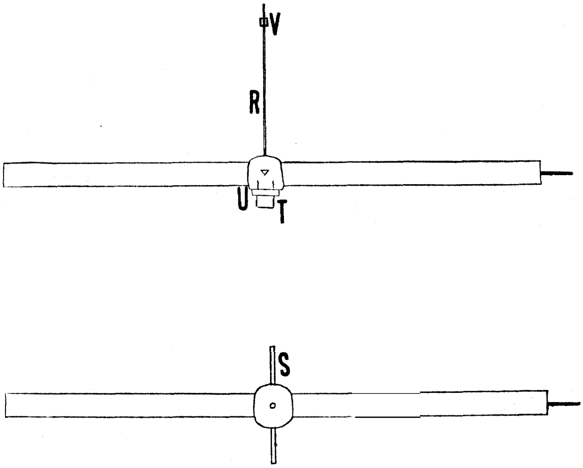
Manipulation

The critical temperature tube had a capacity of 1.88 cc. To insure that the tube was approximately half full of liquid, it was weighed after each filling. In order to be certain that there were no small leaks, the tube was allowed to stand for twelve hours and reweighed. If a constant weight was obtained, the tube was placed in the constant temperature oven. The oven had been heated previously, with the fan running, from three to four hours. The platinum wire was attached to the end of the tube and the oven again heated to above the critical temperature for more than an hour to insure constant temperature and uniform density of the gas within the tube. Differences in densities have been found to exist in the case of pure substances, above the temperature at which the meniscus disappears. According to Hein[1] in the case of pure carbon dioxide at 0.46' above the critical temperature seventy minutes elapsed after the disappearance of the meniscus before an equalization in density resulted.

When the thermometer read about 300° the fan and heat were both turned off. The system was balanced with the rider (J). When cooling had occurred to the critical temperature, the formation of the liquid phase in the lower end of the tube set the pointer of the balance in motion. The critical temperature was read at the first movement of the pointer.



Pig. 2.

The apparatus was checked using sulfur dioxide prepared according to the method employed by Stephens[2] and others in this Laboratory. The hydrofluoric acid was prepared by the method of Stowe.[3]

Results

The critical temperature of sulfur dioxide was found to be 157.8". This temperature checked in two tubes of the anhydrous liquid. Critical temperatures of sulfur dioxide determined previously were

155.4	Sajatschervsky[4]	157.15	Cardoso Bell[4]
156	Cailletet, Mathias[4]	157.8	Niggli[4]
157.263	Centnerszwer[4]	157	Drion[5]
157.20	Briner[4]	159	Sandenburg[5]
157.3	Travers[4]		

---

[1] Hein, *Z. physik. Chem.*, **86**, 385–426 (1914).

[2] Bond and Stephens, THIS JOURNAL, 51, 2910 (1929).

[3] Bond and Stowe, *ibid.*, 53, 30 (1931).

[4] "Phys. Chem. Tabellen," 1923, p. 261.

[5] "Physico-Chem. Tables," 1911, Vol. I, p. 544.

The critical temperature of hydrogen fluoride was determined by this method. The tube was filled with fresh samples of the anhydrous liquid three times, and the following results were obtained

	Reading 1	Reading 2
First filling	230.2°	230.2°
Second filling	230.2	230.2
Third filling	230.0	....

Van Laar calculated the critical temperature of hydrogen fluoride using the formula[6]

$$\frac{T_c}{T_b} = K$$

Using $K = 1.7$, which is the average value of K as calculated from experimental values for hydrogen chloride, hydrogen bromide and hydrogen iodide

$$T_b = 292.5\text{°A.} = 19.5\text{°C.}$$

Substituting in $T_c = KT_b$

$$T_c = 497\text{°A.} = 224\text{°C.}$$

Substituting the observed critical temperature of hydrogen fluoride in the formula

$$\frac{T_c}{T_b} = K$$

we get the-value K = **1.72**, which is close to the observed values for hydrogen chloride, hydrogen bromide and hydrogen iodide.

Summary

A new method for the determination of the critical temperature has been developed. It may be used for substances which attack glass, and for those like nitrogen dioxide, where a meniscus cannot be observed. The critical temperature of anhydrous hydrogen fluoride was found to be **230.2°**.

The value of K in the formula $T_c/T_b = K = 1.72$ for hydrogen fluoride is very close to the average value as calculated from the observed boiling points, and critical temperatures of hydrogen chloride, hydrogen bromide and hydrogen iodide.

REACTIONS INVOLVING HYDROGEN PEROXIDE, IODINE AND IODATE ION. I. INTRODUCTION

BY WILLIAM C. BRAY AND HERMAN A. LIEBHAFSKY

RECEIVED JULY 28, 1930 PUBLISHED JANUARY 12, 1931

Experimental data on the reactions that occur in acid solutions containing hydrogen peroxide, iodine and iodate ion will be presented in a series of papers. The rates of the following reactions have been measured: the oxidation of iodine to iodate

$$I_2 + 5\,H_2O_2 = 2\,H^+ + 2\,IO_3^- + 4\,H_2O \qquad (1)$$

the reduction of iodate to iodine

$$2\,IO_3^- + 2\,H^+ + 5\,H_2O_2 = I_2 + 6\,H_2O + 5\,O_2 \qquad (2)$$

and the catalytic decomposition of hydrogen peroxide

$$H_2O_2 = H_2O + {}^1/_2\,O_2 \qquad (3)$$

Our investigation was undertaken[1] with the hope of finding an intimate relationship between this catalysis and Reactions 1 and 2, in which the peroxide acts, respectively, as an oxidizing agent and as a reducing agent.

Reactions 1 and 2 were demonstrated by Auger[2] in 1911, and, independently, by Caulkins[1] in 1916–1917, but no evidence was presented that they could be obtained free, or nearly free, from the catalysis reactions. Recent experiments, however, have shown that under favorable conditions the amount of hydrogen peroxide catalytically decomposed is not over 5% of that used in Reaction 1, or 40% of that used in Reaction 2, though it may be much greater under other conditions.

We shall first consider the experimental conditions for realizing these reactions and also the well-known reactions of hydrogen peroxide with iodide and iodine

$$2\,I^- + 2\,H^+ + H_2O_2 = I_2 + 2\,H_2O \qquad (4)$$
$$I_2 + H_2O_2 = 2\,I^- + 2\,H^+ + O_2 \qquad (5)$$

The results of a number of qualitative experiments at room temperature are summarized in Table I; observations on catalytic decomposition of the peroxide and on tri-iodide formation are omitted to avoid confusion.

The complete transformation of iodide into iodine, Reaction 4, is possible at a sufficiently high concentration of hydrogen ion, as in Expt. *c;* the transformation of iodine into iodide, Reaction 5, may be accomplished without iodate formation by adding iodine (or tri-iodide) to an alkaline peroxide solution as in d. Both reactions may be demonstrated at a low concentration of hydrogen ion, as in Expts. b and *e;* in each case a steady

---

[1] Bray and Caulkins, THIS JOURNAL, 43, 1262–1267 (1921).

[2] Auger, (a) Compt. rend., 152, 712–713 (1911); (b) *ibid.*, 153, 1005–1007 (1911); (c) in 1905 Skrabal, *Chem.-Ztg.*, 29, 554 (1905), reported iodate formation in acid solution as a result of the oxidizing action of hydrogen peroxide.

state is reached, which varies with the concentration of H^+, I^- and I_2, and in which Reaction **3** is the main or net reaction. This specific result was pointed out and studied quantitatively by Abel in 1908; his brilliant investigation have demonstrated that in this case the catalysis is completely accounted for by Reactions 4 and 5.

TABLE I

REACTIONS OF HYDROGEN PEROXIDE AT VARIOUS CONCENTRATIONS OF HYDROGEN ION

	Reaction of H_2O_2 with			
	I^-	I_2	$I_2 + IO_3^-$	IO_3
10^{-13} M $\overset{+}{H}$	a-—	*d* $I_2 \longrightarrow I^-$ very rapid	*g* $I_2 \longrightarrow I^-$ very rapid	*j* — –
10^{-5} M $\overset{+}{H}$	*b* $I^- \longrightarrow I_2$ moderate rate	*e* $I_2 \longrightarrow I^-$ moderate rate	h—	k $IO_3^- \longrightarrow I_2$ and I– very slow
1 0 M $\overset{+}{H}$	*c* $I^- \longrightarrow I_2$ faster than *e*	f ——	*i* $I_2 \longrightarrow IO_3^-$ rapid	*m* $IO_3^- \longrightarrow I_2$ faster than k

At moderate concentrations of iodate and acid, as in Expts. *i* and *m*, another similar steady state is reached, which varies with the concentrations of hydrogen ion, iodate ion, iodine and hydrogen peroxide. In *i* the transformation of iodine into iodate, Reaction 1, takes place rapidly; while in *m* the much slower complementary reaction, 2, can be demonstrated easily only by removing the iodine as it is formed, *e.* g., by extraction with carbon tetrachloride. In the latter case, if the iodine is not removed, the observed reaction is a slow catalytic decomposition of the peroxide. The demonstration of Reaction 2 is more easily accomplished at a somewhat lower concentration of hydrogen ion, since the steady state concentration of iodine is then larger. In alkaline solutions, however, as in Expt. **j**, the amount of iodate reduced (to iodide) is practically zero;[4] the relatively rapid decomposition of the peroxide, $HO_2^- = OH^- + {}^1/_2 O_2$, prevents the detection of the extremely slow reduction of the iodate.

Both iodate and acid are necessary for the immediate and rapid oxidation of iodine to iodate, Expt. *i*. Thus in the absence of iodate, as in Expt. f, iodine in solution with hydrogen peroxide and acid remains apparently unchanged for several hours before being oxidized. Small initial concentrations of iodate shorten the induction period; but Reaction **1**, when once

---

[3] Abel, (a) *Z.* Elektrochem., 14, 598–607 (1908); (b) Monatsh., **41,** 405–421 (1920); (c) *Z. physik. Chem.*, 96, 1–179 (1920); (d) *ibid.*, **136,** 161–182 (1928).

[4] This is in agreement with the results of Skrabal, Monatsh., 32, 868 (1911), and of Tanatar, Ber., **32,** 1013 (1899); **33,** 205 (1900). At sufficiently low concentrations of hydroxide ion some reduction to iodide is easily demonstrated. Thus in experiments by Caulkins at 60°, in which the initial concentrations were 0.094 M KIO_3, 0.193 M H_2O_2 and (a) 0.022 M NaOH, (β) 0.0026 M NaOH, and the colorless solutions were acidified after nearly all the peroxide had decomposed, appreciable amounts of iodine were formed in (β), but not in(or). By assuming the ionization constant $(H^+)(HO_2^-)/(H_2O_2) = 2.5 \times 10^{-12}$, the initial OH^- concentration is found to be approximately 3×10^{-4} M in (a) and 3×10^{-5} M in (β).

started, proceeds at a rate that is not greatly influenced by changes in the concentrations of iodate, acid and peroxide. Similarly, on lowering the acid concentration in the presence of iodate, induction periods are again encountered; these increase in length until finally Reaction 1 does not take place in the neighborhood of the hydrogen-ion concentration of Expt. *h*.[5] Reaction 1 is thus seen to be autocatalytic only in the sense that the products, iodate and hydrogen ions, eliminate the induction period.

On account of the speed with which iodide, iodate and hydrogen ions react when all are present at rather low concentrations, it is evident from the above results that Reaction 1 takes place only when the iodide concentration does not exceed an extremely small value. Iodide, when present, as in the work of Abel,[3] would react with, or prevent the formation of, intermediate products which are necessary in the oxidation of iodine by hydrogen peroxide. This explanation may not suffice when the solution is alkaline or the concentration of hydrogen ion is very small, but in these cases intermediate products, as hypoiodite, are reduced very rapidly to iodide ion by the peroxide (cf. Expts. g and *d* in Table I). It is thus not surprising that Abel[6] found no trace of iodate in any of his experiments with Reactions 4 and 5 and the related catalysis.

The elimination of the induction period in Reaction 1 involves a transition from the iodide to the iodate regions, *e*. g., from *b* e to *i* m in Table I. The periodic reaction,[1] announced in 1921 as the first example of periodicity in homogeneous solutions, also lies in this transition region, and illustrates its complexity. Rice and Reiff[7] have questioned this claim of homogeneity, and ascribe the periodicity to the presence of minute dust particles. As we have not repeated the experiments of Rice and Reiff, and our own investigation of the periodicity is by no means complete, we have nothing definite to contribute on this question. We must state, however, that in 1922 Bon repeated and extended Caulkins' measurements on periodic oxygen evolution at 60°. Also in our recent work Liebhafsky has made some incidental observations on periodicity in oxygen evolution at 50° and in iodine formation at 0°. On account of the regularity of the results, and their occurrence in the transition region referred to above, we still believe it possible that the periodicity depends on a system of homogeneous reactions, at least one of which is autocatalytic.

While Brode[8] seems to have been the first to state clearly the role of hypoiodite as an intermediate step both in the catalytic decomposition of hydrogen peroxide in an initially neutral iodide solution and in Reaction

---

[5] An effect of the addition of acid similar to that in the series d e f, and the final transition to iodate formation, were noted by Skrabal in 1905; Ref. 2 c.

[6] Abel, Ref. 3 c, p. 30.

[7] Rice and Reiff, *J. Phys. Chem.*, 31, 1352 (1927).

[8] (a) Brode, *Z. physik. Chem.*, 49, 208 (1904); (*b*) cf. Bray, *ibid.*, 54, 485 (1906).

4, we owe to Abel[3] the complete demonstration of the mechanism of the iodide–iodine reactions with hydrogen peroxide. His conclusions and those of Bray and Livingston,[9] in the case of the analogous bromide–bromine–peroxide reactions, are in close agreement, and thus support each other. In fact, these investigations furnish two examples in which the proof of mechanism may be regarded as satisfactory. For the mathematical treatment of the results the reader is referred to the original articles, particularly References 9a, 9*c* and 3d.

All bromide–bromine reactions with hydrogen peroxide in dilute acid solutions depend upon only two rate-determining steps

$$X^- + H^+ + H_2O_2 \longrightarrow HXO + H_2O \qquad (6a)$$
$$HXO + H_2O_2 \longrightarrow X^- + H^+ + H_2O + O_2 \qquad (6b)$$

and the relatively rapid reversible reaction

$$X_2 + H_2O \rightleftharpoons HXO + H^+ + X^- \qquad (6c)$$

Corrections in the concentrations of bromide ion and bromine due to

$$X_2 + X^- \rightleftharpoons X_3^- \qquad (6d)$$

are in general small. The ionization of hypobromous acid can be neglected except in alkaline solutions

$$HXO \rightleftharpoons H^+ + XO^- \qquad (6e)$$

In the case of pure catalysis the absolute rates of the two compensating reactions, 6*a* and 6*b*, are equal at any instant; but the specific reaction rate of the third order reaction, 6*a*, is extremely small in comparison with that of the second order reaction, 6*b*, with the result that the steady state concentration of HXO is always extremely small compared with that of X^-.

In the iodide–iodine reaction 6*a* and 6*b* are each accompanied by a second reaction

$$X^- + H_2O_2 \longrightarrow XO^- + H_2O \qquad (6a')$$
$$XO^- + H_2O_2 \longrightarrow X^- + H_2O + O_2 \qquad (6b')$$

At low concentrations of hydrogen ion Reaction 6*a* can be neglected in comparison with 6*a'*, but both 6*b* and 6*b'*, and therefore the equilibrium 6*e*, must be considered. The concentration of tri-iodide ion is in general much greater than that of iodine, 6*d*. Finally, and this is the most serious difficulty, the hydrolysis equilibrium, 6c, is not established sufficiently rapidly to prevent the direct and reverse reactions from appearing as rate-determining steps in many of the experiments.[3d]

The mechanism of the iodine–iodate–hydrogen peroxide reactions undoubtedly involves intermediate substances, such as I^-, HIO and HIO_2, which are present at very small concentrations. The number of such compounds that may be postulated is very great, and any discussion of inter-

---

[9] (a) Bray and Livingston, This Journal, 45, 1251 (1923); (b) 2048 (1923); (c) 50, 1654 (1928); (d) Livingston, *ibid.*, 48, 53 (1926).

mediate reactions which is qualitative in character or based on incomplete data must be regarded as tentative. The present introduction, accordingly, is intended merely to pave the way for the discussion of mechanism in later papers.

The simplest direct line between iodide and periodate in acid solution is represented by the series

$$I^-, HIO, HIO_2, IO_3^-, IO_4^- \qquad (7)$$

Hypoiodous acid is an extremely weak acid.[10] Iodous acid, which has not been isolated, is to be regarded as a fairly weak acid by analogy with chlorous and nitrous acids, and the remaining three acids are relatively strong electrolytes. While it is practically certain, on the basis of free energy considerations[1,9a] alone, that hydrogen peroxide is capable of oxidizing each substance in the list (except IO_4^-) and of reducing each (except I^-) in reactions similar to 6*a* and 6*b*, the speed of several of these reactions must be concluded to be negligibly small on account of either known stoichiometric results, or the effect of other oxidation–reduction reactions.

Thus Reaction 5 has been isolated by Abel,[3c] free from catalysis, Reaction 3; it follows that under his experimental conditions the rate of the reaction

$$HIO + H_2O_2 \longrightarrow HIO_2 + H_2O \qquad (8)$$

is negligible in comparison with that of

$$HIO + H_2O_2 \longrightarrow H^+ + I^- + H_2O + O_2 \qquad (9)$$

since any HIO_2 formed in 8 would be reduced by H_2O_2 or by $I^- + H^+$, thus giving catalytic decomposition as the net result. We shall assume that Reaction 8 remains negligible in comparison with 9 at the higher acid concentration of our experiments, and at all concentrations of HIO and H_2O_2. Similarly we may conclude, from our evidence as to the isolation of Reaction 2, that the reaction

$$IO_3^- + H_2O_2 \longrightarrow IO_2^- + H_2O + O_2, \text{ or} \qquad (10a)$$

$$IO_3^- + H^+ + H_2O_2 \longrightarrow HIO_2 + H_2O + O_2 \qquad (10b)$$

is more rapid than

$$IO_3^- + H_2O_2 \longrightarrow IO_4^- + H_2O \qquad (11)$$

If the formation of periodate were the only primary step in this reaction, *as* suggested by Tanatar[4] to account for the catalytic action of iodic acid, then the amount of peroxide decomposed catalytically would be at least 80% in excess of that required by Equation 2, which is much greater than the lowest figures in our experiments. The assumption that HIO_2 and IO_2^- are the primary products in the reduction of IO_3^- by H_2O_2 is in agreement with our rate measurements; and we have, somewhat arbitrarily it is true, omitted IO_4^- from further consideration.

---

[10] Fürth, *Z. Elektrochem.*, 28, 57 (1922), gives 10^{-11} as an approximate value for its ionization content **at** 25°.

The possibility of the oxidation of iodide ion by hydrogen peroxide, Reactions 6a and 6a′, must be rejected on account of the presence of acid and iodate. Under these conditions, as has already been indicated in this paper, iodide is oxidized much more rapidly by iodate[11] than by hydrogen peroxide.[12] However, this rapid iodate–iodide reaction is probably also relegated to the background (except in induction periods) by the reaction between iodous acid, I^- and H^+, which must have an extremely high specific rate.

Accepting the convention that second and third order reactions are more probable than those of higher orders, we shall write this reaction in two steps

$$HIO_2 + I^- + H^+ \longrightarrow 2\,HIO + H_2O \qquad (12)$$

$$HIO + I^- + H^+ \rightleftharpoons I_2 + H_2O \qquad (13)$$

The equilibrium in 13 (*cf.* 6*c*) is assumed to be maintained except in the very rapid oxidation of iodine to iodate, Reaction 1.

The reduction of HIO_2 by H_2O_2 is also conceivable

$$HIO_2 + H_2O_2 \longrightarrow HIO + H_2O + O_2 \qquad (14)$$

but this reaction cannot be considered apart from the oxidation of HIO_2 by H_2O_2

$$HIO_2 + H_2O_2 \longrightarrow IO_3^- + H^+ + H_2O \qquad (15)$$

The latter seems to be a necessary step in the very rapid oxidation of I_2 to IO_3^-, Reaction 1, in the presence of moderate concentrations of H^+ and IO_3^- (*cf.* *i* in Table I). Our evidence on the isolation of Reaction 1, nearly free from catalysis, leads to the conclusion that under these conditions the specific rate of Reaction 15 is very great in comparison with that of 14.

The hydrogen peroxide reactions in acid solution that have not been eliminated by the foregoing conclusions are Nos. 9 and 10 in which the peroxide acts as a reducing agent, and No. 15 in which it acts as an oxidizing agent.

The series of intermediate reactions, 10–12–9–13, is in substantial agreement with our rate data for Reaction 2; Nos. 10 and 15 account partly, but far from completely, for the catalysis, and the following steps are available to explain Reaction 1: the hydrolysis of iodine (the reverse of No. 13), the oxidation of iodide presumably to hypoiodous acid by iodate[11] and by iodous acid (No. 12), and the oxidation of iodous acid by hydrogen peroxide (No. 15). It will be noted that in the last series an additional assumption is necessary to account for the rapid oxidation of iodine above the hypoiodite state. Several possibilities are being con-

sidered and will be discussed in later papers. At the present time the favored explanation involves the intermediate substance, $H_2I_2O_3$ or I_2O_2, discussed by Bray in a recent paper.[13]

Summary

The experimental conditions under which the various reactions of hydrogen peroxide in acid solutions containing iodine and iodate or iodide take place have been discussed, and the mechanism of these reactions briefly considered.

REACTIONS INVOLVING HYDROGEN PEROXIDE, IODINE AND IODATE ION.

II. THE PREPARATION OF IODIC ACID. PRELIMINARY RATE MEASUREMENTS

BY WILLIAM C. BRAY AND A. L. CAULKINS

RECEIVED JULY 28, 1930 PUBLISHED JANUARY 12, 1931

On the basis of our first experiments on the oxidation of iodine to iodic acid by hydrogen peroxide (Reaction 1, Part I),[1] a method of preparing iodic acid and iodine pentoxide on a small scale was outlined for use in an undergraduate course. While this method is not as satisfactory as the more recently developed one in which a concentrated solution of chloric acid is the oxidizing agent,[2] its description affords a convenient way of presenting a number of experimental results.

Materials.—Ten grams of very finely divided iodine (resublimed, crystalline iodine is far less satisfactory than that recovered from an iodide solution by precipitation with an oxidizing agent, as chlorine, or hydrogen peroxide at high acid concentration); 10 cc. of concentrated nitric acid; 300–400 cc. of 3% hydrogen peroxide, which is 1.5 to 2 times the theoretical amount required.

Directions.—Place the iodine, nitric acid and about 50 cc. of the peroxide solution in a 750-cc. flask and heat the mixture in a water-bath at about 70°. To minimize the loss of iodine vapor, place a loosely-fitting glass stopper or small funnel in the mouth of the flask. Shake the flask frequently when the solution does not show a deep color due to dissolved iodine. Observe when the reaction starts, as shown by the first decrease in color. Whenever the solution again becomes deeply colored, add more hydrogen peroxide. Continue until the solid iodine (or the hydrogen peroxide) is consumed. Evaporate the solution rapidly to a small volume.

---

[13] Bray, THIS JOURNAL, 52, 3580 (1930).

[1] Part I. Bray and Liebhafsky, THIS JOURNAL, 53, 38 (1931).

[2] Lamb, Bray and Geldard, *ibid.*, 42, 1636 (1920).

To remove the nitric acid and the organic substances introduced with the peroxide, evaporate the solution to dryness in a small porcelain dish; heat the residue in a drying oven for at least two hours, at first at 140–150° and later at 170–180°; extract the iodic acid with boiling water, filter off and reject the dark-colored residue. Evaporate the solution to dryness, and partially dehydrate the solid by heating it in a drying oven at 150–200°, carefully avoiding overheating.

If the product is still dark-colored, add some concentrated nitric acid and treat the mixture again as described in the preceding paragraph, or proceed as follows.

To prepare crystalline iodic acid, HIO_3, dissolve nearly all of the partially dehydrated solid in the minimum amount of hot water, filter, cool the filtrate, place the clear solution in a crystallizing dish in a vacuum desiccator over anhydrous calcium chloride and seed with a crystal of iodic acid if this is necessary. Finally, reject the mother liquor when only a small portion remains, and wash the crystals with a few drops of cold water.

Notes.—While in 0.1 N acid at 25° the reaction between iodine and hydrogen peroxide will not start for several hours, it starts rapidly at a temperature of 70–80° when the acid concentration is molal or greater. When once started the reaction in the solution is rapid even at a low temperature, and the limiting factor is the rate of solution of the solid iodine. For this reason the high temperature is maintained, finely divided iodine is used, and the mixture is shaken frequently. Since hydrogen peroxide reacts also with iodic acid (*cf.* Expt. m, Part I), catalytic decomposition is unavoidable; a 50% excess of peroxide is required in the procedure as here outlined, but much more may be used if the shaking is neglected.

The process would be much more satisfactory if hydrogen peroxide were available at higher concentration and free from preservative. The organic material is partially decomposed and rendered insoluble in the evaporation and subsequent heating, presumably on account of the presence of the nitric acid; but the product is not as white as that obtained with chloric acid.[2]

The yield with respect to iodine is practically quantitative. There is danger of loss by decomposition during the heating of the solid product only if the temperature is not properly controlled, but the permissible temperatures are lower than for material prepared by the chloric acid method,[3] and our product is thus less completely dehydrated.

The Rate of Oxidation in Homogeneous Solution.—In agreement with the observation, noted above, that the reaction proceeds rapidly when once started, it was found that the reaction also starts rapidly when iodate and acid are present initially. The kinetic investigation of this reaction in homogeneous solution was then undertaken. Nearly all the measurements were made at 25°.

[3] *Cf.* Ref. 2, pp. 1644-1645.

A large quantity of a nearly saturated solution of iodine in conductivity water was kept in a thermostat in contact with finely divided iodine, and portions were withdrawn through an asbestos filter. Standardized stock solutions of potassium iodate, sulfuric acid and hydrogen peroxide were also suspended in the thermostat. In each experiment known amounts of iodate and acid were added to a known volume of the iodine solution, the mixture was shaken, after ten minutes a measured volume of the peroxide solution was added rapidly and the mixture was again shaken. The rate was followed by determining the concentration of iodine in samples pipetted out of the reaction mixture. On account of the high speed of the reaction the first samples were withdrawn as rapidly as possible. The first order rate constant was calculated for successive pairs of results by means of the formula

$$k = \frac{2.3}{t_{n+1} - t_n} \log \frac{(I_2)_n}{(I_2)_{n+1}} \tag{1}$$

The units are moles per liter and minutes. The time at which half the peroxide had been added was recorded as t_0. The initial concentration of iodine, $(I_2)_0$, was calculated from the concentration of the stock solution and the volumes of the various solutions taken. A reasonable check was furnished by the analysis of the first sample in a few cases in which there was a noticeable induction period.

The reaction was stopped by adding each sample withdrawn for analysis to carbon tetrachloride and shaking the mixture at once. The time of shaking was recorded as t_n. The corresponding concentration of iodine, $(I_2)_n$, was determined by carefully separating the phases as soon as was convenient, adding the carbon tetrachloride layer to a solution of potassium iodide, and titrating with thiosulfate. Sources of error and further experimental details will be discussed in a later paper. At the present time it is sufficient to note that fairly definite results were obtained by increasing the number of identical or similar experiments.

Thirteen sets of experiments were performed at 25°, with enough duplicates to bring the total to twenty-eight. The range of concentrations covered was as follows

KIO_3, 0 0069–0 042 *M* (6-fold)
H_2SO_4, 0 015–0 300 N (20-fold)
H_2O_2, initial, 0 006–0 210 **(35-fold)**

Typical results are shown in Fig. 1. Values of k are plotted against the concentration of iodine, each concentration being the mean of the initial and final values used in calculating k. To show the high speed of the reaction, the successive time intervals in Expt. A are recorded, in minutes: 1.08, 0.58, 0.59, 0.67, 1.25, 1.02, 28.17. The half time is approximately one minute.

All the experiments were in accord with the following conclusions: the values of k are nearly constant at concentrations of iodine from 1 × to 3 × 10^{-4} *M* (and in some cases to 1.5 × 10^{-4} M), but always fall off markedly at lower concentrations; the "constant" is independent of the concentrations of iodate, acid and peroxide within the ranges investigated. The average, $k = 0.6 \pm 0.1$, was chosen at the time; but single values sometimes deviated from this by as much as ±0.3, and the possibility of a gradual decrease of k during a run was not excluded.

Four experiments at 0°, in which the concentrations of iodate and acid were close to 0.018 *M* and 0.12 *N* and that of the peroxide was varied between 0.033 and 0.093 M, gave an average value of k of 0.027 ± 0.002; but this should be neglected for the present, since the iodate and acid were not varied.

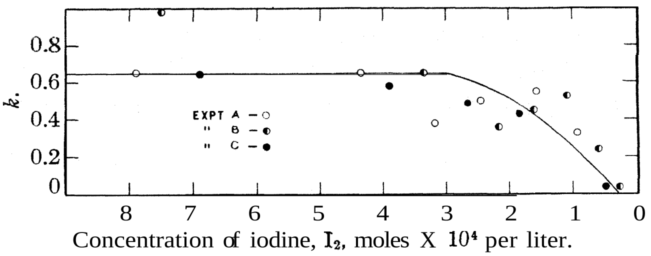

Fig. 1.—Values of the specific reaction rate in three experiments. Initial concentrations: in Expts. A and B, 0.010 M KIO_3, 0.130 *N* H_2SO_4, 0.106 M H_2O_2; in Expt. C, 0.031 *M* KIO_3, 0.130 N H_2SO_4, 0.042 M H_2O_2.

In 1920 similar measurements were made at 25° by Bray and Dr. Harry East Miller, to determine whether the earlier results could be checked, and whether traces of chloride ion played an important role in the reaction. The accelerating effect of chloride had been stressed by Auger (Ref. 2a, Part I). The only difference in procedure was that the iodine was dissolved in an iodic acid solution instead of in distilled water.

In several experiments with 0.043 *M* HIO_3 and 0.013 to 0.042 *M* H_2O_2, k was again found to be 0.6, and the variations were within ±0.1 or less, down to a concentration of iodine between 1 and 2 × 10^{-4} *M*.

In two experiments with higher peroxide concentration, 0.086 M and 0.045 M HIO_3, a decrease of k from 0.6 to about 0.4 was observed in the iodine range where constancy had been observed in other cases. Also, when the iodate concentration was decreased to 0.0090 *M*, lower values of k were obtained: approximately 0.3 with iodic acid alone, and 0.5 when enough sulfuric acid was added to make the acid concentration 0.045 *N*. The earlier statement as to the constancy of k must therefore be regarded as approximate rather than exact.

The effect of the presence of chloride is shown by the results of experiments with 0.045 *M* HIO_3 and 0.013 M H_2O_2, in which the initial concentrations of chloride due to added potassium chloride were 0.0, 0.268×10^{-4} and 1.34×10^{-4} M; the corresponding values of k were 0.6, 0.66 (constant), and 1.0 (decreasing to 0.8). It is evident that the amount of chloride impurity present in our solutions was too small to influence the results.

The simplest interpretation of our results is that the first order reaction is the rate of hydrolysis of iodine, and that the rapid decrease of k at low iodine concentration is due to the effect of the reverse reaction as the hydrolysis equilibrium is being approached. From a consideration of the equations

$$I_2 + H_2O \underset{k_2}{\overset{k_1}{\rightleftarrows}} HIO + H^+ + I^- \tag{2}$$

$$-d(I_2)/dt = k(I_2) = k_1(I_2) - k_2(HIO)(H^+)(I^-) \tag{3}$$

it is evident that k, calculated from the experimental data by means of Equation 1, will be equal to k, when $k_2(HIO)(H^+)(I^-)$ is negligible in comparison with k_1 (I_2) provided that *(2)* is the only reaction in which iodine is being consumed.

The probability of a direct relation to the rate of iodine hydrolysis was recognized from the first; but we hesitated to publish this conclusion before additional evidence was available. This has now been supplied by the recent work of Abel, referred to in Part I (Ref. 3 d), on the reaction of iodine and iodide with hydrogen peroxide (in the absence of iodate); and our results in turn furnish a confirmation of the mechanism he proposes. By means of a mathematical analysis of these reactions, and his own experimental data at 25° for 0.4 M sodium acetate solutions, he concluded that $k_1 = 0.25$. Higher values 0.38–1.1 were obtained from less extensive data for more concentrated acetate solutions, but were considered less reliable. The agreement between our "constant," 0.6 and Abel's values of k_1, is very striking.

We have concluded that the oxidation of iodine by hydrogen peroxide furnishes a direct method of investigating the rate of hydrolysis of iodine, Equation 2.

EFECT OF HYDROGEN-ION CONCENTRATION ON THE FLOCCULATION VALUES OF FERRIC OXIDE SOLS. I

BY FRED HAZEL AND C. H. SORUM

RECEIVED OCTOBER 2, 1930 PUBLISHED JANUARY 12, 1931

Preparatory to the investigation of an irregular series for colloidal iron oxide, using potassium ferrocyanide as the added electrolyte when working with sols of various H^+-ion concentrations, it has been thought worth while to observe the behavior of these sols with a representative list of ions which do not produce the recharging phenomena. It is well known that colloidal iron oxide when freshly prepared by hydrolysis of ferric chloride contains, as the chief contaminants, hydrochloric acid and ferric chloride in relatively large quantities. Moreover, such sols show great stability toward added electrolytes. However, much of this stability is lost when the colloid is dialyzed and the impurities subsequently removed.

In the following study a large volume of a stock sample of the sol was prepared by hydrolysis of ferric chloride and dialyzed for a week or more at a temperature ranging between 80 and 90°. Later measurements showed the product to be quite free from hydrochloric acid, the P_H of the purified system being above 6. To obtain sols with a suitable range of hydrogen-ion concentrations the stock sample was diluted thus

Sol number	Diluted with
1	Equal volume of water
2	Equal volume of approximately $N/5000$ HCl
3	Equal volume of approximately $N/2000$ HCl
4	Equal volume of approximately $N/1000$ HCl
5	Equal volume of approximately $N/500$ HCl
6	Equal volume of approximately $N/200$ HCl

Concentration of sol (before dilution), 1.24 g. Fe/ liter

The H^+-ion concentrations were determined with a glass electrode of the type described by MacInnes and Dole.[1] The membranes were from a glass recommended by them and were about 10 mm. in diameter. A vacuum tube potentiometer was selected for a "null" instrument. The apparatus is described by Partridge.[2] The circuit was modified, however, in that a wall galvanometer was used in place of the milliammeter and a student potentiometer in place of the voltmeter in his hook-up. The principle of operation is the same in both instances but the substitution of the galvanometer permits the use of a triode plate current which is much smaller (of the order of magnitude of 10^{-6} ampere) than that employed in the original device. P_H determinations on buffer solutions

---

[1] MacInnes and Dole, THIS JOURNAL, 52, 29 *(1930).*

[2] Partridge, ibid., 51, 1 (1929).

made with this set-up using glass electrodes have been checked against values obtained with an ordinary, although accurate, hydrogen electrode circuit and have been found to agree within 0.03 of a *PH* unit. Hydrogen-ion concentrations of the sols in this study were checked numerous times with as many as eight different glass electrodes, the results deviating by not more than ±0.05 of a *PH* unit from the value given. (*PH* values have also been determined in other systems where repeated trials have given results dependable to 0.1 of a *PH* unit.[3] Among these systems may be mentioned Fe_2O_3 sol + H_2O_2; acid + H_2O_2; concentrated acid + $SnCl_2$; and methylene blue + hypochlorite.)

[3] Standardization of the electrodes was accomplished by measuring the potential against buffer solutions the *PH* of which had been previously determined by means of a hydrogen electrode. Thus if the e. m. f. of a cell

$$\begin{array}{c|c|c|c} \text{Ag--AgCl} & \text{Glass} & \text{Buffer} & \text{Satd. KCl} \\ 0.1\ N\ \text{HCl} & & P_H\ 4.0 & \text{calomel} \end{array}$$

is 0.135 v., the constant of the circuit, which compensates for any current flowing through the cell at balance and also includes the asymmetry potential of the glass membrane, may be calculated by the equation

$$P_H = \frac{E_{\text{cell}} + C}{0.059} \text{ at } 25^\circ$$

Substituting the values of *PH* and E, we have

$$4.0 = \frac{0.135 + C}{0.059} \text{ or } C = 0.101 \text{ v.}$$

Providing this particular electrode is sensitive to the right degree to changes in H+-ion concentration, it should show for a buffer of *PH* 5.0 an e. m. f. equal to that calculated from the preceding formula

$$5.0 = \frac{E + 0.101}{0.059} \text{ or } E = 0.194 \text{ v.}$$

Similarly a buffer of *PH* 6.0 should have an E value 0.059 v. higher than that for a solution of *PH* 5.0. Of course this is true only if the constant of the circuit has undergone no change during the measurements; hence it is of advantage to check the constant before and after each determination using the standard buffer of *PH* 4.0.

It has been found in the present work that newly prepared electrodes are rarely suitable for immediate use. Thus when a freshly blown electrode completes a cell containing a buffer of *PH* 4 0 it may show a potential of greater than 0.6 v. It is impossible to work with such an electrode because the initial value of E is not constant. The high value of E indicates a large membrane potential. Moreover, such electrodes in the circuit seem to introduce capacity effects that make conditions such that measurements are not practical with the potentiometer described. However, upon aging these electrodes in an acid solution of more or less indifferent concentration, the value of E decreases until after several days it becomes practically constant. In other words, equilibrium is established in the membrane and the asymmetry potential is constant in so far that the constant, C, of the circuit does not vary over ±0.005 v. during a day's run. Happily, also, capacity effects are absent at equilibrium and the electrode can be used for accurate measurements in a cell unprotected by shielding. It has also been found that when newly prepared electrodes show an initial value of E in the vicinity of zero, for the cell containing the standard buffer, they are sluggish in detecting changes in hydrogen-ion concentration even after weeks of aging.

Flocculation values were obtained by adding 2 cc. of sol to 3 cc. of electrolyte in 12.7-cm. pyrex test-tubes and permitting to stand for twenty-four hours. Those concentrations which were just sufficient to produce complete coagulation in the allotted time were taken as the limiting values, the so-called flocculation value being calculated in millimoles per liter from the latter in the usual manner. While this method has its recognized disadvantages, it was applicable in the present case where relative measurements were sought.

Table I includes representative data for some typical electrolytes. The *P*H was determined after two volumes of the particular sols, whose flocculation values are given, were diluted with three volumes of distilled water.

Table I

Representative Data

Sol	**1**	**2**	**3**	**4**	**6**	**6**
*P*H	**5.9**	**5.4**	**4.6**	**3.9**	**3.4**	**2.9**
		Flocculation values in millimoles/liter				
KCl	16	32	56	76	100	120
KBr	16	32	56	80	100	120
NH_4Cl	12	16	40	68	92	116
$^1/_2$ $BaCl_2$	24	40	88	144	208	
$^1/_3$ $FeCl_3$	252	252	252	252	252	252
$^1/_3$ $AlCl_3$	360	360	360	360	360	360
K_2SO_4	0.125	0.12	0.11	0.10	0.09	0.08
$(NH_4)_2SO_4$		.125	.115	.100	.090	.075
$CaSO_4$	.15	.15	.14	.12	.11	.10
K_2CrO_4	.05	.06	.08	.12	.16	.19
$K_2Cr_2O_7$	.030	.04	.065	.080	.090	.100
$K_3Fe(CN)_6$	.016	.020	.026	.026	.026	.026
KH_2PO_4	.036	.048	.064	.072	.088	.104
$K_4Fe(CN)_6$	.012	.016	.024	.028	.028	.028

The electrolytes in the table may be divided into groups: Group I, which includes uni-univalent salts; Group 2, represented by barium chloride; Group 3, represented by ferric chloride and aluminum chloride; Group 4, including potassium sulfate, ammonium sulfate and calcium sulfate; Group 5, with potassium chromate and potassium dichromate; Group 6, which contains potassium ferricyanide and primary potassium phosphate; finally, Group 7, with potassium ferrocyanide.

With a positive sol, such as those used in the present work, the anion of the added electrolyte is the effective agent in producing coagulation. Hence we observe that the flocculation values for the monovalent anions are relatively higher than those for the bivalent ions and these in turn are higher than those for trivalent anions. The reason for the above grouping of electrolytes will become apparent with this and the following considerations. It can be noted that in groups one and two the flocculation values of the sols increase strongly and regularly with increase in hydrogen-ion concentration of the sols. On the other hand ferric chloride and aluminum chloride do not show any variation in this property. of the colloid with changes in the initial *PH* of the sol. The anomaly in the behavior of these two salts is explained by examination of the data in Table II, which gives the *PH* of the sols after dilution of two volumes of the sol with three volumes of water. The *PH* of the coagulated medium obtained by adding the critical concentration of certain of the electrolytes is also shown.

TABLE II

EXPERIMENTAL DATA

Sol.	1	2	3	4	5	6
After dil.	5 9	5.4	4.6	3.9	3.4	2.9
KCl	6 9	5 4	4 7	4.0	3.4	
NH_4Cl	6 0	5 5	4 7	3 9	3.4	2.9
$FeCl_3$	1 7	1 7	1.7	1.7	1.6	1.7
$AlCl_3$	3.5	3 5	3 5	3.5	3.5	3.5
K_2SO_4	6.4	6 0	5 1	4.1	3 5	3.0
$(NH_4)_2SO_4$		6 3	5 5	4 2	3.5	3.0
$K_3Fe(CN)_6$	6 3	6 0	4 9	4.1	3.5	3.0

According to the data in this table, if the *PH* of the coagulated system is determined after the addition of the flocculating concentration of either ferric chloride or aluminum chloride, the *PH* values are constant regardless of the initial PH of the sol. Both aluminum chloride and ferric chloride, being salts of a strong acid and weak bases, hydrolyze to a pronounced degree when dissolved in water to give hydrochloric acid as one of the products. We may then consider that when we use these salts as the coagulators we are adding not only the ions of the salts but also hydrogen ions. The amount of the latter derived by the introduction of the salt in any case will depend, among other things, upon the concentration of hydrochloric acid already present. For example, an aluminum chloride solution of a given concentration when added to sol number 1 with a H^+-ion concentration corresponding to a *PH* of 5.9 will hydrolyze to a greater extent and hence produce more hydrochloric acid than in the case of sol number 6 where the *PH* is 2.9. *In* the simple case we may be dealing with the equilibria

$$AlCl_3 + H_2O \rightleftharpoons AlOHCl_2 + H^+ + Cl^-$$

or

$$2\ AlCl_3 + 6\ H_2O \rightleftharpoons 2\ Al(OH)_3 + 6\ H^+ + 6\ Cl^-$$

and

$$HCl \rightleftharpoons H^+ + Cl^-$$

so that a buffer action is maintained by the common ion effect and enables the one or the other reaction to be reversed, making the gross hydrogen-ion concentration constant.

Freundlich[4] states that small concentrations of hydroxyl ions raise the stability of negative sols but that the symmetrical effect of the H^+ ion with positive sols is less clearly visible since the latter are almost all hydroxide sols so that a chemical action takes place. (Incidentally, in the present work the concentration of acid used in charging the sols did not go above $N/200$ and the amount of ferric ion produced by the solvent action was only sufficient to give a very faint coloration with the ammonium sulfocyanate test.) Somewhat later, Freundlich and Lindau[5] working with colloidal iron oxide have shown that the flocculation values for sodium chloride increase with increasing hydrogen-ion concentration of the sol. Their method was to alter the PH of the system by adding different concentrations of sodium acetate–acetic acid buffers. Mukherjee and Sen,[6] experimenting with an arsenious sulfide sol, account for the large flocculation value of salts with organic ions as being due to increased OH–-ion concentration from hydrolysis, the hydroxyl ion serving to charge the colloidal particles more negatively.

In cases under Groups 1, *2* and **5**, the charging property of the hydrogen ion on colloidal ferric oxide is shown clearly since the stability as measured by flocculation data increases as the acid concentration becomes greater The same is true in Group 6, which includes the trivalent ferricyanide and phosphate ions. Here again we see that the flocculation value increases with increasing acidity. However, an anomaly is encountered when the electrolytes in Group 4 are considered. The flocculation values of potassium sulfate, ammonium sulfate and calcium sulfate decrease with increase in H^+-ion concentration. The decrease in stability in this case is a well-defined, reproducible phenomenon. To avoid any possibility of error in observation of the peculiar conduct of these electrolytes, the experiment has been checked repeatedly using very pure reagents. The results have been the same. At present there is no available explanation for such an unexpected behavior. It may be mentioned, however, that other investigators have observed somewhat similar, if not related, abnormalities in the coagulation of colloids by ions with different valences. Mukherjee and Sen[6] in studying the stabilizing effect of hydrogen sulfide on arsenious sulfide sols found that whereas it took higher concentrations of monovalent ions to coagulate such sols, they behaved in an anomalous manner when solutions of barium chloride, strontium chloride, magnesium sulfate, and thorium nitrate were used, the sols containing hydrogen sulfide becoming less stable. On the other hand, Ghosh and Dhar[7] have found

[7] Ghosh and Dhar, **J.** ***Phys. Chem.,*** 30,830 (1926).

that "when a ferric hydroxide sol is coagulated by hydrochloric acid and potassium sulfate, appreciable stabilization takes place because of the adsorption of hydrogen ions. The precipitation value of potassium sulfate with ferric hydroxide sol is 0.10 millimoles per liter when no acid is present. In the presence of 0.1 cc. of *N*/500 hydrochloric acid the precipitation value becomes 0.15 mml. On further increasing the concentration of acid it is found that the precipitation value of potassium sulfate remains constant when 0.3, 0.4 or 0.5 cc. of *N*/500 hydrochloric acid is added." A comparison of their results, on a sol prepared by the Krecke method follows. Both sols had approximately the same concentration.

Ghosh and Dhar		Hazel and Sorum	
Concn. of HCl after dilution	**F. V., mm./l.**	**Concn. of HCl after dilution**	**F. V., mm./l.**
0	0.10	0	0.125

N/15000	.167	*N*/10000	.11
N/10000	.175	*N*/5000	.10
N/7500	.175	*N*/2500	.09
N/6000	.175	*N*/1000	.08

The agreement is not good and will have to be charged to the complex nature of the system with which we are working.

The potassium ferrocyanide data are for flocculation of a positive sol. Higher concentrations of this electrolyte recharge a positive ferric oxide sol to the negative form and it is thus possible to obtain an irregular series. A later paper will include the relation of the irregular series to H^+-ion concentration of the sol.

Summary

1. The stability of colloidal iron oxide has been shown to be related to the H^+-ion concentration of the sol.
2. The stability increases with increasing acidity for potassium chloride, potassium bromide, ammonium chloride, barium chloride, potassium chromate, potassium dihydrogen phosphate, potassium ferricyanide and potassium ferrocyanide.
3. Ferric chloride and aluminum chloride hydrolyze to such an extent that the initial P_H of the sol is altered to a constant value, the stability of the colloid being independent of the initial P_H but dependent on the constant value.
4. Sulfates are anomalous in that the sols with lower P_H values are less stable than those of higher P_H values.

THE POISONXNG EFFECTS OF WATER VAPOR ON THE ADSORPTION OF CARBON DIOXIDE BY MANGANESE DIOXIDE

BY H. W. FOOTE AND J. K DIXON

RECEIVED OCTOBER 7, 1930 PUBLISHED JANUARY 12, 1931

Manganese dioxide, when pure, catalyzes the reaction between carbon monoxide and oxygen to form carbon dioxide. Water vapor is a strong poison for this reaction, making the oxide inactive.[1] It has been shown that water is adsorbed by manganese dioxide and that, when the pressure is less than about four tenths the saturation value, the adsorption is a surface phenomenon.[2] Water vapor must retard the oxidation of carbon monoxide by covering a part of the surface of the oxide which is available for the adsorption of the reacting gases. The present paper deals mainly with the effects of the presence of water on the adsorption isotherms of carbon dioxide on manganese dioxide at 25°.

Materials, Apparatus and Experimental Procedure

The manganese dioxide used is from the lot prepared and used in previous work.[2] Carbon dioxide, from a tank, was dried by passing through concentrated sulfuric acid and over phosphorus pentoxide.

The apparatus used for determining the adsorption isotherms was of the constant volume type.[3] A small bulb of known volume (20–22 cc), containing the oxide, was connected to a forevolume of known capacity. Gas at a known pressure and temperature in this forevolume was allowed to expand into the adsorption bulb. The oxide adsorbed the gas and the pressure decreased. The pressure decrease was a measure of the amount of gas adsorbed, if correction were made for expansion of the gas into the adsorption bulb. The changes in temperature in the forevolume were noted, the appropriate corrections being applied for these variations.

The apparatus was constructed of pyrex glass. The adsorption bulb was maintained at 25° by means of a large water thermostat. The forevolume contained a McLeod gage, a U-tube for measuring pressures above 2 mm., a bulb of suitable size, and connections to the vacuum pumps and gas generating system. The mercury in the U-tube and McLeod gage was maintained at fixed levels. When the mercury was at these levels, the capacity of the forevolume was known from previous calibration by means of mercury or water.

About 4 g. of manganese dioxide was weighed into the adsorption bulb and, in all experiments, then heated at 190 ± 3° for three hours under the vacuum produced by a mercury pump backed by an oil pump. The oxide was cooled and immersed in the thermostat. The gas under investigation was admitted to the forevolume and its pressure and temperature noted, after the system had been swept out several times. This gas was admitted to the oxide and its pressure and temperature determined at regular time intervals until the pressure attained a constant value. This was taken as the equilibrium point. The stopcock to the adsorption bulb was closed, more gas

admitted to the forevolume, and the next equilibrium point measured in the same way as before.

The surface of the oxide was poisoned with a known amount of water as follows. The forevolume was filled with water vapor up to any desired pressure and its temperature recorded. Connection with the oxide, which had just been outgassed, was made and the vapor was adsorbed, leaving a negligible amount in the gas space. It was necessary to repeat this process several times whenever the amount of water desired corresponded to a pressure in the forevolume greater than the vapor pressure at room temperature.

The weight of outgassed oxide has been used to calculate the amount of gas adsorbed per gram of oxide. In previous work[2] the weight of oxygen and watrr lost by a sample of oxide during heating was determined by direct weighing. The mean of thirteen experiments showed that the loss in weight was practically constant and equivalent to **0.0379** g. per gram of original oxide. The volume of the adsorption bulb was corrected for the volume of the outgassed oxide, the specific volume of the oxide being taken as 0.2168 cc. per gram.'

The equilibrium pressure extended from **3** to 500 mm. of mercury. Since the object was to compare the isotherms for a poisoned and unpoisoned oxide, no attempt was made to read the pressures closer than **0.1** mm. The largest capacity of the forevolume was 821 cc. and the pressure changes in this volume were never less than **5** mm. The results given in the following sections are accurate to 4% or better.

The Adsorption Isotherms of Carbon Dioxide

The capacity of the forevolume in the experiments was 821 cc. The adsorption isotherms of this gas on manganese dioxide at 25° are plotted in Fig. 1, v/m as ordinate and p as abscissa. v/m is the number of cubic centimeters of carbon dioxide, reduced to 0° and 760 mm. pressure, adsorbed per gram of outgassed oxide, and p is the equilibrium pressure in millimeters of mercury. Curve 1 represents the isotherm for an oxide unpoisoned with water vapor. The amount of water necessary to cover the surface of one gram of oxide at 25° we assume is approximately 0.063 g. This assumption is based on the adsorption isotherm of water on manganese dioxide at this temperature.? The weight of water used to poison the oxide of Curve 2 was 0.0096 g. per gram of oxide, or 15% of the surface was covered. In Curves **3** and 4, 34 and **38%** of the surfaces were covered, respectively.

The results show that when approximately 35% of the surface is covered with water vapor, the amount of carbon dioxide adsorbed is reduced by about 50%, the effect being more pronounced at lower pressures. This is a strong indication of the presence of active adsorption patches on the oxide. Since the water covers these patches, the adsorption of carbon dioxide shows a greater decrease than we would expect from the fraction of the surface poisoned.

The small amount of water used in these experiments is adsorbed so completely from the vapor phase that it is very unlikely that carbon dioxide can displace it from the solid to a measurable extent. If it were displaced,

---

[4] Draper, THIS JOURNAL, 50, 2637 (1928).

however, the surface covered by water vapor would be less than calculated without decreasing the partial pressure of carbon dioxide proportionally and the effect would be even more pronounced than stated above.

Two check runs in the absence of water vapor agree with Curve 1. The adsorption and desorption curves nearly coincide at all pressures. The time necessary to attain equilibrium was ten minutes, although readings were taken over a period of one hour. The manganese dioxide of Bray and Hoskins[3] adsorbed only about half the amount of carbon dioxide that we have found for our sample of manganese dioxide, the attainment of equilibrium was slower, and adsorption somewhat irreversible.

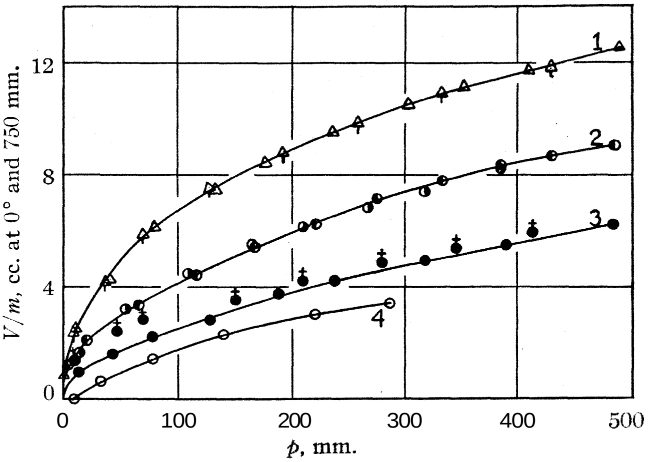

Fig. 1.—Effect of water on the adsorption isotherms of carbon dioxide on manganese dioxide at 25°. % of surface poisoned with water: 0 %, A adsorption, △ desorption; 15%, ◐ ads., ◑ des.; 34%, ● ads., ● des.; 38%, ○ ads.

The Behavior of Carbon Monoxide toward Manganese Dioxide Containing Adsorbed Water.—It is well known that carbon monoxide reacts with manganese dioxide at room temperature to form carbon dioxide and the latter may then leave the surface.[5] However, the carbon monoxide may form manganese carbonate or, after reaction, the carbon dioxide formed may remain in the form of the carbonate.[6] Whether this behavior is to be classed as true adsorption may be questioned. The isotherms have the general form of adsorption isotherms, however, and we shall so refer to them. Since the system carbon monoxide–manganese dioxide is so complicated, we shall report only qualitative results, in which it has been assumed that the decrease in pressure in the forevolume is a measure of the carbon monoxide adsorbed. The carbon monoxide used in the experi-

---

[5] Benton, THIS JOURNAL, 45, 887 (1923); Hoskins and Bray, Ref. 3.

[6] Frazer and Greider, *J. Phys. Chem.*, **29**, 1099 (1925).

ments was prepared by dropping formic acid into concentrated sulfuric acid. It was then purified by passing it over solid potassium hydroxide, through concentrated sulfuric acid and over phosphorus pentoxide.

The adsorption and desorption isotherms of carbon monoxide at 25° were determined for samples of oxide poisoned and unpoisoned with water vapor. The pressure did not attain a constant value, after any new addition of gas, even at the end of four hours, but this further decrease in pressure was slow. Four to five hours were allowed for the system to reach this nearly steady state which was taken as an arbitrary equilibrium point.

The isotherms are highly irreversible, about 50–60% of the gas being retained very strongly by the oxide. The adsorption isotherms are of the same shape as those for carbon dioxide (see Fig. 1), but the amount of carbon monoxide adsorbed is approximately twice as great for the same pressure. The adsorption on a surface of oxide poisoned with water vapor is similar to that of carbon dioxide, especially below 250 mm. pressure. That is, the first fraction of the surface poisoned causes the greatest lowering of adsorption. Further poisoning decreases the adsorption, but by no means in a strictly proportional manner.

Summary

The adsorption isotherms at 25° of carbon dioxide on manganese dioxide with and without adsorbed water have been determined. The adsorption is reversible. Water reduces the adsorption markedly. The results indicate the presence of "active adsorption patches" on the oxide surface since the first portion of water adsorbed results in the greatest lowering of the carbon dioxide adsorbed.

The corresponding behavior of carbon monoxide toward manganese dioxide with and without adsorbed water is more complicated. Adsorption is highly irreversible, but the presence of adsorbed water causes the same qualitative effect that it does with carbon dioxide.

DIFFUSION OF ELECTROLYTES, RON-ELECTROLYTES AND COLLOIDAL ELECTROLYTES[1]

BY JAMES W. MCBAIN AND TSUN HSIEN LIU

RECEIVED OCTOBER 10, 1930 PUBLISHED JANUARY 12, 1931

Diffusion is one of the simplest and most fundamental properties of substances in solution and yet its characteristics are seldom adduced even in discussing such closely allied phenomena as electrical conductivity or its dependence upon concentration. Surprise at this neglect largely disappears when the meager and somewhat conflicting data collected in "International Critical Tables" and in Landolt–Bornstein–Roth are scrutinized and when it is recalled that each number there recorded is the result of prolonged and laborious experiment dependent upon the most painstaking precautions, each result being independent and therefore of no assistance in obtaining further data. Hence, in some instances, the data are conflicting even as regards the sign of the effect of a single factor such as concentration.[2]

The first necessity is therefore to obtain a method by which data that are fully comparable with each other may be readily obtained. It will be shown that standardization of the method recently developed by Northrop[3] enables it to yield results in twenty-four hours that are readily reproducible to within a few tenths of a per cent. and that are thus favorably comparable with those of the laborious classical methods, while exhibiting the further advantage that they permit a ready study of the effect of such factors as viscosity, concentration or admixtures upon rate of diffusion of any one substance. It is shown that the diffusion of electrolytes diminishes to a significant extent with increase of concentration and that the reasoning employed in the discussion of electrical conductivity by Debye, Hückel and Onsager leads to the conclusion that this is in direct proportion to the ratio of the actual osmotic pressure to that at infinite dilution.

The Nernst equation, which applies only to the diffusion of electrolytes at extreme dilution, and the Einstein equation, which applies only to uncharged colloidal particles and large spherical molecules, are generalized and combined to a single equation which appears to hold good for all concentrations, even for such a complex case as solutions of soap, which are crystalloidal when dilute and contain two kinds of colloidal particles when more concentrated. The ready production of new data facilitates the

---

[1] Experiments by T. H. Liu.

[2] For example, taking from Landolt–Bomstein–Roth the data for potassium chloride, perhaps the most carefully studied electrolyte, Öholm at 18° finds for 0.01, 0.1 and 1.0 *N*, 1.46, 1.39 and 1.33, respectively, whereas, on the contrary, Thovert at 17.5° obtains for 0.02, 0.1 and 0.9 N, 1.36, 1.38 and 1.52, respectively. Schulmeister obtained 1.10 for 1.3 N at 10°, but Graham–Stefan found 1.41 for 1.26 N at only 12.5°.

[3] J. H. Northrop and M. L. Anson, J. Gen. *Physiol.*, 12,543 (1929).

examination of many interesting problems such as the dimensions and solvation of molecules and colloidal particles in solution, the great difference found between the gross viscosity of a system and that which determines its diffusion or conductance, and the effect of the simultaneous diffusion of various substances upon each other. For example, it is shown that different substances do not diffuse independently, but that one may construct a liquid diffusion pump whose action is analogous to that of the ordinary gaseous diffusion vacuum pump.

Experimental Method

Northrop's method consists in separating two homogeneous bodies of solution by an indifferent membrane with pores of visible or microscopic size, confining the diffusion gradient to within this membrane. Membranes of alundum and of sintered glass have been used. We have found it advantageous to buy cells direct from the Jena Glasswerke[4] in order that the sintered glass may be fused directly to the remainder of the cell. The pore diameter which they designate as G-4 has proved most suitable, and for our purposes the cells required no alteration before use except to grind away the slightly projecting edge of the glass. The cell is shown in Fig. 1 dipping into a closely fitting beaker of water. We have found that the detailed procedure given in the following paragraph enabled us to obtain the results already indicated without any elaborate precautions for the avoidance of vibration or extreme constancy of temperature. The results are necessarily relative but are standardized, as in using a conductivity cell, by a measurement of a single standard solution such as 0.1 *N* potassium chloride, of which the absolute value is already established.

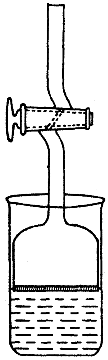

Fig. 1.—The diffusion cell.

After testing for leaks, the volume of the diffusion cell up to the glass stopcock is determined by weighing. It is then suspended by a 5-mm. rubber tube about 15 cm. long and the suspension or stem adjusted until the diaphragm is accurately horizontal as tested against a large mercury surface. This is to minimize the possibility of streaming through the diaphragm. The cell is first cleaned by sucking cleaning solution through the porous disk, using a water pump at the upper end. The liquid is expelled again by applying a pressure of not more than one meter of water. After thorough rinsing, water freed from dissolved gas by boiling or shaking in vacuo is drawn through the diaphragm in order to dissolve any air therein. Bubbles are dislodged by sudden increase in suction, which may serve as a test for the removal of air. In removing the water the pressure is released just as the last layer is about to enter the diaphragm.

The solution to be investigated is freed from dissolved gas by boiling for a few minutes at room temperature in the vacuum of a good water pump. The cell is then rinsed and charged with the solution through the diaphragm and filled completely,

---

[4] Schott und Gen., Jena, Germany; American agent, J. E. Bieber, 1123 Broadway, New **York** City.

without bubbles, past the stopcock which is then closed. The cell is first immersed in a large beaker of pure, gas-free water, and before placing it in the surface of the beaker of gas-free water shown in Fig. 1, the last drop of adherent water is removed by slightly tilting the diaphragm and touching it with a glass rod

The preliminary diffusion proceeds for a few hours or whatever time is necessary to establish a steady diffusion column within the disk. This can be calculated from the time required for that part of the solution which is within the diaphragm to diffuse out entirely; for hydrochloric acid about two hours is required Finally, the cell is transferred, after removal of adherent liquid as before, to a clean beaker containing a quantity of gas-free water equal to the volume of the cell The space between cell and beaker is closed with a ring of rubber dam to minimize evaporation. The measurement now begins. The preliminary diffusion not only creates the uniform diffusion gradient within the diaphragm but enables the solutions to attain the temperature of the thermostat in which the apparatus is placed.

After sufficient diffusion has occurred to permit of an accurate analysis of the dilute solution formed in the beaker, the cell is removed and wiped with filter paper, including the inside of the tubing above the stopcock. The solution is extruded through the diaphragm, the first 10 cc. or so being discarded and a sample of the remainder being taken for analysis.

We have made use of cells whose diaphragms had the following characteristics:[5]

Material	Trade designation	Approximate pore radius, Å.	Diameter and thickness, cm.
Glass	G-3	$(15\text{–}20) \times 10^4$	5×0.3
Glass	G-4	$(2\text{–}5) \times 10^4$	$5 \times .2$
Alundum[6]	RA225	$(8\text{–}10) \times 10^4$	$5 \times .2$
Alundum	RA98	$(10\text{–}15) \times 10^4$	$5 \times .2$

The glass diaphragms allow faster diffusion than those of alundum. Diffusion in the finer glass diaphragm is as fast as in the coarser one, while the possibility of streaming is eliminated. It will be noted that the pores have about ten thousand times the diameter of such large molecules as sucrose and one or two thousand times the diameter of hemoglobin or the smaller particles of blue gold.

Method of Calculation.—From Fick's equation for the amount ds diffusing per interval of time dt

$$ds = DA\frac{dc}{dx}dt$$

where D is the diffusion coefficient and A the effective area of all the pores. The diffusion gradient, dc/dx, being linear within the disk, may be set equal to $\Delta x/\Delta x$, where Δx is the thickness of the disk, whence $ds/dt = DA.\Delta c/\Delta x$ and since the volume V of water in the beaker is equal to that in the cell, $ds/dt = D(A/\Delta x)(c_0 - 2c)$, where c_0 is the initial concentration and c is the concentration to which the solution in the beaker has attained and

---

[5] The pressure required to force air bubbles freely through the diaphragms under water confirmed the radii ascribed to the alundum disks but indicated slightly smaller values than those here given for the glass diaphragms.

[6] Norton Co., Worcester, Massachusetts.

where $c = s/V$. Hence, $dc/dt = Dk'V(c_0 - 2c) = Dk''(c_0 - 2c)$ where k' and k'' are constants. Therefore, ln $(c_0 - 2c) = -2Dk''t + \text{const.}$ Therefore

$$KD = \frac{\log_{10} c_0 - \log_{10}(c_0 - 2c)}{t_E}$$

where K may be entitled the cell constant, t_E is the elapsed time, and c is 0 at the beginning of the experiment if the diffusion is taking place into water. By measuring the diffusion of a standard substance such as 0.1 N potassium chloride, whose diffusion coefficient is known[7] to be 1.448 at 20°, the cell constant K is determined and all diffusion constants D measured with that cell are expressed in absolute values.

Critical Tests of the Experimental Method.—Northrop[8] states that "hydrochloric acid, lactose and several salts were used" and that "the same cell constant was obtained." He applied his cell to the determination of the molecular weight of carbon monoxide hemoglobin, which he found to be 68,500 ± 1000. At first sight this appears highly satisfactory, but actually there is a glaring and unexplained discrepancy with the diffusion observed by Svedberg and Nichols[9] in the ultracentrifuge, which yielded a value of 113,000,[10] from which it was deduced that hemoglobin particles could not be spherical. Hence it is necessary to scrutinize the method more closely.

A. Homogeneity of the Solutions in Cell and Beaker.—Mechanical stirring introduces much more error than it obviates. Mixing is largely automatic since the heavier portion of the solution overlies the lighter portion in both cell and beaker. Imperfect mixing would be revealed in a change of the value of KD with longer elapsed time and might be greatest for fast diffusing substances such as hydrochloric acid. However, the following is the consistent series of data obtained at 20.5' for 0.5 N hydrochloric acid after the experimental procedure described above was adopted. Cell F used in these six experiments had a capacity of 91 cc., and the hydrochloric acid was determined by titration. The second and third columns are the number of cubic centimeters required to titrate the whole of the diffused hydrochloric acid and the number of cubic centimeters to titrate 25 cc. of the solution recovered from the cell, respectively. It is the ratio of these numbers rather than their absolute values which appears in the calculation.

Similarly, values of *KD* equal to 274 and 272 were obtained in cell B for 0.4 N acetic acid when the times were sixty-three and forty-one hours, re-

[9] J. B. Nichols, "Colloid Symposium Monograph," The Chemical Catalog Co., Inc., New York, 1928, Vol. VI, p. 296.

[10] Nichols made the obvious error of inverting the ratio in his arithmetic and writes 41,000 instead of 113,000.

TABLE I

DIFFUSION OF 0.5 *N* HYDROCHLORIC ACID AT 20.5°

t_E, hours	c	c'	KD
19.90	20.22	35.52	688
31.04	20.70	34.42	687
20.97	20.75	34.56	689
40.07	44.85	40.18	686
16.43	16.70	35.50	687
9.20	9.86	37.30	687

spectively. Likewise, for 0.1 *N* potassium chloride with two different methods of analysis KD was equal to 407 and 409 in cell F when the times were forty-two and twenty-five hours, respectively. Finally, the ratio between the diffusion coefficients for 0.1 *N* potassium chloride at 20° and 1.0 *N* sucrose at 25° was 3.79 by this method as compared with 3.82 from Öholm's data.

B. Temperature Expansion.—A fortuitous alteration of temperature by 0.2° would cause an expansion of only 0.006% and cause an absolute error of 0.038% in such an experiment as the first in the table just cited.

C. Streaming through the Diaphragm.—With a fine glass diaphragm such as that employed in cell F it requires seventeen minutes to force through 91 cc. of 0.1 N potassium chloride using a pressure of 85 cm. of water. From this it follows that if there is an inaccuracy of 0.2 mm. in leveling the diaphragm, the flow in twenty-four hours will be about 0.006 cc., causing an error of 0.06% in the result. A sugar solution would be heavier but much more viscous. Another effect of gravity might be sedimentation; this is quite negligible for molecules but for gold particles of 50 Å. radius it might be 4.6% as great as diffusion.

D. The Nature of the Diaphragm.—The most important question that arises with regard to this method of measuring diffusion is whether or not the neighborhood of the extensive surfaces within the diaphragm affects the nature or extent of the diffusion. In the first place, the high mobility of substances upon a solid or liquid surface exposed to a gaseous phase must here be lacking where the solid is immersed in a liquid and the whole space is close-packed with matter. The second conceivable possibility is in the opposite direction and has to be considered more seriously. It is that the surfaces may tend to suppress diffusion through the orientation and immobilization of the adjacent solvent molecules Even if this does occur, and even if it extends to a thickness of many molecular diameters, it might be largely obscured by the fact that the average pore diameter is of the order of 10,000 molecular diameters, and it would completely disappear from the results if the effect were the same upon different solutes. The only way of testing the effectiveness of this or any other specific action of the various diaphragms is by seeing if they give the same numerical result independent of whether glass or alundum is used and of whether the pores are coarse or fine, and by comparing such results with those of the classical methods. For this purpose the following results are adduced.

Cells B, F and G were of fine alundum, glass (G-4), and coarse alundum, respectively, and their cell constants were 294.3, 282.0 and 185.0, respectively. Hydrochloric acid was determined by titration, whereas potassium chloride and sucrose were measured by the Zeiss interferometer, having first prepared a (straight line) graph of interferometer reading against concentration with known solutions. More concentrated solutions were diluted before using the interferometer.

TABLE II

DIFFUSION WITH DIFFERENT DIAPHRAGMS

Solution	Temp, °C.	Cell	t_E, hours	c	c'	KD
0 05 N sucrose	25	F	24.87	139	178	129 6

.1 N KCl	20	F	41.97	248	177	406
.1 N KCl	20	F	25.27	18.85	43.63	409
.1 N KCl	20	F	27.60	20.23	43.07	408
05 N sucrose	25	B	24.52	137	177	135.5
.4 N HCl	21	B	19.18	21.05	39 20	729
4 N HCl	21	B	18.80	20.87	39.30	728
.1 N KCl	20	B	29.00	203	179	425
.1 N KCl	20	B	25.42	18.32	43.40	427
.05 N sucrose	25	G	25.25	111	181	85.2
.05 N sucrose	25	G	30.85	123	181	85.4
.4 N HCl	21	G	19.23	14.63	41.65	457
.4 N HCl	21	G	19.57	14.90	41.70	457

When the above data are compared in various ways, it is seen that the results appear to be independent not merely of the diaphragm but of the method. For example

$$\frac{KD\text{ for }0.4\ N\text{ HCl in "F"}}{KD\text{ for }0.4\ N\text{ HCl in "G"}} = 1.524\text{ and }\frac{KD\text{ for }0.05\ N\text{ sucrose in "F"}}{KD\text{ for }0.05\ N\text{ sucrose in "G"}} = 1.520$$

$$\frac{KD\text{ for }0.4\ N\text{ HCl in "B"}}{KD\text{ for }0.4\ N\text{ HCl in "G"}} = 1.593\text{ and }\frac{KD\text{ for }0.05\ N\text{ in sucrose "B"}}{KD\text{ for }0.05\ N\text{ in sucrose "G"}} = 1.588$$

$$\frac{KD\text{ for }0.4\ N\text{ HCl in "F"}}{KD\text{ for }0.1\ N\text{ KCl in "F"}} = 1.709\text{ and }\frac{KD\text{ for }0.4\ N\text{ HCl in "B"}}{KD\text{ for }0.1\ N\text{ KCl in "B"}} = 1.708$$

The diffusion coefficients of 0.05 *N* sucrose at 25° in cells B, F and G are 0.461, 0.460 and 0.461, respectively; whereas Öholm's values corrected for temperature and viscosity by Einstein's equation would be 0.457. Similarly, for 0.4 N hydrochloric acid at 21° they are 2.476, 2.473 and 2.470, respectively, as compared with Öholm's corrected value, 2.43. Again, the ratio of the diffusion constant here found for the hydrochloric acid to that found for the sucrose is 5.37, whereas from Öholm's corrected data 5.31 would be predicted.

Theoretical Formulation of Diffusion **Data.**—Nernst,[11] on the basis of the close connection between the forces giving rise to diffusion and osmotic pressure, derived the well-known equation for electrolytes in extreme dilution

$$D = \frac{2RT}{\frac{1}{U} + \frac{1}{V}}$$

where U and V are the ionic mobilities at infinite dilution as measured by electrical conductivity. Thus for an electrolyte whose ions have the same mobility at 18°, $D = 0.02243U$. This last expression is applicable to neutral molecules or colloidal particles of the same size as an ion of mobility U or V. In this way Nernst could estimate the approximate diffusion coefficients of neutral molecules or un-ionized electrolytes. Haskell's[12] formula is an expansion of that of Nernst for the diffusion of electrolytes which dissociate into ions of unequal valency.

The other theoretical contribution is that of Einstein[13] for uncharged spherical particles or molecules very large in comparison with those of water

$$D = \frac{RT}{N6\pi\eta r}$$

where r is the radius of the particle, η the viscosity of the medium and the denominator is the sum total of the resistance to movement of each of the particles calculated by Stokes' law.

It is evident that the numerators of the Nernst and Einstein equations are alike in containing the osmotic term RT for each molecular species. Likewise, their denominators contain the sum total of the resistances to movement.experienced by the different ions, molecules and particles present. We may therefore generalize the reasoning which Nernst and Einstein have applied to these two particular cases and write in the numerator the actual osmotic term iRT and in the denominator the sum of all the resistances to motion of the ions, molecules and particles evaluated by whatever methods are available in each case. Hence

$$D = \frac{iRT}{\text{sum of resistances}} = \frac{iRT}{\Sigma(1/U_m)}$$

where $1/U_m$ is the resistance to movement of a particular species and is also equal to RT/D_m where D_m is the diffusion coefficient of that molecular species.

For example, for an incompletely dissociated uni-univalent electrolyte, such as potassium chloride may be at higher concentrations, the diffusion coefficient at any concentration is given by the formula

$$D = \frac{iRT}{\alpha\frac{1}{U} + \alpha\frac{1}{V} + (1 - \alpha)\frac{1}{U_{\mathrm{KCl}}}}$$

The Diffusion of Electrolytes.—The Debye–Hückel–Onsager[14] theory is an analysis of the chief forces acting upon free ions in aqueous solution. They enumerate three whose sum should determine the electrical conductivity of the solution. The first is that due directly to the electrical charge overcoming ordinary friction and is represented by the mobility at infinite dilution. The second, which diminishes the conductivity, is unfortunately termed the electrophoretic force and represents the opposing effects of the viscous drags of the two clouds of ions moving through the same solution in opposite directions. The third likewise tends to lower the conductivity and is called the electrical force of relaxation and is due to the fact that any movement of an ion must be followed by a slight alteration in the distribution and arrangement of all surrounding ions. The result of the last two terms is that the conductivity A at any concentration is given by the expression A = **A,** $- \Lambda_{\mathrm{I}} - \Lambda_{\mathrm{II}}$ so that the conductivity diminishes with increase in concentration if ionization remains **100%** complete.

Now diffusion is simpler than electrical conduction. The prime force acting upon an ion is that represented by the osmotic term RT as driving force and by $1/U_\infty$ as resistance. The second influence enumerated by Debye and Hückel, namely, the opposing viscous drags of the ions when moving past each other in opposite directions, is here essentially eliminated because all ions are moving in the same direction. The negligibility of this effect is most obvious for a case such as potassium chloride where both ions are equally fast but it is likewise true of all other simple electrolytes because after the first few moments in which the Nernst diffusion potential is set up, equal amounts of both ions are diffusing together. Onsager[15] has expressed a similar opinion for such electrolytes as potassium chloride. Cataphoretic forces then will not intervene to lessen the movement of ions with increase of concentration.

The third force envisaged by Debye and Huckel is due to the relaxation or alteration in the distribution of the ionic atmosphere whenever an ion is displaced. It may not be entirely eliminated in diffusion but it is certainly minimized when, as here, we have a linear diffusion gradient and all the ions are traveling in the same direction. What is happening is a uniform dilution of the ionic atmosphere and this is minimized when, as in some of our experiments, the diffusion takes place, not into pure solvent, but only into a slightly less concentrated solution.

The net result is that in diffusion the denominator of our generalized

[15] **L. Onsager,** *Trans. Faraday Soc.*, **23,356 (1927).**

equation, representing the forces opposing movement, remains appreciably constant as long as the ions are not changed or replaced. This leaves the observed decrease with concentration to be explained primarily by the change in the effective osmotic pressure as given in the numerator.

The diffusion data that we have obtained for potassium chloride are given in Table III. The cell constants were obtained from measurements of 0.1 N potassium chloride at 20°, giving values of KD for cell *G-3* of 503, 501 and 504, and for cell G-4 of 481,480 and 484; whence the cell constants are 348.0 and 332.7, respectively.

TABLE III

DIFFUSION COEFFICIENTS OF POTASSIUM CHLORIDE AT 25°

Concn., N	Cell	t_E, hours	c	c'	KD	D
0.02	B	20.47	119.6	122.4	500	1.698
.02	F	21.67	120.0	123.2	477	1.672
.02	*G-3*	22.75	134.3	121.0	588	1.691
.1	G-3	35.82	37.40	41.70	568	1.631
.5	F	30.30	21.25	39.14	445	1.580
.5	B	28.68	20.15	39.10	466	1.567
.5	G-4	23.46	22.75	39.25	524	1.572

It is possible to account for these data as **a** first approximation within less than 2% by using the simplified formula $D = iRT/(1/U + 1/V)$, in which it is assumed that only the numerator changes while the denominator remains constant. This assumption will be referred to briefly again. In this way, taking values for i from a table in Taylor's "Treatise on Physical Chemistry" (where i is van't Hoff's empirical ratio between osmotic effect observed and that expected for an ideal non-electrolyte), we derive Table IV for 25°. The same formula would predict at 20° a value of 1.428 for 0.1 N potassium chloride, which is *1.38%* less than that of the standard value of Cohen and Bruins.

TABLE IV

COMPARISON OF OBSERVED WITH PREDICTED EFFECT OF CONCENTRATION FOR THE DIFFUSION OF POTASSIUM CHLORIDE AT 25°

Concn., N	0	0.02	0.1	0.5
D (obs.)	...	1.685	1.631	1.573
D (calc.)	1.721	1.664	1.605	1.544

Other electrolytes likewise exhibit diffusion coefficients at moderate concentrations which are significantly less than those predicted for complete ionization at infinite dilution, D_∞. Some examples of our data at 25° and of Öholm's at 18° are given in Table V.

Inspection of the data in "International Critical Tables" or Landolt–Bornstein–Roth confirms this deficiency in the diffusion constants for moderate concentrations as compared with those predicted by the Nernst equation for infinite dilution, and the greatly increased magnitude of the

TABLE V

COMPARISON OF DATA WITH THOSE OF ÖHOLM

Solution	D at 25°	D_∞ at 25°	D at 18°	D_∞ at 18°
0.1 N HCl	2.674	2.841	2.23	2.43
.5 N HCl	2.663	2.841	2.22	2.43
1 N LiCl	0.985	1.046	0.951	0.994

effect for ternary electrolytes such as potassium sulfate or for solutions where complexes are known to form would appear to substantiate our contention that the chief factor in diminishing the coefficient of diffusion as the concentration is increased is the falling off in the numerator iRT.

There are three current views as to the reason for the decrease in i with increase in concentration. The first holds to 100% dissociation with the attempt to explain all the data by a combination of interionic attraction with other effects. Both the others retain the principles of interionic attraction but one, in the terminology suggested by Bjerrum, assumes 100% ionization but with a larger and larger proportion of the ions "associated to form neutral pairs as concentration increases. The third view, now widely held, is that dissociation is not complete. McBain and Van Rysselberge[16] decided that mere "association" or clustering is insufficient to explain the fact that anionic clusters or complex anions are commonly formed and complex cations are not, whereas the symmetrical operation of electrical forces would produce comparable numbers of both.

The denominator of our general diffusion equation will, of course, seldom remain quite constant with diminishing dissociation on account of the conflicting effects of molecular volume and of hydration or polarization of the solvent by an ion as compared with a neutral molecule. The magnitudes involved cannot be obtained from a direct comparison between the Nernst prediction for acetic acid 1.37 as against the observed value 0.9 on account of the abnormal mobility of the hydrogen ion. It is more pertinent to recall that, as Nernst suggested, for large organic ions the mobility is equal to that of a neutral molecule of the same size.[17]

The Northrop method can equally well be used with non-aqueous solutions. For example, a saturated solution of potassium chloride in 95% ethyl alcohol gave a value for D of 0.817 at 25°. The Arrhenius conductivity ratio indicates 25% dissociation of the potassium chloride, whence by proportion and taking into account the viscosity ratio between alcohol and water, the diffusion coefficient of undissociated chloride in water would be 0.824 if the molecules were identical in the two solvents. The only interest of this approximation is that the resistance to movement of the potassium chloride molecule so indicated is only 4% greater than the sum of those of the potassium and chlorine ions, which is a rough justification of the

assumption of the constancy of the denominator in the equation used for Table IV. A completely non-polar molecule might he expected to have a higher mobility.

Diffusion of Soap as a Colloidal **Electrolyte.**– The surprising range of applicability of our diffusion equation is illustrated by the information yielded for soap solutions, such as potassium laurate at 25°. The proportions of the various constituents for the different concentrations of potassium laurate have been deduced by McBain and Jenkins[18] from conductivity and osmotic data. it will be seen that the diffusion results are in reasonable agreement with the detailed information already available with regard to each of these constituents.

The experimental data are collected in Table VI. To avoid hydrolysis 0.0015 equivalent of potassium hydroxide was added per liter to the more dilute solutions, and the same addition was made to the water in the beaker.

TABLE VI

DIFFUSION OF POTASSIUM LAURATE INTO WATER (0.0015 *N* KOH) AND INTO LESS CONCENTRATED SOLUTIONS OF POTASSIUM LAURATE AT 25°

Soln., N	In beaker	Cell	t_E, hours	c	c′	KD	D
0.025	Water	G-3	23.10	87.0	511	241.4	0.695
.025	Water	G-4	26.65	90.2	509	233.0	.700
,025	Water	G-3	30.07	95.5	504	244.1	.702
.15	Water	G-3	24.00	187	2912	163.7	.470
.15	Water	G-4	23.92	180	2907	155.4	.467
.50	Water	G-4	20.45	377	2373	146.8	.441
.025	Water						.699
.125	0.05 N	G-4	23.00	115	1421	158.0	.475
.3	.2 *N*	G-4	19.70	119	1920	149.0	,447
.5	.4 *N*	G-3	23.41	132	1929	146.8	.421
.5	.35 *N*	G-3	22.12	164	2925	145.1	.417

The experimental values in Table VI are plotted in Fig. 2 together with the point for zero concentration taken from the Nernst equation assuming mobilities of potassium ion as 74.5 and simple laurate ion as 23.2, which gives the value 0.813 at 25°. It will be noted that the diffusion coefficients as measured against water are only slightly higher than those which are confined to a narrower range of soap solution.

Instead of trying to predict independently the diffusion coefficients for representative concentrations, we may examine those found to see if they agree with reasonable expectation. For example, taking first the 0.025 N solution in which potassium laurate is supposed to be a simple electrolyte with no colloid and about 66% dissociated, the diffusion due to the ions should be 0.66 X 0.813 = 0.532. The difference between this and the observed value, 0.699, leaves 0.163 ascribable to potassium laurate molecules. Hence, the diffusion coefficient of the latter is 0.163/0.34 =

---

[18] J. W. McBain and W. J. Jenkins, Trans. *Chem. Soc.*, 121,2328 (1922).

0.480, and from the Nernst formula for a molecule $D_m = 0.02243\ U_mT/291$ the value of U_m expressed in electrical units gives a mobility of 20.9 for the potassium laurate molecule. This appears quite plausible when compared with the value of 23.2 for the laurate ion. (The temperature correction 291/298 is the osmotic correction, not that of the mobility)

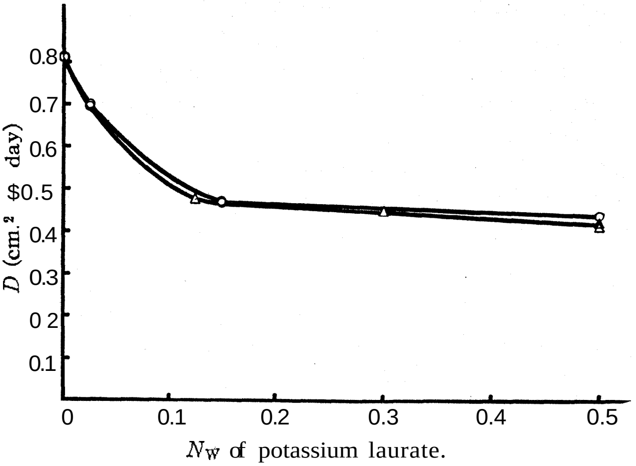

Fig. 2.—Diffusion of potassium laurate at 25°: (a) ○, into water (0.0015 N KOH); (b) △, into less concentrated solutions of potassium laurate.

For 0.5 N potassium laurate there is a wholly different picture in that the soap is now almost entirely in the form of colloid, ionic micelle and neutral micelle. The former is supposed to carry about ten charges and possess a mobility of about 74.5 which is equal to that of the potassium ion. From Haskell's equation we may calculate the diffusion coefficient for a decavalent electrolyte with ten potassium ions to one anion at 25°.

$$D = 0.02243 \times \frac{298}{291} \times \frac{(74.5)^2}{2 \times 74.5} \left(\frac{1}{10} + \frac{1}{1}\right) = 0.941$$

Since only 37% of the solution is in this form, the diffusion contributed by it will be 0.37 × 0.941 = 0.348. That contributed by the 1% of simple ions will be 0.01 × 0.813 = 0.008 and that contributed by the 2% of simple potassium laurate molecules 0.02 × 0.480 = 0.0096. The sum, still omitting that due to the 60% of neutral micelle $(KL)_n$, is 0.366, whereas the total observed is 0.419. This leaves 0.053 for the neutral micelle, whose diffusion coefficient is therefore 0.053/0.60 = 0.088. The significance of this low diffusion constant may be developed by evaluating from it the radius of the neutral micelle according to Einstein's equation for a spherical particle which yields the value 24 Å., or an effective diameter of 48 Å. It is probable that the neutral micelle is not spherical and that its thickness is twice the length of lauric acid, namely, 30 Å. On the other hand, McBain and Jenkins[19] showed by ultrafiltration that its maximum diameter was much less than 150 Å. A real test of this deduction will be possible when we have carried out similar measurements with sodium oleate in which according lo ultrafiltration the neutral micelle is very large.

Returning for a moment to the consideration of the ionic micelle with its ten charges, D = RTU = (0.0230 × 74.5)/10 = 0.171 and the diameter of the ionic micelle equals 0.0883/0.171 × 48 = 25 Å. If the ionic micelle has a radial arrangement, as seems probable, this is less than twice the length of a laurate radical extended to its maximum length, 15 Å., but it is only to be expected that here the chains would coil to a shorter length.

Deductions from the Diffusion Coefficient of Sucrose.—Using cells B, F and G, 0.05 N sucrose at 25° gave diffusion constants equal to 0.461, 0.462, 0.461, 0.462, 0.462; mean, 0.462, as compared with Öholm's 0.457. For 1.0 N sucrose the values 0.381 and 0.376 are obtained with cell G as compared with Öholm's 0.384. This is a remarkable result. The viscosity of these two solutions as determined in a capillary flow viscometer is, namely, 1.047 and 3.080, respectively, times that of water, whereas the diffusion coefficients differ only by 18% in spite of the fact that Einstein's equation predicates that diffusion is inversely proportional to the viscosity.

Evidently, when the increase in viscosity is caused by the diffusing substance, the viscosity correction is definitely not that demanded by Einstein's equation using the viscosity of the solution, but is much less. An explanation may be ventured by picturing that while the increase of the viscosity is due to indiscriminately increased collisions of the large molecule in diffusion when one diffusing molecule of sucrose is hit by another, the retardation of one is often compensated by the acceleration of the other. The situation is reminiscent of that of the closely allied subject of conductivity where it is notorious that the attempt to set it proportional to the first power of the viscosity is an overcorrection. In soap solutions the "viscosity" may vary 1000-fold without affecting the conductivity.

Ulich[21] considered that the reason that many ions have an electrical mobility much greater than corresponds to their supposed size and the viscosity of water, like the small effect which sugar or gelatin or jellies exert upon the electrical mobility of ions, is due to their being very small in comparison with the large molecules such as $(H_2O)_6$ or similarly $(H_2O)_9$, etc. This, however, does not hold in our case where the large molecules of sucrose are unaffected by the high viscosity which they themselves impart.

Calculating the size of the sucrose molecule from its diffusion coefficient in 0.05 N solution, assuming it to be a spherical particle with the density

---

[19] J. W. McBain and W. J. Jenkins, Trans. *Chem. Soc.*, 121,2340 (1922).

[20] A. Einstein, ***Ann. Physik,*** [4] 19,289 (1906).

of solid sucrose, its molecular weight is 388 as compared with its formula weight 342. The difference would be equivalent to a hydration of about two molecules of water.[22]

The Mutual Effect of Diffusing Substances upon Each Other.—It is commonly assumed that substances diffuse quite independently and that they do not influence each other's rate unless they react with each other. Our experiments show that this is by no means true.

Experiments were carried out at 20° with cells B and C, the latter having an alundum diaphragm "RA 228," using 0.5 N hyrochloric acid. First, it was diffused into water, giving values of diffusion constants $D = 2.452$ and 2.448. Next 10% of dextrose was dissolved in the 0.5 N hydrochloric acid and it was diffused into water, giving the values 2.386 and 2.391. Next, 0.5 *N* hydrochloric acid was allowed to diffuse into 10% dextrose in water, giving values of D of only 1.716 and 1.730. Finally, when 10% dextrose was present, both in the hydrochloric acid and in the water into which it was diffusing, the values of D were 2.049 and 2.044. Using an Ostwald capillary viscometer, the viscosity of 10% aqueous dextrose at 20° was found to be 0.01291 as compared with that of water 0.01005, the ratio being 1.283.

Now the ratio of the values of D when dextrose was entirely absent to that when the 10% dextrose was present on both sides of the diaphragm is only 1.196 as compared with the viscosity ratio 1.283. As in the case of sucrose, the viscosity of the solution does not bear a linear proportionality to the effect upon rate of diffusion.

When the dextrose was diffusing with the hydrochloric acid into water, the value of D for the hydrochloric acid was 1.386 times greater than when the dextrose was diffusing in the opposite direction, although the average viscosity and concentration of dextrose must have been nearly the same within the diaphragm in both cases. Hydrochloric acid diffusing alone into water is only 1.025 times faster than when 10% dextrose is diffusing with it. Our explanation is that the molecules in the two diffusing columns bombard each other and thus retard or accelerate each other's motion according as they are opposed or in the same direction.

When the strong acid, hydrochloric, was replaced by the weak acid, acetic, similar effects were produced by the addition of dextrose. 0.5 N acetic acid diffusing alone into water gave $D = 0.929$ and 0.924. When diffusing with 5% dextrose into water the diffusion was, if anything, rather faster, D being 0.929 and 0.927, in spite of the enhanced viscosity. But when the acetic acid alone diffused into 5% aqueous dextrose, the rate was 29% less, D being 0.657 and 0.651.

Dextrose had been used because of its chemical indifference to hydrochloric and acetic acids. Urea is known to combine with acids, its equi-

---

[22] Compare J. W. McBain and S. S. Kistler, *J. Phys. Chem.*, 33, 1806 (1929).

librium constant having been measured, and when 0.5 N hydrochloric acid alone was allowed to diffuse into 5% aqueous urea, *D* actually increased from the value 2.450 for water to 2.501 and 2.490 When the 5% urea was diffusing with the hydrochloric acid into water, *D* fell to the much lower values 1.974 and 1.972. The effects are therefore exactly opposite to those where no chemical combination occurs.

Bombardment by the molecules of an indifferent diffusing column may produce an effect which may be called a liquid diffusion pump since it is analogous to that in a gaseous diffusion vacuum pump, To demonstrate this, the cell was charged with 0.5 *N* acetic acid and the beaker with 0.5 *N* acetic acid containing 10% dextrose. After twenty-three hours the concentration of the acetic acid in the cell had increased and that in the beaker had decreased by about −0.6 and +1.0%, respectively. In a similar experiment after forty-seven hours the changes were −1.6 and + 1.8%, respectively. When hydrochloric acid was used instead of acetic acid, in twenty-four hours the changes were −0.4 and +0.7%. On the other hand, when 5% urea was with 0.3 *N* hydrochloric acid in the cell and 0.5 *N* hydrochloric acid alone in the beaker, the changes were in the opposite direction; hydrochloric acid passed from the beaker to join the urea in the cell, the changes being in twenty-four hours \$0.8 and −0.6%.

Other results with ethyl and methyl alcohols suggest that the bombarding effect of a diffusing column may be approximately proportional to the square of its concentration and to the cross-sectional area of its molecules. It is evident that diffusions of more than one substance are not independent of each other. For example, it is not safe to employ buffer solutions without considering the effects here recorded.

Summary

A procedure is given for the use of the Northrop diffusion cell with diaphragm of sintered glass by which very rapid determinations of diffusion may be made reproducible to within a few tenths of a per cent. It is shown that such results are independent of the nature and porosity of the diaphragm and are equal to the best obtained by the laborious classical methods.

The Nernst equation for electrolytes at infinite dilution and the Einstein equation for uncharged spherical particles are generalized to include all cases of diffusion. It is shown that for simple electrolytes the predominant influence is the value of the van't Hoff i factor.

As an instance of the method of summation of the effects due to different constituents in predicting total diffusion, the data for a typical soap solution are analyzed and found to be in agreement with previous information as to their properties. The data for sugar solutions show that the viscosity contributed by the dissolved substance is not that which determines rate of diffusion.

The diffusion column of one substance may, by the bombardment of its molecules, accelerate, retard or even reverse the diffusion of another substance.

THE PHOTOELECTRIC PROPERTIES OF AMMONIA CATALYSTS

BY A. KEITH BREWER

RECEIVED OCTOBER 14, 1930 PUBLISHED JANUARY 12, 1931

An extended series of experiments carried out at this Laboratory has shown that **reduced** Fe_3O_4 is an excellent catalyst for the synthesis of ammonia[1] and that the activity is materially influenced by the presence of small amounts of impurities or promoters. A general investigation of the physical properties of these catalysts has been undertaken to determine, if possible, the function of the promoter, as well as add to our knowledge of surface catalysts.

An investigation of the thermionic properties in *vacuo* of a large number of possible catalysts carried out by Dr. C. H. Kunsman[2] has resulted in the discovery that these substances, for the most part, are excellent emitters of positive ions. A comparison of the positive ion emissivities and the catalytic properties[3] showed that no direct relationship existed between different catalysts, although for a given catalyst it is possible that some such correlation does exist.

The present paper deals with the photoelectric properties of several of these catalysts both in *vacuo* and in the presence of nitrogen, hydrogen and traces of oxygen.

The catalysts chosen for this research were described by Almquist and Crittenden[4] and are those which have received the greatest amount of study. The composition and activities of these catalysts are given in Table **I.**

TABLE I

DATA ON CATALYSTS

				% NH_3 at 450°

Apparatus and **Method**

A schematic drawing of the apparatus is shown in Fig. I, and is essentially the same as that previously described by the writer.[5]

The catalysts to be tested were coated on platinum filaments in a manner described by Kunsman.[6] Heating above visibility, which might result in sintering or premature fatiguing, was avoided in all except the first coated layer. The filaments were reduced in hydrogen at a temperature between 400 and 450°.

The temperature was measured by means of a platinum–platinum-rhodium thermocouple twisted tightly about the filament.

Commercial hydrogen and nitrogen were used after all traces of oxygen had been removed by glowing tungsten; moisture was removed by liquid air.

A hot mercury arc and a Hilger monochromatic illuminator were used as the source of ultraviolet light. The photoelectric current was measured with a Compton electrometer and high resistance shunt[7] which enabled emission currents to be read from 10^{-15} to 10^{-10} amp.

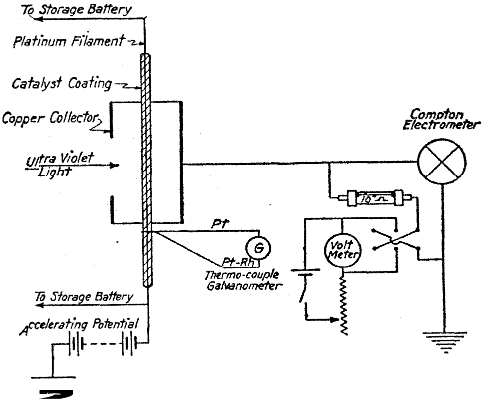

Fig. 1.

The photoelectric threshold was determined by plotting the emission current per unit light intensity against the wave length. The intersection of the curve with the wave length axis is taken as the long wave length limit.

All measurements, unless otherwise specified, were made in the best obtainable vacuum, the pressure at all times being below the sticking point of mercury in the McLeod gage (10^{-6} mm.).

Results

Catalyst 918.—In the study of the coated filament used in these researches the question arose as to the effect of the method of coating on the threshold. A comparison was made, therefore, of a pure iron ribbon and a platinum filament coated with catalyst 918. The results in both cases were substantially the same, showing that the coating process had little or no effect.

[7] Brewer, *Rev. Sci. Inst.*, 1, 325 (1930).

The photoelectric threshold for pure but not outgassed iron is given by Hamer[8] as 2870 ± 40 Å. Cardwell[9] gives the threshold for outgassed iron to be very near 2580 Å.

Lines 1 and 2 of Fig. 2 show the results obtained in the present experiments with pure iron. In the figure the wave length in Å. units is plotted against the deflection per unit light intensity expressed in purely arbitrary units, which are different for the various lines. Line 1 was taken with a non-outgassed filament at room temperature and shows a threshold very near 2860 Å., which is in agreement with the value given by Hamer for similar conditions.

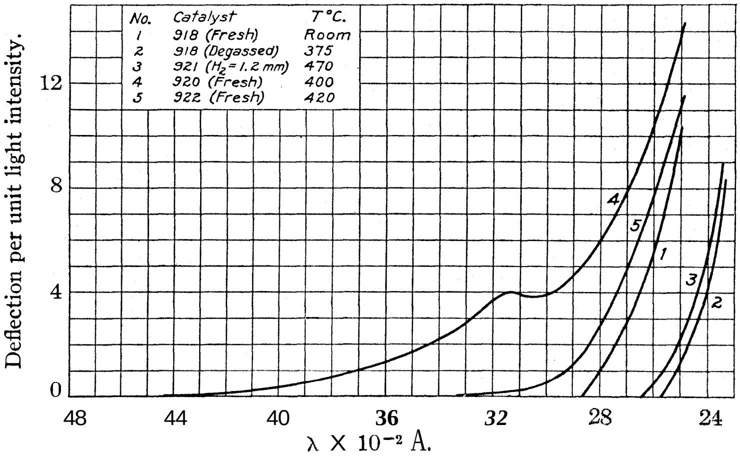

Fig. 2.

The threshold of a fresh filament appeared very sensitive to temperature. Above 200° the threshold started to shift toward shorter wave lengths. After heating at 650° for about twenty-four hours, the threshold shifted to a position as shown by line 2, in which condition it showed a very slight temperature coefficient for temperatures below 700°. The threshold as given by line 2 lies very close to 2575 Å., which is in good agreement with the value given by Cardwell for outgassed iron.

Catalyst 921.—The small quantity of alumina present in 921 had very little or no effect on the threshold as compared to that of pure iron (918). The threshold for the fresh filament was very close to that given by line 1 of Fig. 2, while the degassed filament showed a barely detectable emission for λ2536 Å., and no emission for λ2653 Å.; the threshold, therefore, lies between these two values. The curve itself agreed very well with line 2 of Fig. 2.

Nitrogen and hydrogen had little effect on the photoelectric emissivity,

---

[8] Hamer, *J. Opt. Soc.*, **9**, **251** (1924).

[9] Cardwell, ***Proc. Nat. Acad. Sci.***, **14**, 439 **(1928).**

tending to increase the intensity. This effect was most pronounced in the neighborhood of 1 mm. pressure. Line **3** of Fig. 2 is for 921 in hydrogen at 1.2 mm. pressure. It will be noted that the threshold is shifted about 85 Å. to the red over that for vacuum conditions. The effect of nitrogen is very similar to that of hydrogen; oxygen in traces produced no noticeable result.

Catalyst 920.—The positive ion emissivity from the potassium promoted catalyst has been observed by Kunsman[2] to be large hut unstable. This may also be said to be true for the photoelectric emissivity.

The effect of temperature on the photoelectric emissivity was measured for ascending and descending temperatures as well as for the steady state and was found to be quite different from that observed for 918 and 921.

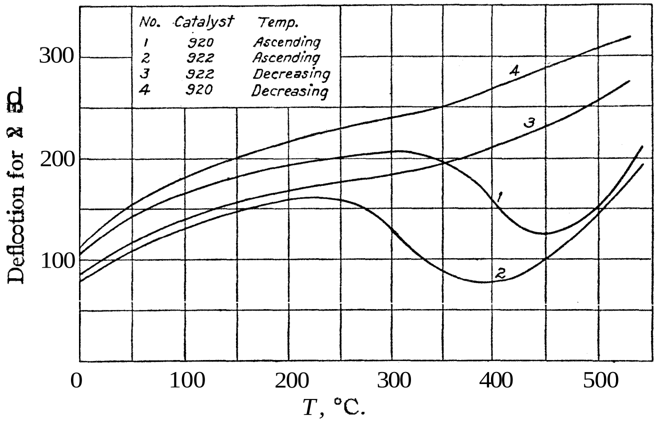

Fig. **3.**

Curve 1 of Fig. 3 for a freshly reduced filament was taken with a rising temperature in which deflection readings were made as quickly as possible after each rise in temperature. It will be seen that the emissivity increased to a maximum in the neighborhood of 300°, followed by a minimum at 450°, and thereafter increased rapidly with temperature. At temperatures just below 600° the photoelectric emissivity became complicated by the thermionic emission of electrons. The approximate photoelectric emissivity up to 700° was measured by placing such a potential on the high resistance shunt that the thermionic current was just balanced out and then measuring the photoelectric current. The results showed little if any increase above 600".

Line 4 of Fig. 3 is for descending temperatures, but otherwise was taken under the same condition as line 1. It will be noted that the pronounced minimum at about 450° is only faintly noticeable.

All experiments on the determination of thresholds were made under steady state conditions, the deflection following line 4 quite closely. At temperatures above 500° these conditions were reached fairly rapidly.

The threshold at room temperature was in the neighborhood of 3200 Å., as only a detectable emission was obtainable with λ3130 Å. As may be expected from Curve 1, Fig. 3, the threshold shifts toward longer wave lengths with rising temperature. Line 4 of Fig. 2 shows the emission per unit intensity at 400° for various wave lengths; emissivity was just detectable at λ4350 Å. and did not occur at A4900 Å.

It will be noted that the characteristics of line 4 are quite different from those of lines 1, 2 and 3. A small maximum is seen at 3100 k., and the foot of the curve, rather than being sharp as is characteristic for pure substances, skirts the wave length axis for a long distance, as is characteristic of composite surfaces.[5]

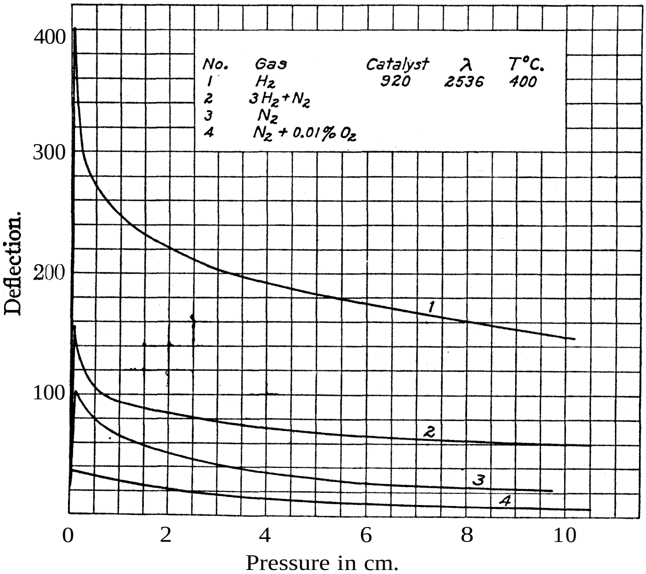

Fig. 4.

The effect of gases on the emissivity is shown in Fig. 4. These runs were taken for A2536 Å. at 400°, and with an accelerating potential of 45 volts.

The emission in hydrogen, nitrogen and the 3–1 mixture of the two gases reached a maximum at about 0.5 mm. pressure. The current intensity was some four times greater in hydrogen than in nitrogen and the 3–1 mixture gave values but slightly higher than did pure nitrogen. Nitrogen containing only a trace of oxygen (estimated at about 0.01%) dropped the emissivity to a point very close to that for pure iron.

Catalyst 922.—The threshold for the cold reduced catalyst is very close to that given by line 1 of Fig. 2 for 918; the K_2O and Al_2O_3, generally considered to be in the form $K_2Al_2O_4$, have but little influence.

The effect of temperature on the emissivity is shown by lines 2 and 3 of Fig. 3, for ascending and descending temperatures, respectively. Line 2 shows a pronounced minimum at 400° which corresponds quite closely to that observed for 920; this minimum is almost completely absent for the descending temperatures.

The threshold of a freshly reduced filament at 420° as given by line 5 of Fig. 2 lies between λ3130 Å. and λ3342 Å. The shape of the curve lies intermediate between that for a pure surface (line 1) and that fur a highly composite surface (line 4), indicating the presence of a small amount of material at the surface with a threshold above that of iron.

In the course of a week's use, in which the filament was repeatedly heated to 500° in nitrogen and in hydrogen and to 700° in a vacuum, the threshold gradually fell to a final value very close to that shown by line 3 for Catalyst 921. This comparatively rapid fatiguing is contrary to what might be expected from the results of Kunsman[2] on the thermionic emission of positive ions, which showed that 922 while not giving as large an initial positive ion emission as 920 is a far more constant source.

Fresh and photoelectrically fatigued filaments were compared, therefore, for positive ion emissivity with the result that the temperature at which an emission became detectable did not increase more than 10° throughout the fatiguing process, although the threshold shifted some 800 Å.

In the presence of gases the photoelectric emissivity of a fresh filament was similar to that shown in Fig. 4 for 920 with the exception that the curves for nitrogen and for hydrogen very nearly coincided. Traces of oxygen had the same pronounced poisoning effect.

In this connection an attempt was made to show the effect of gases on the positive ion emissivity. The problem is complicated because positive ions of the type observed by Kunsman[2] as well as those observed by the writer[10] are both emitted at about the same temperatures. The experiments showed that the temperature at which emission was detected was lowered from 50 to 100° by the presence of a millimeter of gas. Further increases in the gas pressure did not lower the temperature but did increase the current for large accelerating voltages since saturation does not exist in gases, the current becoming proportional to the applied voltage at atmospheric pressure.

Discussion of Results

The thermionic emission in gases from various surfaces is doubtless intimately related to their catalytic properties.[10] This, however, cannot be said for photoelectric emission only in so far as the photoelectric threshold is a measure of the surface forces. Photoelectric emission is generally considered to be confined to the removal of electrons from the emitting

---

[10] Brewer, J. Phys. Chem., 32, 1006 (1928).

surface;[5] no satisfactory evidence exists for the emission of either positive or negative ions by this means. Thus these experiments cannot be interpreted to give a direct picture of the mechanism of reaction. Photoelectric emissivity is, however, a sensitive test for the composite nature of surfaces and so may serve to help define a catalytic material.

In the case of Catalyst 918, we see that the long wave length limit agrees exactly with that of pure iron. From this the conclusion can be drawn that the surface forces, image and intrinsic,[10] of the reduced Fe_3O_4 are identical to those of pure electrolytic iron.

The sharp feet of lines 1 and 2 are indicative of the fact that surface is uniform and not composite. Had the emitting material and hence the long wave length limit varied from point to point over the surface, the above lines would have turned off asymptotic to the wave length axis.

The increase in work function, as is shown by the shift in threshold from 2860 Å. to 2580 Å. during the outgassing process is characteristic of photoelectric emission and is probably due to the removal of a layer of highly polarized gas molecules from the surface.

The close similarity between the values obtained for 918 and for 921 indicates that there is no free aluminum on the surface of the Al_2O_3 promoted catalyst, and also that Al_2O_3 (possibly $FeAl_2O_4$), if it exists at the surface at all, is present in very small quantities.

Catalysts 920 and 922 offer a marked contrast to 918 and 921 in two respects: they possess pronounced temperature coefficients (Fig. 3); and the threshold curves, rather than having the usual sharp feet, skirt the wave length axis for a long distance (Curves 4 and 5, Fig. 2).

The increase in emissivity with rising temperature places these catalysts in the same general class with oxide coated filament such as barium or strontium oxide on platinum. While this peculiar temperature effect has been observed on oxide filaments by many investigators, its cause is still a matter of conjecture. Case[11] feels that in heating the oxide the pure metal is to some extent set free, thus increasing the threshold since the long wave length limit is much higher for the pure metals than for the oxides. Becker[12] has obtained excellent evidence to support his contention that the activity of oxide coated filaments is due to metallic barium on the surface of the barium oxide. Crew,[13] on the other hand, feels that during the heating process a thin film of the base metal of the filament becomes built up over the surface and that the work function of this film decreases with temperature. The characteristics of the threshold curves in Fig. 2 should throw much light on this question.

The distinctive shape of Curves 4 and 5 in Fig. 2 for the long wave

[11] Case, Phys. Rev., 17, 398 (1921).

[13] Crew, ibid., 28, 1265 (1926).

length limit shows unquestionably that the photo electrons arc emitted from a composite surfacr similar in nature to that described where potassium was electrolyzed into platinum.[5] The long wave length limit for iron is very close to 2575 Å., while that for pure potassium is 5600 Å. in layers of one or more molecules deep. The thresholds for K_2O and $K_2Al_2O_4$ are unknown, but they must be at least as low, probably lower, than for pure iron, since the presence of oxvgen, even in traces, drops the long wave length limit to that given by line 2, Fig. 2, for pure iron.

The threshold for 920 at 400° is about 4450 Å., while for 922 under the same conditions it is about 3330 Å. Not only are both of these values far below that for pure potassium, but the current intensity was comparatively low for λ3130, which line is near the maximum wave length sensitivity for potassium.

The conclusion to be drawn from the above consideration is, therefore, that the composite emitting surface in both cases is one of potassium and iron, and that the quantity of free potassium on the surface is small, far less than a monomolecular layer. It will be noted that the ratio of free potassium to iron in 922 is small compared to 920, in spite of the fact that the total potassium contents have the ratio of 26 to 20.

These observations substantiate the contentions of Case and of Vecker that the activity of the oxide is due to a small amount of the metal which has become reduced.

The increase in photoelectric emissivity with rising temperature can only come from an increase in the amount of free potassium on the surface. In Fig. 3 Curves 1 and 2 show an increased emissivity with temperature to about 350" followed by a minimum near 450" with an increase thereafter up to about 700". The minimum is only faintly evident for descending temperatures or for constant temperatures. The most probable explanation of these results is that the increase up to 350° is due to an increased dissociation of K_2O, yielding free potassium, just as was pointed out by Becker for oxide coated emitters. Above 350° evaporation from the surface decreases the free potassium content and results in the minimum at 450°. Above this temperature the diffusion of potassium through the iron to the surface again caused the emissivity to rise. Since the rates of migratibn and evaporation, as well as the dissociation of K_2O decrease with temperature, Curve 3 of Fig. 3 should not show a pronounced minimum for decreasing temperature.

An idea as to the possible source of the free potassium can be had from the character of the emission curves. Catalyst 920 contains only iron and K_2O, hence the potassium must come from the dissociated oxide. Catalyst 922 is made by reducing a mixture of Fe_3O_4, Al_2O_3 and K_2O, during which process all the K_2O is supposed to combine with the Al_2O_3 to form $K_2Al_2O_4$. The potassium must come, therefore, either from the dissociation of the $K_2Al_2O_4$ or from some K_2O which is left uncombined in the iron. Since the long wave length limit shows that the ratio of elemental potassium to the total potassium content is greatly reduced by the presence of the alumina, either the quantity of uncombined K_2O is small or else the $K_2Al_2O_4$ dissociates at such high temperatures that evaporation prevents the accumulation of any appreciable quantity of potassium in the iron. The fact that 922 fatigues rapidly favors the idea that much of the elemental potassium comes from free K_2O within the iron; the similarity of Curves 1 and 2 to 3 and 4 of Fig. 3 points to a common source. This contention is also substantiated by the fact that although the catalyst readily fatigues to the point where the amount of free potassium is negligible, as shown by the photoelectric emissivity, the positive ion emission occurring at higher temperatures is not greatly reduced.

In Table I it was pointed out that K_2O in itself is a catalytic poison and that only when combined with Al_2O_3 is it an effective promoter. The photoelectric data, however, show that both 920 and 922 possess the same types of heterogeneous surfaces, and that the work functions are quite similar. This apparent conflict is doubtless due to the fact that the photoelectric properties of 922 are determined by the uncombined K_2O while the ability of $K_2Al_2O_4$ to promote catalysis may offset the poisoning action of the remaining small amount of free K_2O.

The mechanism involved in the poisoning action of K_2O is uncertain and is receiving further investigation. It seems probable, however, that it is due to the dissociation of K_2O which takes place at the operating temperature (450°) and that the free potassium and not the oxide is the actual poison.

The writer is especially indebted to Dr. C. H. Kunsman for his criticisms and the constructive interest he has taken in this research; also to Mr. Joseph Reuter, instrument maker, and to Mr. Leonardo Testa, glassblower.

Summary

A study of the photoelectric properties of several types of catalysts used in the synthesis of ammonia has yielded the following results.

The unpromoted iron catalyst made from reduced magnetite has the same photoelectric threshold as electrolytic iron; both show no temperature coefficient over the range investigated. The aluminum oxide promoted iron catalysts also have the photoelectric properties of pure iron. From this it follows that the surface forces for pure iron and reduced magnetite are identical, that no free aluminum collects on the surface of the promoted catalyst, and that the concentration of any aluminum oxide on the surface must be small.

The photoelectric properties of iron catalysts containing K_2O and

$K_2Al_2O_4$ are very different from those of pure iron. The emissivity increases markedly with temperature as is the case for oxide coated filaments, indicating dissociation of the potassium oxide at elevated temperatures. The long wave length limit lies intermediate between that of iron and that of potassium, showing the surface to be sparsely covered with elemental potassium. The long wave length limits show clearly that the ratio of elemental potassium to the total potassium content is greatly reduced by the presence of aluminum oxide.

The photoelectric properties of the $K_2Al_2O_4$ promoted catalyst appear to come from the K_2O which has failed to combine with the Al_2O_3. It is suggested that the poisoning action of K_2O alone is due to the ease with which it dissociates, and that it is the free potassium which is the actual poison.

THE SOLUBILITY OF HYDROGEN FLUORIDE IN BENZENE AND IN OCTANE

BY J. H. SIMONS

RECEIVED OCTOBER 17, 1930 PUBLISHED JANUARY 12, 1931

The study of the solubility of gaseous hydrogen fluoride in organic solvents was begun in an attempt to obtain more information about the polymer H_6F_6 whose existence has been indicated by Simons and Hildebrand from considerations of the density of the gas.[1] While the results have not aided greatly in this connection, an example of an unusual type of solution has been found in the case of hydrogen fluoride dissolved in benzene.

Apparatus.—The apparatus, the design of which is shown in Fig. 1, was made entirely of copper with all permanent joints sealed together with silver solder. The three vessels of which the apparatus consisted were held together with screw connections. Two of the vessels were held in separate constant temperature baths; the one served as container for the liquid hydrogen fluoride and the other for the solution. The third vessel, which fastened on the bottom outlet of the solution container, was the constant volume sample tube. Copper is a suitable material for this apparatus, for hydrogen fluoride in the absence of an oxidizing agent, such as oxygen from the air, is without action on it, and oxygen was rigorously excluded.

Materials Used.—The anhydrous hydrogen fluoride was made in the manner described by Simons[2] and distilled directly into the apparatus, which had been carefully cleaned, dried and filled with dry nitrogen. The

---

[1] Simons and Hildebrand, THIS JOURNAL, 46, 2183 (1924).

[2] Simons, *ibid.*, 46, 2179 (1924).

benzene was pure thiophene-free material which was fractionated, dried with phosphorus pentoxide and with sodium, and finally distilled directly into the apparatus. The octane was prepared synthetically in this Laboratory and was carefully dried in the same manner as for the benzene. The nitrogen was the commercial gas from a cylinder from which the oxygen was removed by towers of cuprous ammonium chloride solution. It was dried with sulfuric acid and with phosphorus pentoxide.

Method of Procedure.—For the determinations made without the use of nitrogen, the vessel of hydrogen fluoride was allowed to warm up to the boiling point. The gas formed was passed slowly through the solvent, the solvent vessel being kept at a temperature sufficiently high so that liquid hydrogen fluoride would not condense in it. Equilibrium was considered established when samples of the solution taken over intervals of the passage of the gas gave check analyses. Raising the temperature of the solution vessel gave determinations at higher temperatures.

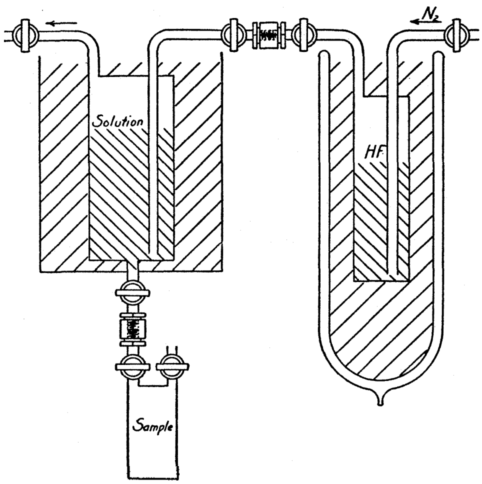

Fig. 1.—Solubility **apparatus.**

For the determinations made with a partial pressure of hydrogen fluoride less than that given by boiling the liquid, nitrogen was passed through the vessel containing it while it was kept at a constant temperature.

The sample for analysis was drawn off into the sample tube, which had a volume of about 20 cc. It was weighed, forced into an aqueous solution containing an excess of sodium hydroxide over that necessary to neutralize the hydrogen fluoride and the excess was titrated with a standard hydrochloric acid solution.

Results

The results of these determinations are recorded in Table I and shown graphically in Fig. 2.

Several different lots of both benzene and hydrogen fluoride were used in these experiments, which extended over a considerable period of time. The agreement of the results indicates that they are free from large accidental errors.

The vapor pressure of hydrogen fluoride from the solution was plotted against its mole fraction at different temperatures as shown in Fig. 3.

It was calculated from the vapor pressure of liquid hydrogen fluoride at the temperature at which the pure liquid was held, the vapor pressure of benzene at the temperature of the solution, and the barometric pressure. Table II shows the data from which the curves were drawn. The mole fractions were taken from the smooth curves in Fig. 2. The straight lines represent the "ideal" vapor pressures of hydrogen fluoride from the solution as calculated from Raoult's law.

It is to he expected that hydrogen fluoride with its high dielectric constant would show a large positive deviation from Raoult's law in benzene solutions. This is found at the higher concentrations but at low concentrations a negative deviation is observed.

This is an example of an unusual type of solution. It is similar to the case of pyridine–water[3] in that both positive and negative deviations from Raoult's law are found in the same curve, but it is different in that pyridine has *a* negative deviation at very high concentration, but **a** positive deviation at moderate or low concentrations.

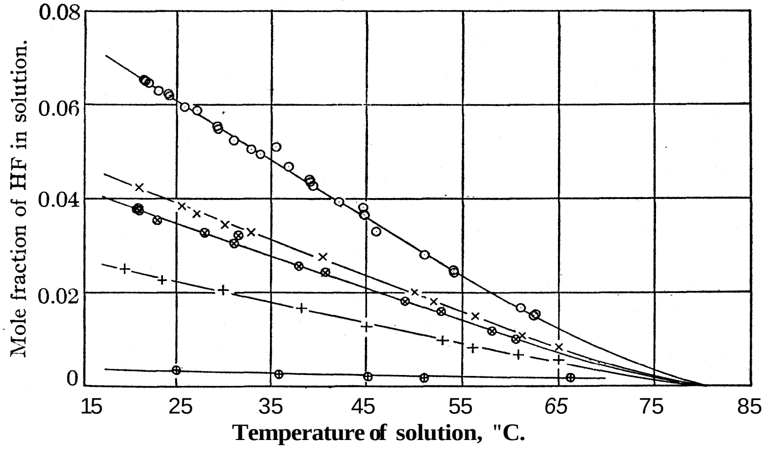

Fig. 2.—Solubility of hydrogen fluoride in benzene and in octane. ○, Solubility in benzene with HF liquid at 19.5°; X, solubility in benzene with HF liquid at 0°; ⊗, solubility in benzene with HF liquid at −18°; +, solubility in benzene with HF liquid at −77°; ⊕, solubility in octane with HF liquid at 19.5°.

A possible explanation of this phenomenon can be given by a consideration of the electric field surrounding the highly polar hydrogen fluoride molecule. When these molecules are in sufficient concentration to exert an

---

[3] J. H. Hildebrand, "Solubility," The Chemical Catalog Co., New York, 1924, p. 41.

influence upon one another, they will be mutually attracted and so tend to be removed from the solution. This explains the positive deviation from Raoult's law at high concentration. When the concentration is so low that the distance between the molecules of hydrogen fluoride is great enough to make the mutual attraction small, then the electric field around each of the hydrogen fluoride molecules will attract even the slightly polar benzene molecules and so cause the vapor pressure of hydrogen fluoride from the solution to be less than would be given by Raoult's law.

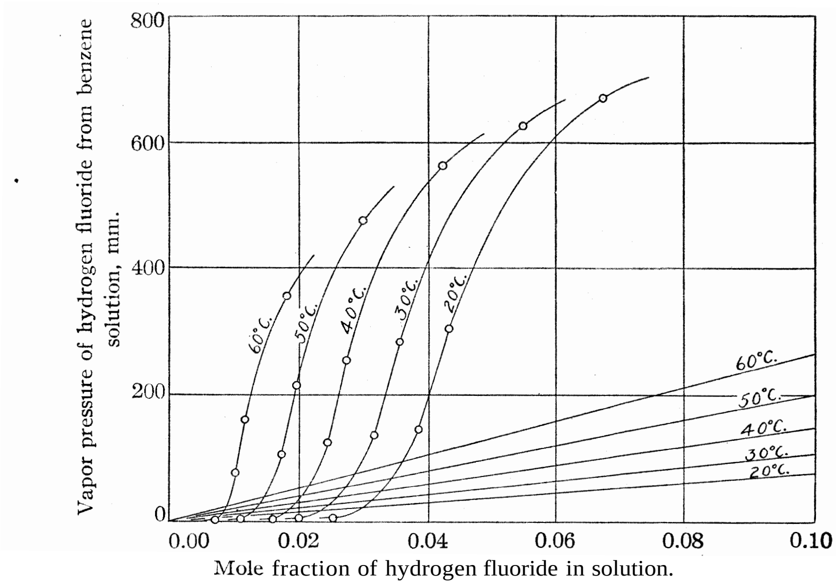

Fig. 3.—Hydrogen fluoride–benzene solution.

The author wishes to acknowledge the assistance of Mr. Eric E. Johnson in making the determinations.

Summary

The solubility of hydrogen fluoride in octane has been measured.

The solubility of hydrogen fluoride in benzene has been measured over a range of temperature and partial pressure of hydrogen fluoride.

The vapor pressure of hydrogen fluoride from a benzene solution shows a negative deviation from Raoult's law at very low concentrations but a high positive deviation at higher concentrations.

A possible explanation of this phenomenon is given.

DIPHENYLAMINE AS INDICATOR IN THE DETERMINATION OF IRON IN SILICATES

BY C. J. SCHOLLENBERGER

RECEIVED OCTOBER 20, 1930 PUBLISHED JANUARY 12, 1931

Since Knop[1] proposed the use of diphenylamine as internal indicator for titration of ferrous iron with dichromate, a number of investigators[2] have reported their experience with this indicator. Reports in general have been favorable, but it has been noted that the color change is not always sharp, and there is a blank attributed to the volume of oxidizing solution consumed by the indicator itself. The optimum conditions for use of this indicator have not been well defined. Knop stated that the presence of phosphoric acid is advantageous, destroying the yellow color due to ferric salts and so making the end-point more easily seen, but mentions no other advantage from its addition. In the titration of vanadic acid by ferrous sulfate and diphenylamine, Willard and Young[2] specified that the solution should be buffered by addition of sodium acetate sufficient for free hydrochloric and sulfuric acids, and phosphoric acid also added. The intense color of the indicator is developed by the vanadic acid to be determined, and discharged upon complete reduction with ferrous sulfate. They report a considerable blank correction. Sarver[2] states that diphenylamine sometimes gives erratic results in ferrous iron titrations with dichromate, but recommends it for the determination of ferrous oxide dissolved from a mineral by sulfuric or hydrochloric and hydrofluoric acids. The addition of excess boric acid and standard dichromate to minimize oxidation of the iron by air, and deliberate back titration with standard ferrous sulfate, are advised. He further states that it is best to keep the volume of solution small and to take the disappearance of the intense blue as the end-point, disregarding any blue tint which persists; fluoboric acid had no noticeable bad effect, but on the contrary seemed advantageous, brightening the color Diphenylamine has been reported to be a very satisfactory indicator in titration of hydroquinone by ceric sulfate, in presence of either sulfuric or hydrochloric acid and absence of iron.[3]

Recently, the author had occasion to determine ferrous oxide in a mineral, and chose Sarver's procedure for the purpose. The decomposition of the sample having been effected in a 50-ml. platinum crucible, sufficiently

large to permit titration in the crucible, the additions of boric acid and excess dichromate were omitted, as it was considered that there would be little chance for oxidation in the brief time required for titration. The solution was titrated directly by dichromate in the presence of sulfuric and free hydrofluoric acid. The brilliance and sharpness of appearance of the intense blue end-point color were surprising, entirely at variance with previous experience and Sarver's description of the behavior of the indicator. This suggested that free hydrofluoric acid map have a desirable effect upon the development of the indicator color[4] and some experiments with solutions were undertaken in order to investigate the matter. The conditions chosen for these titrations were such as might prevail in a determination of ferrous oxide in a mineral by a procedure similar to Sarver's, namely, titration in small volume in presence of considerable concentrations of sulfuric or hydrochloric acid. It was also desired to determine whether total iron in the titrated solution could be determined by a titanous chloride–thiocyanate titration after the oxidation of the ferrous iron in the first titration with dichromate and diphenylamine. The behavior of diphenylamine on back titration witn the reducing agent was of interest, so that the determination fitted in the plan for the work. The reduction titration following the oxidation titration would also serve as a check upon the latter and reveal error due to oxidation by air.

Twentieth normal solutions of ferrous ammonium sulfate and potassium dichromate were prepared by dissolving the proper weights of the pure salts in water, previously boiled and cooled, and diluting to volume. The iron solution was stabilized by addition of 1% sulfuric acid to the water. Titanous chloride of approximately the same strength was prepared by diluting the commercial 20% solution (iron-free) with 10% by volume hydrochloric acid, storing and dispensing from a small bore buret with atmosphere of hydrogen over the solution The diphenylamine solution contained 0.5 g. in 50 ml. of concd. sulfuric acid, and two drops were used for each titration in 20–25 ml. initial volume. All reagents were of C. P. analyzed grade, and the same volumetric apparatus was used throughout with precautions to ensure constant delivery usual in careful work. The strengths of the dichromate and iron solutions were checked by permanganate titrations with sodium oxalate as standard, by direct titration of an aliquot of iron solution with dichromate and ferricyanide as external indicator and by electrometric titrations. All these indicated that the solutions were of equal normality, within 0.2%. In titrations with diphenylamine a tint which did not change in two minutes' standing was considered permanent.

---

[4] After this paper had been submitted to the editors, the author's attention was called to the fact that Szebellédy, *Z. anal. Chem*. **81,** 97 (1930), had previously observed that in the presence of fluorides the diphenylamine end-point is sharper and more satisfactory.

The results of the first series of titrations with diphenylamine as internal indicator are presented in Table I Titrations 1–6 show that in the presence of hydrochloric or sulfuric acid alone diphenylamine is not a good indicator for titrating a ferrous solution with dichromate. The first blue tint (indicated by a sudden darkening of the yellow-green in the hydrochloric acid solutions) precedes complete oxidation of the iron. Taking the appearance of a permanent brilliant blue as the end-point, the indications are apparently quite good in hydrochloric acid, but still low in sulfuric acid solution. Increasing quantities of the latter make the results worse. Upon back titration with titanous chloride, the color fades in reverse order. The thiocyanate end-point in this titration is very sharp, but the results are evidently affected by the volume of dichromate required, hence depend upon the characteristics of diphenylamine in the first titration.

The addition of one-tenth the final volume of 85% phosphoric acid results in sharpening the diphenylamine end-point in a remarkable manner, reducing the volume of dichromate required to take the color from the first permanent blue tint to the brilliant blue end-point color to only about 0.02 ml. The disappearance of the color on back titration is not quite so sharp, but still very satisfactory. The thiocyanate end-point in presence of phosphoric acid was poor, the color for some time prior to the end-point being a faint yellow instead of deep yellow with a pronounced red tinge up to the last drop, as is normal. In the dichrornate titration the phosphoric acid entirely destroyed the yellow due to the ferric ion and so made the appearance of the diphenylamine blue very distinct. However, it is plain that this is not the sole explanation for its good effect, as in the absence of phosphoric acid good results were obtained in the intensely yellow hydrochloric acid solutions (Titrations 1–3), while in sulfuric acid solutions (Titrations 4–6) the yellow color was much less, but the titrations less accurate. In Titration 12 the addition of **3** ml. of phosphoric acid was sufficient to destroy the yellow color, yet the results were low and were improved by a further addition of phosphoric acid. Apparently twice as much of phosphoric as of sulfuric acid is necessary for accurate results. The addition of phosphoric acid results in a greater volume of dichromate being required to develop the diphenylamine color, and this excess of oxidant causes an increase in the volume of titanous solution required to reduce the iron again, so that this does not appear to be due to the presence of an oxidizable impurity. The extra amount of phosphoric acid used in this titration did not make the thiocyanate end-point noticeably worse than with the smaller volume.

In Titrations 13–18 twice the volume of hydrofluoric acid (48%) was substituted for the phosphoric acid. The effect in sharpening the diphenylamine end-point is even more marked; the intense end-point color is permanent after the addition of only 0.01 ml. of dichromate beyond that necessary to produce a faint tinge of blue, but is discharged with equal sharpness on back titration. The thiooyanate end-point in solutions containing free hydrofluoric acid is greatly in error, however, as the color is never intensely red, quickly becomes yellow as the reduction proceeds and even this disappears before all iron is reduced. The addition of boric acid in excess tics up all hydrofluoric acid as fluoboric acid, restores the yellow color of ferric iron or the intense blue of diphenylamine if present and just faded in hack titration, and permits a very satisfactory end-point with thiocyanate. With all proportions of hydrochloric acid tried, the diphenylamine end-point in presence of free hydrofluoric acid was equally sharp, but the total volume of dichromate required to develop the color increased with proportion of hydrochloric acid.

In solutions containing sulfuric and hydrofluoric acids the diphenylamine end-point was Sully as satisfactory in development, but did not disappear quite so sharply on back titration. After addition of boric acid, the thiocyanate end-point was equally good, and the results of both titrations indicate that the relative proportions of hydrofluoric and sulfuric acids are of no importance (Titrations 16–18). However, other experiments to test the effect of dilution, in one keeping the concentration of sulfuric acid constant, indicated that the total volume of sulfuric acid present should not exceed that of hydrofluoric acid. Otherwise, the degree of dilution apparently made little difference, although not without practical importance since the color change is slow at high dilutions (Titrations 30–31)

In the presence of fluoboric acid with either sulfuric or hydrochloric acid (Titrations 19–24), the diphenylamine end-point was invariably premature in appearance and lacked sharpness The behavior was similar to that of a solution containing sulfuric acid alone, and the bad effect of excessive concentration of the latter was increased. The only differences noted were an increase in the intensity of the color at corresponding stages of the titration, as noted by Sarver, and slightly more rapid color changes. Unlike phosphoric and hydrofluoric acids, fluoboric acid does not reduce the yellow color due to ferric ions, and has no bad effect upon the thiocyanate end-point.

The titration curves shown in Fig. 1 were drawn from potentiometric data, using a saturated potassium chloride-calomel electrode at approximately 25°. The volume of solution at the beginning was 20–25 ml. as in the titrations in Table I, contained in a 100-ml. beaker with rod for stirring. The color of the indicator was observed in these titrations, and its appearance noted on the curves as follows: first faint tinge permanent for one minute, an open circle; pronounced color about half that of the brilliant end-point, a circle with central dot; the usual brilliant end-point tint, a cross; maximum color developed by excess dichromate, an inked-in circle.

[a] Four *g.* of powdered boric acid worked to a smooth paste with a little water added previous to titration with titanous chloride. Titration 31 had 10 g. of boric acid.

Curve I shows the effect of excessive concentration of sulfuric acid, about one-fourth the volume at the end of the titration. The e. m. f. readings are highest, and the maximum indicator color was developed prior to complete oxidation of iron.

Curve II shows the effect of fluoboric acid from 6 ml. of hydrofluoric acid, in the presence of 3 ml. of sulfuric acid in a final volume of approximately 30 ml. During the first part of its course this curve follows the first closely. The maximum color was developed just a little short of complete oxidation of iron.

Curve III indicates the effect of a moderate concentration of sulfuric acid, one-tenth the final volume The development of color is premature, but the standard end-point color is reached at about the true end-point, as indicated by the titration curve.

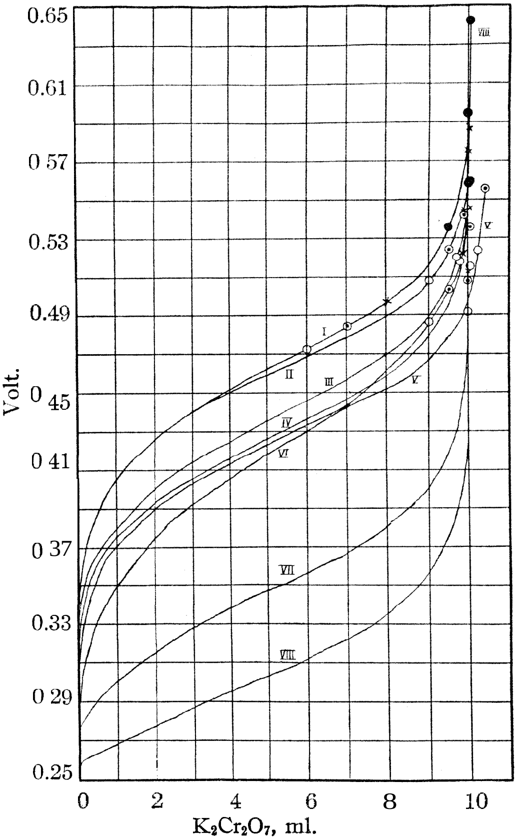

Fig. 1.—Electrometric titration of 10 ml. of 0.05 *N* ferrous ammonium sulfate with various additions by 0.05 *N* dichromate.

Curve IV was intended to show the effect of the sulfate ion in a solution saturated with potassium sulfate upon the activitv of sulfuric acid in one-tenth final volume. The common ion had a noticeable effect upon the e. m. f. without resulting in any important change in the position of the color or electrometric end-points.

Curve V shows the effect of buffering with 5 g. of potassium acetate a solution containing 3 ml. of sulfuric acid in 30 ml. final volume. The effect upon both color and potentiometric end-points is bad, neither being developed by a considerable excess of dichromate. Willard and Young[2] recommended reduction of the effective acidity by addition of acetate and phosphoric acid only in the titration of an oxidizing agent by ferrous sulfate, and not in titration of ferrous salt by an oxidizing reagent.

Curve VI was determined in presence of one-fourth final volume of hydrochloric acid. The intense yellow interfered with observation of the diphenylamine end-point, but it could be seen that it was premature. The electrometric end-point was sharp and accurate.

Curve VII indicates the effect of one-tenth final volume each of sulfuric and 85% phosphoric acids. Phosphoric acid has a very pronounced effect in lowering the oxidation potential, and the standard end-point color is developed at the flex-point of the titration curve. All of the color changes are in the steep portion of the curve, explaining the sharpness of the indicator under these conditions.

Curve VIII shows that one-fifth volume hydrofluoric acid and one-tenth volume sulfuric acid has the optimum effect upon the sharpness of the color end-point with diphenylamine. The first portion of the curve is quite flat, indicating that hydrofluoric acid largely overcomes the oxidation–reduction buffer effect in iron solutions. The asymptotic portion of the curve begins with a sharp bend and is nearly vertical, so that a very small addition of dichromate results in a great increase in potential. The first appearance of color is apparently near the true flex-point of the curve, and other changes are well separated on the e. m. f. scale but produced by very small increments of oxidizing agent, explaining the apparent sensitivity of the indicator in this titration.

With the exception of Curve V, PH buffered by acetate, Curve VIII, determined in presence of free hydrofluoric acid, shows the greatest requirement of dichromate to develop color, *i. e.*, the highest blank. The explanation for this is that the depression in oxidation potential produced by the fluoride ion requires an appreciable addition of dichromate to raise it to the point at which the color appears. As shown very recently by Kolthoff and Sarver,[2] the product of the partial oxidation of diphenylamine is a true oxidation–reduction indicator, developing color at a definite oxidation potential. The experiments herein reported indicate that the development of color is affected by other factors also, e. g., concentration of sulfuric acid. Under the conditions of a practical titration, the color change is perfectly reversible, as shown by such changes and e. m. f. readings on back titration with titanous chloride corresponding with those in the first titration. While Kolthoff and Sarver have shown that there is a certain consumption of oxidizing agent required for development of color, it is evident that a part of the apparent blank noticed in titrations is simply the volume of dichromate necessary to raise the oxidation potential of the solution to the point at which the color appears.

The influence of phosphoric and hydrofluoric acids upon the diphenylamine end-point in iron titrations is due to inactivation of the ferric ion in compounds less ionized than the sulfate, chloride or fluoborate, and the same explanation also applies to the effect upon the thiocyanate end-point. Inactivation of the ferric ion is desirable in the oxidation titration, as it diminishes the buffer effect upon oxidation potential normal to mixtures containing both ferrous and ferric ions. It is undesirable in the reduction titration because ferric fluoride is evidently less dissociated than the thiocyanate, so that the colored compound is not formed.

The practical conclusion to be drawn from the foregoing is that the presence of hydrofluoric acid is advantageous in a titration of ferrous iron with diphenylamine as indicator. Addition of boric acid to inactivate the hydrofluoric acid employed in decomposition of a silicate for ferrous iron determination should be omitted. The reasons for this addition, first recommended by Barnebey,[5] are not of importance if a proper procedure is followed. In the first place, the danger of oxidation by air of ferrous iron in the presence of free hydrofluoric acid has been overemphasized. As Hillebrand and Lundell[6] state, if the solution is cooled before air comes in contact with it and the titration is completed without delay, there is no appreciable error from oxidation by exposure to air. Practically all chance of this can be avoided by titrating in the crucible in which the decomposition was effected. That this is practical is shown by the results obtained in Titrations 28 and 29 in Table I. In the second place, manganese, which is oxidized to the trivalent state by permanganate in the presence of free hydrofluoric acid, does not in the least interfere in a dichromate–diphenylamine titration. This was shown by titrating a solution containing 0.5 g. of manganous sulfate, 3 ml. of sulfuric and 6 ml. of hydrofluoric acids and 10 ml. of iron solution. A large excess of permanganate added to a similar mixture produced no permanganate color, but on addition of diphenylamine the intense color of the latter was developed instantly and required very nearly the theoretical volume of titanous chloride to discharge. Diphenylamine also gave correct indications in a similar direct titration with permanganate.

A further conclusion is that titration by standard titanous chloride solution with thiocyanate as indicator is a practical method for determination of total iron in the case of silicates completely decomposed by hydrofluoric and sulfuric acid treatment. It is only necessary to add excess boric

---

[5] Barnebey, THIS JOURNAL, **37, 1481** (1015).

[6] Hillebrand and Lundell, "Applied Inorganic Analysis." John Wiley and Sons, Inc., New York. 1929, **p.** 775.

acid to the solution just titrated for ferrous iron, as fluoboric acid is harmless, while hydrofluoric acid is very detrimental to either the thiocyanate or methylene blue end-points. The two titrations fit well together; both are at their best when the volume of solution is small and the sulfuric acid concentration is high, about one-tenth final volume being near the optimum. Both titrations show very sharp and distinct color changes at the end-point, so that it is practical to titrate in the platinum crucible in which the sample was decomposed. The observation that hydrofluoric acid lowers the oxidation potential of ferric solutions indicates that decomposition in platinum is probably safer than might be inferred from the known fact that ferric chloride is reduced to some extent by long contact with platinum.

Sarver[2] described a transparent cover of bakelite for a platinum crucible to be used in decomposing the sample of mineral for ferrous iron determination. He neglected, however, to publish a cut of his apparatus, nor was it described in much detail. The author had one made[7] which has given good results in use. It is shown in Fig. 2. The taper is polished, and makes an almost gas-tight joint with the edge of the crucible. It is provided with a tube of bakelite for leading in carbon dioxide from a Kipp generator, and a stoppered opening for adding reagents, stirring, etc. In use the procedure has been as follows: the ground sample is weighed and transferred to the 50-ml. crucible for which the cover was made. The latter is firmly placed, and the crucible set in a hole in asbestos board over a micro burner. By means of a short rubber tube a small bubble counter attached to the source of carbon dioxide is connected to the bakelite tube and the gas allowed to flow for a sufficient time, to expel air from the crucible. About 6 ml. of boiled and cooled water is added, followed by the careful addition of 6 ml. of 1:1 sulfuric acid. This mixture is heated to boiling, while the flow of gas continues. The stopper is removed and 6 ml. of hydrofluoric acid poured in from a small crucible in which it may be measured with sufficient accuracy. By moving the asbestos board the acid in the crucible may be stirred, so that undissolved particles are more easily visible. The gas pressure is kept on all the while and the crucible heated carefully, but the acid need not be boiled vigorously. As the stopper is in place during this time, no air can enter and but little carbon dioxide is used. When decomposition is complete, heating is discontinued and the crucible allowed to cool. When it can be handled without discomfort, it may be lifted from the asbestos board and set in a dish of water to cool more rapidly. When quite cold the stopper is removed and sufficient water added to dilute the solution to about 25 ml. Two drops of diphenylamine solution are added, and the dichromate added carefully, stirring with a platinum spatula. As soon as a drop of the dichromate produces a permanent blue color, the iron is entirely oxidized and the titration of ferrous iron finished. If total iron is to be determined, 4 g. of boric acid rubbed to a smooth paste with a little water, to avoid lumps, is added and stirred until dissolved. This is likely to intensify the blue color of diphenylamine, but it is of no

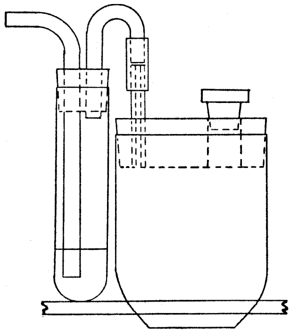

Fig. 2.—Platinum crucible with bakelite cover in place and trap attached.

---

[7] By the Apex Specialties Corp., 1184 Flushing Ave., Brooklyn, N. Y.

consequence as it will disappear later. Five ml. of 10% potassium thiocyanate solution is added, followed by standard titanous chloride until all red has disappeared, and any remaining yellow ceases to diminish with another fractional drop of the solution. If the crucible becomes too full during the course of titration, it is placed in a beaker and upset, the titration being continued without removing the crucible. Even if the solution contains free hydrofluoric acid, the amount of iron dissolved from a pyrex beaker in a short time will cause no appreciable error. After addition of boric acid, the glass is not attacked at all.

Bakelite is not an ideal material for the crucible cover, being somewhat attacked by the hot acid vapors, and evidently decomposed at the surface to some extent, as a pronounced phenolic odor was noted in the solution obtained the first time the cover was used, and poor results were obtained in this titration. After use a half dozen times the odor was no longer noticeable, the behavior on titration was normal and the blank determination indicated that only 0.02 ml. each of 0.05 N dichromate and titanous chloride were necessary for good end-points. By this time the surface of the cover had been attacked to such an extent that it was no longer transparent, so that the stopper had to be removed when it was desired to observe the progress of solution. Escape of gas during the time the stopper is removed is sufficient to prevent entrance of air, and there need be no error from oxidation.

Sarver[2] has stated that the chief reason for the use of dichromate rather than permanganate for titration of ferrous iron dissolved from a sample of mineral is the decreased tendency to oxidation of organic matter by dichromate, so that the latter would be expected to furnish more accurate results in its presence. The author has made a few experiments to determine whether organic matter has an appreciable effect upon the dichromate–diphenylamine titration in presence of sulfuric and hydrofluoric acids. Ammonium oxalate equivalent to 14 ml. of 0.05 N solution was added to a mixture of 10 ml. of 0.05 M ferric sulfate, 6 ml. hydrofluoric and 3 ml. of sulfuric acids, total volume, 20 ml. This was boiled for fifteen minutes in a platinum crucible, simulating the conditions of an actual determination of ferrous oxide in a mineral. Upon titration, 0.02 ml. of dichromate produced a permanent diphenylamine end-point and the usual amount of titanous chloride solution was consumed in reducing the iron, indicating no reduction of ferric salt by the oxalate, and that the latter does not by itself consume dichromate during the titration. However, in similar experiments in which an aliquot of ferrous solution also was added, from 10 to 25% excess dichromate was required to produce the diphenylamine end-point, but in the back titration with titanous chloride only the amount corresponding to the total iron content was consumed. These results indicate that organic matter, at least oxalic acid, can cause high results for ferrous iron, but only in proportion to the amount of the latter present. Numerous examples of similar reactions are known, in which a substance is not normally oxidized by dichromate, but is oxidized to a certain extent when accompanied by an easily oxidized substance. This has been explained as being due to intermediate formation of Cr^{V} which has higher oxidizing potential than Cr^{VI}.[8] The brightening of the diphenylamine color noted when a trace of ferrous salt is added to a slightly overrun titration with dichromate is possibly another instance, but the presence of ferrous iron is not essential to formation of color.

Summary

The properties of diphenylamine as indicator in dichromate titration of a solution containing ferrous iron, hydrofluoric and sulfuric or hydrochloric acids, as obtained in the determination of ferrous oxide in a silicate, have

---

[8] Lang and Kurtz, Z. *anorg. allgem. Chem.*, *181, 111 (1929).*

been investigated. In presence of sufficient hydrofluoric acid in proportion to sulfuric or hydrochloric acid, diphenylamine is an excellent indicator for this titration. The presence of diphenylamine does not prevent an accurate determination of the total iron in the solution by a reduction titration with titanous chloride and thiocyanate indicator, following the oxidation titration, provided the hydrofluoric acid necessary in the first titration is inactivated by addition of excess boric acid prior to the second.

Potentiometric titration curves show that the pronounced effect of hydrofluoric (also phosphoric) acid in increasing the sharpness of the diphenylamine end-point in iron titrations is due to a lowering of the oxidation potential in a solution containing both ferrous and ferric ions, which is high enough under the usual conditions of the titration to cause the indicator color to develop prior to complete oxidation of the iron. The effect of these reagents upon the thiocyanate end-point in the reduction titration and upon the color of solutions containing ferric salts indicates that the underlying cause is the slight dissociation of ferric fluoride (or phosphate).

Based upon these observations, an improved procedure for the determination of ferrous and ferric oxides in silicates is described. Manganese does not interfere in the dichromate titration with diphenylamine in the presence of hydrofluoric acid, but it is shown that in the presence of organic matter results for ferrous oxide may be expected to be high in proportion to the amount of ferrous oxide actually present.

THE REDUCTION POTENTIAL OF THE CERIC–CEROUS ELECTRODE

BY ADOLF H. KUNZ[1]

RECEIVED NOVEMBER 6, 1930 PUBLISHED JANUARY 12, 1931

Introduction

The only work upon the reduction potential of the ceric–cerous electrode recorded in the literature is the early research of Bauer and Glaessner,[2] which involved several factors that diminished its accuracy and reliability. Thus the measurements were made at room temperature, no statement being made about its constancy, and a saturated solution of potassium chloride was used to eliminate liquid potentials. In view of these imperfections and of the recent interest in the use of ceric sulfate solutions for analytical work,[3,4] it seemed advisable to make a thorough study of the

ceric–cerous potential under a wider range of carefully controlled conditions.

The cell studied may be represented as follows

Pt + H_2, H_2SO_4 (0.5 or 1.0 f), H_2SO_4 (0.5 or 1.0 *f*) + $Ce_2(SO_4)_3$ (c_1) + $Ce(SO_4)_2$ (c_2), Pt

There are in this cell three sources of potential: the potential of the hydrogen electrode against sulfuric acid, the potential of the ceric–cerous electrode, and the liquid potential. By making the concentration of the sulfuric acid in both half-cells the same and making the concentration of the sulfates of cerium small, the liquid potential was made negligible.

The author wishes to express appreciation for the suggestions and interest of Professor A. A. Noyes during the progress of the research and for his assistance in preparing this paper for publication.

Apparatus and Materials

The apparatus was essentially that used by Popoff and Kunz[5] in studying the ferric–ferrous electrode. An all-glass electrode vessel was used as before, but the chambers were made smaller to facilitate a more rapid saturation of the acid with hydrogen in the hydrogen half-cell. Instead of a rotary stirrer in the cerium half-cell, the solution was stirred by blowing in an inert gas.

The cell was placed in a thermostat at 25.00° maintained constant within 0.01°. A Leeds and Northrup Type K potentiometer was used.

The hydrogen for the hydrogen electrode was generated by electrolyzing a 5% solution of sodium hydroxide between a nickel and a platinum electrode. The gas was passed through a purifying train and a saturator before entering the cell.

All chemicals with the exception of the cerium salts were of the best grade obtainable and were used without further purification. The water had been redistilled.

The cerium salt was prepared from a commercial cerium oxalate. An analysis by the bismuthate method of Metzger[6] of the ignited oxides obtained from this material showed them to contain less than 48% CeO_2. Assuming that all other rare earths and thorium, iron and calcium might be present, a number of methods were used in attempts to prepare the pure ceric oxide needed.

The best results were obtained by the basic ceric nitrate–bromate process.[7] The crude oxalate was partially ignited to CeO_2, and the residue was moistened with water and treated with nitric acid. The undecomposed oxalate helps reduce the ceric oxide to cerous nitrate. Oxalic acid was added until most of the material was reduced, and the reduction was completed with hydrogen peroxide.

After filtration and evaporation to small bulk to eliminate the large excess of nitric acid, the solution was diluted, potassium bromate was added, and the mixture was boiled until fumes of bromine were evolved. Marble was then added in large pieces, and the boiling was continued with the occasional addition of a little nitric acid. Even with this precaution the precipitate was not free from other rare earths. In the later attempts the basic salt was filtered off and digested for thirty minutes with very dilute nitric acid. Two applications of the entire process were required to produce an oxide which, when converted to the sulfate, would dissolve completely in water.

The purified basic salt was dissolved by nitric acid and oxalic acid and the solution

[6] Metzger, *ibid.*, **31,** 523 (1909).

[7] James and Pratt, *ibid.*, **33,** 1326 (1911).

filtered. Cerous oxalate was then precipitated and thorium was removed by digesting the precipitate with ammonium oxalate solution. The oxide prepared by ignition of this oxalate was very pale yellow.

A weighed portion of the oxide was heated to fuming with sulfuric acid for an hour. The sulfate went into solution in water slowly, but completely. An analysis of this solution made by titration with standard ferrous sulfate after oxidation with persulfate with silver ion as a catalyst as recommended by Willard and Young[8] showed the product to contain 99.89% of cerium dioxide. This is within the limits of the experimental precision obtained in the analyses.

Preparation of Solutions.—A large quantity of the purified ceric oxide was converted to the sulfate by heating it with concentrated sulfuric acid. The solution was diluted to a volume in which the total cerium content was about 0.07 formal and the sulfuric acid about 0.75 formal. The total cerium content per gram of solution was then determined by standard ferrous sulfate after oxidation by persulfate. Similarly, the ceric content was determined by direct titration with standard ferrous sulfate. All titrations were made electrometrically. The close agreement observed between the ceric and the total cerium concentrations indicated that there is very little auto-reduction of the ceric sulfate solutions. Analyses of ceric sulfate solutions in sulfuric acid concentrations used in this study over a period of several months bear out the observations of Willard and Young and of Furman that ceric sulfate solutions are remarkably stable. The total sulfate concentration per gram of solution was then determined gravimetrically after dilution by weight. From these values the amount of water (or of more concentrated sulfuric acid) required to make the formality of the sulfuric acid exactly 0.5 (or any other value) was calculated.

Cerous sulfate solution was prepared by reducing ceric sulfate solution with hydrogen peroxide, crystallizing out the salt by concentration, and washing it free from peroxide. This salt was then dissolved in sulfuric acid, and the solution was diluted to the extent required.

The Electromotive Forces and Electrode Potentials.—The electromotive force E of the cells can be expressed as follows

$$E = E_0 - 0.0591 \log \frac{P_{H} (\mathrm{Ce}^{IV})\ \alpha^{IV}}{a_{H^+}(\mathrm{Ce}^{III})\ \alpha^{III}}$$

The data are given in Table I. Here the "observed" electromotive force represents the electromotive force of the cells as measured at 25°, and the "corrected" electromotive force represents this value corrected to a hydrogen pressure of one atmosphere and to a value of the ratio $(\mathrm{Ce}^{IV})/(\mathrm{Ce}^{III})$ equal to unity. The only other variable within any series of experiments in which the acid concentration is constant should then be the activation ratio α^{IV}/α^{III}; and except in so far as this ratio varies there should be no difference between the values of the corrected electromotive forces of the different cells.

Table I shows that, so long as the sulfuric acid concentration is constant, the electromotive force is changed only slightly (at most by 0.7 mv.) either by varying the total concentration of the two cerium salts (even 15-fold) or by varying the ratio of the concentrations of the ceric and cerous salts (even 13-fold). This shows that the activities of the ceric and cerous

[a] Concentration expressed in millimoles per 1000 g. of solution.

ions Ce^{4+} and Ce^{3+} are always proportional to the concentrations of the respective salts. This result doubtless arises from the fact that sulfuric acid and sulfate ion are present at a substantially constant concentration very much greater than that of the cerium salt.

Inasmuch as the total molal concentration of the cerium salts is at most only 2% of that of the hydrogen ion of the sulfuric acid, the liquid potential must be so small as to be negligible, and the corrected electromotive forces (with sign reversed), namely, the values −1.461 and −1.443, represent almost exactly the electrode potential of the cerous–ceric combinations in the presence of 0.5 *f* and of 1 f sulfuric acid, respectively, referred to the electrode potential (taken as zero) of hydrogen against these two concentrations of acids, respectively.

Since there seem to exist no electromotive force measurements which enable the electrode potential of hydrogen against 0.5 and 1.0f sulfuric acid to be referred to the usual standard of electrode potentials, that of H_2 (1 atm.), H^+ (1 m) taken as zero, the ceric–cerous potentials cannot at present be expressed accurately with reference to this standard. However, the activity of hydrogen ion in 1.0 f sulfuric acid is probably not greatly different from 1 molal in view of the facts that its concentration (owing to the probably complete ionization of the acid into H^+ and HSO_4^- and its relatively small ionization, perhaps 5 to 10%, into $2H^+ + SO_4^=$) is somewhat greater than 1 molal and its activity coefficient is somewhat less than unity (0.823 if like that of 1 *m* HCl). The value -1.44 volts therefore represents (almost certainly within 0.01 volt) the molal reduction potential of ceric and cerous sulfate in 1.0 formal sulfuric acid.

Summary

In this article have been described measurements at 25° of the electromotive force of cells consisting of a hydrogen gas electrode in 0.5 or 1.0 formal sulfuric acid and of a platinum electrode in solutions in the same acid of cerous and ceric sulfates at various small concentrations.

The electromotive force, corrected by the usual logarithmic formula to correspond to a hydrogen gas pressure of one atmosphere and to a ratio of the cerous to ceric salt equal to unity, was found to be 1.461 volts with the 0.5 f sulfuric acid, and 1.443 volts with the 1.0 f sulfuric acid. These values were found to change only very slightly with large variations of the ratio of the concentrations of the two cerium salts, or of their total concentrations, which, however, was always kept so small as to make the ratio of cerium to hydrogen ion very small and the liquid potential of the cells insignificant.

These values cannot be exactly expressed at present on the molal hydrogen electrode standard, since the potential of hydrogen against 0.5 or 1.0 f sulfuric acid is not well known; but the value -1.44 volts is probably exact within ±0.01 volt for the reduction potential on that standard of cerous and ceric sulfates in 1.0 formal sulfuric acid in terms of the total concentrations of trivalent and quadrivalent cerium (not of their ions). It is noteworthy that this reduction potential for the ceric–cerous potential is nearly the same as the potential (-1.48 volts) derived[9] for the molal potential of Mn^{++}, $MnO_4^- + 8H^+$.

ACTIVITY COEFFICIENTS OF ELECTROLYTES. V. THE PRINCIPLE OF SPECIFIC INTERACTION IN CADMIUM AMD MAGNESIUM SULFATE AND CHLORIDE SOLVENTS

BY HAROLD B. FRIEDMAN AND VICTOR K. LA MER

RECEIVED NOVEMBER 7, 1930 PUBLISHED JANUARY 12, 1931

In two recent papers[1,2] from this Laboratory, it has been demonstrated that the principle of specific interaction, which Bronsted has shown to be valid for low valence types of solvents, can be extended to solvents containing higher valence types of strong electrolytes, provided the ratios of the ionic strengths of the two solvents of different valence types remain unaltered on varying the common solvent ion at the same equivalent concentration. Such a restriction is demanded by the Debye–Hückel theory. It is remarkable that Bronsted's principle was found to be valid in complex mixtures where the Debye–Hückel equations are incapable of accounting for the results.

In the first paper cited this aspect of the principle was tested by comparing the solubility ratios of the saturating salt thallous iodate, and also lanthanum iodate, when the anion of the solvent salt was changed from sulfate to chloride at 0.1 N concentrations. The significant ratios were usually constant to 0.2% (maximum 0.6%) in the presence of potassium or sodium as cation. In the specific case of lanthanum iodate the ratios for $(SO_4/Cl)K$ and $(SO_4/Cl)Na$ were 2.045 and 2.094, respectively, data which confirm the principle in a striking manner.

The corresponding $(SO_4/Cl)Mg$ ratio was 1.723 but since the ionic strength ratio for (SO_4/Cl) is different in the presence of magnesium as contrasted with potassium and sodium at the same equivalent concentration, the ratio in the presence of magnesium cannot be expected to equal that in the presence of potassium or sodium.

On the other hand the (SO_4/Cl) ratios for magnesium salts should be the same as for the cadmium salts, if both behave as strong electrolytes, for any given saturating salt and for two saturating salts with a common anion like thallous iodate and lanthanum iodate the (Mg/Cd) ratios should be identical for both saturating salts irrespective of the common anion of the solvent salts.

Since it is generally recognized that cadmium chloride is abnormal in its behavior as a strong electrolyte as judged by transference, conductance and osmotic measurements, a comparison of the (SO_4/Cl) solubility ratios in the presence of Mg and of cadmium is of interest since a comparison of the same ratios in the presence of potassium and sodium has demonstrated the validity of the principle involved.

Experimental

The reader is referred to the previous publications[2] of this series for the details of the preparation of the thallous iodate and lanthanum iodate and the apparatus used in making the solubility measurements. The magnesium sulfate solutions were prepared by weighing out twice recrystallized salt dried to the anhydrous state. The magnesium and cadmium chloride solutions were prepared by diluting to 0.1 N solutions whose strength had been determined by titration for chloride content by the Mohr method.

Cadmium sulfate crystals recrystallized from J. T. Baker's c. p. salt were analyzed electrolytically and found to conform to the formula $CdSO_4 \cdot H_2O$.[3]

The experimental results are summarized in Table I. The quantities after the ± signs refer to the arithmetic mean of the deviations from the average of the individual data. The ratios computed in Table II should therefore be precise to about 1%. The so-called ideal values for the ratios are calculated from the Debye–Hückel limiting law and are submitted only

[3] The details of this procedure have been worked out by Mr. W. G. Parks and will be submitted shortly for publication. The method is precise to 0.01%. This work which deals with the e. m. f. of the cell $Cd(Hg)–CdSO_4(m)–PbSO_4–Pb(Hg)$ shows that cadmium sulfate is virtually completely ionized at least up to *0.01* m, since the activity coefficients of cadmium sulfate can be accurately accounted for between $m = 0.0005$ to $m = 0.01$ by the Gronwall, La Mer and Sandved [*Physik.Z.*, *29*,*358* (1928)] extension of the Debye–Hückel theory using a constant value of *3.6* Å. for the single parameter "a," and the assumption that the dielectric constant is equal to that of pure water. If cadmium sulfate is incompletely dissociated, the influence of this factor is inappreciable up to *0.01* m when electrostatic influences are properly calculated.

as a guide to the extent to which the ratio deviates from the ideal limiting value. Only those ratios having the same ideal value should be identical according to the restatement of the principle of specific interaction

The fact that $(Mg/Cd)SO_4$ ratios for thallous iodate arid lanthanum iodate are sensibly identical, *i. e.*, 0.938 and 0.939, is most gratifying. The $(SO_4/Cl)Mg$ ratios, however, are uniformly 1% lower than are the values previously reported by La Mer and Goldman.[1] Aside from possible inaccuracies in the determination of the solubilities, this is most likely to be ascribed to possible constant error in determining the chloride concentration of the solvents to be 0.1 N by the Mohr methods. Unfortunately we have not had an opportunity to repeat this phase of the work to establish the source of this 1% discrepancy Granting, however, even this limit of uncertainty, it seems very improbable that the 8 and 11% differences in the (SO_4/Cl) Mg ratio as compared to the $(SO_4/Cl)Cd$ ratio for the two saturating salts can arise from analytical error alone. We therefore conclude that the specific interaction principle does not hold when considering such an atypical electrolyte as cadmium chloride, though in view of the marked abnormality which this salt exhibits it is surprising that the principle holds as well as it does.

THE HYDROLYSIS EQUILIBRIA OF TRIPHENYLCHLOROMETHANE AND TRIPHENYLBROMOMETHANE. THE FREE ENERGY OF SOME REACTIONS OF TRIPHENYLCHLOROMETHANE, TIUPHENYLBROMOMETHANE AND TRIPHENYLCARBINOL

BY J. O. HALFORD

RECEIVED NOVEMBER 10, 1930 PUBLISHED JANUARY 12, 1931

The standard free energy of a reaction is related to the equilibrium constant by the familiar equation, $AF^o = -RT \ln K$, and the two functions may be taken as alternative expressions of the tendency of the reaction to take place. However, the standard free energy is more significant, since it is related more directly to the fundamental properties of the substances involved in the reaction, and permits a wider application of the results. One advantage is that the intention to express results as free energies usually leads to experiments so carried out that the data may be applied not only to the reaction measured but to a number of related reactions as well. Certain difficulties may arise as a result, for with a given reaction the conditions most favorable to the production and measurement of equilibrium are not, in general, the best conditions for the determination of free energy relations. This is particularly true of organic equilibria, of which many are known, but few have been measured in such a way as to permit wide application of the results. Organic equilibria are usually established most readily in the liquid phase at high concentration and at elevated temperatures, while the best conditions for their interpretation in the more general form are dilute solutions in which reaction is very slow, and temperatures low enough to permit accurate regulation, sampling and analysis. The type of procedure to be employed and the method of interpretation of the results are illustrated by the work of Lewis and Burrows[1] on the free energy of urea, and that of Branch,[2] on the free energy of formic acid.

The reactions studied in this work have been selected as among the more rapidly established of the known organic equilibria, and it is suggested that for a given type reaction, experimental conditions will be determined most readily by studying first those cases which, regardless of complexity of structure of the compounds involved, will permit the simplest experimental procedure.

When a triaryl carbinol reacts with an acid, the resulting compound of the triarylmethyl with the acid radical may be a substance of the un-ionized type, such as triphenylchloromethane, or of the ionized type, such as triphenylmethyl sulfate. This has been discussed recently by Hantzsch and Buroway.[3] The type of molecule obtained depends on the nature of the acid and of the triaryl carbinol, and also upon the solvent employed. The two processes are represented by the following equations

$$R_3COH + HX = R_3CX + H_2O \qquad (1)$$

$$R_3COH + H^+ = R_3C^+ + H_2O \qquad (2)$$

The extent to which Reaction 2 takes place should be independent of the particular strong acid used, and is known to vary greatly with the triaryl radical involved. Triphenylcarbinol is converted to an ionized salt only by high concentrations of sulfuric and perchloric acids, while the methoxytriphenylcarbinols enter into this type of reaction in the presence of dilute aqueous solutions of any of the strong acids. Measurements of the basicity of the triaryl carbinols, as carried out by Lund and others,[4] are quantitative studies of this type of reaction.

Equation 1 is typical of the action of hydrochloric or hydrobromic acid on the more weakly basic carbinols, and apparently no analogous reaction with the strong oxygen acids is known. The extent to which this reaction takes place depends primarily on the stability of the compound R_3X, and although, as has been stated, a considerable amount of quantitative data is available on reactions of type 2, very little of

specific information has been obtained on the tendency toward the production of the un-ionized type of molecule. It should be interesting to study the effect of substitutions in this case, to set. if an increased tendency toward the production of the ionized salt is accompanied by a change in the tendency of the un-ionized substance to form.

The material presented in this paper includes the development of the method of measurement, its application to the equilibria in the formation and hydrolysis of triphenylchloromethane and triphenylbromomethane, and some results obtained by combining these data with other known thermal constants. The method of measurement takes into account the fact that a typically organic solvent, such as benzene, should be the best medium for the formation of the un-ionized substance, and the results will be more readily interpreted if conditions are such that the activity and free energy of the water and acid are known. With these points in mind, equilibrium was studied in a two-phase system, a benzene phase in which the triphenylcarbinol and triphenylhalogenomethane were dissolved, and an aqueous phase containing the acid.

A benzene solution containing a known concentration of the carbinol or carbinol halide was shaken in contact with an aqueous solution of the halogen acid of such a strength that at equilibrium measurable concentrations of carbinol and halide were produced. The concentration of halide was measured by titration with alkali in the presence of alcohol, and that of the carbinol was obtained by difference. In each case the aqueous layer was tested for the presence of the carbinol salt by neutralization and dilution, but no evidence of its formation was obtained.

The Hydrolysis of Triphenylchloromethane.—The results are summarized in Table I, in which the first column shows the initial concentration of triphenylcarbinol or triphenylchloromethane, and indicates the direction in which equilibrium was approached, the second the concentration, in weight per cent., of the acid in the aqueous layer, the third the concentration, in moles per 1000 g. of solvent, of triphenylchloromethane after reaction, the fourth and fifth the partial pressures of hydrogen chloride and water, taken from the "International Critical Tables,"[5] the sixth, the ratio $p(\mathrm{HCl})m(\mathrm{carbinol})/p(\mathrm{H_2O})m(\mathrm{chloride})$, and the last the time in days through which reaction was allowed to proceed. The reaction under these conditions is very slow and, since only one pair of solutions came to equilibrium, the results would be inconclusive except for the method of checking shown in the following paragraphs. The fact that equilibrium was reached only in the presence of the highest acid concentration suggests catalysis by the acid.

The equilibrium constant is taken as the mean of the two values obtained

Table I

The Hydrolysis of Triphenylchloromethane in Benzene at 25° by Aqueous Hydrochloric Acid

Initial solution	HCl, wt., %	m $(C_6H_5)_3CCl$	p (HCl), mm. Hg	p (H_2O), mm. Hg	K	Time, days
0.193 M $(C_6H_5)_3CCl$	21.65	0.110	0.56	12.9	0.032	15
	24.20	.158	1.75	11.2	.034	5
	25.90	.176	3.5	10.0	.034	4
	26.60	.172	4.3	9.5	.0523	3
0.206 M $(C_6H_5)_3COH$	24.20	.138	1.75	11.2	.077	7
	26.60	.185	4.3	9.5	.0514	4

with 26.6% acid. The data of Table I may be summarized as follows. For the reaction

$$(C_6H_5)_3CCl \text{ (in benzene)} + H_2O(g) = (C_6H_5)_3COH \text{ (in benzene)} + HCl(g);$$

$$K_{298} = 0.0518;\ \Delta F^\circ_{298} = 1755 \text{ cal.} \quad (3)$$

Here the standard free energy refers to the gases at one atmosphere pressure and the solutes at equal concentrations or mole fractions.

The Hydrolysis of Triphenylchloromethane in the Presence of Solid Triphenylchloromethane and **Triphenylcarbinol.**—If a large excess of the solid phases is kept in contact with aqueous hydrochloric acid, the acid concentration should reach a definite equilibrium value which depends only on the temperature. In order to establish this equilibrium it is necessary to add to the system enough benzene or petroleum ether to give a non-aqueous reaction medium, and to start with a concentration of acid not far different from the equilibrium value, for relatively large quantities of the organic materials produce by reaction only small changes in the acid concentration. Apparent equilibria may be reached, due to coating of one of the solid phases, and a measurement is acceptable only when it has remained constant for several days after the addition of fresh portions of each of the solids. The hydrochloric acid solution which at 25° remains unchanged in contact with solid triphenylchloromethane and triphenylcarbinol was found to contain 24.82% of hydrogen chloride. Whence, for the reaction

$$(C_6H_5)_3CCl(s) + H_2O(g) = (C_6H_5)_3COH(s) + HCl(g);$$

$$K_{298} = 0.2195,\ \Delta F^\circ_{298} = 900 \text{ cal.} \quad (4)$$

The Solubility and Free Energy of Solution of Triphenylchloromethane, Triphenylbromomethane and Triphenylcarbinol in Benzene.—In order to show the relation between Equations **3** and 4, the free energy of solution of each of the solids must be determined. This requires measurement of the solubility and of the change of activity with concentration from the working concentration to the saturated solution. This was effected by measuring the vapor pressure lowering of benzene by the solute. The solution was introduced into a bulb to which a closed arm mercury manometer had been sealed. The apparatus was evacuated repeatedly until consistent readings were obtained with a cathetometer sensitive to 0.2 mm. Meniscus correction was minimized by taking all readings, including that with pure benzene, against the same manometer, and making frequent observations of the character of the meniscus. The temperature was constant to 0.01°. The analysis for triphenylchloromethane or triphenylbromomethane, carried out after the measurement, depended on the acid produced by hydrolysis. Triphenylcarbinol was determined as residue after evaporation of the benzene. When the residue was dissolved in acetone and the evaporation repeated, a slightly smaller figure was obtained. This was accepted as correct. The pressure readings with triphenylbromomethane were not reproducible, and the depressions were about half as large as those calculated from Raoult's law. Table XI shows the results of the measurements. The approximation to Kaoult's law was sufficiently close, in the solutions of triphenylchloromethane and triphenylcarbinol, for the present purpose, and only a few measurements were required. The first column shows the substance, the second the mole fraction of the solute, the third the vapor pressure lowering, the fourth the value calculated from Raoult's law, and the last the solubility in g. per 100 g. of benzene.

TABLE II

SOLUTIONS OF TRIPHENYLCHLOROMETHANE, TRIPHENYLBROMOMETHANE AND TRIPHENYLCARBINOL IN BENZENE; SOLUBILITY AND VAPOR PRESSURE LOWERING AT 25°

Substance	N_2	Δp (mm. Hg.)	Δp (Raoult's law)	Solubility
$(C_6H_5)_3CCl$	0.1938	20 6	19.0	85.8
$(C_6H_5)_3CCl$	.0624	6.2	5.9	
$(C_6H_5)_3CBr$	.0843			39.5
$(C_6H_5)_3COH$	.0472	5.3	4.6	16.5

Since, for the equilibria under consideration, the deviations from Raoult's law tend to cancel, the free energy of each of the substances in solution is assumed to be a simple logarithmic function of the mole fraction. For the reactions

$$(C_6H_5)_3CCl(s) = (C_6H_5)_3CCl \text{ (in benzene, } N_2 = 0.0724); \ \Delta F^\circ_{298} = -576 \text{ cal.} \quad (5)$$

$$(C_6H_5)_3COH(s) = (C_6H_5)_3COH \text{ (in benzene, } N_2 = 0.0724); \ \Delta F^\circ_{298} = 261 \text{ cal.} \quad (6)$$

By combining Equations 4, 5 and 6, a check on Equation 3 is obtained. The value of the free energy is 1737 cal. sufficiently closely to justify the interpretation of the equilibrium data. In subsequent calculations the value 1750 will be used. By combining the above equations with the appropriate free energies from Lewis and Randall,[6] the results may be expressed in the following forms

$$(C_6H_5)_3CCl(s) + H_2O(1) = (C_6H_5)_3COH(s) + H^+ + Cl^-; \ \Delta F^\circ_{298} = -5722 \text{ cal.} \quad (7)$$

---

[6] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., Inc., New York, 1923.

$(C_6H_5)_3CCl$ (in benzene) $+ H_2O(l) = (C_6H_5)_3COH$ (in benzene) $+ H^+ + Cl^-$;
$AF^\circ_{298} = -4872$ cal. (8)

$(C_6H_5)_3CCl(s) + {}^1/_2O_2(g) + {}^1/_2H_2(g) = (C_6H_5)_3COH(s) + {}^1/_2Cl_2(g)$;
$\Delta F^\circ_{298} = -30{,}915$ cal. (9)

$(C_6H_5)_3CCl$ (in benzene) $+ {}^1/_2O_2(g) + {}^1/_2H_2(g) = (C_6H_5)_3COH$ (in benzene) $+ {}^1/_2 Cl_2(g)$;
$\Delta F^\circ_{298} = -30{,}065$ cal. (10)

The Hydrolysis of **Triphenylbromomethane.**—Constant boiling hydrobromic acid was found after two distillations to be sufficiently free from bromine. Preliminary measurements indicated that the optimum concentration was in the neighborhood of 41%, and this was readily obtained by diluting the constant boiling acid. Triphenylbromomethane was prepared by the action of acetyl bromide on triphenylcarbinol, and its analysis showed 99.6% purity. Benzene solutions of the carbinol and bromide containing 0.2 mole per 1000 g. of solvent were shaken with 41% hydrobromic acid. It was found necessary to exclude strong light from the reaction mixtures, because of a tendency to form triphenylmethyl peroxide and liberate bromine. This reaction will be discussed in another communication. Equilibrium was reached after fourteen days. The results are not as accurate as those with triphenylchloromethane, due mainly to the character of the available vapor pressure or activity data on strong solutions of hydrobromic acid. Starting with the triphenylbromomethane solution the equilibrium constant was 6.5×10^{-4}, and for the reverse reaction, 7.7×10^{-4}. For the reaction

$(C_6H_5)_3CBr$ (in benzene) $+ H_2O(g) = (C_6H_5)_3COH$ (in benzene) $+ HBr(g)$;
$OF,'',, = 4310$ cal. (11)

The error in the above result is probably not more than 100 calories.

The following forms of expressing the result are of interest

$(C_6H_5)_3CBr$ (in benzene) $+ H_2O(l) = (C_6H_5)_3COH$ (in benzene) $+ H^+ + Br^-$;
$\Delta F^\circ_{298} = -5690$ cal. (12)

$(C_6H_5)_3CBr$ (in benzene) $+ {}^1/_2O_2(g) + {}^1/_2H_2(g) = (C_6H_5)_3COH$ (in benzene) $+$
${}^1/_2Br_2(l)$; $\Delta F^\circ_{298} = -37{,}660$ cal. (13)

Preparation of Triphenylchloromethane from **Triphenylcarbinol.**—The standard procedure effects the conversion by the action of acetyl chloride or dry hydrogen chloride on the carbinol in ether or benzene. The data of Equation 4 and Table II suggest the following modification. The carbinol and about twice the amount of benzene required to dissolve the chloride to be formed are placed in a flask or separatory funnel and an equal volume of concd. hydrochloric acid is added. The progress of the reaction may be observed as the mixture is shaken. The excess carbinol goes into solution in a few minutes. At this point the hydrochloric acid is drawn off and replaced, the shaking is continued for a few minutes and the benzene layer is separated and dried over calcium chloride. After drying, part of the benzene is removed by distillation on the steam-bath, and crystallization obtained by the addition of petroleum ether. Triphenylchloromethane melting at 112–113° was prepared from the carbinol by this procedure in 90% yield. A similar preparation in ether solution was carried out by Baeyer and Villiger.[7]

The Reaction of Triphenylchloromethane with Hydrogen Bromide and with Bromine.—Subtracting Equation 11 from Equation **3** shows the feasibility of replacing chlorine by bromine by the action of hydrogen bromide in benzene solution

$$(C_6H_5)_3CCl\text{ (in benzene)} + HBr(g) = (C_6H_5)_3CBr\text{ (in benzene)} + HCl(g);\quad \Delta F^\circ_{298} = -2560\text{ cal.} \qquad (14)$$

This reaction will probably take place in either direction because of the ease with which a stream of gas from a generator will carry away the gas which is formed.[8]

For the reaction of triphenylchloromethane with bromine, from Equations 10 and 13

$$(C_6H_5)_3CCl\text{ (in benzene)} + {}^1/_2Br_2(l) = (C_6H_5)_3CBr\text{ (in benzene)} + {}^1/_2Cl_2(g);\quad \Delta F^\circ_{298} = 8080\text{ cal.} \qquad (15)$$

showing a strong tendency for chlorine to replace bromine in the compound.

The Reaction of Triphenylchloromethane with Bromide Ion and with Metallic Bromides.—The equations follow

$$(C_6H_5)_3CCl\text{ (in benzene)} + Br^- = (C_6H_5)_3CBr\text{ (in benzene)} + Cl^-;\quad \Delta F^\circ_{298} = 820\text{ cal.} \qquad (16)$$

$$(C_6H_5)_3CCl\text{ (in benzene)} + AgBr(s) = (C_6H_5)_3CBr\text{ (in benzene)} + AgCl(s);\quad \Delta F^\circ_{298} = 4282\text{ cal.} \qquad (17)$$

$$(C_6H_5)_3CCl\text{ (in benzene)} + HgBr(s) = (C_6H_5)_3CBr\text{ (in benzene)} + HgCl(s);\quad \Delta F^\circ_{298} = 3940\text{ cal.} \qquad (18)$$

Equation 16 states that in benzene solution in contact with an aqueous layer containing bromide and chloride ions at unit activity, equilibrium is established when the concentration of triphenylchloromethane is about three times that of triphenylbromomethane. According to Equation 17, if triphenylbromomethane in benzene is kept in contact with silver chloride, a 99.9% conversion to triphenylchloromethane should occur. This is consistent with the results of Gomberg and Cone, who found that the bromine in a number[9] of related compounds was replaced by this procedure.

The Relative Dissociation Tendency of Triphenylchloromethane and **Triphenylbromomethane.**—Equation 15 may be considered as the difference of two reactions of dissociation

$$(C_6H_5)_3CCl\text{ (in benzene)} = (C_6H_5)_3C + {}^1/_2\,Cl_2(g),\text{ and} \qquad (19)$$

$$(C_6H_5)_3CBr\text{ (in benzene)} = (C_6H_5)_3C + {}^1/_2Br_2(l) \qquad (20)$$

---

[7] See Gomberg, *Ber.,* 35,2404 (1902).

[8] Straus, *Ann.,* **363,** 323 (1909).

[9] Gomberg, Ref. 7; Gomberg and Cone, THIS JOURNAL, 33,531 (1911)

.Although the individual equilibrium constants are not known, the ratio K_{19}/K_{20} is the constant of Equation 15, namely 10^{-6}, indicating that under comparable conditions in benzene the dissociation of the bromide is 10^6 times that of the chloride.

Similarly, Equation 16 may be divided into two ionic dissociations

$$(C_6H_5)_3CCl \text{ (in benzene)} = (C_6H_5)_3C^+ + Cl^-, \text{ and} \qquad (21)$$
$$(C_6H_5)_3CBr \text{ (in benzene)} = (C_6H_5)_3C^+ + Br^- \qquad (22)$$

The interpretation in this case is less definite, because the free energies of aqueous chloride and bromide ions were used in the original equation, and the result is of more interest if applied to non-aqueous solutions. Strictly, it means that a benzene solution of triphenylbromomethane in contact with aqueous bromide ion at unit activity should produce in either phase three times the concentration of triphenylmethyl ions developed by an equally strong benzene solution of triphenylchloromethane in contact with aqueous chloride ion at unit activity. Since, however, the work of transferring bromide and chloride ions from one medium to another is probably about the same, one may conclude that in benzene, and probably in other solvents as well, triphenylbromomethane has the slightly greater tendency to dissociate into ions. The conductance measurements of Walden,[10] made in liquid sulfur oxide, show a difference somewhat larger than the factor of three which may be estimated from Equation 18.

Summary

1. Data are presented on the equilibria in the hydrolysis of triphenylchloromethane and triphenylbromomethane in benzene by aqueous hydrochloric and hydrobromic acids.

2. The solubilities of triphenylchloromethane, triphenylbromomethane and triphenylcarbinol in benzene have been measured, and some data on the lowering of the vapor pressure of benzene by these substances have been obtained.

3. The results, expressed as free energies, have been combined with other free energy data to give information about the reaction of triphenylchloromethane with hydrogen bromide, bromine, silver bromide and mercurous bromide. The relative tendencies of triphenylchloromethane and triphenylbromomethane to dissociate into ions and neutral molecules have been discussed.

THE CATHODE RAY TUBE IN X-RAY SPECTROSCOPY AND QUANTITATIVE ANALYSIS

BY GORTON R. FONDA AND GEORGE B. COLLINS

RECEIVED NOVEMBER 12, 1930 PUBLISHED JANUARY 12, 1931

The methods of x ray spectroscopy have for several years proved of value in their application to chemical analysis. The lines in an x-ray series are so few as to obviate the confusion that sometimes arises in the case of the complex arc and spark spectra. Qualitative analysis by means of x-ray spectra is simple and direct. Quantitative analysis, based on measurements of line intensity, involves a knowledge of the influence of several factors upon the intensity. It has been used with well-known success in certain special cases and is capable of general application for elements of higher atomic number than fluorine.

Hitherto two tnethods have been in vogue that involve excitation. According to the first, the sample to be analyzed is made the target in an x-ray tube, as by rubbing it onto the surface of the anode. It was in this way, for instance, that Hevesy and Coster[1] detected hafnium and the subject has been pursued still more recently.[2]

The second method may be denominated fluorescent, as it involves exciting the x-ray spectra of a sample placed outside of the x-ray tube by allowing radiation from the latter to fall upon it. Experiments with this method have been discussed by Schreiber and by Hevesy, Rohm and Foessler.[3] The latter article is noteworthy for its tables of "comparison elements" which may suitably be added to the sample as a calibrating medium for the analysis of any particular element.

It is the purpose of the present paper to describe a third method according to which the x-ray spectrum of a sample is excited directly by allowing the electrons from a cathode ray tube to impinge upon it as target. The possibility of doing this has been known and a paper has in fact been published showing that it is possible to get sufficient energy from such a tube to allow of recording photographically a spectrum line.[4] Another purpose is to present information on the use of an ionization chamber and a vacuum tube amplifier as a means of registering the spectral lines and recording their intensity. In all quantitative work hitherto which has come to our attention, the lines of the spectra have been recorded photographically and their intensities measured with a microphotometer. We have used this

method also, but our description will deal more particularly with the ionization one because of its novelty.

The intensity of a line in an x-ray spectrum is not directly a measurement of the concentration of the element emitting that line, as compared with other elements, even when corresponding lines of the same spectrum are considered. Its relative intensity varies from the following causes. **(1)** The heating of the sample during excitation may lead to a change in relative concentration due to a greater volatility of one of the constituents.

(2) The reflecting power, R, of the crystal used as a grating varies with the wave length of the individual lines as expressed by the formula for sodium chloride[6]

$$R = 6.757 \frac{1 + \cos^2 2\theta}{\sin 2\theta} \lambda^{0.25}$$

where θ is the critical angle of reflection for a line of wave length λ.

(3) The intensity, I, depends also upon the excitation voltage, V_0, of the series to which the line belongs, according to the relationship $I = \text{const.} (V - V_0)^k$, where V is the voltage applied to the impinging electrons and k is an exponent whose value is 2, at least within a certain range of the exciting voltage.[6]

(4) Absorption by whatever media lie between the source of the x-rays and the ionization chamber or photographic film.

(5) Excitation of one element by another takes place if there is present in appreciable extent a second element of neighboring atomic number, one of whose lines is of shorter wave length than the absorption band of the first element. In this case the line of the first element is intensified and that of the second element is of course weakened as a result of its absorption.

(6) In the case of fluorescent radiation, the more remote an element is in wave length from that of the exciting radiation, the weaker will be its intensity.'

(7) The relation between intensity and blackening of the film enters, if the recording of intensity be done photographically. This depends upon the extent of absorption and accordingly upon the wave length.[8]

The simplest case for analytical treatment by x-rays is that of a binary alloy whose metals are of adjacent atomic number. . Mutual excitation is absent and the other causes of variation in intensity enumerated above may be made so small under proper choice of conditions that corrections for them can safely be applied despite some uncertainty in their exact magnitude. In other cases the Hevesy method can be used by adding a

comparison element. This involves a preliminary calibration of synthetic mixtures of the element to be analyzed.

In the case of routine analyses of similar mixtures in which the ratio of two constituents varies, the addition of a comparison element is not necessary, a simple calibration to show the relation between intensity and composition being sufficient.

In the use of the cathode ray tube or the fluorescent method, there is the advantage that the sample may simply be exposed to radiation from an exciting tube. This saves the time of introducing it to a tube and also makes it possible better to cool the sample.

Cathode Ray Tube and High Voltage Equipment

The cathode ray tube used was of the type developed by Coolidge[9] but considerably smaller than that described by him. its aluminum window of special design had a minimum thickness of 0.013 mm. and a diameter of 6 mm., and was soldered to the opening in the anode arm Due to its small diameter, a support was unnecessary. It was designed and constructed by Mr. George Hotaling of this Laboratory and we are indebted to him for supplying us with it.

It was evacuated continuously with a mercury condensation pump to assure maintenance of a satisfactory vacuum. It is hoped that eventually these tubes can be sealed off at a good vacuum during manufacture. The window was water cooled.

The tube was operated in a vertical position. with the window uppermost and the sample placed above it at an angle of 10° to the surface of the window, an angle that was found to give the maximum intensity of x-rays in a horizontal direction. The energy of the cathode rays was sufficient to heat the sample considerably. To reduce this and at the same time to prevent oxidation of the sample, a jet of hydrogen was played over it. When the sample was a metal plate, its temperature in a current of hydrogen did not rise above about 60° under bombardment at 85 kv. and 0.2 ma., the operating conditions during an analysis. When cadmium iodide, whose boiling point is 710°, was used as the sample and bombarded at 88 kv. in air without cooling, it sublimed in heavy clouds at 0.4 ma., slightly at 0.3 ma. and imperceptibly at 0.25 ma. It is readily possible, of course, to use much more rigid cooling wherever desired, such as cooling water or ice or liquid air placed upon the sample.

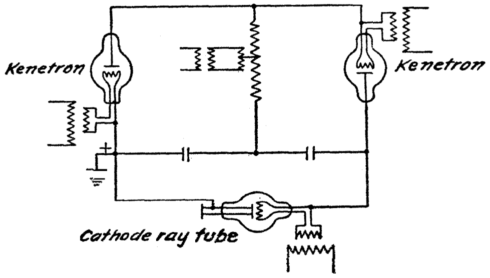

Fig. 1.—Diagram of high voltage set.

The tube was operated by a high voltage d. c. outfit to avoid heating of the window under a. c. operation by electrons of too low velocity to contribute to excitation of x-ray spectra. The circuit used is shown diagrammatically in Fig. 1: 60-cycle regulated a. c. at 110 v. was supplied from a control transformer. A 1:1 transformer, whose secondary was insulated for 100 kv., supplied an x-ray high voltage transformer, with middle points of windings connected, resting on porcelain insulators 40 cm. high. The output from

---

[9] Coolidge. J. Franklin *Inst.,* 202, 693 (1926).

this was shared between two kenetrons supplying a bank of fourteen condensers, each of 2.5 mf. capacity and capable of standing about 7000 v.[10] The voltage delivered to the cathode ray tube is double that coming from the x-ray transformer as the current is alternately rectified by each kenetron and delivered to one-half of the bank of condensers. The function of the latter is to deliver a current of nearly uniform voltage—the capacity of each half being such that it may deliver energy to the tube without appreciable voltage drop during the half cycle when the rectified current is being delivered to the other half of the condensers.

The filament of the kenetron on the grounded side was lighted by a transformer of low voltage insulation; the filaments of the other and of the cathode ray tube were necessarily operated by transformers whose secondaries were insulated 100 kv. above ground.

To assure uniformity of voltage distribution along the condensers, the terminals of each were connected to a resistance of 23 megohms. This was constructed in the following manner. A long glass tube 2 cm in diameter was filled with a solution of 1 part of grain alcohol to 2.5 parts of xylol, and wire terminals sealed into it every 12 cm. were connected to the condenser terminals. The high voltage set was calibrated with 6.25-cm. brass spheres.[11]

Experiments with Ionization Chamber.—The spectrometer was made of brass in the laboratory machine shop. Reflection was from the 100 plane of a sodium chloride crystal which could be rotated by an arm about the center of a circular table, 12.5 cm. in diameter, graduated in degrees. Another arm extended 20 cm. beyond the table and carried a box containing the ionization chamber and the amplifying units. A vernier attachment allowed the crystal to be set at four minute intervals. The crystal was chosen from several specimens of halite, after many had been rejected because of surface irregularities which were either manifest to the eye or else sufficient to give distorted intensity curves.

A slit, kept at a width of 11 mm., was placed at the opening of the ionization chamber, at a distance of 12 cm. from the center of rotation. The collimating slits, whose opening was varied from 0.3 to 0.9 mm., were placed 4 and 12 cm. from the axis of the spectrometer. The front slit was 3.5 cm. from the axis of the cathode ray tube.

The brass ionization chamber was made of two concentric cylinders of 1-mm. material, 20 cm. long. The inner one served as one electrode and had a section of a cylinder soldered to the bottom. All connections to it were insulated with hard rubber. The other electrode was a 3-mm. rod with amber insulation, directly connected to the control grid. Aluminum foil, 0.015-mm. thick, was cemented across the opening.

The chamber was filled with methyl bromide. In the absence of leaks, its performance was consistent for weeks at a time. The chamber was large enough to allow of complete absorption of radiation on the long wave length side of the bromine absorption edge.

The amplifying system is shown diagrammatically in Fig. 2. The basis of it is the new four-element vacuum tube, FP-54, characterized by a very high input resistance. The operation[12] of it and of the amplifying system is based upon the facts that x-rays entering the ionization chamber produce an ionization current proportional to their in-

---

[10] A brief outline of this system is given in Glocker, "Materialprüfung mit Röntgenstrahlen," p. 28, 1927, and a discussion of the condenser requirements can be found in Hull, Gen. *Elec. Review,* 19, 173 (1916).

[11] Peek, "Dielectric Phenomena in High Voltage Engineering," 1915, p. 89.

[12] Metcalf and Thompson, *Phys. Rev.,* 36, 1489 (1930); Nottingham, J. Franklin *Inst.,* 209, 287 (1930), gives a helpful discussion of similar amplifying systems, although based on three-element tubes.

tensity and that this ionization current determines the potential of the control grid of the tube. This grid potential affects the plate current and the variations in it are read on a sensitive galvanometer, with the normal initial plate current balanced out by means of an adjustable voltage. Since the characteristic curve of the tube may be considered straight within the range used, the galvanometer deflection may be taken directly as a measure of the relative intensities of the x-rays entering the chamber.

Considerable difficulty was experienced in obtaining a suitable grid resistance. Mixtures of xylol and alcohol, copper oxide fused into glass and India ink lines on paper were found to be unsatisfactory. When they were made large enough to give the required sensitivity, they polarized readily. A pencil line on hard rubber was fairly satisfactory, giving galvanometer deflections which were reasonably steady. The best resistance, however, and the one which we used in the tests described here, was one made by Dr. Lewi Tonks of this Laboratory and which he kindly loaned to us. It was made by the distillation of tungsten from a wire upon a glass fiber in an evacuated tube.

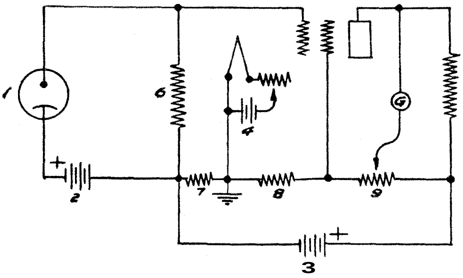

Fig. 2.—Diagram of amplifying set.

1, Ionization chamber; 2, 180-v. B battery units; 3, 12-v. storage battery; 4, 6-v. storage battery; 5, 50,000-ohm. resistance; 6, $3(10)^{10}$-ohm. grid resistance; 7–9, 500-ohm. resistances.

The sensitivity of the set may be calculated from a knowledge of the galvanometer sensitivity $S = 5.5(10)^{-10}$ amp., the mutual conductance of the tube $G_m = 21$ μa./V, the grid resistance $R = 3\ (10)^{10}$ ohms, the grid voltage V_g, the grid current I_G, and the plate current I_p.

$$G_m = I_p/V_g = S/V_g$$

Since $V_G = I_G R$, $I_G = S/G_m R = 8.7\ (10)^{-16}$ amp. This expression for the sensitivity gives the smallest measurable grid current.

As the high voltage outfit was not enclosed, adequate screening was our greatest difficulty. As the first step, to make the connection from chamber to grid as short, and at the same time as well insulated, as possible, all of the amplifying set, including the vacuum tube and resistances Nos. 5–9, was mounted with the chamber on the movable spectrometer arm in a completely enclosed wooden box lined with tin foil and covered with 2-mm. aluminum sheet and with the side toward the crystal faced with lead 3 mm. thick. The box contained calcium chloride as drying agent. The entire spectrometer was enclosed in a galvanized iron box, open at the top. The upper part of the cathode ray tube, including the window and sample, was enclosed in a lead box open at the bottom and with a small opening opposite the sample.

The flexible connection from the amplifying set to the batteries and galvanometer was enclosed in the metal casing of BX cable. The batteries, insulated on pieces of bakelite, were also enclosed with galvanized iron, and the galvanometer with a tin box. All of the metal protective enclosures were grounded and all connections soldered. Steady conditions in the amplifying system were obtained by allowing it to run for half an hour.

An approximate estimate of the sensitivity of the spectrometer was obtained from an experiment with a copper target. With the tube operating at 85 kv. and 0.2 ma., and with 0.4 mm. slits, the peak of the Kα doublet gave a net deflection of 90 cm. with an accuracy of 0.5 cm. on a scale 2.6 m. distant, corresponding to an ionization current of $3\ (10)^{-13}$ amp.

Measurements were based on the first order of the K radiation, using the intensity coming from the unresolved Kα doublet. The slit in front of the ionization chamber was kept at an opening of 11 mm., to have assurance that all of the reflected energy would enter the chamber. Actually the chamber could be turned through an angle of 2° for a particular setting of the crystal before a decrease in intensity was noticed. In practice the angle of the chamber was kept at twice the angle of the crystal, being reset for every 30' change in the latter. The curves for intensity against crystal angle were plotted on coordinate paper and the area of the doublet, lying above the continuous radiation, was measured by counting squares, as this method gave greater accuracy than a planimeter.

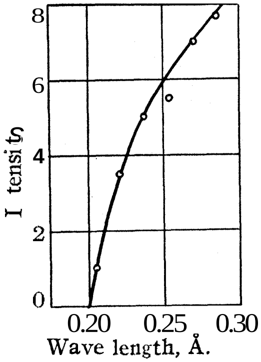

Fig. 3.—Continuous radiation curve for tungsten at 74.7 kv.

The loss in velocity of the electrons in passing through the aluminum window was determined by measuring the continuous radiation of tungsten on the short wave length side. The curve expressing the results is given in Fig. 3. The abscissas are plotted not as angular setting of the crystal, but rather as wave length, in terms of $\lambda = 5.628 \sin \Theta$. Zero radiation occurs sharply at 0.200 Å., from which the exciting voltage can be calculated as $V_0 = 12.34/\lambda = 61.7$ kv. As the window produces some straggling, this represents the optimum velocity. The potential applied to the tube was 74.7 kv. Terrill's[13] formula for the loss in velocity in aluminum foil is $v^2 - V^2 = 1.1(10)^{12}x$. If this is applied to our case, for a thickness x of 0.0013 cm. and a primary velocity v of 74.7 kv., the final velocity V should be 64.5 kv. For a final velocity of 61.7 kv., that obtained by us, the thickness should be 0.0016 cm. The latter value probably expresses better our effective loss in velocity, as the thickness of gas contributes to it and also irregularities on the surface of the window, which was made purposely non-uniform.

It seemed important to determine how the intensity of the Kα doublet varies with the voltage, not only to show the changes in the energy available for analytical purposes, but also to get a closer value for the correction factor determining the relation between line intensity, **I**, and the difference between the applied voltage, V, and the exciting voltage, V_0. This relation was expressed by Webster and Clark[14] for the K series of rhodium as $I = \text{const.} (V - V_0)^{3/2}$. Kettmann[15] and Stumpen[16] found that near the exciting voltage the exponent was 2 for the K series of chromium, copper,

---

[16] Stumpen, *ibid.*, 36, 1 (1926).

molybdenum and silver, but decreased for higher voltages. Lorentz[6] studied carefully the K series of aluminum and found that the exponent was 2 up to double the exciting voltage, decreasing thereafter up to about nine-fold the exciting voltage; from that point on the intensity itself decreased.

We have made intensity measurements at 0.2 ma. on molybdenum up to four-fold the exciting voltage and on iron up to eleven-fold. In both cases the exponent remained 2 throughout the range, and there was no evidence of reaching an optimum value. The data are given in Table I. In calculating the exponent it was of course necessary to use values of the voltage which are characteristic of the optimum electron velocity at the target. This was done by means of the Terrill equation, using x = 0.0016, and is expressed in the table as "electron velocity, *V*."

The results are shown in the curves of Fig. 4. To show the extent to which they justify an exponent of 2, the intensity is plotted in Fig. 5 on log paper against $V - V_0$, using values for V_0 of 19.9 for molybdenum and 7.1

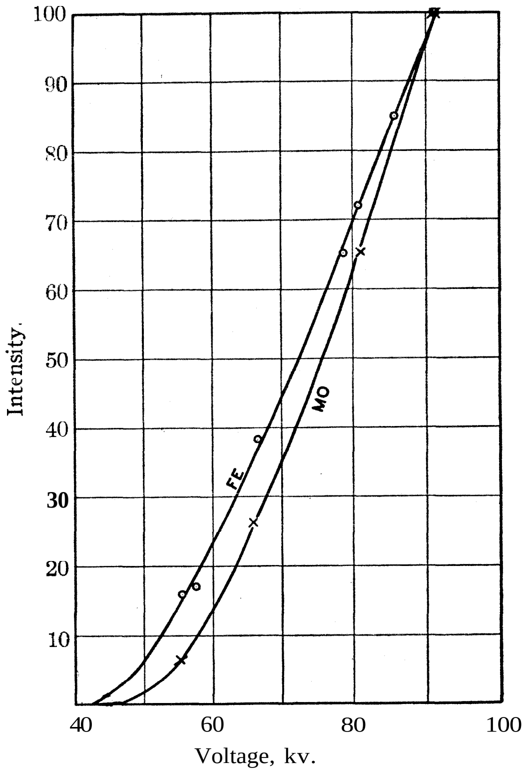

Fig. 4.—Variation of intensity with voltage for Kα doublet of iron and molybdenum.

TABLE I

EFFECT OF VOLTAGE UPON INTENSITY OF Kα DOUBLET

Applied voltage. Kv.	Electron velocity, V	Intensity *Kα* Doublet	
		Mo	Fe
90.8	80.4	100.0	100.0
85.7	74.6	..	85.0
80.8	69.0	65.4	71.9
78.7	66.6	..	65.0
66.6	51.7	..	38.0
65.8	50.8	26.4	..
57.5	39.3	..	17.0
55.2	35.9	6.4	15.8

for iron. The exponent is calculated from the slope of the curves to be **2.03** for molybdenum and 1.97 for iron, with no evidence of decreasing to lower values.

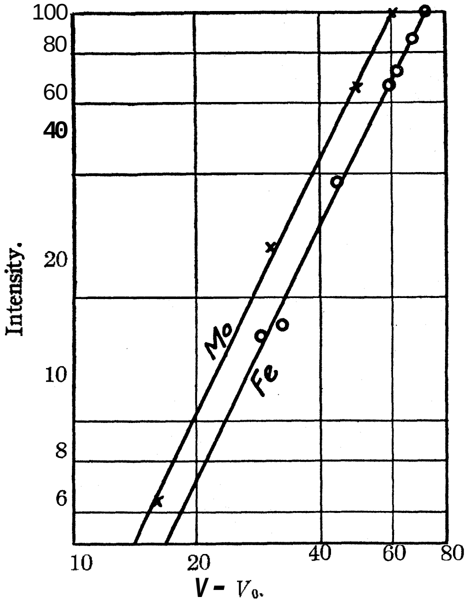

Fig. 5.—Variation of intensity of Ka doublet with $V - V_0$.

This distinction from the results of others whose experiments were with x-ray tubes may be due to the presence of a certain range of velocity in the beam coming from the cathode ray tube. At a low voltage it would accordingly excite a smaller intensity of radiation than would the electrons of uniform velocity in an x-ray tube. As the voltage increases, the difference would lessen.

The variation in intensity with current is shown in Fig. 6 for the case of the $K\alpha$ peak of molybdenum.

In the analytical work the cathode ray tube was operated at 85 kv. and 0.2 ma. The measurements were checked by repeating a run, either in whole or in part. About one hour was required for such an examination of a binary alloy. In some of the cases a further check was made by repeating the run on a different day, generally on a fresh surface of the sample. This is denoted in the tables by a separate entry.

In all cases the alloys had a polished surface and for the most part were in flat pieces which had been rolled down from stock. The composition was determined by chemical analysis which was kindly carried out for us by Dr. Dorothy H. Brophy of this Laboratory.

No high degree of accuracy

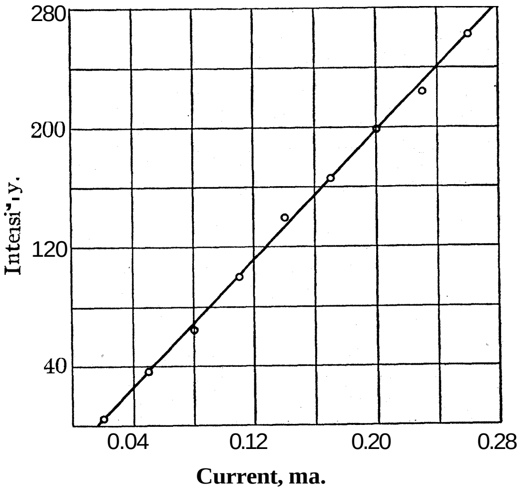

Fig. 6.—Variation of intensity with current for peak of $K\alpha$ doublet of molybdenum.

is claitned for the results found, for the aim was rather to explore the possibilities before spending too much effort in refining features of the apparatus. One of its weak features was the crystal. As already mentioned, several were discarded during preliminary work. The final one used in these experiments was not above reproach. Indeed in going over the curves after the work had been completed, it was noticed that in some of them there was still present a slight distortion at the base of the Kα doublet and that the results from these showed rather poor agreement under repetition. By chance, however, the setting of the crystal had been slightly altered at one time and the results obtained thereafter appeared more reasonable and are the ones reported below.

TABLE II

RELATION BETWEEN COMPOSITION AND INTENSITY OF Kα RADIATION FOR ALLOYS OF ADJACENT ATOMIC NUMBER; SLITS SET AT 0.30 MM.

Alloy	Composition, atomic, % Cu	Intensity, % Cu
Copper–zinc	64 5	64 6
Copper–zinc	ti4 5	84.4
Copper–nickel	4 8	6.1
Copper–nickel	39.1	33.1
Copper–nickel	64.7	65.6
Copper–nickel	94 1	93 7

The results on two binary alloys whose constituents are adjacent in atomic number are given in Table II. These represent the simplest cases, as mutual excitation is absent.

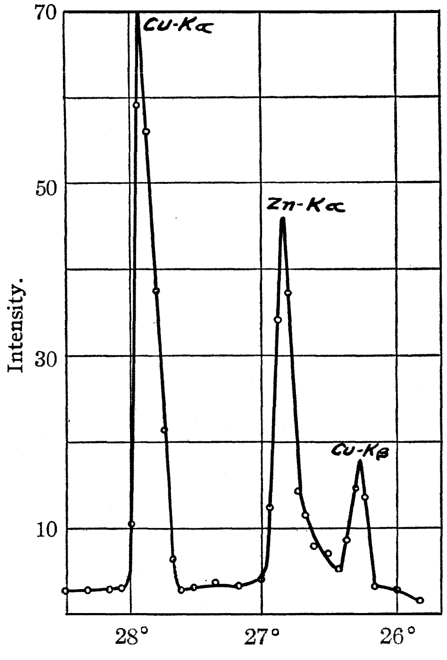

Fig. 7.—Intensity curves for copper–zinc alloy containing 64.5 atomic per cent. of copper; slits, 0.30 mm.

A typical curve from which the areas denoting intensity were measured is shown in Fig. 7. In all of them equally smooth curves could be drawn through the points denoting the observations. The angular settings noted are purely relative. Actually in all cases the angles corresponding to the peaks of the curves were found to give with reasonable accuracy the values of λ for the Kα_1 arid Kβ_1 lines. In Fig. 8 is given a curve showing for the copper–nickel alloys the relation between composition and relative intensity. Theoretically, the latter should be proportional to the atomic per cent. Actually, the effects of crystal reflectivity and of absorption by air and chamber window act to increase slightly the relative intensity of the radiation from the elements of higher atomic number. It is for this reason that in the copper–nickel alloys the relative intensity of the copper radiation runs somewhat high. The curve of Fig. 8, however, is typical of a calibration curve which could be used in analyzing an unknown. For the same reason, the relative intensity of the copper radiation from the copper–zinc alloy should be lower—the values obtained in our analysis are therefore somewhat too high.

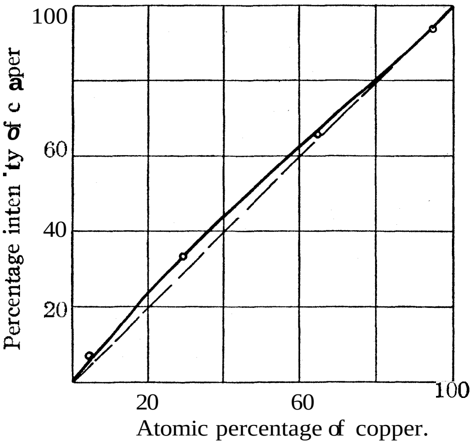

Fig. 8.—Relation between intensity of Kα doublet and composition for copper–nickel alloys.

The other case for which mutual excitation should be absent occurs for two elements whose atomic numbers are remote. Molybdenum and iron were selected and three different compositions were examined. Unfortunately, they had been made up in small samples and bad segregation had evidently occurred. Simply a resetting of the sample led to a different relationship of intensities, although for any one setting good agreement was found on repetition. The results are, therefore, of no value analytically, but they are given in Fig. 9 for an alloy to which 9.3 atomic per cent. of molybdenum had been introduced, to show the differences for the two Kα doublets. That of iron is of such long wave length, 1.932 Å., that the continuous radiation in its neighborhood is very low, whereas that of molybdenum at 0.708 Å. is near the peak in the continuous radiation curve. The intensity of the molybdenum radiation is essentially very much greater than that of iron for equal amounts of each because of its higher reflection from the crystal and greater transmission of the air and chamber window.

As illustrative of the case in which strong mutual excitation is present, the iron–nickel alloys were chosen. The Kα_1 line of nickel is at 1.654 Å.,

TABLE III

RELATION BETWEEN COMPOSITION AND INTENSITY OF Kα RADIATION FOR IRON–NICKEL ALLOYS; SLITS SET AT 0.90 MM.

Composition atomic, % Fe....	91.7	91.7	64.8	64.8	55.5	22.8	5.9
Intensity, % Fe..............	87.8	87.7	67.8	68.4	60.8	26.6	6.9

just within the absorption edge of iron, 1.738 Å., at which its K radiation is excited. The results are given in Table III.

A typical set of curves is shown in Fig. 10 and the relation between all of the alloys is given in Fig. 11. The situation is rather complicated The effect of crystal reflectivity and of absorption is to decrease the intensity of the iron, but for all alloys containing less than 80 atomic per cent. iron, the predominating effect on the intensity is the excitation produced by the nickel, accompanied, of course, by a partial absorption of the nickel radiation by the iron. In general, one would not expect this effect to be appreciable for small amounts of nickel. On applying the corrections for the first two effects and for that of voltage to the alloy containing 91.7 atomic per cent. iron, a value of 91.9% was obtained from the relative intensities.

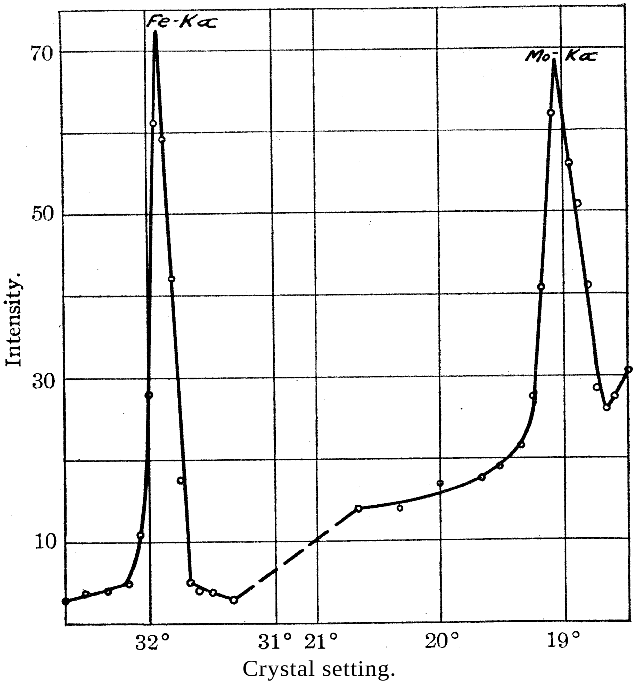

Fig. 9.—Intensity curves for molybdenum–iron alloy; slits, 0.40 mm.

Experiments with Photographic Recording.—Some experiments were also carried out on binary alloys with a Seemann spectrometer, using a crystal of sodium chloride and a wedge placed above it to form the slit. The opening of the spectrometer was placed 2–3 cm. from the window of the cathode ray tube, and the sample as before was right above the window, making a 10° angle with it.

The density of the lines on the film was measured for us by Mr. F. Ben-ford of this Laboratory by means of a mercury lamp with a Fabry and Buisson microphotometer.

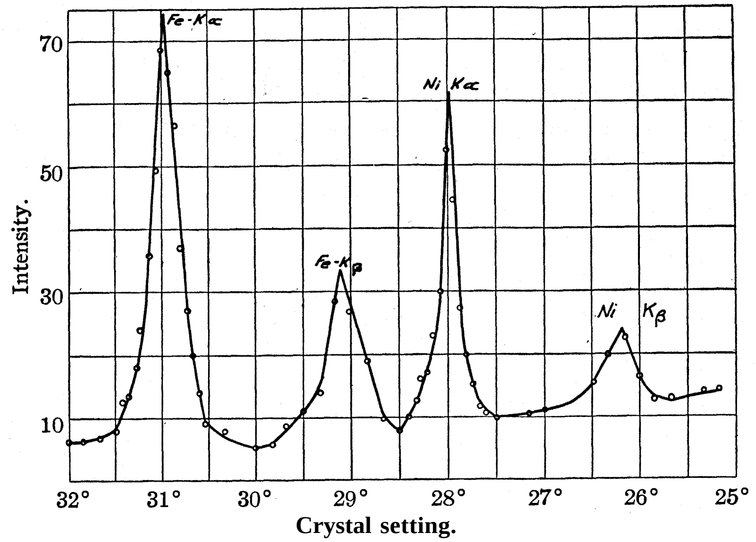

Fig. 10.—Intensity curves for iron–nickel alloy containing 64.8 atomic per cent. of iron; slits, 0.90 mm.

With the cathode ray tube at 88 kv., experiments were made with various polished binary alloys. For those containing about equal parts of metals of adjacent atomic number, silver and cadmium and tin and antimony, the spectrometer was oscillated over a 3° angle. At a slit width of 0.05 mm., sufficient to resolve the Kα doublet, the time of exposure to attain a line density in Briggs logarithms of 0.4 was eighty minutes at 0.3 ma. and 110 minutes at 0.2 ma.; with a slit of 0.50 mm., the time was reduced to forty and sixty minutes, respectively. For a single element the time required to attain the same density was sixteen minutes, using a 1° oscillation, a slit width of 0.05 mμ and a current of 0.2 ma.

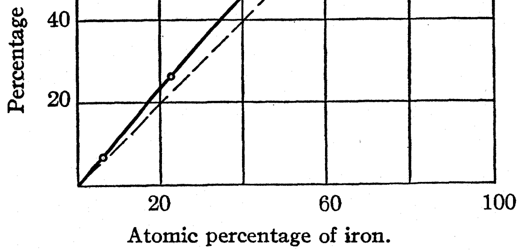

Fig. 11.—Relation between intensity of Kα doublet and composition for iron–nickel alloys.

Tests were made with the pure metals for various times to get the relation between photographic density and intensity of x-radiation, and also the relative photographic activity of the different metals. Applying this correction and the small ones for the reflecting power of the crystal and the voltage effect, a value of 59.6 atomic per cent. silver was found for a silver--cadmium alloy containing 60.2 atomic per cent., and 49.2 atomic per cent. of tin for a tin--antimony alloy containing 49.4 atomic per cent.

Conclusion

The ionization method as applied to our present apparatus was capable of detecting qualitatively about 0.5% of an element, and quantitatively 3% or more. The apparatus as described is of a preliminary nature, but it serves to show the possible scope. Even with the present cathode ray tube, some simple and obvious changes would add greatly to the effective radiation. One is operation of the tube in a horizontal position so that the excited portion of the sample would have the shape of a vertical slit, thus introducing about three-fold more energy to the chamber. Another is operation at higher voltage.

The limit of sensitivity for the amplifying set likewise is many-fold greater than for that employed by us. Even the present one would be applicable for use with the x-ray tubes described by others for quantitative work, where the energy available is so great that very much smaller percentages could be detected.

It is a pleasure for us to acknowledge the cooperation of many in the laboratory staff. We are particularly grateful to Dr. W. P. Jesse and Dr. C. W. Hewlett for the help coming from their experience with the technique of x-ray spectroscopy, to Mr. B. J. Thompson for suggestions in adjusting the amplifying set, and to Dr. A. L. Marshall in regard to the high voltage outfit.

Summary

1. The use of a cathode ray tube is described for exciting x-radiation of samples placed before its window, and also the use of an ionization chamber and an amplifying system for recording the intensity.

2. The variation in the intensity of the Kα doublet for Mo and Fe is shown to follow the relation $\mathbf{I} = c(V - V_0)^2$, up to a voltage four-fold that of V_0, the exciting voltage for Mo, and eleven-fold for Fe. The exponent accordingly remains constant over a greater voltage range than has been observed in x-ray tubes.

3. The application of the cathode ray tube to the quantitative analysis of alloys is shown by both the ionization and the photographic methods.

PERMANGANATE DECOMPOSITION IN ALKALINE MEDIA[1]

BY R. H. FERGUSON, WM. LERCH AND J. E. DAY

RECEIVED NOVEMBER 18, 1930 PUBLISHED JANUARY 12, 1931

The purpose of this investigation was *(a)* to measure the effect of hydroxyl-ion concentration and of temperature on the rate of the reaction

$$4MnO_4^- + 4OH^- \longrightarrow 4MnO_4^{=} + 2H_2O + O_2 \qquad (1)$$

and (b) to study the possible reversibility of this reaction in the absence of extraneous materials other than the reaction medium (water).

One of the authors,[2] when oxidizing ethyl alcohol by potassium permanganate solutions containing potassium hydroxide, observed that the available oxygen values of the strongly alkaline permanganate solutions were measurably lessened if not used promptly. In 1917 Day prepared a solution containing 340.8 g. of stick caustic potash (purified over alcohol), 30.404 g. of potassium permanganate and one liter of water, and kept the mixture at room temperature. By the end of one year the available oxygen had dropped 25%; in four years, 50%; and in ten years, 53%. A portion of this final dark green solution was held at 95°, manganese dioxide appearing and the supernatant liquid becoming colorless in about six days. The potassium permanganate (available oxygen = 98.67% of the theoretical) had not been aged and freed of any probable dioxide.

Preparation of Materials

Unless otherwise stated all filtrations were made through asbestos fiber supported in a Biichner funnel. The fiber was purified by digestion with sodium hydroxide, then with hydrochloric acid, and the product well washed, suspended in dilute sulfuric acid, treated with potassium permanganate solution and finally washed until free from chloride and sulfate ion.

Potassium hydroxide, when prepared by Ruby's[3] method, reduced a permanganate solution, hence the solutions of the two alkalies (potassium and sodium) used in this investigation were obtained by metathesis from purified non-reducing saturated solutions of barium hydroxide and 2 *N* solutions of the corresponding alkali metal sulfate. After reaction the decanted solutions were freed of the last traces of barium sulfate by

[1] The results of the preliminary work leading up to this more complete investigation were presented by William Lerch to the Graduate School of the University of Wisconsin, June, 1922, in candidacy for the degree of Master of Science; and in abbreviated form at the Pittsburgh Meeting of the American Chemical Society, September, 1922. The present paper is from the dissertation presented by R. H. Ferguson to the Graduate School of The Ohio State University, June, 1927, in candidacy for the degree of Doctor of Philosophy, a digest being given at the St. Louis Meeting of the American Chemical Society, April 18, 1928.

[3] Ruby. *ibid.*, 43, 294 (1921).

filtration in a carbon dioxide-free atmosphere. These solutions were concentrated to approximately 13 N in large loosely covered glass pyrex beakers. The final product was further appropriately treated until it gave negative tests[4] for carbonate, chloride, barium and sulfate ions. Ten-cc. samples acidulated with sulfuric acid did not reduce one drop of 0.1 *N* potassium permanganate.

A slightly less than saturated solution of potassium permanganate was placed in a clear glass-stoppered bottle and aged in ordinary light for five months, then filtered six times, at two-day intervals, through specially prepared[6] asbestos wool. An ultramicroscopic examination of the final solution showed no evidence of colloidal manganese dioxide. The last filter was tested for the presence of manganese dioxide with negative results. The dioxide test was made by first carefully washing the undisturbed filter free from potassium permanganate and then determining the oxidation titer of the filter by the oxalic acid–permanganate method.

A sodium permanganate solution was prepared from Kahlbaum's best product in the same manner as was the potassium salt except that because of the relatively greater impureness of the sodium compound, it was allowed to age for a year with six periodic filtrations through asbestos. The sixth filter gave a negative test for manganese dioxide.

These two permanganate solutions were then standardized against sodium oxalate (Bureau of Standards) and kept in stoppered black-coated bottles. The molar concentration of the potassium permanganate solution was 0.1248, this value being an approximate mean of the concentration used in an acid medium in quantitative analysis and that in an alkaline medium in organic oxidation. Because of the reputedly poor keeping quality of sodium permanganate, its concentration was brought down to 0.0680 M.

Experimental

All reactions were carried out in flasks (Fig. 1) kept in a constant temperature bath. A is a pyrex Kjeldahl flask constricted at the top. The pyrex cup E is sealed into the rubber stopper B by means of plaster of Paris, C. The collection, in the cup, of condensed steam from the reaction mixture was practically avoided by keeping the cup nearly filled with mercury, D, when the inverted 30-cm. glass condenser was in position. Care was always exercised in preventing the mercury from getting into the flask contents. The condenser was equipped with a guard tube filled with soda lime and cotton. A strip of blotting paper fastened around the condenser just above the cup E prevented condensed water vapor from the thermostat from getting into the reaction mixture by the route of the mercury seal when samples were withdrawn. The water-bath thermostats was electrically heated and was controlled to within 0.1°.

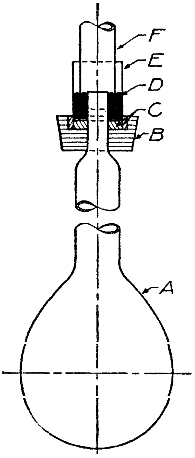

Fig. 1.

In each reaction mixture the initial strength of the potassium permanganate was 0.156 mole and that of the sodium permanganate was 0.085 mole of available oxygen per liter. Two hundred cc. of the permanganate solution of the necessary concentration was placed in the reaction flask and a like volume of the alkali solution of the desired concentration in another flask. The two solutions were then brought to the desired

[6] Day and Ferguson, "A Constant Temperature Bath," This Laboratory, 1927, unpublished.

temperature and the alkali solution added to the permanganate solution at a sufficiently slow rate to avoid entirely the precipitation[7] of any of the permanganate. After vigorous shaking for several minutes the reaction mixture was placed in the thermostat and the flask-condenser connection made as in Fig. 1. The progress of each reaction was determined by periodically measuring the amount of available oxygen in a 10-cc. portion of the reaction mixture. The reaction in the sample was stopped by the addition to the sample of a measured quantity (65 cc. for the potassium and 35 cc. for the sodium series) of a sulfuric acid solution of standard oxalic acid and this then back-titrated for the oxygen titer with standard potassium permanganate. For the 75 and 95° series the sampling pipet was brought to about the temperature of the reaction mixture to avoid volume errors.

The identity of oxygen as an evolved product from the reaction mixtures was established by the glowing splint test and also by absorption in a hydrochloric acid solution of cuprous chloride.[8] Samples of the reaction mixture after the available oxygen titer became constant were examined under the ultramicroscope for colloidal manganese dioxide.

Results and Discussion

The use of a mechanical stirrer in the reaction apparatus, described above and partially shown in Fig. 1, added greatly to the tediousness of sample withdrawal. A modified form of this apparatus, consisting of an 18-cm. glass condenser sealed to a short-necked pyrex flask, was equipped with a mechanical stirrer. In Table I is shown the relative effect of slow (60 r. p. m.) stirring (Col. 1) and no stirring (Col. 2) upon the water medium reaction between 12.4 N potassium hydroxide and 0.634 N potassium permanganate at 50°. The velocity of the reaction was increased slightly but the extent was practically the same. Because of the difficulty in effecting condensation of the water with the 18-cm. condenser as well as the added manipulation in the removal of samples for analysis, the use of this apparatus was discontinued.

TABLE I

COMPARATIVE DATA

Time, hours	Available oxygen, mole per liter Col. 1	Col. 2

12	.151	.152
48	.149	.149
96	.143	.145
144	.142	.143
192	.139	.142

The effect of four concentrations of potassium hydroxide and of three temperatures on the conversion of potassium permanganate into a manganese compound, or compounds, of lower manganese valence is shown in Figs. 2, 3 and 4. The molar ratios (before mixing) of permanganate to alkali are approximately 1:45, 57, 76 and 99. The behavior of sodium

permanganate in the presence of sodium hydroxide under conditions similar to those for the two potassium compounds is presented in Figs. 5,

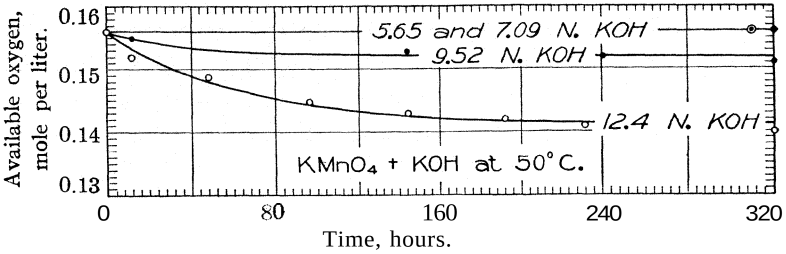

Fig. 2.

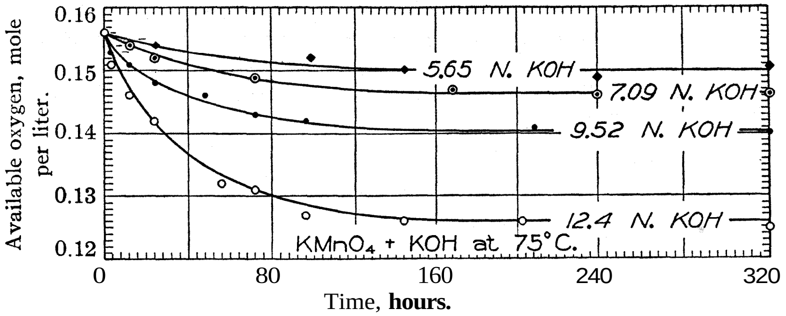

Fig. 3.

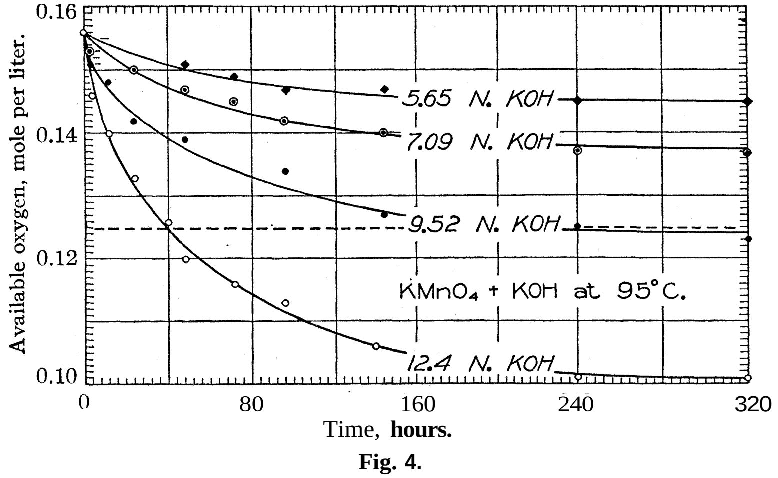

Fig. 4.

6 and 7. In the case of this permanganate, and the corresponding hydroxide, the integral molar ratios are 1:46, 60, 97 and 169. The available oxygen value is that calculated on the basis of normal solutions for oxidation–reduction in acid media.

Whether or not the dissolved glass from the extensive action of the strong alkali upon the reaction flasks at 95° may have influenced these reactions catalytically or otherwise was not studied.

Figures 2–7, inclusive, show that the extent of the loss of available oxygen is a function both of the concentration of the hydroxide and also of the temperature. There is, for each temperature, a minimum concentration of alkali necessary for a depreciation of the available oxygen in the reaction mixture. This alkali value may be roughly estimated from Figs. 2, 5 and 6. For certain alkalinities, there was either no reaction or else it was not measurable by the method used. An experiment with potassium permanganate and 12.4 N potassium hydroxide at room temperature (about 30°) for 240 hours gave no measurable loss of available oxygen.

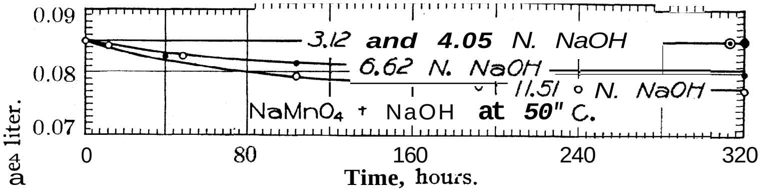

Fig. 5.

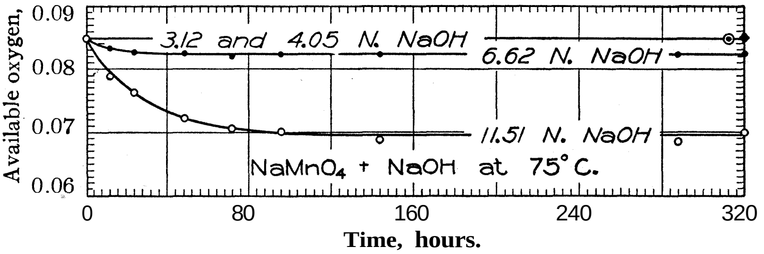

Fig. 6.

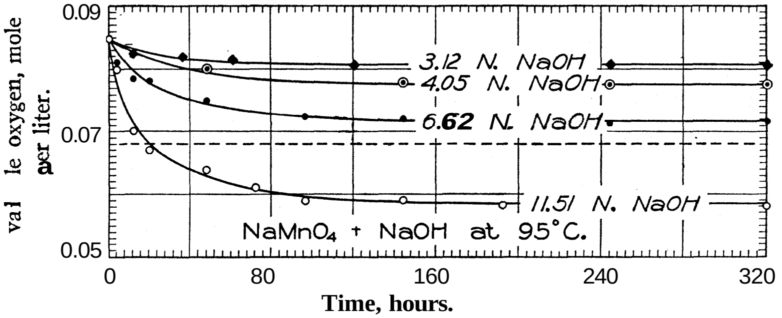

Fig. 7.

The color changes as identified by the naked eye in ordinary daylight through a north window for the potassium permanganate–potassium hydroxide reactions are given in Table II. Aliquot portions of the final and also of several of the intermediate reaction mixtures of the 9.52 and 12.4 N potassium hydroxide series at 95° were filtered through asbestos and the filters examined for any precipitate with negative results. Under the ultramicroscope samples of the intermediates showed no suspension; samples of the finals, when cooled and exposed to the air, seemingly underwent some decomposition with the formation of a suspension, hence a positive decision was impossible. A second aliquot of each of these two final solutions when diluted (1–5) with water changed in color to a pink accompanied by residue formation presumably in accordance with

TABLE II

COLOR CHANGES

Temp., °C.	Alkalinity			
	5.65 &*	7.09 *N*	9.52 *N*	12.4 *N*
50	Purple	Purple	Almost black	Black
75	Purple	Darker purple	Green	Green
95	Darker but not green		Purple → black → green	

$$3MnO_4^{=} + 2H_2O \longrightarrow 2MnO_4^- + MnO_2 + 4OH^{-\,9} \qquad (2)$$

A third aliquot of the hot 12.4 N potassium hydroxide final mixture was heated with a concentrated solution of potassium hydroxide and rapidly cooled; a fourth portion was treated with the concentrated alkali and evaporated isothermally at 95'—neither procedure giving uniform results, even on repetition. In a few cases a crystalline product separated out from the cooled samples, whereas a mixture of manganese dioxide and a crystalline substance usually separated from the evaporated sample. The crystalline product from both procedures was of a dark green color and had the following crystallographic properties.

The crystals were imperfect rhombohedrons, pseudo hexagonal, striated vertically, almost opaque, showed no pleochroism and no color change under the Nicol prism of the polarizing microscope. They were always contaminated with manganese dioxide and alkali, and usually permanganate crystals could also be detected. Purification of them was difficult as a drop of water would give a dark green solution which upon dilution turned pink with the precipitation of manganese dioxide

These crystallographic data show these crystals to be identical with potassium manganate.[10] Gorgeu[11] by a slightly different procedure obtained the double salt $KMnO_4 \cdot K_2MnO_4$ crystallizing in the monoclinic system. The above experimental data, however, warrant the conclusion that potassium manganate and not a double salt is the product of the reaction.

The color changes for the corresponding sodium permanganate–sodium hydroxide reactions are given in Table III. Most of the efforts to obtain a crystalline product from the 6.62 and 11.51 *N* sodium hydroxide series at 95° were unsuccessful, as the crystals generally disappeared or decomposed in the course of their isolation and purification. If a little water or dilute alkali was brought in contact with them a dark green mass resulted which upon being dried was found to be mainly manganese dioxide. The few which were secured were so contaminated with alkali that it was impossible to purify them for crystallographic analysis. Finally, by allowing a dark green reaction mixture to stand for twenty-four hours after treatment with concentrated sodium hydroxide, and then cooling somewhat, a good crop of well-formed dark green (almost black) crystals was obtained. A few of these upon treatment with a drop or two of water gave a dark green solution and on further dilution gradually turned pink. The remainder was dried by a short contact with blotting paper and then over sulfuric acid, and examined under the polarizing microscope.

TABLE III

COLOR CHANGES

Temp., °C.	Alkalinity			
	3.12 N	4.05 *N*	6.62 N	11.51 N
50	Purple	Purple	Dark purple	Greenish
75	Purple	Purple	Green	Greenish
95	Purple	Dark purple	Greenish	Green

They consisted of orthorhombic prisms striated vertically with cleavage parallel to the side pinacoid and gave a very dark purple color upon fresh fracture which quickly tarnished to a brown. The crystals rapidly decomposed in the air. Their color was so dark that no interference figures were observable with polarized light.

These crystals may have been either sodium manganate or the hydrated form.[12] The evidence favors some form of sodium manganate as a product of the reaction between sodium permanganate and sodium hydroxide.

At 95° with both the potassium and sodium series of reactions, a gas (identified as oxygen) was very slowly but visibly given off. There was no visible gaseous evolution in the 50 and 75° series.

The available oxygen titer is a measure of either the permanganate or manganate ions, hence any intermediate titer does not give the measure of either ion when both are present. Obviously then no conclusive calculations of the velocity constants are possible. For indicative purposes only, the authors calculated the approximate velocity constants using the commonly accepted integrated equations for first- and second-order reactions and also the differential equation

$$-\frac{d(MnO_4^-)}{dt} = 4\frac{d(O_2)}{dt} = K_2(MnO_4^-)^2 \qquad (3)$$

---

[12] Auger, *Compt. rend.*, 151, 69 (1910).

for a second order reaction and found that these values favored a reaction of the second order with respect to MnO_4^-.

These approximate constants also tend to support the intermediate formation of an hydrated ion as indicated in the equation

$$MnO_4^- + 4OH^- \longrightarrow MnO_4^- \cdot 4OH^- \longrightarrow MnO_4^= + 2H_2O + O_2 \qquad (4)$$

For example, in the 95° $KMnO_4$–KOH series, the constants (from the integrated bimolecular equation) for the alkalinities 5.65, 7.09, 9.52 and 12.4 N were substantially the same at 48, 96, 144 and 240 hours, respectively.

Jolles[13] prepared potassium manganate in accordance with Equation 1 and reported theoretical yields by using concentrated solutions of alkali and permanganate. Kassner and Keller[14] obtained a green solution but were unable to isolate any of the manganate. Without question, manganese dioxide is formed from the permanganate when reducing agents (particularly organic) are present. In the present investigation no microscopic evidence was found showing the formation of either precipitated or colloidal manganese dioxide. If it was a reaction product, it was present in less than colloidal dimensions or else was consumed in a subsequent or simultaneous reaction. Equation 1 then is substantiated in so far as the dioxide is concerned. Sackur and Taegener[15] found that Equation 1 was not reversed by the addition of atmospheric oxygen. No one has reported the study of the effect of atomic oxygen or ozone. If the non-reversibility of Equation 1 is accepted, then an equilibrium condition in the reactions reported herein cannot be considered. The method used by the authors in estimating the available oxygen is based on

$$4MnO_4^- + 12H^+ \longrightarrow 4Mn^{++} + 6H_2O + 5O_2 \qquad (5)$$

If the reaction indicated in Equation 1 proceeded to completion, only one-fifth of the total available oxygen in a reaction mixture would have been evolved. The initial titer of all of the potassium permanganate reaction mixtures was 0.156 mole of available oxygen. The maximum loss of available oxygen, then, on the basis of Equation 1, would be 0.0312 mole and the lowest possible solution titer would be 0.1248 (0.068, for the $NaMnO_4$ series) mole of oxygen. With the exception of the experiment involving the permanganate and 12.4 N hydroxide (see broken line in Fig. 4 and also Table IV) the oxygen titer in the potassium ion experiments was above 0.1248 mole. In this one exception the oxygen value did not become constant until it reached 0.101 mole or there was an oxygen loss of 35.2%, which is 15.2% more than is required by Equation 1. This extra loss might seem a substantiation of the equation

$$4MnO_4^- + 2H_2O \longrightarrow 4MnO_2 + 4OH^- + 3O_2 \qquad (6)$$

---

[15] Sackur and Taegener, Z. ***Elektrochem.,*** 18,718 (1912).

of Sackur and Taegener. Smith[16] assumed the formation of a peroxide from the oxygen which remained in solution. While this or a similar possibility has not been proved, an analogous compound $H_2O_2 \cdot K_2CrO_4$[17] has been isolated. Maksimov,[18] upon dissolving the potassium or sodium permanganate in solutions of their respective hydroxides, obtained the dioxide and oxygen and postulated the presence of the alkali peroxide in the resulting solution. As evolved oxygen was not detected in the reaction mixtures of lower alkalinity in this investigation, it is possible that a portion or all of the oxygen set free in the major reaction may have been consumed in the formation of an alkali peroxide. This, however, is not in harmony with our knowledge of the interactions of alkali peroxides and water. It is more likely that the oxygen was in solution for those reactions at the lower temperatures. For the $NaMnO_4$–$NaOH$ series of reactions the highest percentage loss of available oxygen for each of the temperatures (50, 75 and 95°) was 8.2, 17.6 and 23.5%, respectively.

One gram of manganese dioxide dried at 100° was added to a reaction flask containing 200 cc. of 12.4 N potassium hydroxide and 200 cc. of the potassium permanganate and the reaction allowed to proceed at 95°. The contrast in behavior between this mixture and another containing none of the dioxide is given in Table IV. At about seventy-two hours the reaction mixture turned brown in color and further analysis by the procedure previously used became impossible. The manganese dioxide not only increased the speed of the reaction but also brought about complete decomposition. A second experiment in which was used manganese dioxide from another source gave widely different results, except that the rate of decomposition was not apparently changed for the first twenty-four hours, but at the end of this time the brown decomposition resulted as before. These observations with added manganese dioxide confirm

in a general way the work of Brand and Ramsbottom,[19] although these investigators do not mention total decomposition as having taken place. The previous history then of the dioxide is of importance in this reaction.

The oxides of manganese are good adsorbents of both alkali metal and hydroxyl ions. The gel form of manganese dioxide has been prepared, which suggests that the hydrated sol form may also exist. Hydrated ferric oxide sol is not visible under the ultramicroscope and this invisibility may also hold for the possible hydrated manganese dioxide sol. The dioxide may also have been present as a true solution in the highly alkaline media used in this investigation. The final conclusion is that neither the colloidal nor the precipitated form of manganese dioxide was a reaction product of the reactions recorded in Fig. 2 for the reasons that: (a) the oxygen loss ceased beyond a certain time; (b) manganate was present in the final solutions (see Tables II and III); and (c) added colloidal and precipitated manganese dioxide caused the complete disappearance of the permanganate and manganate from the reactions studied in this and other investigations.

Gorgeu[20] obtained the double salt $KMnO_4 \cdot K_2MnO_4$ [or $(K_{1.5}MnO_4)_2$] from an alkaline solution of the two salts, which was soluble in a 20% potassium hydroxide solution without decomposition. Potassium mangani-manganate having the formula $5K_2O \cdot Mn_5O_{13}$ [or $(K_2MnO_{3.6})_5$] and sodium mangani-manganate having the formula $4Na_2O \cdot Mn_2O_5$ [or $(Na_4MnO_{4.5})_2$], have been described by Sackur[21] and also by Auger.[22] Morawsky and Stingl[23] found potassium in combination with the hydrated oxide or oxides of manganese and assigned to this the formula $Mn_4KH_3O_{10}$ [or $(K_{0.25}MnO_{2.125})_8 \cdot (H_2O)_3$]. In view of the above facts it seems likely that a more or less continuous series of (a) double salts, or (b) double oxides of the alkali metal and manganese existed in the reaction mixtures described in this paper. The identification of the hydrated manganates and not other manganese compounds is still unexplained.

Manganese Dioxide.—The character of the' manganese dioxide obtained and observed during these experiments is of interest. A suspension of manganese dioxide formed when a dark green reaction mixture, consisting probably of potassium permanganate, manganate, water and potassium hydroxide, was diluted. The color of this dioxide was almost jet black when wet, which slowly changed to a dark brown upon being washed and dried at 100°. The oxide obtained from different dilutions of the reaction mixture likewise varied in color—brownish-black to light

brown—as did the samples obtained from the permanganates of sodium and potassium. One of the authors[24] observed this same sort of color variation when working with alkaline permanganate solutions in the presence of organic reducing agents.

When a 400-cc. dark green alkaline reaction mixture of sodium permanganate and sodium hydroxide was diluted with 100 cc. of distilled water and evaporated over an open flame, a point was reached where a jelly-like precipitate of manganese dioxide was formed. This form and its conversion into a hydro-sol has been described by Witzemann.[25] His procedure for obtaining it varied from the above in that he reduced an alkaline permanganate solution with glucose and other organic material. The jelly obtained in the present investigation when diluted with water and dried at 100° formed a hard wax-like cake, which had a resinous luster upon fresh fracture. Inorganic jellies of this type have been described by Weiser[26] in a comprehensive review, but no mention is made of the jelly form of manganese dioxide. This jelly was quite stable in alkaline solution, but upon dilution changed into the suspensoid form.

Summary

1. Aqueous solutions of potassium and sodium hydroxides were prepared which when acidified with sulfuric acid did not reduce a dilute solution of potassium permanganate.

2. Aqueous solutions of potassium and sodium permanganate were prepared which were free from both precipitate and colloidal-size particles of the oxides of manganese.

3. Studies of the reactions between these permanganates and their corresponding hydroxides at 50, 75 and 95° show that *(a)* the reactions are very slow; *(h)* an increase in temperature increases the speed of the reactions with progressive lowering of the available oxygen; (c) beyond a certain minimal concentration of alkali an increase in the alkalinity progressively lowers the available oxygen to constancy with time; (d) potassium manganate and oxygen and sodium manganate and oxygen were isolated and identified as reaction products in their respective reaction series; (e) manganese dioxide either in precipitated or colloidal state was not isolated or identified in these reactions: (f) both series of reactions are probably bimolecular and the equation

$$4MnO_4^{-} + 4OH^{-} \longrightarrow 4MnO_4^{=} + 2H_2O + O_2$$

satisfactorily accounts for the reactions at 50 and 75° but not at 95°; (g) at 95° the reaction mixtures for both the Na^+ and K^+ series lost more

available oxygen than is demanded by the equation in (f); and *(h)* the results obtained are best explained on the assumption that a continuous series of double salts of manganese or double oxides of the alkali metal and manganese were formed in the strongly alkaline solutions.

4. The initial presence of precipitated manganese dioxide in a reaction mixture brings about an ultimate decomposition of the perrnanganate to the dioxide in a relatively short time when compared with the time for the reactions summarized in **3** *(a)*.

5. Slow stirring of a reaction mixture increases the speed slightly without appreciably influencing the point of apparent rest in the reaction.

6. A new method for the preparation of manganese dioxide gel is described.

THE ELECTROMOTIVE ACTIVATION OF OXYGEN

BY ARTHUR B. LAMB AND LUCIUS W. ELDER, JR.

RECEIVED DECEMBER 1, 1930 PUBLISHED JANUARY 12, 1931

The achievement of a fuel cell, in which the free energy of combination of hydrogen or some comparable gaseous fuel with oxygen is converted directly into electric energy, has encountered its most serious difficulties at the oxygen electrode. Gaseous oxygen establishes its potential sluggishly and imperfectly on inert electrodes at ordinary temperatures, even on open circuit, and an oxygen electrode on closed circuit polarizes at once if any appreciable current is withdrawn.

These difficulties have been overcome to some extent by operating the electrodes in suitable electrolytes at elevated temperatures.[1] Similarly progress has been made in the electromotive activation of oxygen by the use of catalysts. These catalysts have been of two types. In the one type, the catalytic action is confined to the surface of the electrode, the catalyst being either a part of the electrode itself or a reaction product formed upon its surface, which enhances the electromotive activity of the gaseous oxygen. Electrodes where catalysts of this type are effective are the familiar platinized platinum and similar electrodes, and the electrode of copper immersed in a solution of potassium hydroxide described by K. A. Hofmann.[2] In the second type the catalytic action takes place throughout the bulk of the electrolyte. This type of catalyst must be susceptible of rapid oxidation by gaseous oxygen under the conditions in the cell, and its oxidation product must be a rapid depolarizer.

[1] Haber and Bruner, Z. *Elektrochem.*, 10, 712 (1904); Taitelbaum, *ibid.*, 16, 286 (1910); Baur, Treadwell and Trümpler, *ibid.*, 27, 199 (1921); *Helv. Chim. Acta*, 4, 325 (1921); Rideal and Evans, *Trans. Favaday Soc.*, 17,466 (1921).

[2] Hofmann, *Ber.*, 51,1526 (1918); 52,1185 (1919); 53,914 (1920).

This second type of catalyst, or bulk catalyst, as one may call it, has the marked advantage over the first type, or surface catalyst, in that with it the chemical oxidation of the catalyst by the gaseous oxygen, which in general is a relatively slow step in the process as a whole, can take place far more abundantly, and with adequate stirring the oxidized catalyst can be brought into effective contact with the electrode. Nernst[3] patented this method some time ago, and suggested a variety of catalysts for its execution, but apparently it has not as yet been put into successful operation. Nevertheless, the method has seemed to us to be of considerable promise, and the experiments which we shall describe below have been directed toward its further development.

The catalyst to be used in such a method of overcoming the easy polarizability of the oxygen electrode should meet several requirements. As pointed out above, it should be susceptible of rapid oxidation by gaseous oxygen under the conditions in the cell, and its oxidation product should be a rapid depolarizer. But it is also desirable that the normal potential of the catalyst system approximate that of the reversible oxygen electrode in the electrolyte used. Other things being equal, this will afford the highest working potential for the electrode.

There are a number of catalyst systems which give rapidly adjusting and reversible potentials, but unfortunately they absorb oxygen very slowly. Conversely, there are several such systems which absorb oxygen rapidly, but their potentials are very low. Examples of the former group are the thallous–thallic and vanadyl–vanadic acid systems; of the latter are the vanadous–vanadic and the chromous–chromic systems. The ferrous–ferric system occupies a somewhat favorable intermediate position; it establishes its potential with great rapidity on various electrodes; it has a fairly high normal potential; but it reacts with gaseous oxygen with only slight (though measurable) rapidity. However, the kinetics of this reaction have been studied to some extent, and a variety of factors which increase its velocity, particularly secondary catalysts, such as copper salts, platinum black and charcoal, have been recognized.

We have, therefore, undertaken a further study of the velocity of oxidation of ferrous solutions by gaseous oxygen, since this is the limiting factor in the utility of the ferrous–ferric system as a bulk catalyst. For this study we have perfected a method of determining the rate of oxidation of ferrous solutions by means of electromotive force measurements. Using this method we have ascertained the effects of a variety of factors on the velocity of the reaction. Finally, we have tested the actual depolarizing efficiency of certain of the systems which had shown the maximum velocity of reaction with gaseous oxygen.

Procedure and Apparatus

Velocity of Oxidation of Ferrous Sulfate Solutions by Gaseous Oxygen.—Oxygen in air was bubbled through the solution to be studied and the progress of the oxidation was followed by measurements of the potential of a bright platinum electrode immersed in the solution.

The apparatus (see Fig. 1), constructed chiefly of pyrex glass, comprised a short, wide test-tube **(A)** containing the solution of iron salt (50.2 cc.); a tubular stirrer (S), with four slightly re-curved tips (C) at its base at right angles to its axis; a baffle (D) to prevent undue swirling of the liquid; an electrode (K); and a saturated potassium chloride bridge (F), connecting the ferrous salt solution with *a* reservoir (H), filled also with saturated potassium chloride solution and connected in turn with the tip (N) of the calomel electrode. The whole was immersed to within a few millimeters of its top in a thermostat bath (P) maintained at a temperature of 30.0 ± 0.1°.

The stirrer was rotated by means of an induction motor at constant speed and rapidly enough to force air through the solution in a fine, white foam. The standard rate of stirring was 1250 r. p. m.

The electrode was of bright platinum wire 2–3 cm. in length. It and the salt bridge (F) were lowered into the solution only at the time of reading. When not in use it was kept short-circuited with several duplicate electrodes in a ferrous–ferric salt mixture, and was washed and ignited to a red heat before each run. In this way constant and reproducible potentials could be secured. Preliminary measurements showed that the potential of the electrode in any given solution was independent of the presence of the gaseous oxygen.

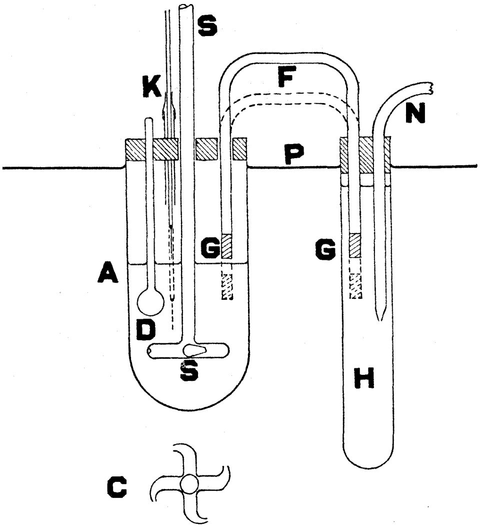

Fig. 1.—Apparatus for kinetic measurements.

The calomel electrode was of the saturated type prepared according to the method of Fales and Mudge,[4] using all the customary precautions in purifying the materials. Three such electrodes were prepared. Their potentials checked against each other from time to time showed an average agreement to within ±0.0005 v. Fales and Mudge give the absolute potential of this electrode as $E_0 = 0.5266$ v., which corresponds to E_h

---

[4] Fales and Mudge, This journal, 42, **2453** (1920).

$= +0.253$ v. on the hydrogen scale. The potentiometer was of the compensating type, using an Eppley–Weston standard cell.

Materials.—The ferrous sulfate used was recrystallized from one to two per cent. sulfuric acid and dried to incipient efflorescence in air. Prepared in this way we found that it could be kept for months without appreciable oxidation. The solutions were made up by weight from the above material, and their composition checked by analysis. Ferrous iron was determined in the usual manner by titration with potassium permanganate. Ferric iron was titrated in partially oxidized solutions containing 0.005 to 0.01 N Fe^{+++} by iodimetry under carbon dioxide, using specially prepared reagents.[5] The initial ferric-ion concentration of the "unoxidized" stock solution was calculated from this by applying Equation 3 (see below) to the corresponding potentials. This equation holds fairly accurately over this small range at such low concentrations. For subsequent runs it was only necessary to weigh out a sample of equal weight to make the same volume of solution and compare its initial potential with that of the calibration, as outlined above.

Computation of the Progress of the Oxidation from the Potentials.—We had hoped to be able to compute the progress of the oxidation directly from the observed change in potential AE, since

$$\Delta E = \frac{RT}{F}\ln\left[\frac{\gamma_2{}^{+++}\,\mathrm{Fe_2}{}^{+++}}{\gamma_1{}^{+++}\,\mathrm{Fe_1}{}^{+++}} \times \frac{\gamma_1{}^{++}\,\mathrm{Fe_1}{}^{++}}{\gamma_2{}^{++}\,\mathrm{Fe_2}{}^{++}}\right] \tag{1}$$

where γ^{++} and γ^{+++} represent the activity coefficients of the ferrous and ferric ions and the subscripts 1 and 2 refer to the initial and final concentrations, respectively. This equation becomes

$$AE = \frac{RT}{F}\ln\left[\frac{(\mathrm{Fe_1}{}^{+++} + AC)}{\mathrm{Fe_1}{}^{+++}} \times \frac{\mathrm{Fe_1}{}^{++}}{(\mathrm{Fe_1}{}^{++} - \Delta C)}\right] + \frac{RT}{F}\ln\left[\frac{\gamma_2{}^{+++}\,\gamma_1{}^{++}}{\gamma_1{}^{+++}\,\gamma_2{}^{++}}\right] \tag{2}$$

where AC represents the change in the concentration of the ferric ion corresponding to the change in potential AE.

From Equation 2 it is clear that to compute AC in this way for any value of Fe^{++} and Fe^{+++} we must know, in addition to AE, either the activity coefficients of the ferrous and ferric ions under the conditions of our experiments (which unfortunately we do not), or we must be able to consider the last term on the right of the equation as equal to zero. In this case Equation 2 can easily be rewritten as

$$\Delta C = \mathrm{Fe_1}{}^{+++}\,\mathrm{Fe_1}{}^{++}\left[\frac{e^{(F\Delta E/RT)} - 1}{\mathrm{Fe_1}{}^{++} + \mathrm{Fe_1}{}^{+++}e^{F\Delta E/RT}}\right] \tag{3}$$

which gives AC directly in terms of known or measured quantities.

We have conducted numerous experiments to test this latter alternative, measuring the changes of potential produced by the addition of known amounts of potassium permanganate to solutions of ferrous sulfate. Corrections were applied for the disturbing effects of the reaction

---

[5] Morse and Burton, Am. *Chem.* J., 10, 321 (1888).

products from the potassium permanganate which will be explained later in another connection. We found that the change in concentration of the ferric ion could be calculated accurately by means of the simplified Equation **3** only when the concentrations lay within certain narrow limits, namely, when the ferric ion was less than about 0.001 *M* and the sulfuric acid was between 1.0 *M* and 0.01 M. When the concentrations departed from these limits, the divergence of the observed potentials from the calculated values became considerable and in extreme cases the discrepancy was as much as 500%. This is shown by the typical results collected in Table I.

TABLE I

COMPARISON OF CALCULATED AND ACTUAL CONCENTRATIONS

Solution, m. mol.	ΔE obs. (corr.), mv.	ΔC Calcd. from ΔE, m. mol.	ΔC Actual from $KMnO_4$, m. mol.	Solution m. mol.	ΔE obs. (corr.), mv.	ΔC Calcd. from ΔE, m. mol.	ΔC Actual from $KMnO_4$, m. mol.
$Fe^{+++} = 0.405$ $Fe_2SO_4 = 183$ $H_2SO_4 = 11.0$	33.0	1.03	0.98	$Fe^{+++} = 0.172$ $FeSO_4 = 150$ $H_2SO_4 = 3000$	32.5	0.422	1.94
	46.0	1.94	1.95		46.7	.855	3.87
	54.8	2.87	2.93		54.1	1.18	5.80
	60.3	3.61	3.90		62.2	1.68	7.74
$Fe^{+++} = 3.98$ $FeSO_4 = 178$ $H_2SO_4 = 12.0$	5.4	0.90	0.98	$Fe^{+++} = 5.35$ $FeSO_4 = 131$ $H_2SO_4 = 500$	3.9	0.82	0.84
	10.1	1.83	1.95		4.5	.95	.98
	12.8	2.44	2.93		4.6	.98	1.00
	15.3	3.05	3.90		8.1	1.82	1.84

The explanation of these discrepancies probably is that at high concentrations of sulfuric acid or of ferric ions the activity coefficients are markedly different from unity; at low concentrations of sulfuric acid, on the other hand, the hydrolysis of the ferric salt becomes of importance. Whatever the explanation, it is clear that this direct method of computation cannot be used successfully.

Failing then an accurate method of calculating the amount of oxidation from the corresponding potential change, resort was taken to a purely empirical method of calibration. Blank experiments were run in the solutions whose rates of oxidation were to be measured, where a known amount of oxidation was secured by the addition of measured quantities of potassium permanganate. The observed potential changes thus obtained were then corrected for the dilution produced by the introduction of the permanganate solution and for the effect of the potassium and manganous ions. These correction terms were ascertained by adding to a control solution equal volumes of a solution of potassium and manganous sulfates to approximately the same concentration as that resulting from the reduction of the standard potassium permanganate. The resulting potential change is the desired correction term. This procedure affords a measure of the change in potential due solely to the introduction of oxygen.

The following data for a particular solution will serve as an illustration (Table II).

TABLE II

CALIBRATION DATA FOR $FeSO_4$ 0.148 M; H_2SO_4 1.0 M

Initial $E_C = +0.3614$

$KMnO_4$, 0.002528 N, cc.	ΔC equiv. concn. of oxygen per liter of original $FeSO_4$	AE observed, mv.	Correction term. mv.	AE corrected, mv.
9.85	0.000495	13.8	− 1.5	15.3
19.70	.000991	22.9	− 3.7	26.6
29.55	.001487	30.1	− 8.5	38.6
39.40	.001982	36.3	− 9.5	45.8

The corrected values of AE were plotted against the corresponding values of AC and the resulting curve served as a calibration curve (Fig. 2). In using it, the initial potential of the system being observed was compared with the initial potential of the calibration curve and the value of AC corresponding to this difference was subtracted from each subsequent value of AC read from the curve. In other words, the curve applied to each run was referred to the initial potential of that run as origin. An example follows, using the calibration data given above.

In order to facilitate comparison of the velocities under varying conditions, we have computed velocity constants from corresponding values of t and AC, both assuming a first- and a second-order reaction. In most cases reasonably constant values (average deviation from the mean = ±10%) were obtained on *both* assumptions. This result is readily understood when it is appreciated that in most of our experiments only about one per cent. of the ferrous salt present was oxidized, so that experimental and other variations would mask the relatively small differences in the trend of the constants calculated on the two different assumptions. In a later section experiments to ascertain more definitely the order of the reaction are described. Since our aim here was primarily to secure a means of comparison, we have, in general, used the constant for a second order reaction

$$K_2 = 1/t \frac{\Delta C}{\text{Fe}_1^{++}(\text{Fe}_1^{++} - \Delta C)}$$

as easier to compute arithmetically. Occasionally the velocity measurements have given constants with a drift or trend, sometimes in the one direction and sometimes in the other, for no assignable reason. Duplicate measurements have often eliminated this uncertainty, so that it has apparently been due to some accidental effect. Where such drifting constants have been obtained, the average value is relatively uncertain and we have indicated this by enclosing such values in parentheses.

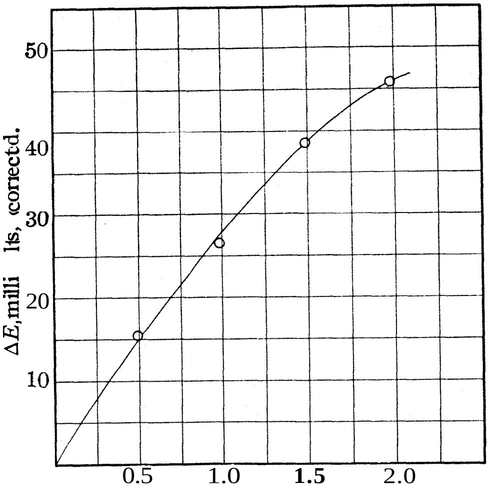

Fig. 2.—Calibration **curve.**

The usual average deviation of the constants in any one run was, as stated above, ±10%. The usual reproducibility of our results for a given solution is shown, for instance, by the average values of the constant (K_2) obtained in seven duplicate runs on the solution $FeSO_4$ 0.169 *M*, H_2SO_4 0.50 *M*, as follows: 313, 338, 265, 263, 307, 261, 259 X 10^{-5}; grand average 287 × 10^{-5} ± 9%.

Experimental Results

Effect of Variations in the Rate of Stirring.—The normal rate of stirring, as pointed out above, was 1250 r. p. m. Although the "atomization" of the injected air was excellent, it was necessary to find out whether the observed rate of oxidation was limited by the rate of solution of the oxygen, or by the rate of reaction of the dissolved oxygen. To accomplish this we have varied the rate of stirring under various conditions over relatively wide ranges. The results are shown in the following table (Table V) where the average values of the constants obtained in the various runs are recorded, computed on the assumption of a second-order reaction.

TABLE V

EFFECT OF RATE OF STIRRING ON VELOCITY OF REACTION

$FeSO_4$ 0.15 *M*; H_2SO_4 1.0 *M*;				$FeSO_4$ 0.15 *M*; H_2SO_4 0.5 *M*; 1 g. of charcoal per 50 cc.			$FeSO_4$ 0.15 M; H_2SO_4 1.0 M 10 g. of charcoal per 50 cc.		
	Kz × 10^5				K_2 × 10^5			K_2 × 10^5	
Expt.	720 r. p. m.	1250 r. p. m.	1640 r. p. m.	Expt.	1250 r. p. m.	1640 r. p. m.	Expt.	1250 r. p. m.	1920 r. p. m.
1	290	253	349	1	81300	75000	1	305000	713000
2	271	289	268	2	65400	84100	2	311000	408000
3	...	295	267	3	79500	...		...	...
4	...	(309)	...	4	67500	...			
5	...	(211)	...	5	66400	...			
	...	...	...	6	66900	...		...	...
Mean	280	279	295	Mean	71200	79500	Mean	308000	560000
K_2 at 1250 r.p.m. = 6.36 × 10^{-5} eq. of O_2 per liter per hr.				K_2 at 1250 r. p. m. = 0.0115 eq. of O_2 per liter per hr.			K_2 at 1250 r. p. m. = 0.0328 eq. of O_2 per liter per hr.		

It is obvious from the above results that only those reactions which proceed at a rate greater than about 0.0115 equivalent of O_2 per liter per hour, corresponding to a second-order constant K_2 of about 0.7 (i.e., 70,000 × 10^{-5}), are affected appreciably by the rate of stirring at a rate of 1250 r. p. m.

Effect of the Variation of Concentration of the Oxygen.—The times required for 0.5% oxidation by means of air and pure (commercial) oxygen, in different portions of the same solution, are given in the following table (Table VI).

TABLE VI

EFFECT OF THE CONCENTRATION OF THE OXYGEN

Times to 0.5% oxidation: $FeSO_4$ 0.15 M; H_2SO_4 0.50 M

Expt.	Air, hrs.	Oxygen, hrs.
1	14.5	3.10
2	14.4	2.50
3	10.3	..
4	11.2	..
5	13	..
	12.7 ± 1.6	2.80 ± 0.3

The ratio of the times is 1:4.54, or substantially what would be expected (1:5.0) on the assumption that the reaction is unimolecular with respect to the oxygen.

Effect of Variation in the Concentration of the Ferrous Sulfate.—As pointed out above, the percentage oxidation of the ferrous sulfate in these experiments was relatively so inconsiderable that the constancy of any particular "velocity constant" based on a single initial concentration affords no certain evidence as to the order of the reaction with respect to the ferrous sulfate. To obtain more conclusive evidence on this point we have carried out two sets of comparative experiments where there were marked differences in the initial concentration of the ferrous sulfate, and have compared the times required to produce 1% oxidation. The data are presented in Table VII.

TABLE VII

EFFECT OF THE CONCENTRATION OF FERROUS SULFATE

Ratio of total ferrous concentrations........... 1:8.0....................... 1:7.3

Ratio of velocities............1:5.3.......................1:6.5

One can see from the above results that the initial velocities are approximately proportional to total ferrous salt concentrations in the two pairs of comparable solutions. This indicates, since the oxygen concentration was kept constant throughout the runs, that the reaction is approximately bimolecular with respect to the ferrous salt. The deviations are about what one would expect if the velocity were directly proportional to the activity of the ferrous ion rather than to the total ferrous salt concentration, but the data are hardly accurate enough to justify any numerical calculation.

Effect of Variation in the Concentration of the Acid.—The data obtained bearing on this point are collected in Table VIII.

TABLE VIII

EFFECT OF VARIATION IN THE CONCENTRATION OF THE ACID

$FeSO_4$ *M* H_2SO_4 *M*	0.146 0.008	0.176 0.012	0.146 0.055	0.169 0.23	0.17 0.50	0.181 1.0	0.170 2.0	0.15 3.0
Expt.	$K_2 \times 10^5$

2	(1250)	580	377	357	265	289	(245)	234
3	..	...	...	281	263	295	...	
4	..	...	...	236	307	...	...	
5	..	...	...	269	261	...	...	...
Mean	(1265)	554	415	286	287	279	(229)	264

These mean values of K_2 are also plotted in Fig. 3. It is evident that change of acid concentration between the limits of 3.0 M and 0.23 M produces scarcely any change in reaction velocity; indeed, the change is scarcely beyond the limits of error. A decrease in acid concentration below 0.23 M, however, increases the velocity, the rate of increase rising rapidly as the acid becomes more dilute. This relation is in accord with the fact that acid solutions of ferrous sulfate are relatively stable in air, whereas ferrous hydroxide absorbs oxygen from air with great rapidity.

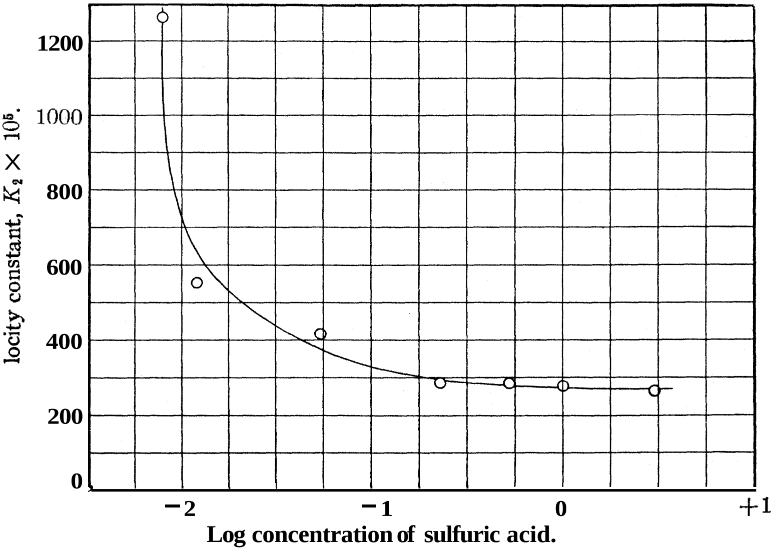

Fig. 3.—Variation of the velocity with the concentration of the sulfuric acid. $FeSO_4$, 0.15–0.18 M.

Effect of Neutral Salts.—Sufficient of each of a variety of salts was added to portions of a stock solution to be 0.1 M. The velocity constants obtained are collected in Table IX.

[a] These solutions contained 0.23 M H_2SO_4.

Similar experiments were made with Ag_2SO_4 0.1 M and Hg_2SO_4 0.001 M, and except for the fact that they were in whole or in part reduced by the ferrous sulfate, the results were substantially identical with those obtained with the solutions already cited.

It follows from the data that these salts are practically without effect on the velocity of oxidation of the ferrous sulfate by the gaseous oxygen.[6]

The Effect of Copper Sulfate.—It has long been known that copper salts accelerate the oxidation of ferrous salt solutions by oxidizing agents[7] and by gaseous oxygen.[8] The results of our measurements are given in Table X.

The mean values in 0.23 *M* acid with varying concentrations of copper sulfate are plotted in Fig. 4; those obtained with 0.1 copper sulfate in varying concentrations of acid are plotted in Fig. 5.

These results show that copper sulfate has a pronounced effect on the oxidation of the ferrous salt solutions, and that, in sharp contrast with solutions containing no copper sulfate, the rate of oxidation increases rapidly with increasing acid concentration. It also appears that in 0.23 M sulfuric acid the accelerating effect of the copper sulfate increases markedly with its concentration, following quite accurately a logarithmic relationship. In lower concentrations of acid the increase with concentration is less marked, and at the lowest concentration there appears to be no well-defined change with the concentration.

Potassium Ferrocyanide Solutions.—It was of interest to measure the rate of oxidation of potassium ferrocyanide by gaseous oxygen be-

---

[6] Chromic sulfate showed a slight depressing effect.

cause, in contrast to the simple ferrous salts, it can be studied in neutral solution.

Potassium ferrocyanide can be titrated against permanganate in very dilute solution, when acidified, by the method of de Haën.[9] Solutions more concentrated than about 0.05 M, and especially solutions free from acid, deposit a precipitate of potassium manganese ferrocyanide.

We have, therefore, tried iodine for this titration. A 0.10013 M solution of freshly recrystallized and air-dried $K_4Fe(CN)_6{\cdot}3H_2O$ was prepared, and portions of it were shaken with an excess of a 0.0766 N solution of iodine under carbon dioxide. After fifteen minutes the excess iodine was titrated back with a 0.0985 N solution of thiosulfate. Two analyses of the stock solution by this method gave its normality as 0.09982 M and 0.10002 M, or on the average 0.09992, agreeing with the calculated value of 0.10013 to within two-tenths of one per cent.

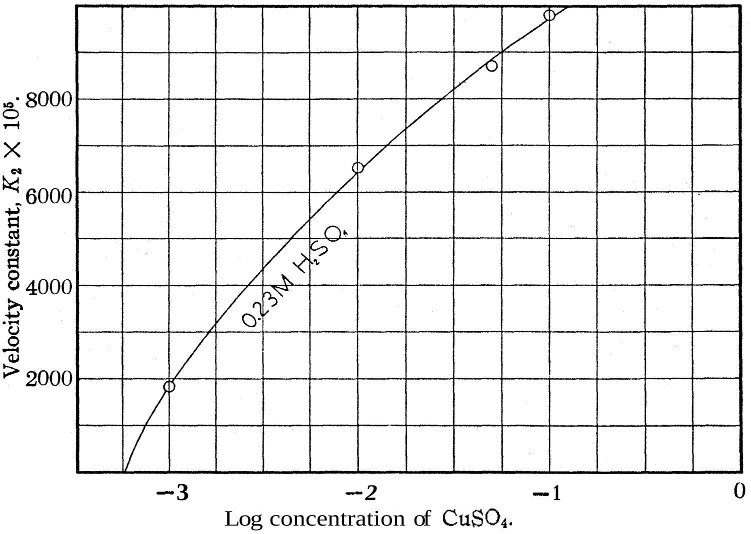

Fig. 4.—Variation of the velocity with the concentration of copper sulfate. $FeSO_4$, 0.15–0.18 M.

A calibration of the potential was carried out against known mixtures of ferro- and ferricyanide, using potassium iodide 0.5 M as a blank solution, by the method as outlined under the similar calibration of the ferrous–ferric potential. The results are given in Table XI.

Two oxygen absorption experiments were now run with a neutral solution of 0.150 *M* ferrocyanide, and identical values of $K_2 = 111 \times 10^{-5}$ were obtained. This shows that in neutral solution the ferrocyanide

.03940	152.9	13.7	139.2

is oxidized about one-half as fast as is ferrous sulfate in solutions from 3 M to 0.01 *M* in sulfuric acid.

Two similar experiments were then made with portions of this same stock solution to which copper sulfate 0.001 M had been added. Values of $K_2 = 121$ and 151×10^{-5}, averaging 136×10^{-5} were obtained. It is evident that the copper sulfate produces no significant change in the velocity. This may be due to the fact that a precipitate of copper ferro- and ferricyanide is formed in the solution to which it is added, so that the copper ion may be present only in very minute amounts. It is of interest that the velocity of oxidation of the neutral ferrocyanide solution is substantially equal to that of the acid solutions of the ferrous sulfate. Either the ferrocyanide ion is directly oxidized by the gaseous oxygen, or the rapidity of oxidation of the ferrous ion in the neutral solution, in spite of its infinitesimal concentration, is tremendously greater than in the acid solution of the simple ferrous salts.

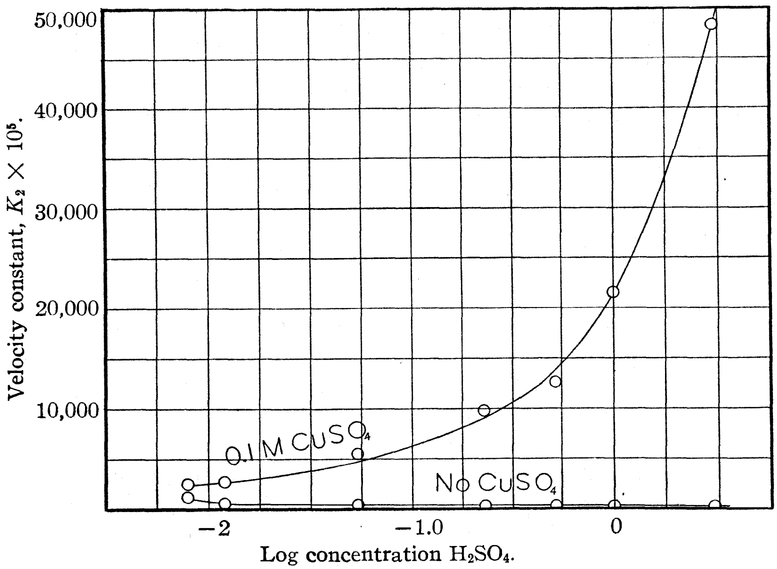

Fig. 5.—Effect of copper sulfate at various concentrations of sulfuric acid.

Solutions Containing Pyrophosphates.—Solutions of ferrous sulfate containing sodium pyrophosphate were found by Spoehr[10] to absorb oxygen rapidly, the originally green solution becoming deep red. Later Smith and Spoehr[11] measured the rate of the oxidation in order to ascertain the order of the reaction. These measurements were made by shaking 150 cc. of the solution with oxygen at constant pressure in a mechanically operated shaker making 120 strokes per minute. They found that the half-period of the reaction averaged about 57.5 seconds, irrespective of the concentration of the reactants. They concluded from this that the reaction was of the first order.

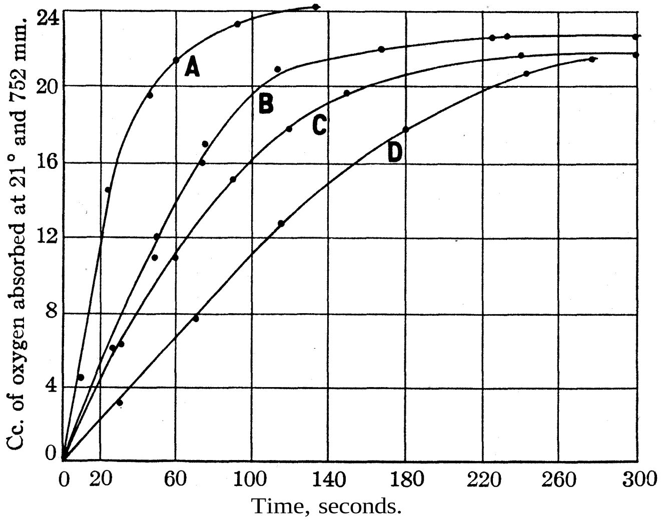

Fig. 6.—Velocity of oxidation of solutions containing pyrophosphate at different rates of stirring. A—170 r. p. m.; B—130 r. p. m.; C—120 r. p. m. (Smith and Spoehr); D—90 r. p. m.

We have repeated the measurements of Smith and Spoehr, adhering as closely as possible to the exact dimensions of their apparatus and to all the details of their procedure. With 150 cc. of a solution containing one gram of ferrous sulfate and 4.82 g. of sodium pyrophosphate, identical with that employed by them, and shaken at a rate of 130 strokes per minute, a half-period of about fifty seconds was obtained, confirming the numerical results of Smith and Spoehr as closely as could be expected.

However, we then repeated this experiment *at other rates of stirring. Our* results, together with the corresponding ones of Smith and Spoehr, are shown in Fig. 6.

It can be seen from these results that the velocity is largely a matter of the rate of stirring. Indeed, the half-period plotted against the rate of

---

[10] Spoehr, THIS JOURNAL. 46, 1499 (1924).

[11] Smith and Spoehr, *ibid.*, 48, 107 (1926).

stirring gives a nearly linear curve. What is being measured is, therefore, not the rate of the chemical reaction itself, but a *rate of diffusion*. It is well known that this, in general, follows a logarithmic course and, therefore, simulates a first order reaction. The conclusion of Smith and Spoehr as to the order of the chemical reaction, based on these measurements, is, we believe, unwarranted.

In order to compare their results in ferro-pyrophosphate solution with our results in solutions of other iron salts, we have measured the rate of oxidation in this solution by our usual electrometric method. The potential change was calibrated in terms of oxygen by fitting to the apparatus of Smith and Spoehr an electrode, a salt bridge and a calomel electrode. The solutions were mixed under purified nitrogen, and the potentials observed before and after successive additions of pure oxygen, measured under known conditions of temperature and pressure in the calibrated buret included in the apparatus. A leveling bulb was attached to the buret for pumping and measuring the gas at atmospheric pressure. The oxygen introduced was not always completely absorbed, but the volume of gas absorbed was measured after ten minutes' shaking, after which no appreciable change in volume was observed. Under these conditions the potential measured before and after the volume measurement was the same to within ±0.2 millivolt. The results obtained, compared with those on a corresponding solution of ferrous sulfate and a similar solution of ferrous sulfate containing charcoal (to be described later), are shown in Table XII.

Table XII

Comparison of Results

	$FeSO_4$ 0.15 *M* $Na_2P_2O_7$ .023 *M*	$FeSO_4$ 0.15 *M* H_2SO_4 1.0 *M*	$FeSO_4$ 0.18 *M* H_2SO_4 1.0 *M* Charcoal 10 *g*.
E_C, v..........	−0.114	+0.361	+0.500

Eq. O_2/1 hr....	0.049	0.000053	0.038

It can be seen that the velocity of oxidation is indeed high, about 1000 times greater than in the ferrous sulfate solution. However, the potential is so very much lower that the solution is of little interest to us in the present investigation; indeed, it is scarcely more practical than such systems as the vanadous–vanadic, etc., previously referred to.

Heterogeneous Systems

The Effect of Coconut Charcoal.—A sample of granular, commercial, steam-activated coconut charcoal of the variety used in gas masks was ground in a mill and screened. Two lots were prepared, one of fineness between 60 and 100 mesh, and one finer than 100 mesh. Introduction of 1 g. of the 60–100 mesh material into 50 cc. of a 0.150 M $FeSO_4$–0.50 *M*

H_2SO_4 solution gave in duplicate experiments velocity constants (× 10^5) of 81,300 and 65,400, respectively. This is an increase of about 200 times, as compared with the velocity in the solution in the absence of the charcoal.

A series of experiments in duplicate was then made, using this same electrolyte, to find out the variation of the velocity with the amount of the charcoal. The average values of the velocity constant are given in Table XIII and are plotted in Fig. 7.

TABLE XIII

VARIATION OF THE VELOCITY WITH THE AMOUNT OF CHARCOAL

[a] Average of six experiments whose average deviation was ±6000.

These results show that the accelerating effect of the charcoal is approximately proportional to its amount. The slight decrease with amounts up to 1 g. and the considerable decrease with 10 g. may well be due to the less efficient stirring under these conditions.

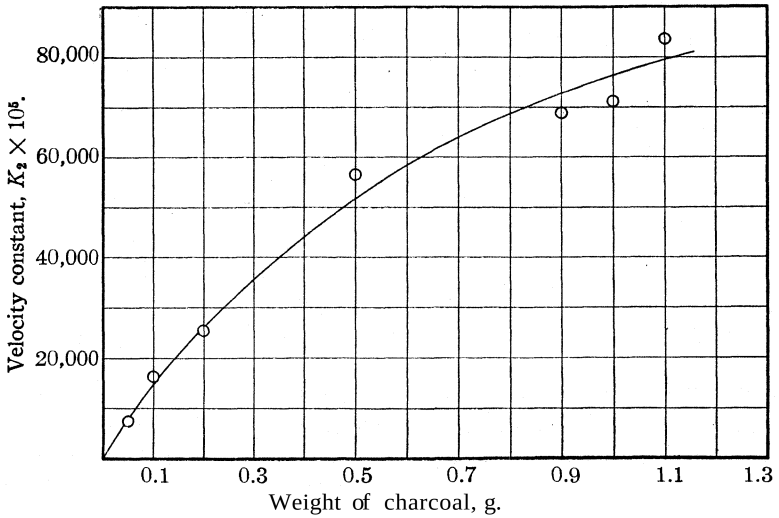

Fig. 7.—Variation of the velocity with the weight of the charcoal.

Two series of experiments were then made to find out the variation, if any, of this effect with the acidity of the ferrous sulfate solution. In one series 1 g. and in the other 10 g. of charcoal were used. The results are collected in Table XIV, and are plotted in Fig. 8.

Table XXV

Variation or the Effect of the Charcoal with the Acidity

It can be seen that with a constant amount of charcoal the velocity varies considerably with change in the concentration of the acid, a maximum velocity being reached in each case at 0.50 to 1.0 *M* acid.

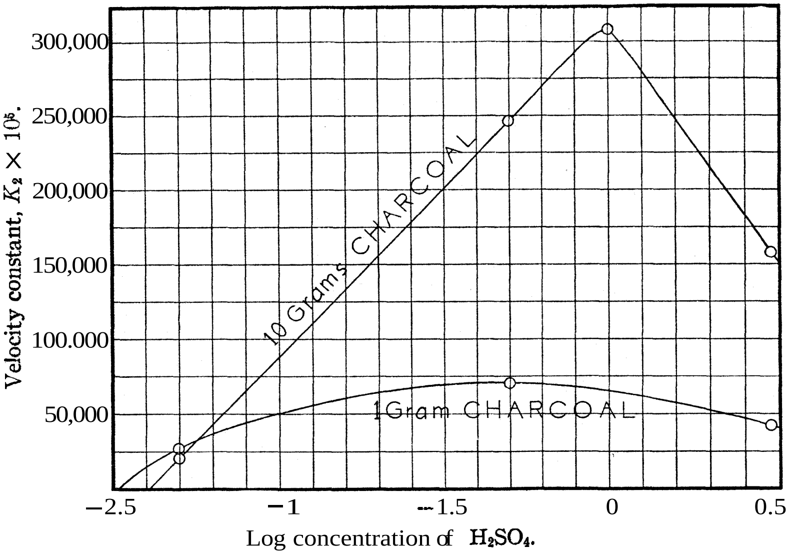

Fig. 8.—Variation of the velocity in the presence of charcoal with the concentration of the sulfuric acid. $FeSO_4$, 0.15 M.

Experiments were also made on the effect of charcoal on the rate of oxidation of solutions containing copper sulfate. The results of these experiments and of the corresponding blank experiments are collected in Table XV.

These results show that the velocities of oxidation with and without the copper sulfate are substantially the same, indicating that the action of the copper sulfate in the presence of the charcoal is either suppressed, or at most is only arithmetically additive.

To ascertain whether these data were significantly affected by the

TABLE XV

SIMULTANEOUS EFFECT OF CHARCOAL AND COPPER SULFATE

Solution: 0.150 *M* $FeSO_4$; 0.50 M H_2SO_4

Catalysts added	... ...	0.10 M $CuSO_4$ ...	.... 1 g. charcoal	0.10 M $CuSO_4$ I g. charcoal
$K_2 \times 10^5$	263 307	13300 12000	79500 67500	(77000) (66000)
$K_2 \times 10^5$ (Mean)	285	12600	73500	(72000)

alkaline ash of the charcoal (or by a possible preferential adsorption of sulfuric acid) 1-g. samples of charcoal of different degrees of fineness were each shaken with 50 cc. of 0.5 M sulfuric acid, filtered off by suction and the concentration of the filtrates determined by titration. It was found that the concentration had changed by about 2%, corresponding to a removal of about 0.0005 mole of sulfuric acid from the solutions by the charcoal. No significant variation of this percentage was observed with the different mesh sizes of the charcoal. This change in concentration is too small to have been of any significance in the above measurements.

Similar experiments were made with a solution 0.5 M in sulfuric acid and 0.01 M in copper sulfate. Here again about 2% of the acid was removed and about 1% of the copper sulfate. This latter result indicates that the apparent inactivity of the copper sulfate in the solution with charcoal could not have been due to its removal from solution by adsorption.

The Effect **of** Platinum Black.—Two grams of scrap platinum was converted into platinum black by the method of Willstatter and Jaquet[12] and this was dried overnight over sulfuric acid in a vacuum desiccator. Suspensions of 0.5 g. of this material in 50 cc. of a 0.15 *M* $FeSO_4$–0.5 M H_2SO_4 solution were subjected to oxidation with air, and velocity constants of (341,000) and (347,000), averaging (344,000) X 10^{-5} were obtained. Suspensions of only 0.25 g. of this material in the same volumes of the same solution gave a velocity constant of only 75,800 × 10^{-5}. This more than proportional decrease in the velocity with the smaller amount of catalyst suggested a possible progressive poisoning of the catalyst.

To test this, the platinum black catalysts were removed from the solution, thoroughly washed, then replaced in the cells with fresh 50-cc. portions of the original solution, and the velocity of oxidation of each suspension was again measured. The 0.5-g. sample gave a constant of (19,900); the 0.25-g. sample in two experiments gave constants of (17,400) and (17,600), averaging (17,500) × 10^{-5}. These low values show that the catalyst had indeed become much less active with use.

The Effect **of** Silica Gel.—A sample of a commercial silica gel was powdered to pass a 60-mesh (per inch) screen. A suspension of one gram of this material in 50 cc. of a 0.15 M $FeSO_4$–0.5 M H_2SO_4 solution gave an oxidation velocity constant of 865, corresponding to about a three-

---

[12] Willstatter and Jaquet, Ber., 51, 767 (1918).

fold increase as compared with the velocity constant given by the same solution without the silica gel. This increase, while a decided one, is scarcely one one-hundredth of that produced by charcoal in this same solution, and is only one three-hundredth of that produced by half as much platinum black.

Discussion of the Kinetic Results

The unimolecular behavior of the gaseous oxygen in the oxidation of these solutions of ferrous salts agrees with the observations of McBain[13] made with solutions of ferrous sulfate and with those of Just[14] made in his study of the autoxidation of solutions of ferrous bicarbonate. Similarly, the bimolecular behavior of the ferrous sulfate agrees with the observations of McBain,[13] Ennos[15] and Boselli,[16] made with the same substance but not with those of Just made with ferrous bicarbonate. On the other hand, the relatively slight retarding effect of acid on the velocity of oxidation in the absence of catalysts (a decrease of only four times in passing from 0.008 to 0.23 M acid) is not compatible with McBain's hypothesis that the rate of oxidation of the solution is primarily determined by the rate of oxidation of the relatively minute hydrolyzed portion of the ferrous sulfate.[17] Even less compatible with this hypothesis are our measurements showing that in the presence of catalysts (copper sulfate or charcoal) the velocity of oxidation increases with increasing concentration of acid.

Our finding of the outstanding activity of copper sulfate in accelerating the oxidation of ferrous sulfate solutions by gaseous oxygen confirms the observations of Boselli[16] upon this substance, as contrasted with those of Banerjee,[18] and is in agreement with the work of Meyerhof,[19] Reinders and Vles[20] and others on the autoxidation of numerous other substances.

The outstanding fact established by our experiments is that the very substances, namely, charcoal, platinum and cupric salts, which hasten markedly the decomposition of hydrogen peroxide, particularly in the presence of ferrous salt solution,[21] also greatly accelerate the oxidation of ferrous salt solutions by gaseous oxygen. This parallelism at once suggests that the two phenomena may be intimately related.

[21] See Lemoine, *Compt. rend.*, 162, 657, 702 and 725 (1916); Bohnson and Robertson, THIS JOURNAL, 45, 2493, 2512 (1923); Warburg, *Biochem. Z.*, 113, 257 (1921); 119, 134 (1921).

An alluring hypothesis to explain this parallelism would be as follows. Hydrogen peroxide might conceivably be formed slowly from oxygen and water. Once formed it would react relatively rapidly with the ferrous salt. The slowness of the oxidation of the ferrous salt solutions would then be due to the slow rate of formation of the hydrogen peroxide. Catalysts which accelerate the oxidation of the solutions would then do this by virtue of the acceleration of the formation of hydrogen peroxide. But, by the fundamental principles of catalysis, the very catalysts which hasten this formation of hydrogen peroxide from oxygen and water will correspondingly hasten the decomposition of hydrogen peroxide into these substances. On this hypothesis, then, the above-mentioned parallelism would be expected.

A difficulty with this attractive hypothesis is that from energetic considerations it appears that even the maximum possible partial pressure, that is, the equilibrium partial pressure, of hydrogen peroxide in a 1:1 gaseous mixture of oxygen and water vapor at room temperature is only of the order of 10^{-22} atmospheres.[22] The equilibrium concentration of hydrogen peroxide in a saturated aqueous solution of oxygen at room temperature would be correspondingly infinitesimal[23] and, therefore, apparently quite inadequate to bring about the relatively rapid oxidation of ferrous salt solutions by gaseous oxygen which does, indeed, take place when catalysts are present.

There are still other objections to this explanation. Goard and Rideal[24] found that copper salts do not catalyze the oxidation of ferrous salts by hydrogen peroxide in *acid* solutions. Again, while Bohnson and Robertson did find a marked accelerating effect of copper salts on the decomposition of hydrogen peroxide, a maximum effect was observed at very low concentrations of copper salt, while in our experiments the catalytic effect increased progressively with the concentration of the copper salt.

Another mechanism involving hydrogen peroxide which has been proposed recently by Jander[25] can be represented as follows

Slow, primary reaction	$2FeO + O_2 + H_2O = Fe_2O_3 + H_2O_2$
Rapid, following reaction	$2FeO + H_2O_2 = Fe_2O_3 + H_2O$

This mechanism obviates the thermodynamic difficulties of the former explanation. However, the activity of copper salts in catalyzing this reaction, in view of the above-mentioned observation of Goard and Rideal, would appear to exclude it.

---

[22] Computed from the free energy data for this reaction given by Lewis and Randall, "Thermodynamics," McGraw-Hill Book Company, Inc., New York, **1923,** p. 496. See also Lewis and Randall, THIS JOURNAL, 26, 1916 (1914).

[23] This same conclusion follows from computations by Baur based on data of Nernst, given in Abegg, "Handbuch," Leipzig, **1908,** Vol. II, 1, p. 99.

[24] Goard and Rideal, *Proc. Roy. Soc.* (London), **105A,** 163 (1924).

[25] Abegg's "Handbuch" Leipzig, **1930,** Vol. IV, **3d.** Section, 2d part, pp. B13–14.

It appears, therefore, to be unlikely that these explanations, in spite of their simplicity, can be correct. Apparently, hydrogen peroxide is not the effective actor in all of these oxidations. Instead, it is probable that specific intermediate compounds, presumably peroxides of the several catalysts themselves, are primarily formed, which either oxidize directly the ferrous salt more rapidly, or accomplish this same result by hastening the formation or decomposition of a peroxide of iron which many authors consider to be involved in the oxidation of ferrous salts.

Peroxide in the Charcoal.—In view of this likelihood that a specific peroxide is involved in the case of each catalyst, we tested for a peroxide in or on the charcoal. For this purpose we stirred a suspension of 2 g. of the previously mentioned 100 mesh charcoal in 100 cc. of distilled water for five minutes with a current of air. This charcoal was then filtered off and successive small portions were shaken with pure water, or with solutions of sulfuric acid of various concentrations. The charcoal was again filtered off and the filtrates added to separate portions of acidified starch–iodide solution. No color developed in the filtrates from the suspensions in water, but a deep and nearly constant color, indicating the presence of a peroxide, appeared in a few seconds with the filtrates from the suspensions in 0.5, 1.0 and 1.5 molar sulfuric acid. The color was considerably less intense with the filtrate from the suspensions in 2.0 M acid, so that there was an evident maximum of color development at about 1.0 *M* acid.

These observations indicate that a peroxide is present in this charcoal, which is either insoluble or inactive in pure water, and has its maximum solubility or activity in solutions of sulfuric acid at an acid concentration of about 1 M. The location of this maximum activity is in striking agreement with that of the maximum velocity of oxidation observed in our kinetic measurements, using this charcoal as a catalyst in solutions of sulfuric acid of various concentrations.

A rough titration indicated that 1 g. of the 100 mesh charcoal in 50 cc. of water produces in dilute sulfuric acid about 0.0001 equivalent of active oxygen.

Further tests using 0.1 M sulfuric acid showed (1) that a positive test for a peroxide is obtained when fresh, dry charcoal without any deliberate aeration is acidified under an atmosphere of carbon dioxide (in the absence of air); (2) that charcoal once extracted with acid gives no further test for peroxide when shaken with fresh acid in an atmosphere of carbon dioxide; **(3)** that the same sample of charcoal once extracted with acid can again be made to give an equally positive test for peroxide by shaking the residual charcoal with more water and air, and repeating the extraction with acid; (4) that this successive aeration and extraction by acid can be repeated at least twice, and usually several times, with the same sample of charcoal; *(5)* that no difference in behavior is observed if the suspension of charcoal is aerated first and then acidified immediately before filtration, or if it is first acidified and then aerated.

These observations indicate that this charcoal acquired a charge of the peroxide in the process of manufacture; that this can be removed by shaking with dilute sulfuric acid; that a fresh charge can be rapidly added by exposure to air; that this process can be repeated at least twice and that the re-oxidation will take place equally well in neutral or acid solutions.[26]

All of these conclusions and, in particular, the parallelism in acid solutions of various concentrations between the activity of the charcoal as a catalyst and its activity in liberating indirectly iodine from starch–iodide solutions harmonize with our above conclusions drawn from the kinetic measurements.

Narcotics.—To obtain further information as to the presence of a peroxide in the charcoal, we have made tests similar to those of Warburg[27] on the oxidation of cystine by charcoal and air. He found that minute amounts of certain substances markedly retarded on this oxidation. We have tested the effect of two of his substances, phenyl urea and amyl alcohol, and in addition acetanilide, on the oxidation of ferrous sulfate solutions by charcoal and air.

The phenyl urea was made from aniline hydrochloride and potassium cyanate;[28] the other two were commercial preparations and were used without further purification.

The kinetic results obtained, both in uncatalyzed and catalyzed systems, are shown in the following table (Table XVI).

It can be seen from these results that, while no effect is produced on the uncatalyzed reaction, a marked depression of the velocity results when even small amounts of these "narcotics" are added to the catalyzed reaction mixtures. A plausible explanation of these results is that the "narcotics" combine with or, in any case, render less active relatively minute active ingredients or products, presumably peroxides of the catalysts.

Direct Measurement of the Efficiency of **Depolarization.**—The above

kinetic measurements permit us, as we have seen, to evaluate the activity of the various catalysts studied in accelerating the oxidation of the ferrous sulfate solution. The greater the activity of the catalyst in this respect, the greater should be the activity of the system as a depolarizer. Wc have measured the efficiency of depolarization of certain of these systems directly by bubbling oxygen through them, surrounding an electrode through which a current was passed in such a direction as would tend to evolve hydrogen upon it. The single potential of this electrode when the oxygen is absorbed at a constant rate, that is, when a steady current is maintained, compared with the single potential of this electrode immersed in the same solution when no current is passing, is a measure of the efficiency of the particular system.

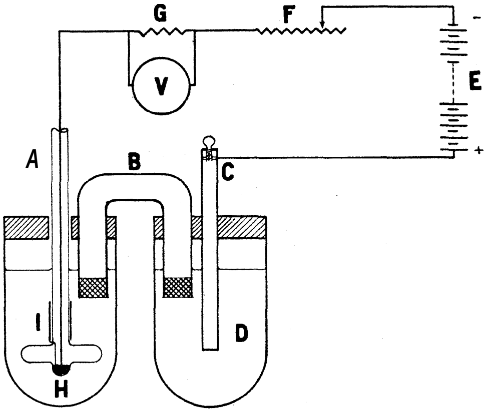

Fig. 9.—Apparatus for measuring the efficiency of depolarization.

The apparatus used for these measurements is shown diagrammatically in Fig. 9. A hollow stirrer from the previously described apparatus (Fig. 1) was provided with a sealed-in electrode (I) of polished platinum foil, connected by means of a mercury cup (H) at the bottom of the stirrer (A) with a copper wire leading through the hollow shaft of the stirrer to the battery (E). This arrangement provides a compact rotating air electrode on which concentration polarization is reduced to a minimum. The other pole, selected for its relatively slight tendency to polarize, consisted of a zinc bar (C) immersed in a saturated zinc sulfate solution (D) in a similar half-cell. The internal circuit between the two half-cells was completed by means of a saturated potassium chloride salt-bridge (B) in a pyrex glass tube of 8-mm. bore, plugged at each end with cotton wool. The external circuit, containing a 40-volt battery (E), a variable resistance (F) for current control and a milliammeter (G-V), is shown in the diagram. The external e. m. f. is imposed in such a way as to make the platinum electrode negative, *i.* e., to impress reducing conditions upon the air electrode. The relatively high potential of the battery was necessary to overcome particularly the resistance of the bridge. The milliammeter circuit contained a Weston millivoltmeter with a calibrated shunt resistance. The left-hand cell contained in addition a movable platinum electrode which could be immersed in the solution in order to determine its composition with respect to oxidizing and reducing ions. The single electrode potentials of this extra electrode and of the working (rotating) electrode were measured through a separate salt-bridge against the saturated calomel reference electrode in the usual way.

Our procedure was as follows. The solution of iron salt containing the catalyst was introduced into the left-hand cell and the air supply turned on. After a few preliminary readings on open circuit, the circuit was closed and the rheostat adjusted so that from 60 to 100 milliamperes flowed through the cell with the stirrer operating at 1250 r. p. m. Readings were then taken at intervals of the potential of the working electrode and that of the extra electrode. The difference between the two gives directly the polarization potential. Readings were continued until the potentials became constant or until it was evident that the potentials were not going to become constant.

Using this apparatus and procedure the efficiency of depolarization by gaseous oxygen was measured in the solution which had been found to exhibit the highest velocity of oxidation by gaseous oxygen. In making these measurements the circuit through the apparatus was closed at a predetermined instant and the current of air was then started. The observed values of the polarizing current and the potentials of the working and of the accessory electrodes are given in Table XVII.

It can be seen from these data that the initial closing of the circuit before the air supply and stirring had been started lowered considerably the potential of the working electrode. This potential rose slowly as the air supply was continued, reaching a nearly steady state at a potential of $E_h = +0.250 + 0.253 = 0.503$. When the current was now cut off and the air supply continued, the potential rose rapidly to that of the accessory electrode, $E_h = +0.410 + 0.253 = 0.663$. When the same current drain was again started after this preliminary aeration with no current flowing, the potential of the working electrode dropped only to $E_h = +0.353 + 0.253 = 0.606$ volt, indicating a polarization of only $+0.400 - 0.353 = 0.047$ volt. The measurements on the accessory electrode showed that no significant change occurred in the composition of the solution.

TABLE XVII

EFFICIENCY OF DEPOLARIZATION

50 cc. of solution: 1.1 M $FeSO_4$; 0.9 M H_2SO_4 + 10 g. of charcoal

Time, Hrs. min.	Current, m. a.	Potential Working electrode, $E_C = 0$, v.	Potential Accessory electrode, $E_C = 0$, v.
12:15	85.9	+0.199	.....
12:35	85.9	+ .213	
1:56	85.9	+ .241	
2:05	85.9	+ .247	.....
2:20	85.9	+ .247	.....
2:35	85.9	+ .250	
2:45	85.9	+ .250	.....
2:56	0.0	.....	+0.4060
3:00	.0	.....	+ .4059
3:08	.0	+ .4092	.....
3:11	.0	+ .4103	.....
3:15	85.9		+ .400
3:20	85.9	.....	+ .400
3:25	85.9	+ .352	.....
3:40	85.9	+ .354	.....
3:45	85.9	+ .352	
3:55	85.9	+ .353	

From these data the rate of oxygen absorption per liter of solution per hour can be calculated. It evidently equals (0.0859 X 3600 X 1000)/(96,500 X 50) = 0.0641 eq. of oxygen per liter per hour at an open circuit potential of +0.406 volt.

This rate of absorption can be compared with that found in the direct experiments on the velocity of oxidation. The data obtained in our experiments on solutions of this same composition at the same stirring rate of 1250 r. p. m. are collected in the following table.

TABLE XVIII

$FeSO_4$ 1.1 M; H_2SO_4 0.9 M; charcoal 10 g.

Expt.	Time, hrs.	ΔC, M	E_C, v.	Oxygen, eq./liter-hr.
1	1.88	0.118	+0.4147	0.0627
2	1.88	.102	+ .4104	.0543
3	3.80	.240	+ .4446	.0632
		Average	+ .423	.0601

It can be seen that the average rate of absorption of oxygen (0.0601) agrees closely with that found in the depolarization experiments (0.0641) being slightly less, as would be expected, at the somewhat higher potential (+0.423 as compared with 0.406). The agreement of these two results derived from such fundamentally different data affords very satisfactory evidence of their individual correctness.

In the following table the performance of one of these oxygen electrodes is compared with that of previous oxygen electrodes operating at room temperature, namely, the copper–cuprous oxide electrode of Hofmann[29] and the platinized carbon electrode of St. v. Náray-Szabó.[30]

TABLE XIX

EFFICIENCY OF SEVERAL OXYGEN ELECTRODES

[a] Potential of cell. [b] Estimated.

It can be seen that the present electrode, although it exhibits a lower open circuit potential, shows at a much higher current density a higher working potential, a much higher energy output and a much lower polarization. Indeed, it appears not to have been equaled in these respects except by the oxygen electrode of Baur operating at elevated temperature~. The relatively considerable activity of this electrode is to be ascribed not only to the intrinsic effectiveness of the catalyst, but also to the fact that it operates as a "bulk" as contrasted with a "surface" type of catalyst, as set forth in our introductory paragraphs.

These results were obtained with electrodes of 4 sq. cm. area immersed in 50 cc. of electrolyte. Assuming that a proportionate increase in these dimensions would be without effect on the efficiency of this electrode and that the normal hydrogen electrode with which it is in series is unpolarized and of negligible internal resistance, the cell would have an energy output of 0.94 watt per liter, or 0.94 kilowatt per cubic meter of electrolyte. These assumptions as to the hydrogen electrode are obviously ideal; but it does not appear improbable that a much more favorable ratio between the area of the electrode and the volume of the electrolyte than that used in our experiments might be secured, so that an even higher energy output per unit of volume might well be realized. **A** discussion of these matters, however, lies outside the scope of this article.

Summary

1. In an attempt to overcome by means of catalysts the well-known sluggishness of the oxygen electrode, the kinetics of the reaction between solutions of ferrous sulfate and gaseous oxygen has been re-investigated, particularly with reference to the accelerating effect of various secondary

---

[29] Hofmann, Ber., 51, 1531 (1918).

[30] St. V. Náray-Szabó, Z. *Elektrochem.*, 33, 18 *(1927)*.

[31] Baur, *Helv. Chim. Acta*, 4,325 (1921).

or accessory catalysts. For this purpose an electrometric method was perfected for ascertaining the progress of the oxidation, which is independent of the, at present, unknown activity coefficients of the ferrous and ferric ions in these solutions.

It has been found from the measurements thus made (a) that the reaction is unimolecular with respect to the oxygen, and bimolecular with respect to the ferrous sulfate; (b) that the velocity of the reaction is independent of the concentration of the sulfuric acid at concentrations of 0.1 molar and higher, but increases progressively at lower acidities; (c) that a large number of metallic ions are without noticeable effect but copper ions have a pronounced accelerating effect; (d) that coconut charcoal and platinum black have pronounced accelerating effects, while silica gel is inactive; (e) that the accelerating effect of the charcoal reaches a maximum in 1 molar acid.

The conclusion is drawn that specific peroxides are presumably responsible for the accelerating action. Confirming this, a peroxide-like substance has been extracted in minute amounts from the aerated coconut charcoal, while several so-called narcotics have been found to have a pronounced depressing effect on the velocity of the reaction when catalyzed either by charcoal or by copper salts.

2. Neutral solutions of potassium ferrocyanide have been found by similar measurements to oxidize about half as rapidly as do corresponding solutions of ferrous sulfate in 0.01 to 3.0 molar sulfuric acid. Copper salts are here without significant effect.

3. Solutions of ferrous sulfate containing sodium pyrophosphates have been found to oxidize about 1000 times faster than ferrous sulfate in 0.1 to 3.0 molar sulfuric acid. Their oxidizing potential is, however, nearly half a volt lower. The conclusion previously reached by others that this is a reaction of the first order with respect to the ferrous salt has been shown to be based on an error of interpretation.

4. Direct measurements of the depolarizing activity of ferrous sulfate solutions containing certain of these accessory catalysts have been made. Electrodes utilizing these solutions exhibit, as compared with previously studied oxygen electrodes at room temperature, at a higher current density, a higher working potential, a higher energy output and a much lower polarization.

5. The rates of absorption of the oxygen in these direct measurements of depolarization have been found to check closely the rates of absorption determined in a very different way in the kinetic measurements.

NOTES

A Note on the Preparation of Iodine Trichloride.—The authors were confronted recently with the problem of preparing two kilograms of iodine trichloride, sealed in glass ampoules in 50-g. quantities. Trial of the most promising methods suggested in the literature showed them to be unsuited for the preparation of a definite quantity of this relatively unstable material in place in glass tubes. The following very satisfactory method was worked out, and is described here because of the great economy of time and material which it effected.

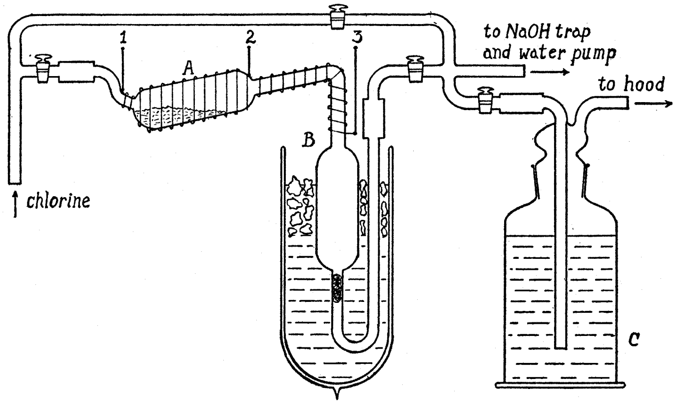

Fig. 1.—Apparatus for making iodine trichloride.

A slight excess of iodine was placed as shown in tube A, Fig. 1, before A and B were sealed together. The tubes were then placed in the system and B was immersed in ice water to a point 2 cm. from the bottom. The connecting tube between points 2 and 3 was heated electrically to about 100° to prevent deposition of the trichloride. Chlorine was then allowed to flow through the system at the rate of 80–90 cc. per minute until the iodine appeared to be completely,liquefied owing to the formation of the monochloride. Some trichloride was also formed and was deposited mainly in the lower end of B on the loose plug of glass wool, thus helping to prevent the loss of the larger quantity of trichloride which came over later. The electrical heating was then extended to include A and was adjusted so as to keep the liquid monochloride just below its boiling point (100°). The ice water-bath around B was raised to a point I cm. from the top of this tube for the remainder of the run. The rate of flow of chlorine was increased to about 170 cc. per minute. At the conclusion of a run the system was partially evacuated, the tubes were disconnected at the rubber joints, which were closed with screw clamps, and B was carefully sealed off at a convenient place at each end.

It was found that a rate of flow of chlorine faster than that stipulated or especially a temperature high enough to boil the liquid in A resulted in a too rapid deposition of the trichloride in B, with consequent plugging of this tube. The size of the tubing employed in construction of the apparatus was also found to be important. If B was less than 3 cm. in diameter or less than 9 cm. long, the deposit of trichloride invariably plugged up the tube so as to stop the flow of chlorine, thus forcing the system apart at one of the rubber connections, or at best nearly doubling the time required for a run owing to the decreased rate of sublimation of the trichloride. The tubing connecting A and B was 1 cm. in diameter, and the rest of the system was constructed of 8-mm. tubing, pyrex glass being used throughout. It was also found that if the final position of the cooling bath around B was higher than that indicated, plugging of the trichloride was likely to result.

Under the above conditions a dense core of iodine trichloride, light orange in color and containing only traces of monochloride, was formed in B, leaving no residue in A and resulting in only a slight loss of product beyond the glass wool in B. Small amounts of the trichloride were decomposed to the monochloride in the final sealing-off process. To produce 50 g. of product, 27.2 g. of iodine is required; 30-g. samples of iodine were used, yielding slightly more than 52 g. of product. The time required was slightly more than two hours per sample, including the necessary glassblowing.

The Analysis of Dilute Iodine Solutions.—The investigation of a reaction system comprising iodine, iodate ion and hydrogen peroxide required the accurate determination of the rate of disappearance of iodine when the amount initially present in a sample was less than 3 mg. From time to time the iodine was extracted with about 25 cc. of carbon tetrachloride, enough of the aqueous solution being taken to supply iodine equivalent to 1 to 5 cc. of 0.004 N sodium thiosulfate. The details of the method which enabled satisfactory determination of iodine even at concentrations below 10^{-5} M in the aqueous solution are as follows.

The carbon tetrachloride containing the iodine is transferred to a 500-cc. glass-stoppered flask containing approximately 50 cc. of a 1% potassium iodide solution, made sufficiently acid (about 0.001 N) to neutralize any basic substance added as preservative to the sodium thiosulfate solution. Freshly prepared 0.004 N thiosulfate is then run in until the carbon tetrachloride layer is practically colorless after shaking; 5 cc. of starch solution is then added, and the end-point taken as the mid-point of the drop which causes the last trace of bluish color to disappear from the carbon tetrachloride layer.

On moderate shaking after the addition of the starch, the carbon tetrachloride layer remains in small bubbles of which the surface is blue even when the aqueous layer has been rendered entirely colorless in the approach to the end-point. Since the starch tends to remain in the water layer while the iodine tends to become concentrated in the carbon tetrachloride, conditions in the interface between the two layers are particularly favorable for the formation of the blue starch–iodine compound. With practice, the drop of thiosulfate which causes the removal of the last trace of this color can be easily observed—the more so since the carbon tetrachloride layer on shaking often assumes a slight yellow tinge when all of the iodine has gone. This combination of the starch and carbon tetrachloride end-points is advantageous since it permits concentration of the iodine, which the starch end-point does not, and since, in the presence of the I^- essential to satisfactory titration of iodine with sodium thiosulfate, it is more sensitive than is the carbon tetrachloride end-point alone.

Under the most favorable conditions $4(10^{-5})$ g. of iodine in 40 cc. of aqueous solution, corresponding to a concentration of 4×10^{-6} *M*, could be detected by the above method; the starch solution when used alone permitted the detection of iodine in a 2×10^{-6} M solution, a value for the sensitiveness which agrees with earlier results obtained by Dr. H. E. Miller of this Laboratory. The starch solution was prepared by a method similar to that of Mutnianski,[1] recently described by Kolthoff,[2] except that potato instead of "soluble" starch was used. When potato starch is used, the solution must be boiled for a short time after the starch is added. Decantation after allowing suspended matter to settle insures a clear solution.

X-RAY INVESTIGATIONS OF OPTICALLY ACTIVE COMPOUNDS. II. DIPHENYL AND SOME OF ITS ACTIVE AND INACTIVE DERIVATIVES[1,2]

BY GEORGE L. CLARK AND LUCY W. PICKETT

RECEIVED JUNE 23, 1930 PUBLISHED JANUARY 12, 1931

The problem to which this x-ray diffraction analysis is being applied as a mode of attack is that of the stereoisomerism of derivatives of diphenyl. It is known that the substitution of certain groups in the 2,2′,6,6′-positions of diphenyl gives compounds which may be resolved into stereoisomers. Many of these compounds have been prepared by Dr. Roger Adams[3] and his students for the purpose of determining which groups give rise to this effect. It is thought that the presence of sufficiently large groups prevents a free rotation of the two rings and hence two active forms of such a compound exist The crystallographic examination was undertaken in order to find, in the crystal at least, the positions, symmetry, and approximate shape of the molecules of the derivatives of diphenyl, and to see whether there is any differentiation apparent in the crystalline structure between those compounds which resolve into active isomers and those which do not.

Experimental

1. General Methods Employed

(a) Preparation of Sample.—Well-formed crystals of the substance under investigation were prepared by the slow evaporation of a barely saturated solution protected from dust. A single crystal, preferably one millimeter in its longest dimension, was selected for mounting. This was examined under the microscope for vibration axes and mounted either by eye or under the microscope on a glass fiber which was then attached to a goniometer head.

(b) A Rotation Photograph.—Rotation and oscillation photographs were used in the greater part of this work. The single crystal, mounted so that an important crystallographic direction was parallel to the axis of rotation, was rotated in a pin-hole defined beam of copper radiation from a Siegbahn–Hadding or Shearer gas-type tube. Inasmuch as the general radiation is inappreciable in intensity and the Kα can easily be distinguished from the Kβ, unfiltered radiation was employed in practically all of the work. A circular camera of 5-cm. radius surrounded the crystal as a center. Exposures varied from two to eight hours depending on the focus of the beam and the size and absorption of the crystal.

When the crystal was lined up with the crystallographic axis coinciding with the

axis of rotation, the photograph consisted of spots arranged in straight rows. If the two axes made an angle with each other, this was evidenced by the fact that the central line of spots was split into two lines crossing each other at an angle which is twice the angle between the axis of the crystal and the axis of rotation. Thus a correction could be made in the goniometer setting and the correct lining up of the axis obtained by somewhat of a trial and error process. The rows of spots in the photograph are termed layer lines, the one containing the undeviated beam being the 0 line and the others numbering 1, 2, 3, etc., from that line.

The unit length along the axis of rotation may be calculated directly from the photograph through the use of the relation $I \sin \Phi = n \lambda$ where λ is the wave length of the radiation used (1.54 for Cu-Kα), n is the number of the layer line, I is the desired unit, and Φ may be measured as the angle whose tangent is the distance from the 0 layer line to layer line n, divided by the distance from crystal to film.

Rotation pictures can then be taken about the other two axes, and their position measured from the settings on the goniometer head From measurements of the layer lines of each of these, the dimensions of the unit cell are directly obtained.

The number of molecules in the unit cell may be calculated from these data together with the experimentally measured density of the crystal by means of the following formula

$$a \times b \times c \times \sin \beta = \frac{\text{mol. wt. X n}}{\text{Avogadro's number}} \times d$$

a, b and c are lengths of the unit cell expressed in cm., d is density and n is number of molecules in the unit cell.

The assignment of indices to the spots on the films is the next step and is attended with somewhat more difficulty. In a rotation photograph about the c axis, for instance, reflections from all the planes with index $hk0$ are present in the zero layer line, while planes of the hkl series reflect in the first layer line, $hk2$ planes in the second layer line, etc. The spacings corresponding to the spots on the zero line can be calculated by means of the usual Bragg formula $n\lambda = 2d \sin \Theta$. Furthermore, spots with the same h and k indices lie on lines which are curved but nearly vertical in general. The exact position of these lines has been worked out. In spite of these very helpful principles, the complexity of the photographs makes a certain identification of the spots difficult and two devices were employed in this work to make the identification less arduous.

One was the construction of a table which gave for each distance on the film under the conditions used the corresponding interplanar spacing. Thus, once the table was constructed, a large number of individual calculations was avoided.

The second was the use of oscillation photographs to analyze and simplify the diagram. Instead of rotating the crystal through 360°, it was oscillated 15° at a time, and a series of overlapping oscillation pictures were taken. As there were fewer spots on each of these, each spot could be identified with more certainty, especially as one could calculate from the position of the crystal whether the plane which was suspected could have been in position within that 15° oscillation to give a reflection.

(c) A Laue Photograph.—To aid in determining the symmetry in certain cases Laue photographs were taken. Unfiltered molybdenum radiation was employed for this purpose, and the crystal was mounted in a pin-hole beam so that the beam was parallel to a crystallographic axis. If the alignment was perfect, a symmetrical design of spots was obtained, to which indices could be ascribed after a gnomonic projection.

(d) Assignment of Space Group.—Astbury and Yardley[4] have compiled tables in which the missing reflections characteristic of each of the **230** space groups are listed. After the spots have been identified by the method described in the previous section, the classes which are consistently absent are noted and the space group found from reference to the tables. Often several space groups have the same missing reflections, in which case the number of molecules in the unit cell, the external symmetry, and other information about the crystal may help to clear the ambiguity. Further information must be obtained by individual methods varying with the substance used.

2. Data for Crystals

(a) **Diphenyl.**—The commercial product was purified by recrystallization four times from 95% alcohol followed by a slow recrystallization from absolute alcohol. Diphenyl crystallizes in thin flat plates with the 001 planes as the extended face and shows preferred cleavage along the a and b axes. The crystal unit was found to be monoclinic with the dimensions $a = 8.11$, $b = 5.67$, $c = 9.57$, $\beta = 94.5°$. After this work was completed. an analysis by Hengstenberg and Mark[5] was found in which the following dimensions were obtained: $a = 8.22$, $b = 5.69$, $c = 9.50$, $\beta = 94.8°$. The two sets of data show very fair agreement. An analysis of the spacings showed that the reflections from all of the planes $h0l$, where h is odd, were absent as well as those from the $0k0$ planes where k is odd. This indicates that the structure is of monoclinic prismatic type and belongs to the space group C_{2h}^5, which is based on the simple monoclinic lattice. From the fact that the density of diphenyl is 1.165, the number of molecules in the unit cell must be 2. The space group C_{2h}^5 requires 4 asymmetric molecules in the unit cell or two molecules each of which contains a center of symmetry and therefore diphenyl in the crystalline state must possess centro-symmetry.

There are four possible equivalent positions for two molecules which may be expressed analytically as follows

---

(a) $^1/_4\,^1/_4\,0;\ ^3/_4\,^3/_4\,0$

(b) $^1/_4\,^1/_4\,^1/_2;\ ^3/_4\,^3/_4\,^1/_2$

(c) $^1/_4\,^3/_4\,0;\ ^3/_4\,^1/_4\,0$

(d) $^1/_4\,^3/_4\,^1/_2;\ ^3/_4\,^1/_4\,^1/_2$

(b) **Dimesityl.**—Dimesityl crystallizes from an alcohol–water mixture in colorless rectangular plates or in needles. The product used was obtained prepared in this Laboratory from Dr. Stanley. Its density, determined by immersing a crystal in an aqueous salt solution of the same density, is 1.020.

Rotation and oscillation pictures indicated the following dimensions: $a = 8.21$, $b = 8.58$, $c = 22.25$, $\beta = 96.30°$. There are, therefore, four molecules in the unit cell.

A table showing the relative intensities of the reflections noted is found in Table I. A scrutiny of this table reveals the fact that the planes $h0l$ where 1 is odd as well as the plane 010, show no reflection. The only space group that fits these facts is C_{2h}^5 based on the simple monoclinic lattice Γ_m. Either two molecules with a center of symmetry or four asymmetric molecules may be placed in one unit cell in this space group. Hence the dimesityl molecule must be asymmetric.

The equivalent positions in this space group may be expressed by the coordinates $xyz;\ x, y + {}^1/_2, \bar{z};\ x + {}^1/_2, \bar{y}, z;\ {}^1/_2 - x, {}^1/_2 - y, \bar{z}$.

(c) **3,3′-Diaminodimesityl.**—This compound has been resolved into two active forms by Adams and Moyer. Samples of each of these were loaned for crystal analysis. The compound formed fine crystals and proved very difficult to obtain in crystals large enough to work with. After repeated trials lasting over several months, one crystal of the 1-form was obtained, and soon after a very tiny crystal of the d-form. The crystals formed in six-sided, colorless, slightly yellow plates from an alcohol–water mixture containing about 80% alcohol.

A very complete series of oscillation photographs of the former was taken. Powder photographs of the d- and I-forms showed the same spacings, and the few oscillation photographs of the d-form which were taken were exactly like those of the 1-form in a similar position. Thus it was concluded that the d- and I-forms were identical as regards x-ray reflection, a fact which has been noted before where stereoisomers were concerned.

The dimensions of the unit cell were calculated as a = 8.26, b = 8.58, c = 22.62. The three axes were obtained at right angles to each other on the goniometer. The number of molecules in the unit cell is four.

The photographs obtained were so nearly similar to those of dimesityl that they might easily have been mistaken for each other. A detailed comparison of the intensity of the individual spots is presented in Table I. It may be seen from the table that those reflections are missing for the planes $h0l$ where I is odd, while 010 is either missing or extremely weak. Although the angle β cannot be distinguished with absolute certainty from 90°, the similarity to dimesityl indicates that the space groups are probably the same, C_{2h}^5, and that β is within 30' of 90°.

TABLE I

COMPARISON OF INTENSITIES OR REFLECTIONS FROM DIMESITYL AND *l*-3,3'-DIAMINO-DIMESITYL

Planes	Dimesityl	Diamino-dimesityl	Planes	Dimesityl	Diamino-dimesityl
001	0	0	101	0	0
002	7	5	102	5	6
003	0	0	103	0	0
004	7	7	104	4	7
005	0	0	105	0	0
006	6	7	106	4	6
007	0	0	107	0	0
008	5	5	201	0	0
010	0	1	202	4	5
020	5	6	203	0	0
011	1	1	110	1	2
012	6	7	210	5	6
013	5	5	220	7	6
014	4	4	310	0	1
015	4	2	410	0	0
016	5	5	211	4	5
017	4	4	212	5	6
021	0	1	213	4	5
022	4	4	214	2	1
023	4	1	215	2	4
100	7	7	311	2	4
200	6	5	312	2	4
300	1	1	313	2	3

0 absent; 1 very weak; 2 weak; 3 medium weak; 4 medium; 5 medium strong; 6 strong; 7 very strong.

(d) **Hexachlorodiphenyl.**—The photographing of hexachlorodiphenyl involved a difficulty not encountered in any of the foregoing work in that the compound because of its many chlorine atoms is highly absorptive to the copper radiation. On this account very small crystals were used and longer exposures were necessary.

Hexachlorodiphenyl was prepared by Mr. Julius White in this Laboratory. It crystallizes from alcohol in colorless six-sided tablets. Optical measurement disclosed a monoclinic habit of the crystal with $\beta = 88°$. Three photographs at right angles showing clearly defined layer lines were obtained and the dimensions of the unit cell calculated as follows: a = 15.80, b = 8.54, c = 10.74. A closer examination of the diagrams about the c axis showed that very faint lines of spots lay between those taken as the layer lines and hence that the above c dimension should be doubled. Thus the true dimensions of the unit cell are a = 15.80, b = 8.54, c = 21.48.

The following spots were identified as present: 002, 004, 022, 024, 026, 020, 013, 015, 200, 400, 210, 310, 410, 320, 420, 520, 202, 204, 120, 210, 310, 110, 220, 330, 111, 112, 113, etc., while 001, 003, 010, 012, 014, 100, 300, 102, 103, 104, 105 were absent. This may be summarized by stating that interferences for those planes are absent which have indices Okl where $k + l$ is odd, and $h0l$ if h is odd.

The density as measured by the flotation method in a sulfuric acid and water mixture was 1.655. The number of molecules in a unit cell calculated from this figure is 7.98 or 8.

The only space groups in the orthorhombic or monoclinic systems which have the above mentioned spacings absent are C_{2v}^{9} and Q_h^{16} (also written V_h^{16}). The first allows for only four asymmetric molecules in the unit cell and hence would necessitate the assumption of polymerization. The second allows eight asymmetric molecules and hence is the more probable.

The space group Q_h^{16} has eight equivalent positions as follows: xyz; $x + {}^1/_2, {}^1/_2 - y, \bar{z}$; $\bar{x}, y + {}^1/_2, {}^1/_2 - z$; ${}^1/_2 - x, \bar{y}, z + {}^1/_2$; ${}^1/_2 - x, {}^1/_2 - y, \bar{z}$; $\bar{x}yz$; $x + {}^1/_2, \bar{y}, z + {}^1/_2$; $x, y + {}^1/_2, {}^1/_2 - z$.

After an optical examination indicated a monoclinic form while the x-ray data very clearly indicated an orthorhombic space group, all of the diffraction films were carefully reexamined. It is absolutely impossible to fit these data to any monoclinic space group, so the conclusion is that the crystal was not sufficiently perfect to enable unambiguous microscopic examination or else that the crystal actually has an outer pseudo-monoclinic form. There can be absolutely no question concerning the clear-cut x-ray data.

(e) Diphenic Acid.—Diphenic acid crystallizes readily from an acetic acid and water mixture in colorless six-sided tablets. Its density as determined by flotation in a sulfuric acid and water mixture is 1.40 It exhibits parallel extinction between two crossed nicol prisms.

An optical examination by Dr. E. T. Wherry of the U. S. Department of Agriculture of diphenic acid crystals disclosed the following facts. Making the shortest dimension axis a and the longest axis c and then making the prism (120) and the side-dome (011) gives

Axis c = **tan** ρ of (011); p *observed* 49°; $c/b = 1\ 15$
Axis a = **cot** ϕ of (120); ϕ *observed* 59°; $a/b = 1.20$

Rotation photographs of three axes at right angles to each other were taken in the usual manner. The dimensions of the unit cell were calculated as a = 13.80, b = 11.90, c = 14.12 with eight as the number of molecules in the unit cell with b = 1, $c/b = 1.15$ and $a/b = 1.19$, in excellent agreement with optical data. A series of oscillation pictures indicated that the following planes gave reflections: 002, 003, 004, 006, 106, 107, 108, 109, 116, 117, 118, 126, 127, 012, 014, 021, 022, 023, 024, 200, 110, 310, 211, 221, 020, 012, 032, 022. Inspection shows that the following set of planes are definitely present; hkl where $h + k + l$ is odd, Okl where $k + 1$ is odd, $h0l$ where $h + l$ is odd, $hk0$ where h or k is odd, $0kl$ where k or l is odd, $h0l$ where h or l is odd. None of the planes $hk0$ for which $h + k$ is odd are present. The following planes are definitely absent: 310, 410, 010, 030, 100,300,011, 013, 031, 033. The first six of these are characterized by the classification, $hk0$ where h + k is odd. The last four are probably missing for some other reason than that of space groups, Only those planes have been listed which could be identified without ambiguity, though further inspection strengthened the conclusion that only those planes were consistently absent which had the indices $hk0$ where h + k is odd.

The only space group which necessitates this particular spacing is the orthorhombic group Q_h^{13} (V_h^{13}) based on the simple orthorhombic lattice. This group contains eight unsymmetric molecules in the unit cell. Hence the diphenic acid molecule possesses no symmetry in the crystalline state, a result to be anticipated from the formula. The eight equivalent positions in this space group may be expressed analytically: X, y, z; $X + {}^1/_2, {}^1/_2 - y, \bar{z}$; ${}^1/_2 - x, y + {}^1/_2, \bar{z}$; $\bar{x}, \bar{y}, z$; ${}^1/_2 - x, {}^1/_2 - y, \bar{z}$; $\bar{x}, Y, z$; $x, \bar{y}, z$; $x + {}^1/_2, y + {}^1/_2, \bar{z}$.

(f) *o*-Tolidine.—The tolidine used was prepared in this Laboratory as the crude product and purified in the following manner: 10 g. was suspended in hot water and hydrochloric acid added to form the soluble hydrochloride. This was boiled with norite for twenty minutes, filtered hot, allowed to cool somewhat and neutralized with sodium hydroxide. The product was recrystallized from 80% alcohol. It crystallized nicely in rectangular tablets slightly brown in color.

An examination under the polarizing microscope showed that the crystals exhibit parallel extinction. An optical examination by Dr. Wherry proved the crystals to be orthorhombic. According to the classification of Wherry and Adams,[6] the material is endo-rhombic, but often ecto-monoclinic. With the longest dimension of the crystal oriented as axis a, and the shortest dimension c, the front-dome (101) and the side-dome (102), the measurements gave

Axis $c = {}^1/_2 \tan \rho$ of (012); p observed 57° 30'; $c/b = 3\ 14$
Axis $a = c/\tan \rho$ of (101); ρ observed 75°; $a/b = 0.84$

Examinations by Laue, rotation and oscillating crystal methods revealed the unit cell as orthorhombic with the dimensions $a = 6.50$, $b = 7.48$, $c = 23.62$ Å.; with $b = 1$, $c/b = 3.15$ and $a/b = 0.86$, in excellent agreement with the optical data. The density was determined as 1.215 and from this the number of molecules in the unit cell was found to be four.

The 001 planes where 1 is odd, and the $h00$ planes where h is odd are definitely absent, while the $0k0$ planes where k is odd are either absent or extremely weak. No other class of reflections is absent. Hence the space group is either the orthorhombic group Q^3 or Q^4 (V^3 or V^4). There is the possibility that the crystal might be monoclinic with an angle of 90 ± 0.5°

---

[6] Wherry and Adams, *J. Washington Acad. Sci.*, 9, 153 (1919).

and hence belong to the space group C_{2h}^2. In any case the molecule is asymmetric since there are four molecules in the unit cell.

The following table summarizes the results obtained for the crystal structures of the compounds.

		Unit cell dimensions						
	System	a	b	c		n	Space group	Symmetry of molecule
Diphenyl	Mono.	8.11	5.67	9.57	94°30′	2	C_{2h}^5	Center of symmetry
Dimesityl	Mono.	8 21	8 58	22 25	96°30′	4	C_{2h}^5	None
3,3′-Diaminodimesityl	Mono.	8 26	8 58	22 62	90° ± 30′	4	C_{2h}^5	None
Hexachlorodiphenyl	Orth.	15 80	8 54	21 48	90°	8	Q_h^{16}	None
o-Tolidine	Orth.	6 50	7.48	23 62		4	Q^4	None
Diphenic acid	Orth.	13 80	11 90	14 12		8	Q_h^{13}	None

Discussion of Results

The table just preceding summarizes the information which may be deduced directly from the x-ray data. Without accurate measurements of intensities and interpretations based thereon, statements concerning the disposition or size of molecules within the crystal unit cells and the exact relation of the parts of the molecule to each other must be partly in the nature of speculations. In the following discussion all available data have been called on to construct what appears to be rational conclusions concerning those questions of great theoretical chemical interest. These are to be considered as suggestions rather than as certain facts, pending exact assignment of coördinates for all the atoms within the unit cell.

The first conclusion to be drawn is that the two benzene rings in the diphenyl molecule are in prolongation of each other rather than doubled over on each other. This picture is one that is accepted by most organic chemists today and this serves as interesting confirmation. The evidence for this is that the molecule possesses a center of symmetry, a condition that could only be true for the prolongated molecule.

Secondly, the rings probably are not flat. In that case the molecule would be expected to have at least one plane of symmetry, and such is not present. Furthermore, assuming the molecules to be exactly in the *bc* plane, the intensities of successive order of the *h*00 planes would fall off regularly and such is not the case. Thus it is probable that the carbon atoms are in staggered or puckered rings, a conclusion which was reached by Hengstenberg and Mark. The 9.57 dimension may represent the length of the molecule, while the halvings of the 8.11 dimension show that two molecules share this length. Thus a single molecule might be considered to occupy a space approximately 4 X 5.7 X 9.5. It is probable that 5.7 is the width of the molecule, *i. e.*, the length in the meta direction of a benzene ring, and that the molecule is at a slight angle to the *c* axis in the *ac* plane, so that the actual thickness is less than 4.1 and the length greater than 9.5.

It is of interest to compare the unit cell dimensions for para benzene derivatives obtained by Dr. Caspari with the data for diphenyl derivatives. He recorded the following measurements.

	a	*b*	*c*	*n*
Quinol	13.24	5.20	8.11	4
p-Aminophenol	13.06	5.32	8.25	4
p-Phenylenediamine	12.46 × 2	5.93	8.29	8

The dimension of 5+ corresponding to the width of the ring checks with that obtained for diphenyl. The dimension 8–8.5 is also common to the diphenyl derivatives. Caspari suggests that it may correspond to the length of the molecule, while the hypothesis in this work is that it represents the thickness of two molecules and the longest dimension represents the length of two molecules. The halving of the **8.3** dimension in phenylenediamine as well as the space group involved suggests that the latter interpretation may be correct, although the evidence is not conclusive.

Hengstenberg and Mark obtained the following comparison for diphenyl, phenanthrene and fluorene.

	a	*b*	$c \sin \beta$
Diphenyl	8.22	5.69	**9.45**
Fluorene	8.48	**5.73**	**2 × 9.42**
Phenanthrene	**8.60**	**6.11**	**2 × 9.52**

. If the b axis represents the width, the *c* axis the length and the *a* axis the width of two molecules, the dimensions are very consistent with those obtained in the present work.

In the case of dimesityl and also of hexachlorodiphenyl, the molecule possesses no symmetry. This is of significance because the structural formulas of these two substances indicate the same symmetry that diphenyl itself possesses. The fact that such symmetry is missing leads to the conclusion that the two rings are either bent or turned at an angle to each other in these compounds. The other compounds exhibit asymmetry, as is to be expected from their formulas.

The spacings observed in the diagrams of dimesityl indicate that two molecules share the *c* axis and also the b axis, and that the molecule may extend with its length along the *c* axis, with a tilt of unknown amount. Thus the approximate volume occupied by one molecule might be 8.2 × 4.3 × **11.1.** The difference between **11.12** and.9.57 represents the difference between the space occupied by two methyl and two hydrogen groups together with the change in space caused by a distortion of the molecule as a whole or a change in tilt. Inasmuch as one-half of the difference, 0.8, is too small to account for the replacement of hydrogen by methyl alone, there must be a tilt or a compression of the molecule as a whole. The thickness of the molecule is slightly greater than that of diphenyl, while the width is increased by 2.55, a change which might be expected from the substitution of two hydrogens by two methyl groups.

The dimensions and intensities of reflection of 3,3-diaminodimesityl, both as the levo and dextro form, show that the structure is nearly identical with that of dimesityl, except for a very slight increase in the width of the molecule and in the length. This confirmed the expectation that the insertion of amino groups between the 2- and 4-substituted methyl groups would cause little change in the structure of the molecule as a whole. The similarity is interesting in view of the fact that although dimesityl cannot be resolved because the benzene rings are symmetrical, both compounds offer the same resistance to free rotation about the diphenyl linkage.

While hexachlorodiphenyl at first glance appears different from the others, its similarity becomes apparent when the *a* unit length is halved. Since all three of the spacings are halved, the domain of each molecule is approximately 7.9 X 4.3 X 10.74. This is exactly equal in thickness and shorter in both length and width than dimesityl. If it is assumed for the moment that the difference in width, $8.21 - 15.80/2 = 0.31$, represents the difference in space occupied by two methyl groups and two chlorine atoms, while the difference in length, $22.25 - 21.48 = 0.77$, accounts for the substitution of four methyl by four chlorine, the average difference between one methyl group and one chlorine atom would be 0.17.

The o-tolidine and the diphenic acid are not strictly comparable to the other compounds and were analyzed as incidental to **the** main problem. The dimensions of the o-tolidine indicate that it is similar in general structure to the other compounds. The unit c axis, 23.62, probably represents the length of two molecules, while 6.50 is reasonably the width of a molecule. The fact that the molecule would be longer than dimesityl and less thick than diphenyl indicates that this picture may not be correct in detail. However, this investigation was not pursued further, inasmuch as the compound bore little relation to the problem under investigation.

It is evident from the dimensions and also from the space group that diphenic acid crystallizes in a very different arrangement from that of the other compounds. The fact that carboxyl groups exert forces upon each other which result in a doubling of molecules has already been noted in the case of aliphatic long-chain compounds. It is probable that the presence of these polar groups distorts the diphenyl molecule into a very different orientation. It is certain .from the dimensions that the molecule cannot lie elongated along any of the axes and it is reasonable to suppose that the two rings are bent or turned at an angle to each other. The fact that this acid forms an anhydride readily would indicate that the two carboxyl groups are in close proximity. The solution of this problem, though interesting in itself, would shed no light on the question of stereoisomerism and therefore was not studied further.

The following premises have emerged from the above discussion as a basis for the complete picture of the positions of the molecules of diphenyl derivatives. The diphenyl molecule is symmetrical about a center; dimesityl and hexachlorodiphenyl have no symmetry. The molecules in all cases lie with their length parallel or at a slight tilt to the c axis. The rings of carbon atoms are in each case probably staggered and have a thickness which is constantly 4.3 for the derivatives and 4.1 for diphenyl itself. The width across the ring is 5.6 for diphenyl, 7.9 for hexachlorodiphenyl and 8.1 for dimesityl and its diamino derivative. The respective lengths of these compounds are 0.5, 10.75, 11.1 and 11.3.

Discounting the staggering for the moment, there are the possibilities that the two rings may lie in the same plane, in planes at small angles to each other, or at right angles. The space considerations do not favor the first. The facts that the molecules are asymmetric and that they occupy the spaces given in the preceding paragraph lead to the conclusion that the two rings are in planes turned from each other at an angle of not greater than 45° in the 2,2′,6,6′-derivatives of diphenyl, while the rings in diphenyl itself are coplanar.

Summary

1. Unique solutions of the crystal structure for diphenyl and five of its derivatives have been determined by rotating and oscillating crystal methods.
2. The possible size, shape and position of the molecules of these compounds are discussed.

SYNTHESIS OF QUINOLINE COMPOUNDS. VI. PREPARATION OF CERTAIN ACYLAMINO DERIVATIVES OF 8-HYDROXYQUINOLINE

BY KONOMU MATSUMURA AND CHUSABURO SONE

RECEIVED JULY 17, 1930 PUBLISHED JANUARY 12, 1931

The acyl derivatives of aminohydroxyquinoline described in this paper were prepared in connection with a study of the bactericidal action of quinoline compounds.

Experimental

The aminohydroxyquinoline (1 mole) and acetic anhydride (1.1 moles) were allowed to react in ether solution for three days at room temperature in the presence of finely ground sodium acetate, with occasional stirring. The ether was then evaporated and sufficient water was added to dissolve the sodium acetate. The product was filtered, washed and finally recrystallized. The yields were very good.

In general, these quinoline derivatives are sparingly soluble in water and ether, fairly soluble in benzene and very soluble in alcohol and chloroform. Their salts with mineral acids can be crystallized from alcohol and they are all soluble in water except the hydrochloride of 7-iodo-5-acetamino-8-hydroxyquinoline, which undergoes hydrolysis with separation of free base.

TABLE I

HYDROXYQUINOLINE DERIVATIVES

No.	Quinoline derivative	Form	Solvent	M. p., °C.
1	7-Iodo-5-acetamino-8-hydroxy-	Colorless needles	EtOH	212
2	5-Acetamino-8-hydroxy-	Colorless prisms	$CHCl_3$	218–219
3	5-Acetamino-6-hydroxy-	Colorless needles	EtOH	278 (dec.)

THE REDUCTION OF NAPHTHALENE BY ALKALI METALS IN LIQUID AMMONIA[1]

BY CHARLES BUSHNELL WOOSTER AND FRANK B. SMITH

RECEIVED JULY 26, 1930 PUBLISHED JANUARY 12, 1931

The reaction between sodium and naphthalene in liquid ammonia solution was first investigated by Lebeau and Picon[2] and the products which they obtained at 15° were sodium amide and tetrahydronaphthalene. These facts are equally open to two different interpretations.

I. It may be assumed that the naphthalene was reduced by nascent hydrogen generated by a reaction between the alkali metal and the solvent.

$$4Na + 4NH_3 \longrightarrow 4NaNH_2 + 4(H) \qquad (1)$$

$$4(H) + C_{10}H_8 \longrightarrow C_{10}H_{12} \qquad (2)$$

This hypothesis is analogous to that advanced by Kekulé, Kolbe, von Baeyer and others[3] to explain reductions of organic substances with sodium amalgam and water.

II. The formation of tetrahydronaphthalene may also be attributed to a solvolytic action of the solvent upon an organo-alkali compound which was formed as an intermediate product.

$$C_{10}H_8 + 4Na \longrightarrow C_{10}H_8Na_4 \qquad (3)$$

$$C_{10}H_8Na_4 + 4NH_3 \longrightarrow C_{10}H_{12} + 4NaNH_2 \qquad (4)$$

This assumption is analogous to an alternative theory of amalgam reduction recently proposed by Willstatter, Seitz and Bumm.[4]

This reaction, therefore, is of especial interest as a test case for indicating the possibilities of wider application of the two general hypotheses.

Dipotassium[5] and dilithium[6] derivatives of naphthalene have been pre-

---

pared by the action of alkali metals on the pure hydrocarbon at elevated temperatures and on its solutions in organic solvents at room temperature, respectively, but thus far no similar derivatives containing a higher proportion of alkali metal have been reported. Preliminary observations indicated the formation of a compound between potassium and the hydrocarbon in liquid ammonia at lower temperatures, and, accordingly, a more detailed study of the reaction under these conditions was undertaken.

Experimental Part

Ratio of Sodium and Potassium to Naphthalene.—It is an evident consequence of the second hypothesis outlined above that the maximum amount of sodium entering into reaction must bear a definite relation to the quantity of naphthalene used, whereas no such restriction is demanded by the first hypothesis. In attempting to determine the number of sodium atoms which react with a molecule of naphthalene, considerable experimental difficulties were encountered. It was equally difficult to titrate a known amount of sodium with naphthalene or a known amount of naphthalene with sodium because the reaction does not go to completion with ease. If an excess of sodium were used, titration with ammonium bromide to the disappearance of the blue color of the free metal would lead to erroneous results, since ammonium bromide would also react with a sodium compound of naphthalene. Advantage was taken of the fact that ammonium bromide reacts with free sodium to liberate hydrogen, whereas no hydrogen would be formed in its reaction with a sodium compound of naphthalene. This method was open to a possible source of error, since the hydrogen evolved might itself react with naphthalene or its reduction products, thus making the apparent sodium ratio too high. If ethyl bromide were used instead, the ethane evolved would not react with naphthalene or its reduction products, but the reaction between ethyl bromide and the organo-alkali compound might also generate gaseous products and indicate too low a sodium ratio.[7] However, if the same value were obtained by both methods, it would seem reasonable to suppose that these possible sources of error are merely hypothetical.

The apparatus employed was similar to that previously described.[8] It was found necessary, however, to alter the design of the reaction tube in order to promote complete reaction. The gaseous ammonia was admitted through an inlet at the very bottom of

---

[7] Another possibility requiring consideration is that of gas formation between ethyl bromide and the sodium amide resulting from Reaction 1 or 4. However, ethyl bromide reacts but slowly with sodium amide in liquid ammonia at −40° and even in the more rapid reaction at room temperature, only small amounts of ethylene are formed [Picon, Bull. *soc. chim.*, 35, 979–81 (1924)] It may be expected, therefore, that ethylene would not be evolved in quantities too large to be removed by solution in the water over which the gases were collected.

[8] Wooster, THIS JOURNAL, 51, 1859 (1929).

the reaction tube to insure vigorous stirring and the top of the reaction tube was fitted with a ground-in dropping funnel which permitted liquids or solutions to drip directly into the agitated reaction mixture.

The sodium was cut under petroleum ether, weighed under "Nujol," washed with petroleum ether, placed in the bottom of the reaction tube and ammonia condensed upon it A suitable amount of pure, dry naphthalene was dissolved in a small quantity of dry toluene and the solution added slowly with vigorous stirring to the sodium solution after which the reaction mixture was stirred slowly with a stream of ammonia gas for a period of several hours. In Experiments 1 and 2, dry ammonium bromide was then added and the evolved gas collected over water. The greenish color of the reaction mixture was slowly discharged and gave way to a bright transparent red, after which no more gas was evolved upon further addition of ammonium bromide, although the red color eventually disappeared. The collected gas was dried and characterized by its density as hydrogen. In Experiments **3** and 4, pure, dry ethyl bromide was used instead of ammonium bromide to dissipate the free sodium. The procedure and observations were analogous to those just described except that the gas collected was found by its density to be ethane. In experiments using potassium instead of sodium, it was found that the amount of gas liberated by the action of ammonium bromide depended somewhat on the length of time the reaction was allowed to proceed. If sufficient time elapsed, the reaction mixture eventually turned red before ammonium bromide was added, and the action of this reagent did not result in the formation of any gas. This behavior is apparently due to a slow ammonolysis of the excess potassium, since hydrogen is evolved during the process. In Experiments 5 and 6 no ammonium bromide was added and hydrogen was collected from the very beginning of the reaction until the red color appeared, when the evolution of gas ceased. The results of these experiments appear in Table **I**.

TABLE I

RATIO OF SODIUM AND POTASSIUM TO NAPHTHALENE

No.	Metal, g.	$C_{10}H_8$, g.	Gas, cc.	Na or K consumed, atoms/mole of $C_{10}H_8$
1	0.4585 (Na)	0.5609	35.65 (H_2)	3.83
2	2.6411 (Na)	2.9468	315.1 (H_2)	3.77
3	2.0620 (Na)	2.3040	181.0 (C_2H_6)	4.09
4	1.6240 (Na)	1.6628	204.1 (C_2H_6)	4.04
5	1.6158 (K)	1.0037	128.4 (H_2)	3.81
6	1.4161 (K)	0.9021	114.4 (H_2)	3.70

It seems evident from the first four values in column five that only four atoms of sodium per molecule of naphthalene react regardless of the quantity of excess metal present and (within reasonable limits) of the time elapsed, the somewhat low values obtained in the first two experiments being doubtless due to the presence of small amounts of hydrogen in the ammonia, incident to the previous drying of this solvent with sodium. This is decidedly in favor of the second mechanism, outlined in the introduction, and it may be concluded that the four sodium atoms primarily add to a molecule of naphthalene.

The last two values in column five indicate that approximately four equivalents of potassium per mole of naphthalene reacted without the formation of gaseous products. Although in this case the gradual ammonolysis of the potassium[9] prevents a discrimination between the two mechanisms on the basis of the quantitative results, the formation of the characteristic transparent red solution strongly suggests the presence of an organo-alkali compound.

Identification of the Product of Hydrolysis of the Sodium Derivative.—Although the evidence presented above indicates that four atoms of sodium react with each molecule of naphthalene, it does not indicate which positions the sodium atoms enter. Accordingly, the hydrolysis product of the sodium compound was prepared and its properties studied for the purpose of identification.

Twenty-three grams of sodium was dissolved in liquid ammonia in a large Dewar flask equipped with a mechanical stirrer;[10] 30 g. of naphthalene, or slightly less than one molecule to every four atoms of sodium, was then added slowly in ether solution and the reaction mixture stirred for twenty-four hours. Ammonium bromide was added in excess and after the ammonia had been allowed to evaporate, the Dewar flask was washed out with water. The oil which separated was taken up in ether and the aqueous solution extracted with this solvent. The combined ethereal extracts were dried over sodium hydroxide and evaporated on a water-bath leaving a yellow oil which was carefully distilled *in vecuo.* A colorless, highly refractive oil boiling at 50–55° under less than 1 mm. pressure constituted the main reaction product. This substance did not react with solutions of bromine in carbon tetrachloride at room temperature and the reaction which occurred upon heating with liquid bromine was accompanied by the evolution of hydrobromic acid. These facts distinguish the product from the dihydronaphthalenes and, accordingly, it was compared with a carefully distilled sample of commercial tetralin. Both substances, independently and when mixed, boiled at 207–207.5" under 753 mm., and the density of both was 0.965 ± 0.0005 at 25°. Since tetralin has been demonstrated to be 1,2,3,4-tetrahydronaphthalene,[11] the four sodium atoms must add in the 1,2,3,4 positions.

Observations Indicating Ammonolysis.—When the residue from the evaporation of ammonia from the sodium and naphthalene reaction mixture was heated by surrounding the evacuated reaction tube with a steam jacket, a liquid distilled and collected in drops on the cool upper walls of the tube. This circumstance indicates the formation of tetrahydronaphthalene by ammonolysis at higher temperatures and accounts for the fact that Lebeau and Picon were able to obtain this substance directly from the interaction of sodium and naphthalene.

It remained to be determined whether in liquid ammonia at its boiling point the tetrasodium tetrahydronaphthalene was entirely stable or whether it was partly ammonolyzed. The following observation suggested the latter to be the case. When oxygen was passed through the reaction mixture the presence of nitrite ions in the residue could be shown by a qualitative test with potassium iodide, hydrochloric acid and carbon

---

[9] This action may well be ascribed to the catalytic influence of the potassium amide formed in the ammonolysis of the potassium compound of naphthalene [unpublished observations of one of the authors (C. B. W.)]. Sodium amide exerts a similar influence upon the ammonolysis of sodium [Kraus, THIS JOURNAL, 29, 1569 (1907)], but this reaction is too slow to interfere with the experiments described.

[10] This apparatus has been previously described [Wooster and Mitchell, *ibid.*, 52, 691 (1930)].

[11] Schroeter, *Ann.*, 426, 83 (1922).

disulfide. This proves the presence of sodium amide in the original solution since it is oxidized under these conditions with formation of sodium nitrite.[12]

Quantitative Study of the Ammonolysis.—Although it is true that the occurrence of ammonolysis would result in an increase in weight of the reaction residue, this fact does not serve as a basis for a suitable method of attacking the problem under consideration. Apart from the errors introduced by the volatility of the products, it is evident that the increase in weight exhibited by the contents of a reaction tube which has been evacuated after it has attained room temperature will be determined by the state of equilibrium characteristic of the residue at room temperature and not of the solution in liquid ammonia at its boiling point. If, on the other hand, the tube is evacuated at the temperature of boiling ammonia, the equilibrium may be displaced during the evaporation of the solvent and the result may also be influenced by the weight of solvent retained as ammonia of crystallization.

Consequently, a method of analysis was sought which could be applied directly to the liquid ammonia solutions. No such method was found which was capable of precision, but a procedure was developed which provided approximate values of the degree of ammonolysis. This procedure was based upon a study of the products formed in oxidizing the reaction mixture. Rengade,[12] by leading oxygen into solutions of cesium, potassium and sodium amides in liquid ammonia, found oxidation to take place according to the equation,

$$2MNH_2 + 1^1/_2O_2 = MOH + MNO_2 + NH_3$$
$$(M = Cs, K \text{ or } Na) \qquad (5)$$

The oxidation of metallic sodium in liquid ammonia yields the peroxide, Na_2O_2.[13]

According to Kraus and Rosen[14] sodium peroxide and triphenylmethyl peroxide may be obtained by the oxidation of sodium triphenylmethide in liquid ammonia. It is reasonable to suppose that the sodium or potassium in combination with naphthalene would also be oxidized to the peroxide. Thus if a reaction mixture contained sodium amide, a sodium hydronaphthalene and free sodium, the inorganic oxidation products should be sodium nitrite, sodium hydroxide and sodium peroxide. Since the oxidation of the materials in solution is reasonably rapid, and since both the organo-alkali compound and the alkali metal amide are simultaneously attacked and destroyed, displacement of the ammonolytic equilibrium would be minimized, and it might be expected that a determination of the amounts of nitrite and peroxide formed would furnish an approximate estimate of the degree of ammonolysis.

[12] Rengade, *Ann. chim. phys.*, 11, 348 (1907).

[13] Kraus and Whyte, THIS JOURNAL, 48,1781 (1926).

[14] Kraus and Rosen, *ibid.*, 47, 2739 (1925).

The sodium peroxide was separated from sodium nitrite by treating the ice-cold aqueous solution of the residue left after oxidation and subsequent evaporation of the ammonia, with an ice-cold solution of barium chloride, as described by Schrader.[15] The precipitate of barium peroxide was separated by filtration, washed, dried and analyzed. The filtrate was then analyzed for nitrite ions.

The method of nitrite analysis used was that developed by Gerlinger,[16] in which the nitrite solution is boiled with a concentrated solution of ammonium chloride in an atmosphere of carbon dioxide, and the nitrogen evolved is collected over potassium hydroxide solution. The amount of nitrite is calculated from the amount of nitrogen liberated, according to the equation

$$NH_4Cl + MNO_2 \longrightarrow MCl + 2H_2O + N_2 \qquad (6)$$

A method of peroxide determination was developed in which the solid barium peroxide was added to a strong solution of potassium iodide, strong hydrochloric acid added, and the liberated iodine titrated with standard thiosulfate solution. Calculations were based on the equation

$$BaO_2 + 4HCl + 2KI + 2Na_2S_2O_3 \longrightarrow 2H_2O + BaCl_2 + 2KCl + 2NaI + Na_2S_4O_6 \qquad (7)$$

In order to determine how nearly quantitatively potassium and sodium amides were oxidized under the conditions of the experiments, potassium was converted to the amide, oxidized and the products analyzed. Sodium was converted partially to the amide, the mixture of amide and free metal oxidized and the products analyzed. (The extent of the ammonolysis was in each case determined by collecting the hydrogen formed.) The results are indicated in Table II, where all amounts are given in milliatoms or millimoles.

TABLE II

OXIDATION OF SODIUM AND POTASSIUM AMIDES

No.	Metal	Amount	Amide formed	Nitrite Found	Nitrite Calcd.	Peroxide Found	Peroxide Calcd.
1	Potassium	26.5	25.6	10.6	12 8	None	None
2	Potassium	31.3	303	128	15.2	None	None
3	Sodium	47.7	30.2	12.0	15.1	0.1	17.5

In the following experiments a slight excess over four atoms of alkali metal was allowed to react with each molecule of naphthalene. In the case of potassium, the excess metal was converted to the amide before oxidation. Excess sodium was left as free metal before oxidation. The results of several experiments are summarized in Tables III and IV, where all corrected values are calculated by the use of the data in Table II. All quantities are given in milliatoms or millimoles.

The corrected amount of sodium amide formed by ammonolysis of the organo-alkali compound is given in column six. In the experiment re-

[16] Gerlinger, *Z. angew. Chem.*, 50, 1250 (1901).

TABLE III

OXIDATION OF SODIUM COMPOUND, FREE SODIUM AND SODIUM AMIDE

No.	Sodium	$C_{10}H_8$	Nitrite	Amide Found	Amide Corr.	Peroxide	Free metal	Sodium compound
1	43.06	1007	12.40	24.92	31.15	9.05	278	9.03
2	57.23	14.00	17.82	35.64	44.05	9.89	1.23	9.35

corded in Table II very little peroxide was obtained from the oxidation of the free metal; accordingly the major portion of the peroxide obtained in these oxidations was ascribed to the oxidation of the organo-alkali compound, as may be seen upon examination of column nine. The results indicate that of the four sodium atoms which are known to react with naphthalene, **3.09** and **3.15** are converted into sodium amide by the solvent while **0.90** and 0.67 atoms appear definitely to remain in combination with the naphthalene.

TABLE IV

OXIDATION OF POTASSIUM COMPOUND AND POTASSIUM AMIDE

				Amide				
No.	Potassium	$C_{10}H_8$	Nitrite	Found	Corr.	From excess	From ammonolysis	Peroxide
1	27.4	6.5	7.9	15.8	18.8	1.4	17.4	0.4
2	27.1	6.5	8.4	16.6	19.8	1.1	18.7	.5

The values in column eight represent the amounts of potassium amide presumably resulting from ammonolysis of tetrapotassium tetrahydronaphthalene. They correspond to 2.68 and **3.04** molecules per molecule of naphthalene, respectively. As no free metal was present during the oxidation in these experiments, the peroxide[17] could only result from the oxidation of an organo-alkali compound. Thus the existence of peroxide in the oxidation products together with the observation of the characteristic red color, previously noted, constitute definite evidence of the presence of an organo-alkali compound in the reaction mixture. Furthermore, the approximate correspondence between the results given in Tables III and IV indicates that the reaction between potassium and naphthalene is not essentially different from that which takes place when sodium is used.

Discussion

The evidence presented in this paper shows that the reduction of naphthalene with sodium in liquid ammonia takes place through the intermediate formation of a 1,2,3,4-tetrasodium addition product which is

---

[17] The low values for the peroxide given in the table may to a large extent be ascribed to the fact that potassium peroxide is capable of further oxidation under the conditions of these experiments and that the higher oxides so formed might escape notice in the analytical procedure employed. In contrast to these low peroxide values, but in agreement with the amounts of amide formed, the general behavior of alkali metal amides in liquid ammonia suggests that the potassium compounds would be less susceptible to ammonolysis than the corresponding sodium compounds.

approximately three-fourths ammonolyzed even in solution at $-33.5°$. This confirms the mechanism derived by an extension to this case of the theory proposed by Willstatter, Seitz and Bumm[4] to explain amalgam reductions.

It is of interest to note that of the compounds which were also found by Lebeau and Picon[18] to be reduced to hydro derivatives with formation of sodium amide: anthracene,[19] phenanthrene, biphenyl,[20] stilbene and phenylethylene[21] have been found to yield addition products with the alkali metals or with organo-alkali compounds, whereas the compounds which failed to undergo such a reduction (amylene, benzene, toluene, cymene, terpinene, terpinoline, carvene, terebene, a-pinene and menthene) have not as yet been found capable of adding the alkali metals, although several have been specially investigated with this point in view.[22] This coincidence cannot fail to suggest that these other reductions observed by Lebeau and Picon proceed by means of a mechanism similar to that just demonstrated to operate in the reduction of naphthalene.

It is perhaps also worth mention that whereas catalytic reduction of naphthalene always yields a tetrahydro or more highly hydrogenated derivative,[23] the reducing action of sodium in alcohol[24] may also yield a dihydro derivative in which the additional hydrogen atoms occupy the same positions (1,4) as do the alkali metal atoms in the dilithium and dipotassium addition products which have been prepared. Here again the postulate of an intermediate organo-alkali compound in the reduction process is in harmony with the evidence available.

Summary

1. It has been shown that the reduction of naphthalene with sodium in liquid ammonia takes place through the intermediate formation of a 1,2,3,4-tetrasodium addition product, which is approximately three-fourths ammonolyzed even in solution at $-33.5°$.

2. The reaction with potassium apparently follows essentially the same course as that with sodium.

3. These facts confirm the mechanism derived by extending to this reaction the theory proposed by Willstatter, Seitz and Bumm to explain reductions of organic compounds with sodium amalgam and water.

4. Certain facts have been pointed out which suggest a similar mecha-

SYNTHESIS OF SOME NEW COMPOUNDS IN THE PYRROLE AND PYRROLIDINE SERIES

BY LYMAN C. CRAIG WITH R. M. HIXON

RECEIVED JULY 28, 1930 PUBLISHED JANUARY 12, 1931

A previous paper[1] reported the preparation of pyrrolidine, N-phenylpyrrolidine and N-cyclohexylpyrrolidine. In extending the series for the contemplated study of insecticidal action and physical properties, the benzyl, methyl, butyl and *p*-tolyl derivatives were desired.

The aliphatic N-substituted derivatives can be prepared by the general method of Britton[2] or by addition of RX to the free base. Contrary to the literature[3] the yield by the latter method is low due to the formation of the quaternary derivative. The general method to be recommended for the preparation of N-substituted derivatives where R is a saturated aliphatic radical is to prepare the N-substituted pyrrole and reduce it catalytically as pyrrole was reduced. The presence of excess acid is necessary for a successful reduction. Substitution on the nitrogen appears to stabilize the ring toward polymerization by acid, eliminating the difficulty encountered with the carbon substituted derivatives.[4] J. P. Wibaut[5] reduced methylpyrrole catalytically with Adams and Shriner catalyst in glacial acetic acid, but his reduction required large amounts of catalyst and shaking for a long period of time. If alcohol acidified with hydrochloric acid is used as a solvent, the reduction requires only 0.2 g. of catalyst and is complete in three hours. The same catalyst may be used several times. N-Methylpyrrole has also been reduced successfully to N-methylpyrrolidine by passing its vapor over palladium[6] at 160°.

Tadeus Reichstein[7] gave a method for the characterization of N-substituted pyrroles by the use of a diazo reaction. Reduction can also be used for this purpose since the yield is practically quantitative and the resulting pyrrolidine derivative can easily be identified as the picrate.

In the N-butylpyrrole synthesis the formation of the substituted acid

amide is greater than with the N-methylpyrrole or pyrrole synthesis. By the use of reduced pressure in the distillation of the mucic acid salt, the yield of butylpyrrole was practically doubled.

p-Toluidine condenses smoothly with tetramethylene chloride to give satisfactory yields of N-p-tolylpyrrolidine.

Experimental

N-Normal-butylpyrrole.—The method of preparation was that of Reichstein except that mucic acid was used instead of saccharic. To 86 g. of mucic acid in enough water to make a thin paste, 60 g. of butylamine was added. Upon cooling the reaction mixture solidified. It was transferred to a 500-cc. Claisen flask and subjected to distillation under reduced pressure (35 mm.). The distillate contained 35 g. of an oil which was extracted with ether, dried and fractionated, giving 13.5 g. distilling at a temperature of 165–180°. This was used for reduction. It was a colorless oil and had a very disagreeable sharp odor.

N-Butylpyrrole-a-carboxy-normal-butylamide.—The high-boiling residue (21.5 g.) from above was subjected to distillation under reduced pressure (165–170° under 10–12 mm. pressure). The colorless distillate solidified. It melted at 57° and crystallized in needles from an alcohol–water mixture.*

An attempt to hydrolyze the substituted acid amide by refluxing over strong caustic was unsuccessful, as was also an attempt using alcoholic potash at 130°. The compound was finally hydrolyzed by heating for ten hours at 200°, 10 g. of the amide in an alcoholic solution containing 8 g. of potassium hydroxide in 4 cc. of 95% alcohol. After hydrolyzing, most of the alcohol was distilled off and water added to the residue. Fractionation of this mixture by solubility in ether, acid solution and basic solution yielded about 1 g. of unchanged amide, N-butylamine and an acid fraction. The oily acid fraction, which was N-butylpyrrole-a-carboxylic acid, was finally characterized by conversion to the acid amide. It is soluble in all organic solvents and insoluble in water. The calcium, barium and silver salts were too soluble to crystallize. Six grams of the free acid was subjected to distillation under 6 mm. pressure. From the distillate three grams of an alkali-insoluble oil was obtained that distilled at 165 to 178° and had all the characteristics of N-butylpyrrole. Two grams of the original acid was present in the distillate. Evidently carbon dioxide splits off quite readily from this acid.

N-Butylpyrrole-a-acid Amide.—To 1 cc. of the free acid an excess of thionyl chloride was added. After heating, as much of the excess thionyl chloride was evaporated as was possible using reduced pressure and heating on the water-bath. The residue was dropped into cold concentrated ammonia and the resulting oily mass extracted with ether. The ether extract was evaporated to dryness and the residue recrystallized from hot water. The yield is low; m. p. 108°.

Anal. Calcd. for $C_9H_{19}N_2O$: C, 64.9; H, 8.99. Found: C, 64.98, 65.00; H, 8.52, 8.88.

Reduction of N-Methylpyrrole and N-Butylpyrrole.—The N-methylpyrrole was prepared by the method of Bell and Lapper.[9] To 10 cc. of pyrrole base in 100 cc. of absolute alcohol, 0.2 g. of Adams and Shriner catalyst and an equivalent of hydrochloric acid were added. In three hours in the case of N-methylpyrrole and five hours in the case of N-butylpyrrole the reduction was complete. The catalyst was filtered off and

---

[8] Reichstein reported a compound, which corresponded to the above, as N-butylpyrrole-a-isobutylamide. This must be a typographical error, since normal-butylamine was used in the synthesis of his compound.

[9] Bell and Lapper, *Ber.*, 10, 1861 (1877).

the alcohol removed by distillation. The residue was washed with ether and treated with solid potassium hydroxide until an oil separated. The oil was dried over solid potassium hydroxide and distilled, The N-methylpyrrolidine distilled entirely at 76–78°, the yirld being almost the theoretical. N-Methylpyrrolidine has a stifling odor and a very high vapor pressure at room temperature. Its vapor pressure is 99 mm. at 25°. This may account for the emphasis in the literature placed on its physiological properties.

The yield of N-butylpyrrolidine is 88% of the theoretical. It is slightly soluble in water and has an odor similar to pyrrolidine. The picrate crystallized in leaflets from 95% alcohol and showed a constant melting point of 124°. An attempt was made to prepare a chloroplatinate by addition of a solution of chloroplatinic acid to the hydrochloride of the free base but the salt appeared to be too soluble to crystallize. A chloroaurate was prepared by this method using chloro-auric acid. It was very soluble in alcohol but crystallized in yellow leaflets from hot water. It melted without decomposition at 78°.

Anal. Calcd. for $C_8H_{17}NHAuCl_4$: Au, 42.13. Found: Au, 42.14, 42.08.

N-*p*-Tolylpyrrolidine.—To 5 g. of tetramethylene chloride[10] (boiling point 154–164°) 12.6 g. of p-toluidine was added. Upon heating on a steam-bath for ten hours, it formed a solid mass of crystals that entirely dissolved in dilute hydrochloric acid. The acid solution was washed with ether, made strongly alkaline and the oily layer run through a primary–secondary–tertiary amine separation with benzenesulfonyl chloride. A yield of 4.5 g. of a tertiary amine was obtained. It was dried over solid potassium hydroxide and distilled at a constant temperature of 120° under 8 mm. pressure. It crystallized in leaflets from an alcohol–water mixture and showed a constant melting point of 42.5°. It has a rather pleasant odor

A chloroplatinate was prepared in the usual way but it could only be recrystallized from water containing considerable hydrochloric acid, as reduction took place in water alone. It showed a decomposition point of 175°. For analysis the material was recrystallized and dried at room temperature in a vacuum desiccator.

Anal. Calcd. for $(C_{11}H_{15}N)_2H_2PtCl_6$: Pt, 26.68. Found: Pt, 26.70, 26.67.

N-Benzylpyrrolidine.—This compound was first prepared by Schlinck.[11] He reported a nearly quantitative yield which could not be duplicated by the same method. To 5 cc. of pyrrolidine,[12] one-half equivalent of benzyl chloride was added (a full equivalent gave a lower yield of N-benzylpyrrolidine than a half). The mixture was warmed for two hours on a water-bath. Dilute hydrochloric acid was added and the unreacted halide removed by washing with ether. Upon addition of caustic solution, an oil separated; when solid potassium hydroxide was added, a third layer appeared. The top layer was drawn off and identified as N-benzylpyrrolidine. It amounted to 4 g. or a yield of 40% of the theoretical. Its picrate melted at 128° as reported by Schlinck.

The second layer (the larger) was viscous, insoluble in ether, very soluble in water and required a concentrated solution of potassium hydroxide to make it separate. It could not be prepared in a form suitable for analysis but its properties are what would be expected of dibenzylpyrrolidinium hydroxide.

Summary

It has been shown that the N-substituted pyrroles can be reduced easily to the corresponding pyrrolidine compounds in alcohol–hydrochloric acid

THE CATALYTIC EFFECT OF MAGNESIUM ALCOHOLATES ON THE REACTION OF GRIGNARD REAGENTS WITH CARBON DIOXIDE[1]

BY CORLISS R. KINNEY AND M. L. MAYHUE

RECEIVED AUGUST 12, 1930 PUBLISHED JANUARY 12, 1931

Although many substances have been shown to have deleterious effects in Grignard reactions, nothing appears to be known about the effect of alcohols, which are often present in the organo halides from which the reagents are made. The catalytic behavior of alcohols or their magnesium derivatives was first brought to our attention by the variable yield of triphenylacetic acid obtained from triphenylmethylmagnesium chloride and carbon dioxide. A study of the reaction showed definitely that the presence of small amounts of triphenylcarbinol in the triphenylchloromethane used to make the reagent very materially lowered the yield of triphenylacetic acid.

The systematic addition of increasing quantities of triphenylcarbinol gave a yield curve shown in Fig. 1 as the lower curve, in which an addition of 15.3 mols per cent. of triphenylcarbinol caused the yield of triphenylacetic acid to drop from 75%[2] to 0%. The upper straight line in Fig. 1 represents the yield of acid to be expected based on the yield of acid without addition of the carbinol and subtracting an amount corresponding to the diminution in yield caused by the reaction of a part of the reagent with the carbinol.

The lowering in yield of acid was not caused by an interference in the reaction of the triphenylchloromethane with the magnesium to form the Grignard reagent, since the same amount of triphenylcarbinol (15.3 mole per cent.) when added after the reagent *had* been prepared prevented the reaction

---

[1] Parts of this paper have been presented at the Berkeley and Eugene meetings of the Pacific Division of the American Association for the Advancement of Science and at the Minneapolis meeting of the American Chemical Society.

[2] The maximum yield obtained was 87.5%, but the method used was not adaptable to the study at hand.

with carbon dioxide from taking place. The same result was observed when the mixture was *stirred* and *refluxed* continuously for twenty-four hours. However, in another experiment a similar solution of triphenylmethylmagnesium chloride, containing 15.3 mole per cent. of carbinol was allowed to *stand* in contact with carbon dioxide, at room temperature, for sixty hours. A moderate yield of acid was obtained and is shown in Fig. 1 midway between the two curves mentioned above and is connected with the lower or experimental curve by a dotted line.

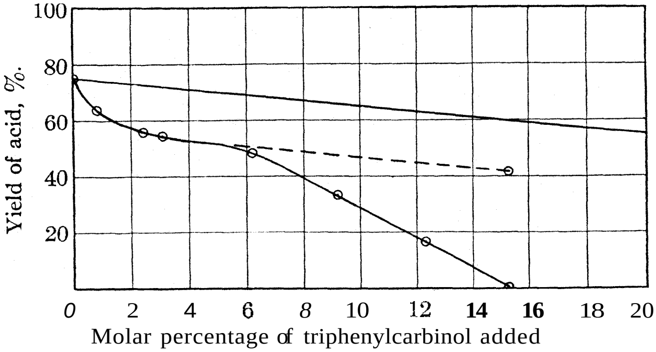

Fig 1—The effect of triphenylcarbinol on the yield of triphenyl acetic acid obtained by the reaction of triphenylmethylmagnesium chloride with carbon dioxide.

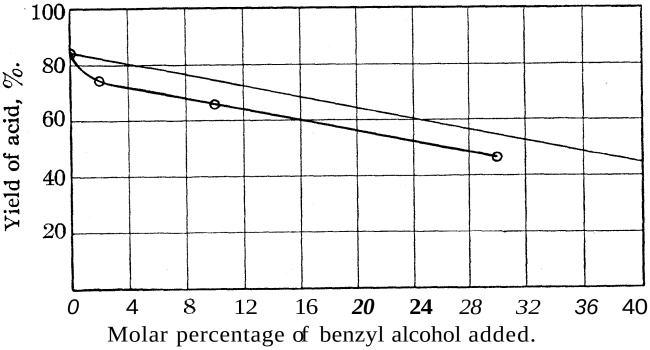

Fig. 2.—The effect of benzyl alcohol on the yield of phenylacetic acid obtained by the reaction of benzylmagnesium chloride with carbon dioxide.

If the curve in Fig. 1 is compared with those of the other reagents investigated (Figs. 2, 3, 4) it will be noted that the curve for triphenylmethylmagnesium chloride differs from all of the others in that there is a downward change in direction of the curve beyond about 6 mole per cent. addition of carbinol, but that the dotted line makes a curve that compares very nicely with all of the others. There seems to be at least two possible explanations of this unique behavior of triphenylmethylmagnesium chloride. In the first place this reagent, as well as many of its reaction products, differs from the other reagents in being much less soluble in ether. The reaction of the reagent with carbon dioxide is accompanied by the solution of the yellowish precipitate of the reagent with the formation of a clear deep blood-red solution which more or less quickly, depending upon the rate of addition of the carbon dioxide, precipitates a yellowish-white substance which is probably the magnesium salt of triphenylacetic acid. When triphenylcarbinol was added, however, in amounts corresponding to the downward drop in the curve (6 mole per cent. or more) the reagent did not dissolve nor was a red solution produced, indicating that in the heterogeneous mixture a new factor influencing the course of the reaction was present. This

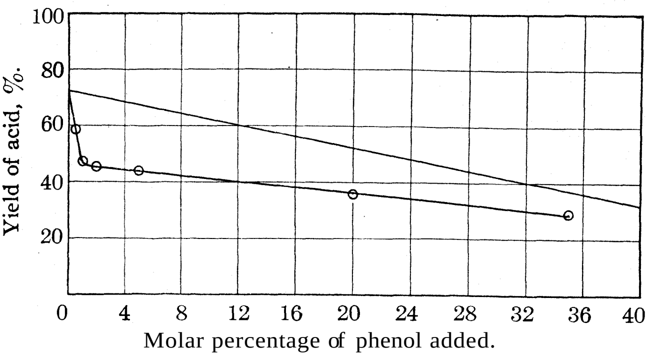

Fig. 3.—The effect of phenol on the yield of benzoic acid obtained by the reaction of phenylmagnesium bromide with carbon dioxide.

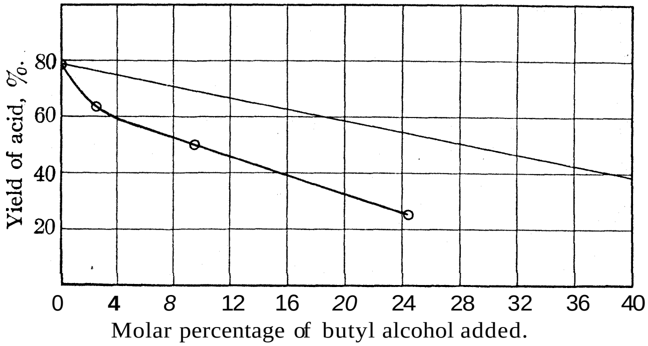

Fig. 4.—The effect of butyl alcohol on the yield of valeric acid obtained by the reaction of butylmagnesium bromide with carbon dioxide.

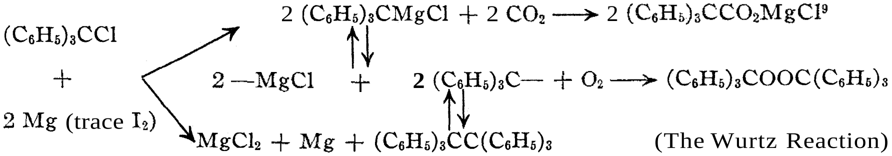
point on the curve might well correspond to the formation of a precipitate of the magnesium derivative of triphenylcarbinol.

Gilman and McGlumphy[3] and Gomberg and Bachmann[4] have shown recently that triphenylmethylmagnesium iodide may be prepared from triphenylmethyl and magnesious iodide, a reaction which explains the high yields of triarylmethylmagnesium halides from the tertiary halides of the type of triphenylchloromethane. This reaction is incorporated in the combined reactions given below. The reverse process, the dissociation of triphenylmethylmagnesium chloride into triphenylmethyl, seems probable in view of the fact that oxygen[6] reacts smoothly with the solution to give an almost quantitative yield of triphenylmethyl peroxide,[6] a reaction more characteristic of triphenylmethyl than of Grignard reagents.[7] Thus, the reactions of triphenylmethylmagnesium chloride are complicated by the possible presence of triphenylmethyl,[8] which may in part be responsible for the greater effect of triphenylcarbinol on this reagent. These interrelationships are expressed in the following reactions.



$$\begin{tikzcd}
 & 2\,(C_6H_5)_3CMgCl + 2\,CO_2 \arrow[r] \arrow[d, leftrightarrow] & 2\,(C_6H_5)_3CCO_2MgCl^{9} \\
(C_6H_5)_3CCl + 2\,Mg\ (\text{trace } I_2) \arrow[ur] \arrow[dr] & 2\,\text{—}MgCl + 2\,(C_6H_5)_3C\text{—} + O_2 \arrow[r] \arrow[d, leftrightarrow] & (C_6H_5)_3COOC(C_6H_5)_3 \\
 & MgCl_2 + Mg + (C_6H_5)_3CC(C_6H_5)_3 & \text{(The Wurtz Reaction)}
\end{tikzcd}$$

Gilman and St. John[9a] have recently shown that bromomagnesium triphenylcarbinolate when heated in ether solution was transformed slowly into triphenylmethane, and that in the presence of ethylmagnesium bromide the transformation did not take place. This reaction suggests the possibility that triphenylmethane was responsible for the decreased yield of triphenylacetic acid. However, the addition of triphenylmethane to a solution of triphenylmethylmagnesium chloride had little effect on the yield of acid obtained therefrom.

The reagent most closely related to triphenylmethylmagnesium chloride

[5] Gilman and Fothergill, Ref. 3, p. 3151, have presented other evidence for the dissociation of triphenylmethylmagnesium chloride.

[6] This reaction has been observed by Schmidlin, *Ber.*, **39,** 4183 (1906); 41, 423 (1908).

[7] Several studies of the reaction of Grignard reagents with oxygen have been recorded but peroxides have not been isolated excepting from the triarylmagnesium halides although the assumption has been made by a number of authors that peroxides are formed as intermediates.

[8] Gomberg and Bachmann, Ref. **4,** p. **2456,** have suggested that the presence of triphenylmethyl in the reaction of triphenylchloromethane with magnesium has been the cause of certain misunderstandings in connection with this reagent.

[9] This reaction is affected very greatly by the presence of triphenyl carbinol.

[9a] Gilman and St. John, Rec. *trav. chim.*, November, 1930.

that was studied was diphenylmethylmagnesium chloride. Only small yields of this reagent were obtainable,[10] the major product being tetraphenylethane. The yield, furthermore, was very dependent on the history of the diphenylchloromethane from which the reagent was made, as, for example, a yield of 23% obtained with freshly distilled chloride dropped to 4% by merely allowing the chloride to stand in a brown, glass-stoppered bottle for three weeks.

Many attempts were made by Mr. Langlois in this Laboratory to overcome these difficulties and to dissociate tetraphenylethane in the presence of magnesious iodide, endeavoring to produce diphenylmethylmagnesium chloride in a way similar to the formation of triphenylmethylmagnesium chloride from triphenylmethyl and magnesious iodide and to effect the cleavage of tetraphenylethane with magnesious iodide similar to the cleavage observed with the alkali metals.[11] The reaction, unfortunately, was not realized even working to temperatures as high as 300° in an atmosphere of carbon dioxide.

The effect of diphenylcarbinol on the reaction of diphenylmethylmagnesium chloride with carbon dioxide could not be determined accurately because of the experimental difficulties with the reagent. One comparable result is given in the experimental part which shows only a slight diminution of the yield. This small effect may be masked by the presence of diphenylcarbinol in the chloride used to make the reagent.

The results obtained for phenylmethyl or benzylmagnesium chloride, phenylmagnesium chloride and butylmagnesium bromide were more conclusive (Curves 2, 3, 4). In the reaction of all of these reagents with carbon dioxide the presence of a small quantity of the alcohol or phenol corresponding to the reagent produced a marked drop in the yield of acid beyond that caused by the expected reaction of the carbinol with a part of the reagent. The latter is shown by the upper line in each diagram. Further additions caused further diminutions in the yields of the acids, but the lowering of the yield was much less precipitous.

The results shown in the diagrams (1, 2, 3, 4) above were all obtained by adding the carbinol along with the organo halide from which the reagents were made. The effects of adding the carbinol after the reagents had been made are shown in Table I, in which it is to be noted that in all cases, except the action of phenol on phenylmagnesium bromide, about the same lowering in yield was obtained. With the exception mentioned the loss in yield was considerable while not nearly as great as that caused by adding the phenol with the phenyl bromide when making the reagent.

The effect of adding phenol to triphenylmethylmagnesium chloride and

---

[10] Gilman and Zoellner, THIS JOURNAL, 52, 3984 (1930), have succeeded recently in materially increasing the yield of this reagent and the acid obtained from it.

[11] Ziegler and Thielmann, Ber., 56B, 1740 (1923).

TABLE I

RESULTS OR EXPERIMENTS

Reagent	Mole per cent of carbinol added	Yield to be expected, %	Yield adding carbinol	
			before, %	after, %
Triphenylmethylmagnesium chloride	15.3	59 7	0	0
Benzylmagnesium chloride	10	74.5	65 8	62.5
Phenylmagnesium bromide	1	71 1	47	61 4
Butylmagnesium bromide	9.5	68 9	50	48

triphenylcarbinol to phenylmagnesium bromide was determined in attempting to find some explanation for the catalysis. In these two determinations the yields of the acids were about the expected amount based on the maximum yields and subtracting for the amount of carbinol added. Thus the effect appears to be concerned with the carbinol corresponding to the Grignard reagent. However, the reaction of triphenylmethylmagnesium chloride with carbon dioxide was very materially affected by the addition of small quantities of benzaldehyde, the addition of 28.4 mole per cent. of benzaldehyde being sufficient entirely to prevent the formation of the acid with carbon dioxide. These results are shown in Fig. 5, the depression curve being the lower straight line.

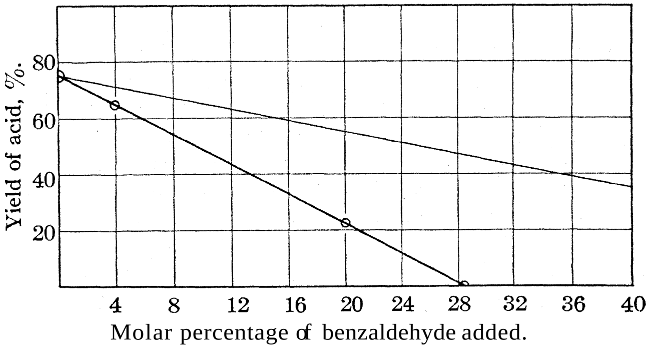

Fig. 5.—The effect of benzaldehyde on the yield of triphenylacetic acid obtained by the reaction of triphenylmethylmagnesium chloride with carbon dioxide.

The explanation offered for the depressing effect of benzaldehyde is that the reagent reacted with the aldehyde, forming the magnesium derivative of α,β,β,β-tetraphenylethyl alcohol, which appears to be about half as effective as triphenylcarbinol.

The addition of alcohols to the reaction of Grignard reagents with carbonyl compounds other than carbon dioxide would be expected to cause very little lowering of the yield because of the fact that high yields are obtainable from the reaction in spite of the fact that magnesium alcoholates are produced as the reaction progresses.

$$RMgX + RCHO \longrightarrow R_2CHOMgX$$

This view was tested in one experiment only in which 2.43 mole per cent. of butyl alcohol was added to butylmagnesium bromide and then the reagent allowed to react in the usual way with benzaldehyde. The lowering in yield was 2.5% as compared with the addition of 2.43%.

The mechanism of the catalytic effect of the presence of magnesium alcoholates on the reaction of Grignard reagents with carbon dioxide is not clear at this time. The curves seem to have a characteristic shape and the percentage depression is much greater for smaller additions of the alcohol. Some further studies under way may help to clear this up.

Experimental Part

Reactions Involving Triphenylmethylmagnesium Chloride.—The triphenylmethylmagnesium chloride was prepared in essentially the way that Gilman and Zoellner[12] recommend, except that we did not carry out the reaction under an inert atmosphere. This probably is quite advantageous as we obtained an increase of 12.5% in the yield of triphenylacetic acid by carrying out the entire reaction in an astmosphere of dry carbon dioxide (compare Expt. 4 with 3).

Especial care was taken to free the triphenylchloromethane from impurities by dissolving the crude product of the Friedel and Crafts reaction in a minimum of boiling chloroform followed by dilution with three volumes of ether as the solution cooled. The chloride crystallized well, the recovery was good and the color was practically removed. The material was then recrystallized from boiling gasoline as it was found that the trace of chloroform present interfered with the reaction. The melting point was 115°. Moisture should be excluded from the chloride as the hydrogen chloride produced as well as the carbinol was found to be an active negative catalyst.

Crude triphenylchloromethane direct from the Friedel and Crafts synthesis was quite reactive. Several preparations were found to react smoothly with magnesium to form the Grignard reagent, while the more purified material described above did not. This led to an investigation of the effect of anhydrous aluminum chloride, which may have been present in the crude material, as a catalyst for the Grignard reaction. Anhydrous aluminum chloride did start the reaction nicely, but the yield of triphenylacetic acid was somewhat lower than when using iodine. For the preparation of triphenylacetic acid, freshly prepared crude chloride from the Friedel and Crafts reaction gives yields sufficiently high to make the purification of the halide unprofitable.

Since we were studying the effect of adding various substances to the reaction it was not convenient to carry out the reaction in an atmosphere of carbon dioxide. The procedure used was briefly as follows: 7 g. of the purified triphenylchloromethane, 0.2 g. of iodine, 2 g. of powdered magnesium and 200 cc. of sodium-dried ether were allowed to react for one hour with stirring and gentle refluxing. Carbon dioxide was then admitted and the stirring and refluxing were continued for three hours. The mixture was then decomposed and the triphenylacetic acid isolated according to Schmidlin.[13] In Table II are given the results of a number of experiments which have some variation from this general procedure and which show the effect of the history of the chloride used, the substitution of aluminum chloride for the iodine, etc.

The addition of triphenylcarbinol lowered the yield of triphenylacetic acid according to the results listed in Table III. The carbinol added is given in mole per cent. of the chloride used in making the reagent. The

TABLE II

RESULTS OF EXPERIMENTS

No.	Variation in the experiment	Yield of triphenylacetic acid, %
1	Chloride recryst. from CH_3COCl	66 and 41.5
2	Chloride recryst. from $CHCl_3$–Et_2O	16.6
3	Chloride recryst. from $CHCl_3$–Et_2O, then gasoline	75 and 75
4	Same as No. 3 except CO_2 was passed in before introducing the chloride	87.5 (86.4 with 0.2 g. of triphenylmethyil peroxide in addition)
5	Same as No. 4 except that freshly made crude chloride from the Friedel and Crafts reaction was used	81.6 and 81.6
6	Used 0.1 g. of $AlCl_3$ (anhyd.) instead of iodine to start the reaction	60.8 (67.8 with 0.2 g. of I_2 in addition)
7	Passed in dry HCl for 30 sec., no iodine	0 (29 with 0.2 g. of I_2 in addition)

carbinol was added with the chloride and then the experiment was treated exactly as Expt. 3, Table II.

TABLE III

RESULTS OF EXPERIMENTS

	1	2	3	4	5	6	7	8
Mole per cent. of $(C_6H_5)_3COH$ added before the preparation of the Grignard reagent	0	0.8	2.4	3.1	6.2	9.2	12.3	15.3
Yield of triphenylacetic acid, %	75	63.5	58.0	52.5				
			55.3	55.3	48.4	33 2	16.6	0
	75			56.0	.			

In Table IV 15.3 mole per cent. of triphenylcarbinol was added in each case after the chloride had reacted for one hour and the Grignard reagent had formed normally, but before the carbon dioxide was passed through the flask.

TABLE IV

RESULTS OF EXPERIMENTS

No.		Yield, %
1	15.3 mole per cent. of carbinol added after the reagent had been formed	0
2	Same as No. 1, except that the mixture was allowed to stand with carbon dioxide for about 60 hours	41.5
3	Same as No. 1 except the mixture was refluxed and stirred for 24 hours	0

The yield of acid when 50% of phenol was added was 31.9%.

In order to determine whether the chloromagnesium triphenylcarbinolate was responsible for the decreased yield of triphenylacetic acid (by causing the latter substance to decompose during the reaction), 1 g. of triphenylcarbinol and 6.86 g. of triphenylacetic acid were added to ethylmagnesium bromide made from 0.05 mole of ethyl bromide. The mixture was refluxed in ether for seven hours and the triphenylacetic acid recovered in the usual way. The weight of acid was 6.55 g., showing that very little decomposition took place.

Reactions Involving Diphenylmethylmagnesium Chloride and Tetraphenyl Ethane.[14]—The preparation of diphenylmethylmagnesium chloride was quite similar to that given by Gilman and Kirby.[15] The best yield of diphenylacetic acid was obtained from freshly distilled chloride and amounted to 23.8% in a 0.05-mole experiment. The remainder of the material was recovered practically quantitatively as tetraphenylethane (6 4 g.). The chloride was redistilled and a yield of 9.0% was obtained when 1 g. of diphenylcarbinol (0.0054 mole) was added to the same quantity of reagent.

The dissociation of tetraphenylethane in the presence of magnesious iodide was attempted in an atmosphere of carbon dioxide in a boiling ether–benzene mixture, in boiling xylene, in a kerosene fraction at 200°, and in a mixture of isoamyl ether and anthracene at 300°, but in no case was any diphenylacetic acid isolated. The tetraphenylethane was recovered unchanged.

Reactions Involving Benzylmagnesium Chloride.—The method of preparation of benzylmagnesium chloride was that of Gilman and McCracken.[16] The benzyl chloride of a C. P. grade was shaken with cold concentrated sulfuric acid to remove any benzyl alcohol or other easily sulfonated substances, neutralized with anhydrous potassium carbonate, filtered and fractionated. The fraction used boiled constantly at 91° under diminished pressure. An excess of magnesium clippings and 0.2 g. of iodine were used with 0.1 mole of benzvl chloride in all of the reactions. The chloride was allowed to react with the magnesium for one hour and the carbon dioxide was passed over the surface of the liquid for three hours. The temperature control was found to be very important. The best procedure was to cool the reaction mixture to 10° as the benzyl chloride was added over a period of forty-five minutes, followed by a fifteen-minute refluxing, then cooling again to 10° while the carbon dioxide was passed into the flask.

TABLE V

EXPERIMENTAL RESULTS

Amount of benzyl alcohol added, mole per cent.	0	2	10	30
Yield of phenylacetic acid, %	84.5	74.3	65.8	46.3

The yield of phenylacetic acid obtained upon adding 10% of benzyl alcohol after the preparation of the reagent was 62.5%.

Reactions Involving Phenylmagnesium Bromide.—The method of preparing the phenylmagnesium bromide was that given by Gilman and Parker.[17] The bromobenzene was a C. P. grade and was fractionated twice through an efficient column filled with Lessing contact rings. The fraction used boiled at 146° at 640 mm. pressure. One-tenth mole experiments were made with an excess of magnesium clippings and 0.2 g. of iodine. The yield of benzoic acid was determined by extracting the alkali-soluble material with potassium hydroxide solution. followed by acidification, and repeated ether extraction. The ether solution was evaporated and the yield of benzoic acid determined

TABLE VI

EXPERIMENTAL RESULTS

by subtracting the weight of phenol added to the reaction from the crude weight of benzoic acid.

The yield of benzoic acid obtained by adding 1% of phenol after the reagent had been prepared was 61.4 and 63.5% when 15.3 mole per cent. of triphenylcarbinol was added in the same way, In the latter experiment 40% of the triphenylcarbinol was recovered as triphenylmethyl peroxide.[18]

Reactions Involving Butylmagnesium Bromide.—The preparation was essentially that of Gilman and Parker.[17] The butyl bromide was a C. P. grade and was further purified by shaking with cold concentrated sulfuric acid and by fractionation through a column filled with Lessing contact rings. The bromide boiled at 94.5° at 640 mm. pressure. An excess of magnesium clippings and 0.2 g. of iodine were used with 0.1 mole of butyl bromide in each experiment. The yield was determined by extracting the acid with alkali, liberating the acid with hydrochloric acid, collecting the product with ether and finally fractionating the ether–valeric acid mixture.

TABLE VII

EXPERIMENTAL RESULTS

	1	2	3	4
Mole per cent. of butyl alcohol added	0	2.43	9.46	24.3
Yield of valeric acid, %	78.4	63.5	60.0	26.2

The yield of valeric acid obtained by adding 9.5% of butyl alcohol after the reagent had been prepared was 48.0%.

The normal reaction of butylmagnesium bromide with benzaldehyde gave a yield of 62.2% of phenylbutylcarbinol. Upon adding 2.43 mole per cent. of butyl alcohol after the reagent had been prepared, but before the addition of the benzaldehyde, the yield was lowered to 59.7%, a loss of 2.5%.

Summary

Curves are given showing the depression in yield of the reaction of several Grignard reagents with carbon dioxide caused by the addition of relatively small quantities of the alcohols corresponding to the reagents. Reactions are given which indicate an equilibrium relationship between triphenylmethylmagnesium chloride and triphenylmethyl. Cleavage of tetraphenylethane with magnesious iodide was not successful.

DERIVATIVES OF DULCIN[1]

BY E. WERTHEIM

RECEIVED AUGUST 30, 1930 PUBLISHED JANUARY 12, 1931

Since the first preparation of dulcin many derivatives of this interesting compound have been made. In some of these the character of the N side chain has been altered[2] while in others there is a duplication of function[3] or a substitution of various groups on the benzene ring.[4] Certain generalizations have been drawn relative to the effect of constitution upon taste[5] but the state of existing knowledge of this subject is unsatisfactory because an insufficient number of derivatives has been examined. The preparation of new derivatives as reported in this and other papers was undertaken in this Laboratory in the hope of obtaining a more complete understanding of the basic problem.

Reaction of Dulcin with Ethyl Chloroformate.—This reaction yields both types of derivatives noted above, those with altered side chain and with duplicated function. The following compounds were prepared: ethyl p-phenetyl-allophanate, *p*-phenetyl-biuret, bis-(*p*-phenetyl)-urea and bis-(*p*-phenetyl)-biuret. All were found to be tasteless.

Sulfur Derivatives of Dulcin.—*p*-Anisyl- and *p*-phenetyl-thiourea have already been prepared.[6] The taste of the former has not been reported; the latter is very bitter.[7] A bitter taste is characteristic for the reported aromatic thioureas while numerous urea compounds are sweet tasting. In the thioanisyl- and thiophenetyl-urea reported herein (isomeric with the compounds of Dyson and George) the thio-ether group (normally giving a bitter taste) is "opposed" to the carbamido group. The result in each case is a practically tasteless compound. Thioanisyl- and thiophenetyl-thiourea in which both oxygen atoms are substituted by sulfur were also prepared. These derivatives have a strongly bitter taste which is very lasting.[8]

Experimental Part

Ethyl *p*-**Phenetyl-allophanate.** *p*-$EtOC_6H_4NHCONHCO_2Et$.—A mixture of 20 g. of dulcin and 10 g. of ethyl chloroformate was heated in the free flame until homogeneous and then in an oil-bath maintained at a temperature of 100° for two hours. Upon cooling the mix solidified. It was twice recrystallized from hot amyl alcohol or from equal parts of amyl and ethyl alcohols. The crystals were washed with petroleum ether and ethanol; yield, about 3.5 g.; white needles, m. p., 139–140°; tasteless; soluble in benzene, xylene, ethanol, amyl alcohol, hot water and acetic acid.

p-Phenetyl-biuret, *p*-$EtOC_6H_4NHCONHCONH_2$.—Four grams of ethyl *p*-phenetyl-allophanate together with 10 cc. of concentrated ammonium hydroxide was placed in a sealed tube and heated to a temperature of 100" for four hours. At this time the tube contained a white solid and red supernatant liquid. The materials were washed from the tube with hot water and, after neutralization with dilute hydrochloric acid, subjected to filtration. The solid was dried, after which it was well washed with hot benzene (to remove unchanged allophanate), followed by petroleum ether. After recrystallization from dilute acetic acid the compound had a melting point of 185–186°; yield, 1.3 g.; white, amorphous, tasteless compound; soluble in ethanol, hot xylene, acetic acid; sparingly soluble in benzene.

Bis-(*p*-phenetyl)-urea, (*p*-$EtOC_6H_4NH)_2CO$.—A mixture of 5 g. of ethyl chloroformate and 18 g. of dulcin was heated in an oil-bath for two hours at a temperature of 175". The resulting solid was washed with hot ethanol and filtered by suction. It was next washed several times with hot acetic acid, then with ether. (The acetic acid solution was reserved—see below.) The compound was recrystallized from benzyl alcohol and washed with ether: yield, 0.6 g.; white microscopic needles; tasteless; melting point, 225–226°. The identity of the compound was confirmed by analysis for nitrogen.[9]

Bis-(*p*-phenetyl)-biuret, (*p*-$EtOC_6H_4NHCO)_2NH$.—The acetic acid washings of diphenetyl-urea (see above) when chilled in ice water gave a precipitate which was removed by filtration and washed with ether; yield, 1.4 g.; m. p., 208–209°; white microscopic oblong platelets; tasteless.

TABLE I

ANALYTICAL DATA OF DULCIN DERIVATIVES

Compound	Formula	Carbon, % Calcd.	Carbon, % Found	Hydrogen, % Calcd.	Hydrogen, % Found	Nitrogen, % Calcd.	Nitrogen, % Found
Ethyl *p*-phenetyl allophanate	$C_{12}H_{16}O_4N_2$	57.15	56.71 57.11	6.35	6.98 6.50	11.11	11.01
p-Phenetyl-biuret	$C_{10}H_{13}O_3N_3$	53.81	53.48 53.71	5.83	7.40 5.85	18.83	18.51
Bis-(*p*-phenetyl)-biuret	$C_{18}H_{21}O_4N_3$	62.99	62.99	6.12	6.31	12.24	11.96 11.97

p-**Nitrothiophenol.**—This compound was prepared essentially as directed by Mayer.[10] The yield from 31 g. of nitrochlorobenzene was about 10 g.

---

mitted. In all cases the solid compounds were tasted, also the following solutions, (1) 0.01 g. of compound in 500 cc. of water (38°), (2) 0.01 g. of compound in 50 cc. of ethanol made up to 500 cc. with water. The limited solubility of the compounds prevented the preparation of more concentrated solutions.

[9] This compound was previously reported by Gattermann and Cantzler, *Ber.*, 25, 1090 (1892), m. p. 225–226°; by Sonn, *ibid.*, 47, 2441 (1914), m. p. 225" and by Migliacci and Gargiulo, *Gazz. chim. ital.*, 58, 110 (1928), m. p. 220°.

[10] Mayer, *Ber.*, 42, 3050 (1909).

p-**Nitrothiophenetole.**—This was made from **20** g. of p-nitrothiophenol, **3** g. of sodium, **20** g. of ethyl iodide and about **100** cc. of ethanol as outlined by Monier-Williams;[11] yield, 15–20 g.

p-**Nitrothioanisole.**—The same method was used as for nitrothiophenetole. From **20** g. of p-nitrothiophenol, **3** g. of sodium. **24** g. of methyl iodide and about **100** cc. of methyl alcohol a yield of about **15** g. was realized.[12]

p-**Thiophenetidine.**—The directions of Monier-Williams were followed:'' **20** g. of p-nitrothiophenetole, **39** g. of tin and **62** cc. of concentrated hydrochloric acid gave a yield of about **12** g.

p-**Thioanisidine.**—*p*-Nitrothioanisole was reduced with zinc dust and hydrochloric acid. The directions of Zincke and Jörg[13] were modified in that the preparation was set aside for only three hours and that solid sodium sulfate was used to precipitate the amine sulfate. Twenty grams of nitrothioanisole gave **8–10** g. of the final product.

p-**Thiophenetylurea,** p-$\mathrm{EtSC_6H_4NHCONH_2}$.—Five grams of *p*-thiophenetidine was put into solution in **50** cc. of water upon the addition of **5** cc. of concentrated hydrochloric acid. **A** solution of **5** g. of potassium cyanate in **25** cc. of water was added in small amounts whiie the flask was given a thorough shaking. The resulting precipitate was dried and subsequently recrystallized from acetone: yield, **2.5** g.; m. p. 149–150°; glistening white platelets; soluble in the common organic solvents and in hot water. With concentrated sulfuric acid a colorless solution is formed which becomes pale green upon application of heat and again colorless. The solid compound produces a stinging effect upon the tip of the tongue followed by a very slight bitter taste. The prepared solutions were tasteless.

p-**Thioanisylurea,** p-$\mathrm{MeC_6H_4NHCONH_2}$.—Four grams of *p*-thioanisidine dissolved in *a* solution of **2.35** cc. of concentrated hydrochloric acid and **40** cc. of water was treated with **1.8** g. of potassium cyanate in **25** cc. of water. The compound was recrystallized when dry from dilute ethanol plus a few drops of ammonium hydroxide; yield, **1** g.; white needles, m. p. **164–165'**; tasteless.

p-**Thiophenetylthiourea,** p-$\mathrm{EtSC_6H_4NHCSNH_2}$.—Solutions of 2 g. of *p*-thiophenetidine in **15** cc. of water and **2** cc. of concentrated hydrochloric acid, and **2** g. of ammonium thiocyanate in **10** cc. of water were mixed and slowly evaporated to dryness. The dry mass was allowed to stand for about twenty hours, then pulverized and washed with water. It was next covered with hot ethanol, which was subsequently removed by filtration. When cooled the ethanol solution deposited the compound in light yellow platelets: yield, **0.5** g.; m. p. 136–137°; lasting bitter taste.

p-**Thioanisylthiourea,** p-$\mathrm{MeC_6H_4NHCSNH_2}$.—Five and four-tenths grams of *p*-thioanisidine was treated with **25** cc. of water and **3.12** cc. of concentrated hydrochloric acid. The solution was filtered and mixed with a solution of **2.65** g. of ammonium

TABLE II

SULFUR DERIVATIVES OF DULCIN

Compound	Formula	Carbon, % Calcd.	Carbon, % Found	Hydrogen, % Calcd.	Hydrogen, % Found	Nitrogen, % Calcd.	Nitrogen, % Found	Sulfur. % Calcd.	Sulfur. % Found

thiocyanate in 25 cc. of water. The combined solution was slowly evaporated until a friable solid mass was obtained. This was allowed to stand overnight, then pulverized and washed with boiling water. It was then repeatedly washed with hot water, made strongly ammoniacal and alkaline by the use of sodium and ammonium hydroxide solutions. The compound was finally washed with ethanol and with ether. Some was recrystallized from benzyl alcohol but was not improved by this treatment: yield, about 4 g.; platelets of faint yellow color, m.p. 198–199°; persistent bitter taste.

Summary

Derivatives of dulcin have been prepared in which the N side chain is altered and in which the phenetyl group is duplicated; these are tasteless. Substitution of the ether oxygen of dulcin by sulfur gives tasteless derivatives, while substitution of both oxygens by sulfur yields compounds with a very bitter taste. Seven new compounds are reported.

NATURAL AND SYNTHETIC RUBBER. VI. THE PYROLYSIS OF NATURAL RUBBER IN THE PRESENCE OF METALLIC OXIDES

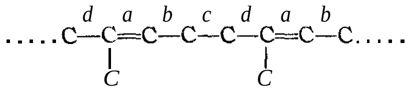
BY THOMAS MIDGLEY, JR., AND ALBERT L. HENNE

RECEIVED SEPTEMBER 2, 1930 PUBLISHED JANUARY 12, 1931

The first paper of this series[1] describes the influence of metals on the pyrolysis of natural rubber: it shows that the presence of a metal does not change the nature of the pyrolysis products, but affects their relative proportions. In this respect magnesium and zinc are most active. The fact that both zinc oxide and magnesium oxide influence the vulcanization process makes it desirable to study the influence of these compounds on the pyrolysis of rubber.

Experiments similar to these previously reported show that zinc oxide or magnesium oxide acts similarly to zinc or magnesium; zinc oxide has by far the stronger effect. Briefly the nature and proportion of pyrolysis products obtained with zinc oxide duplicate those obtained with magnesium, within experimental error.

Let the rubber molecule be represented by a long open-chain formula, and the various bonds of the chain be designated by letters



$$\cdots\cdots\mathrm{C}\overset{d}{-}\underset{\overset{|}{C}}{\mathrm{C}}\overset{a}{=}\mathrm{C}\overset{b}{-}\mathrm{C}\overset{c}{-}\mathrm{C}\overset{d}{-}\underset{\overset{|}{C}}{\mathrm{C}}\overset{a}{=}\mathrm{C}\overset{b}{-}\mathrm{C}\cdots\cdots$$

The relative numbers of ruptures at a, b, c and d during the pyrolysis of straight rubber have been computed from the data previously reported, and are represented by $a = 0$, $b = 0.6$, $c = 100$ and $d = 0.7$. However, a similar computation indicates that, in the case of rubber pyrolyzed with

---

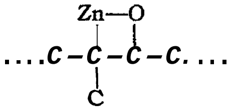
[1] Midgley and Henne, THIS JOURNAL, 51, 1215 (1929).

magnesium, the ruptures are as follows: $a = 0$, $b = 12.7$, $c = 100$ and $d = 12.1$. In both cases b equals d within experimental error.

Since zinc oxide has the same effect as magnesium upon pyrolysis, it appears that its presence multiplies by about 17 the number of ruptures of the b and d-bonds.

If d and b derive their strength from the fact that they are adjacent to the double bond a, it may be expected that any agent affecting the unsaturation of *a* will increase the similarity of d and b to c. If the agent be such as to remove entirely the unsaturated character of a, the bonds d, b and c might even become almost identical in strength, though complete identity would be prevented by the presence of the methyl side chains.

However, the formation of a chemical individual such as



$$\begin{array}{ccccccc} & & \mathrm{Zn} & - & \mathrm{O} & & \\ & & | & & | & & \\ \ldots\mathrm{C} & - & \mathrm{C} & - & \mathrm{C} & - & \mathrm{C}\ldots \\ & & | & & & & \\ & & \mathrm{C} & & & & \end{array}$$

with a zinc oxide molecule linked on the carbon chain by chemical valences does not seem to be supported by the facts: the pyrolysis products do not contain any compound formed by rupture of the chain at a; no oxygenated product is to be detected; and zinc oxide is not in the least reduced to the metal. Moreover, the seventh paper of this series shows that ruptures of *a* do occur in the pyrolysis of hard rubber where a is chemically saturated with sulfur.

Summary

Pale crepe rubber pyrolyzed in the presence of zinc oxide or magnesium oxide gives the same decomposition products as in the absence of the oxides, but in different proportions. This modification is attributed to an action of the oxides upon the double bonds of the rubber molecule.

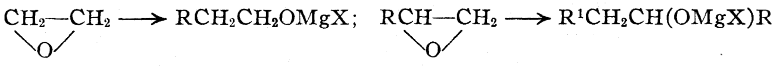
THE ACTION OF ORGANIC MAGNESIUM COMPOUNDS ON ALPHA OXIDO KETONES AND ESTERS

By E. P. Kohler, N. K. Richtmyer and W. F. Hester

Received September 8, 1930 Published January 12, 1931

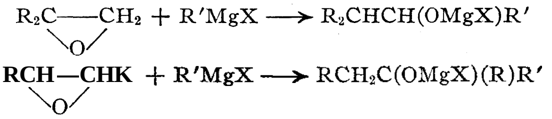
Oxido ketones and glycidic esters have two unsaturated groups in a relation which in other unsaturated compounds is known as conjugated. This relation, doubtless, is responsible for the ease with which they can be rearranged, but, owing to the nature of the reagents employed hitherto, little is known about the intermediates in these rearrangements. We have therefore undertaken an investigation of the behavior of representative oxido ketones and esters toward organic magnesium compounds, since these are capable of forming stable addition products with ethylene oxides as well as with ketones and esters.

From the work of Grignard[1] and a number of later investigators[2] it is known that organic magnesium compounds react much less readily with ethylene oxides than with ketones and esters. It is known also that the outcome of a reaction between an organic magnesium compound and an oxide depends almost entirely upon the number of hydrocarbon residues bounding the oxide ring. Thus the products which are obtained from ethylene oxide itself, and from its mono-alkyl and mono-aryl derivatives, indicate that the reagent opens the ring in the manner to be expected from other reactions of these oxides



$$\underset{\diagdown O \diagup}{CH_2{-}CH_2} \longrightarrow RCH_2CH_2OMgX; \quad \underset{\diagdown O \diagup}{RCH{-}CH_2} \longrightarrow R^1CH_2CH(OMgX)R$$

But no such simple reaction occurs in the case of disubstituted oxides



$$\underset{\diagdown O \diagup}{R_2C{-}CH_2} + R'MgX \longrightarrow R_2CHCH(OMgX)R'$$
$$\underset{\diagdown O \diagup}{RCH{-}CHK} + R'MgX \longrightarrow RCH_2C(OMgX)(R)R'$$

In order to account for these "abnormal" products it is customary to assume that the Grignard reagent first rearranges oxides of this type to the corresponding aldehydes or ketones and then combines with these rearrangement products in the usual manner

$$\underset{\diagdown O \diagup}{R_2C{-}CH_2} \longrightarrow R_2CHCHO \longrightarrow R_2CHCH(OMgX)R'$$

In agreement with what would be expected from an application of these facts to an oxido ketone in which the carbonyl group is not attached to

---

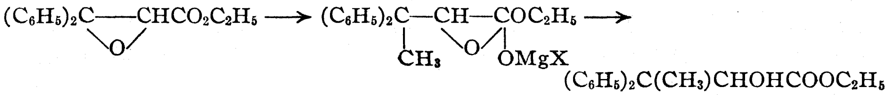
[1] Grignard, *Compt. rend.*, 136, 1260 (1903).

[2] See for example Fourneau and Tiffeneau, Bull. *soc. chim.*, [4]33, 741 (1905); *Compt. rend.*, 145, 439 (1907); Hess, Ber., 46, 3117 (1913); Henry, *Compt. rend.*, 145, 21, 406, 453 (1907).

the oxide ring, Haller and Ramart-Lucas[3] found that in a substance of this type the carbonyl group alone was attacked, despite the fact that a highly branched chain must have created a considerable hindrance to the reaction

More interesting was a result reported by Bardon and Ramart[4] in the only case in which an organic magnesium compound has been allowed to react with a substance in which an oxido and a carbonyl group are adjoining

Here the carbonyl group reappeared intact, the ring was opened in a unique manner, and, since the authors obtained the same substance in boiling ether as in a freezing mixture, the primary product had to be a magnesium derivative of such a character as to prevent further reaction. A result like this could be explained only by 1,4-addition to the conjugated system

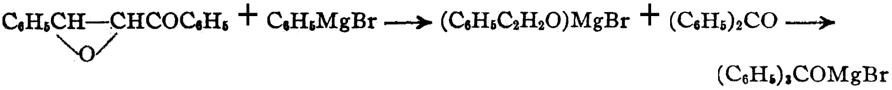


Our own experiments began with the oxide of benzal acetophenone,  a solid α-oxido ketone which can be obtained in a perfectly pure state and in any desired quantity. In view of the results reported by Bardon and Ramart, the behavior of this substance was surprising. It reacted very readily with two molecules of phenyl magnesium bromide and gave one molecule of triphenyl carbinol. It also reacted in a similar manner with ethyl magnesium bromide and gave phenyl diethyl carbinol. The reaction therefore results in cleavage, the hydrocarbon residues from the two molecules of the magnesium compound appear in the carbinol, and the cleavage is not due to an accumulation of phenyl groups.

In addition to the carbinol, the reaction between the oxido ketone and magnesium compounds yielded only resins, which are evidently due to extensive polymerization. Since these resins were of no service it became necessary to resort to a less symmetrical oxido ketone in order to establish the point of cleavage. To this end the oxide of anisal acetophenone was prepared and added to excess of phenyl magnesium bromide in the same manner. It likewise gave triphenyl carbinol and a resin. It was evident, therefore, that the cleavage occurred between the carbinol group and the oxido ring, and it seemed likely that it took place during the early stages of the reaction

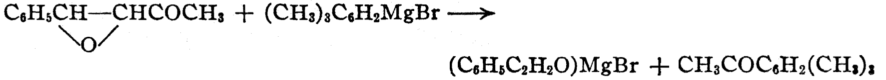
[3] Haller and Ramart-Lucas, Compt. rend., 159, 146 (1914).

[4] Bardon and Ramart, *ibid.*, 183,214 (1926).



$$C_6H_5\underbrace{CH\text{—}CH}_{O}COC_6H_5 + C_6H_5MgBr \longrightarrow (C_6H_5C_2H_2O)MgBr + (C_6H_5)_2CO \longrightarrow (C_6H_5)_3COMgBr$$

That one of the primary cleavage products is a ketone was definitely established by treating the oxide of benzal acetone with mesityl magnesium bromide, this combination having been selected became if any aceto mesitylene were formed it would survive, since organic magnesium compounds do not combine with mesitylenic ketones. In addition to the usual resin, this combination gave only aceto mesitylene



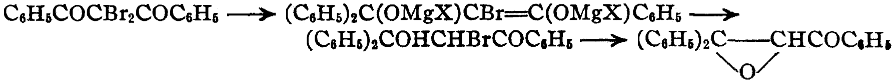
$$C_6H_5\underbrace{CH\text{—}CH}_{O}COCH_3 + (CH_3)_3C_6H_2MgBr \longrightarrow (C_6H_5C_2H_2O)MgBr + CH_3COC_6H_2(CH_3)_3$$

Having established both the stage and the place of this peculiar cleavage, it now became necessary to secure information on the second cleavage product. It seemed improbable that this could be accomplished without employing more highly substituted oxido ketones which might give magnesium derivatives less prone to polymerization. No such substances were known and none could be made by known methods of preparation. After many vain attempts we finally secured one in the following manner.

It has long been known that phenyl magnesium bromide removes bromine from a-bromo ketones and forms magnesium derivatives of the corresponding enols[5]

$$RCHBrCOC_6H_5 + 2C_6H_5MgBr \longrightarrow RCH{=}C(OMgBr)C_6H_5 + C_6H_5C_6H_5 + MgBr_2$$

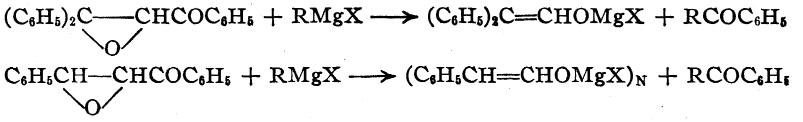
Applied to dibromo dibenzoyl methane, this process resulted in a bromohydrin that was readily converted into an a-oxido ketone of known structure



$$C_6H_5COCBr_2COC_6H_5 \longrightarrow (C_6H_5)_2C(OMgX)CBr{=}C(OMgX)C_6H_5 \longrightarrow \underset{\text{I}}{(C_6H_5)_2COHCHBrCOC_6H_5} \longrightarrow \underset{\text{II}}{(C_6H_5)_2\underbrace{C\text{——}CH}_{O}COC_6H_5}$$

I II

When this new oxido ketone was added to phenyl magnesium bromide it gave but two products, triphenyl carbinol and diphenyl acetaldehyde. From all that had gone before it was quite clear that the aldehyde represented the oxide group but we nevertheless repeated the operation with ethyl magnesium bromide and proved that in this case also the second product is diphenyl acetaldehyde. The action of organic magnesium compounds on a-oxido ketones can, therefore, be represented as follows



$$(C_6H_5)_2\underbrace{C\text{——}CH}_{O}COC_6H_5 + RMgX \longrightarrow (C_6H_5)_2C{=}CHOMgX + RCOC_6H_5$$

$$C_6H_5\underbrace{CH\text{—}CH}_{O}COC_6H_5 + RMgX \longrightarrow (C_6H_5CH{=}CHOMgX)_N + RCOC_6H_5$$

While these equations accurately represent one phase of the reaction, they leave the process almost as mysterious as before because they supply

[5] Kohler and Johnstin, Am. *Chem. J.*, **33**, 39 (1905).

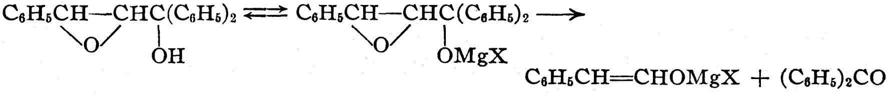
no adequate reason for the cleavage. These same a-oxido ketones react with substances which, in general, are much more destructive than organic magnesium compounds—ammonia, hydrazine, even alcoholic potassium hydroxide—and the entire molecule reappears in the product; there must therefore be some very special reason for this invariable cleavage by organic magnesium compounds. In a search for this reason the procedure was reversed; a single equivalent of phenyl magnesium bromide was added to an ethereal solution of the oxido ketone at −10° and the mixture was immediately decomposed with iced acid. The result was the oxido carbinol

$$C_6H_5\underbrace{CH-CH}_{O}C(C_6H_5)_2OH$$

III

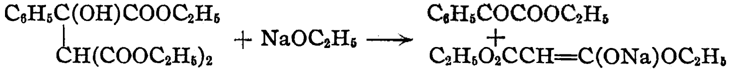
This oxido carbinol can be heated far above its melting point without causing any change and it is not decomposed by methyl alcoholic potassium hydroxide, but when it is added to phenyl magnesium bromide it is promptly cleaved, the final products as usual being triphenyl carbinol and resin. This cleavage is not due to the action of excess of reagent because the oxido carbinol can be made in any desired quantity by adding the oxido ketone to excess of reagent in the usual manner, provided only that the operation is carried out at a sufficiently low temperature and the mixture is decomposed immediately. Moreover, none of the oxido carbinol is obtained when the mixture resulting from the addition of a single equivalent of the reagent is allowed to remain at the ordinary temperature for some time before it is decomposed; it then yields the usual resin and—because no reagent is available for transforming it into triphenyl carbinol—benzophenone.

Thus it has been established, step by step, that cleavage represents the spontaneous decomposition of a magnesium compound which is formed by the addition of one molecule of the reagent to the oxido ketone



$$C_6H_5\underbrace{CH-CH}_{O}\underset{OH}{C}(C_6H_5)_2 \rightleftharpoons C_6H_5\underbrace{CH-CH}_{O}\underset{OMgX}{C}(C_6H_5)_2 \longrightarrow C_6H_5CH=CHOMgX + (C_6H_5)_2CO$$

The magnesium derivative therefore decomposes at temperatures which are more than 100° below those at which the corresponding alcohol is perfectly stable. Some, no doubt, will attribute this great difference in the stability of the carbinol and its magnesium derivative to ionization; others, probably, will find an explanation in chelation. Fundamentally, the cleavage of the carbinol by the addition of an organic magnesium compound is the same as the reversal of an aldol condensation in the presence of alkali, for example[6]



$$\begin{array}{l} C_6H_5C(OH)COOC_2H_5 \\ | \\ CH(COOC_2H_5)_2 \end{array} + NaOC_2H_5 \longrightarrow \begin{array}{c} C_6H_5COCOOC_2H_5 \\ + \\ C_2H_5O_2CCH=C(ONa)OC_2H_5 \end{array}$$

---

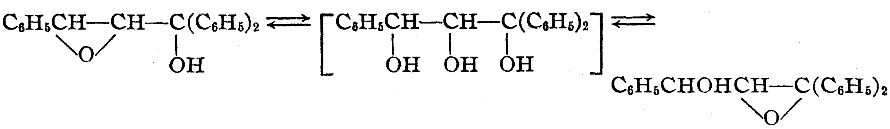
[6] Kohler and Corson, THIS JOURNAL, 45, 1975 (1923).

It therefore becomes necessary to consider why alkalies do not produce a corresponding effect on the oxido carbinol. The substance is, in fact, as sensitive to alkalies as it is to Grignard reagents, and alkalies transform it in a manner that is at least as interesting. Thus cold dilute methyl alcoholic potassium hydroxide gradually isomerizes it into an oxido alcohol which still contains an ethylene oxide ring

$$C_6H_5CH{-}CHC(C_6H_5)_2OH \longrightarrow C_6H_5CHOHCH{-}C(C_6H_5)_2 \longrightarrow C_6H_5COCH{-}C(C_6H_5)_2$$

III IV II

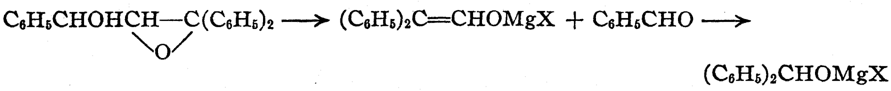
This unexpected isomer gave no little trouble but in the end its structure was established with certainty by oxidation to the oxido ketone II. The process by which this new oxide is formed is probably reversible but it has not as yet been possible to establish this fact with certainty. Since methyl alcoholic alkalies are capable of adding water and methyl alcohol to ethylene oxides, it is conceivable that the rearrangement may occur by way of an open-chained compound



$$C_6H_5CH{-}CH{-}C(C_6H_5)_2 \rightleftarrows \left[\begin{array}{c}C_6H_5CH{-}CH{-}C(C_6H_5)_2\\ OH \quad OH \quad OH\end{array}\right] \rightleftarrows C_6H_5CHOHCH{-}C(C_6H_5)_2$$

But in view of the fact that but one case is known in which it has been possible to convert a glycol into an ethylene oxide,[7] this mechanism seems exceedingly improbable. It is much more likely that the process is similar to that which is responsible for the rearrangement of substituted allyl alcohols, and that the oxide ring offers the same opportunity that is supplied by the double linkage in the alcohol. Whatever the route, the carbinol is rearranged instead of cleaved because, owing to its lack of acidity, it has little tendency to form a potassium compound corresponding to the magnesium derivative.

The product of this rearrangement—the oxido alcohol IV—is by far the most interesting substance that has appeared during the investigation. Like its isomer it can be heated far above its melting point without change, but, as would be expected from what has gone before, it is cleaved by phenyl magnesium bromide and the products in this case are diphenyl acetaldehyde and benzhydrol



$$C_6H_5CHOHCH{-}C(C_6H_5)_2 \longrightarrow (C_6H_5)_2C{=}CHOMgX + C_6H_5CHO \longrightarrow (C_6H_5)_2CHOMgX$$

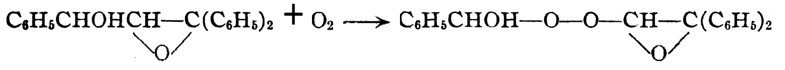
The oxido alcohol is also very readily cleaved by dilute acids, a process which does not appear to be quite so inevitable as the foregoing, because it occurs under conditions which usually lead to the addition of methyl

---

[7] Gardeur, *Bull. acad. roy. med. Belg.*, [3] 34, 67 (1897).

alcohol to an ethylene oxide rather than to the rearrangement of the oxide to an aldehyde

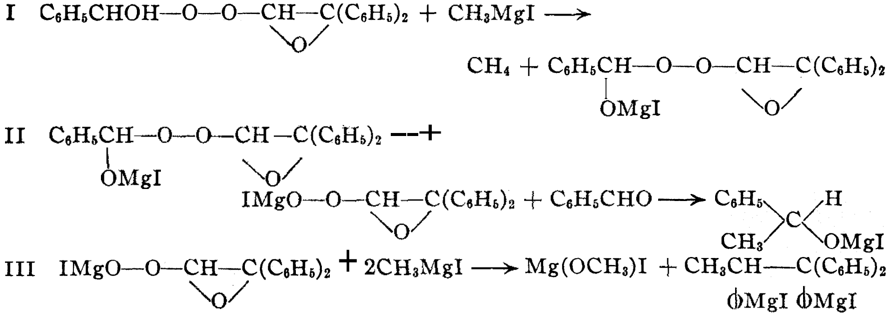
Perhaps the most interesting property of the oxido alcohol is shown in its behavior toward free oxygen. Some preparations appear to undergo no change when they are kept in contact with air in diffused daylight, but others which have been obtained in essentially the same manner undergo autoxidation with sufficient rapidity to produce a perceptible rise in temperature. The process is accompanied by the formation of benzaldehyde and other degradation products, but the principal product is a peroxide which is formed by the insertion of two atoms of oxygen next to the oxide ring.



IV V

The evidence for this strange formula is as follows. When the substance was heated, it decomposed briskly at the melting point and formed benzaldehyde, formic acid and benzophenone

A quantitative analysis with methyl magnesium iodide in isoamyl ether showed that the substance reacted with slightly more than four moles of the reagent and liberated one mole of gas, indicating the presence of one hydroxyl group. When this reaction was repeated in ordinary ether the products were methyl diphenyl glycol—proving the presence of the oxide ring—and methyl phenyl carbinol



These transformations show that the peroxide belongs to a class which heretofore has been obtained only from free radicals or substances which are readily dissociated into free radicals. The problems suggested by its formation are still under investigation but it is clear already that these oxido carbinols and oxido alcohols constitute a remarkable group of substances.

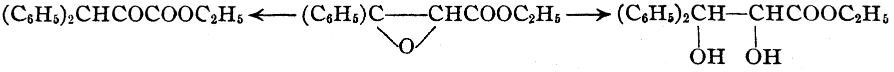
Nothing in the foregoing account suggests the kind of conjugation of the oxido and carbonyl groups that it is necessary to assume in order to explain the results which Bardon and Ramart obtained with diphenyl glycidic ester. We prepared this ester and treated it with phenyl magnesium bromide. Rather to our surprise we found that it was not cleaved. Depending only on the conditions under which the reaction was carried out, it yielded in succession the hydroxy ester VII, the hydroxy ketone VIII and the glycol IX—substances which are manifestly derived from the keto ester VI which is isomeric with the glycidic ester

$$\underset{\text{VI}}{(C_6H_5)_2CHCOCOOC_2H_5} \longrightarrow \underset{\text{VII}}{(C_6H_5)_2CHC(C_6H_5)OHCOOC_2H_5} \longrightarrow$$
$$\underset{\text{VIII}}{(C_6H_5)_2CHC(C_6H_5)OHCOC_6H_5} \longrightarrow \underset{\text{IX}}{(C_6H_5)_2CHC(C_6H_5)OHC(C_6H_5)_2OH}$$

The great rapidity with which the first reaction occurs even in a freezing mixture led to the suspicion that the supposed glycidic ester of Pointet,[8] and of Bardon and Ramart,[4] was in reality the ketonic ester. This proved to be the case because the substance does not combine with water, but readily forms a phenyl hydrazone at the ordinary temperature and is oxidized to diphenyl acetic acid by alkaline hydrogen peroxide

$$(C_6H_5)_2CHC({=}NNHC_6H_5)COOC_2H_5 \longleftarrow (C_6H_5)_2CHCOCOOC_2H_5 \longrightarrow$$
$$(C_6H_5)_2CHCOOH + CO_2 + C_2H_5OH$$

The ester had been prepared by condensing benzophenone with chloro-ethyl acetate both by the method of Pointet and by that of Claisen.[9] The primary product of this condensation is the desired glycidic ester, but this cannot be separated from the unchanged benzophenone. When the mixture is distilled under diminished pressure the glycidic ester is rearranged to the ketonic ester,[10] and when it is distilled with steam the glycidic ester combines with water and forms a glycolic ester



$$\underset{\text{VI}}{(C_6H_5)_2CHCOCOOC_2H_5} \longleftarrow (C_6H_5)C\underset{O}{—}CHCOOC_2H_5 \longrightarrow \underset{\text{X}}{(C_6H_5)_2\underset{OH}{CH}—\underset{OH}{CH}COOC_2H_5}$$

When the crude condensation product—a mixture of the glycidic ester, benzophenone and chloro-ethyl acetate—was added to excess of phenyl magnesium bromide, the product contained diphenylacetaldehyde, showing both that the ester is cleaved in the manner to be expected and also that the products described by Bardon and Ramart are derived from the ketonic ester

$$(C_6H_5)_2CHCOCOOC_2H_5 \longrightarrow (C_6H_5)_2CHC(OH)CH_3COOC_2H_5 \longrightarrow$$
$$(C_6H_5)_2C(OH)CH_3COOH$$

---

[8] Pointet, *Compt. rend.*, 148, 418 (1909).

[9] Claisen, *Ber.*, 38, 693 (1905).

[10] Troell, *ibid.*, 61, 2498 (1928), likewise concluded that distillation converts the glycidic into the ketonic ester but could not induce the latter to crystallize.

Two other substances were treated with phenyl magnesium bromide—an aliphatic glycidic ester and an oxido ketone with a phenyl group in the a-position

$(CH_3)_2C\text{—}CHCOOC_2H_5$ (—O—)

XI

$NO_2C_6H_4CH\text{—}C(C_6H_5)COC_6H_5$ (—O—)

XII

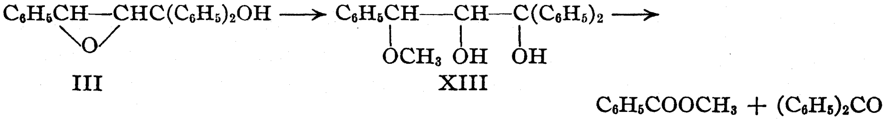
Both gave triphenyl carbinol. There is, therefore, no evidence that any oxido compounds can form 1,4-addition products with organic magnesium compounds.

Experimental Part

I. Experiments with α-Oxido Ketones

Four oxido ketones were treated with organic magnesium compounds for the various reasons specified in the introductory section, but only the reaction between the oxide of benzalacetophenone and phenyl magnesium bromide was studied with care. The structure of the primary product of this reaction was established in the following manner.

An analysis of the substance with methyl magnesium iodide in the machine[11] showed that it contains one hydroxyl group and one other reactive group. In the presence of a little hydrochloric acid the substance combines with methyl alcohol to form a methyl ether which has two hydroxyl groups, but no other group capable of reacting with methyl magnesium iodide; the substance is, therefore, an oxide. The methyl ether formed by addition of methyl alcohol is oxidized by chromic acid to methyl benzoate and benzophenone



$$C_6H_5CH\text{—}CHC(C_6H_5)_2OH \longrightarrow C_6H_5\underset{OCH_3}{CH}\text{—}\underset{OH}{CH}\text{—}\underset{OH}{C}(C_6H_5)_2 \longrightarrow C_6H_5COOCH_3 + (C_6H_5)_2CO$$

III XIII

Moreover, the dihydroxy ether was synthesized by a method recently described by Kohler and Addinall.[12] For this purpose benzalacetophenone dibromide was treated with sodium alcoholate and thus converted into an acetal which was readily hydrolyzed to the corresponding ketone. And when this ketone was treated with phenyl magnesium bromide it gave the same dihydroxy ether that had been obtained from the oxido carbinol

$$C_6H_5CHBrCHBrCOC_6H_5 \longrightarrow \underset{\text{XIV}}{C_6H_5CH(OCH_3)CHOHC(OCH_3)_2C_6H_5} \longrightarrow$$

$$\underset{\text{XV}}{C_6H_5CH(OCH_3)CHOHCOC_6H_5} \longrightarrow \underset{\text{XIII}}{C_6H_5CH(OCH_3)CHOHC(C_6H_5)_2OH}$$

Three of the oxido ketones were prepared by the excellent method of Weitz and Scheffer,[13] but for the preparation of benzalacetophenone oxide,

---

[11] Kohler and Richtmyer, This journal, 52, 3736 (1930).

[12] Kohler and Addinall, *ibid.*, 52, 3728 (1930).

[13] Weitz and Scheffer, Ber., 54,2329 (1921).

which was needed in large quantities, the method was modified in the interest of economy and convenience. The procedure is as follows.

Eighty grams of sodium peroxide powder is slowly poured into 650 cc. of cracked ice and water contained in a flask immersed in a good freezing mixture and provided with an efficient motor stirrer; 142 cc. of concentrated (12 normal) hydrochloric acid is then allowed to drop in slowly, stirring vigorously and keeping the temperature below 5° throughout, if necessary by adding a little more cracked ice from time to time. At the end, 50 cc. of alcohol is added.

In the meantime 104 g. (0.5 mole) of benzalacetophenone is dissolved in 2 liters of alcohol and brought to 35° in a beaker supplied with an effective motor stirrer. The cold peroxide solution is at once filtered through glass wool and run into the benzalacetophenone solution with vigorous stirring, in a continuous rapid stream; the addition should be completed within two minutes. Seed is added at intervals until, near the end, the oxide crystallizes rapidly. The yellow color of benzalacetophenone then fades, and the solution becomes practically colorless. The vessel is immersed in a freezing mixture, and stirred slowly until the temperature reaches zero, when the oxide is at once filtered and washed well with cold 60% alcohol; 95 g. of white crystalline oxide, of m. p. 85–90°, is obtained, a yield of 85%. The filtrate contains about 5 or 10 g. more, which is hardly worth recovering. The oxide is easily purified by dissolving in cold acetone, filtering, evaporating to a small volume and adding petroleum ether. The product crystallizes in snow-white flakes, melting at 89–90°. When treated with methyl magnesium iodide in the "machine" it liberates only a negligible amount of gas but consumes two moles of reagent.

Reaction with Ethyl Magnesium Bromide.—To an ethereal solution containing five equivalents of ethyl magnesium bromide was added 35 g. of powdered oxide; stirring was continued at room temperature for forty minutes. The reaction mixture was decomposed with ice and concentrated hydrochloric acid, and the ethereal solution washed, dried and evaporated. Steam distillation left a yellow gummy residue, but the distillate consisted of a colorless oil which was identified by its physical constants and an analysis as diethyl phenyl carbinol. There was obtained 17 g. (66%) of liquid boiling at 110–112° at 20 mm., with n_D^{20} 1.5172. Klages[14] records a boiling point of 107–109° at 14 mm., and n_D^{12} 1.5166.

Anal. Calcd. for $C_{11}H_{16}O$: C, 80.5; H, 9.8. Found: C, 80.1; H, 9.6.

Reaction with Phenyl Magnesium Bromide.—When solid benzalacetophenone oxide is added to a solution containing five equivalents of phenyl Grignard reagent at room temperature, heat is evolved, and the solution passes through a characteristic purple stage which we have come to associate with the formation of triphenyl carbinol in reactions of this type. At the end the solution becomes greenish, and a thick, dark-colored gum adheres to the walls of the flask. The solution, upon decomposition with ice and acid, yields large amounts of triphenyl carbinol, while the gum produces mainly a thick yellow sirup which gives no test for phenyl acetaldehyde and has resisted all attempts at depolymerization. The yield of triphenyl carbinol is about 70%.

Preparation of the Oxido **Carbinol, III.—A** Grignard reagent was prepared from 8 g. of magnesium (0.33 mole) and 47 g. (0.30 mole) of bromobenzene in 600 cc. of ether. The filtered solution, in a 3-necked flask equipped with thermometer and, mechanical stirrer, was chilled in a freezing mixture so that its temperature was always below $-10°$. Finely powdered oxide (34 g. = 0.15 mole) was added in the course of thirty minutes, and the mixture stirred for another fifteen minutes. The flask then contained a clear, pale green liquid, arid a gum which contained solid unchanged oxide as well as products

---

[14] Klages, *Ber.*, 36, 3692 (1903).

resulting from the action of more than one equivalent of Grignard reagent on the oxide. The liquid was decanted at once into a mixture of ice and concentrated hydrochloric acid; the ethereal layer was washed with several portions of water, dried over calcium chloride, and evaporated to a small volume. Upon dilution with petroleum ether it deposited 22 g. of practically pure product.

If prepared by the inverse method, the procedure was as follows. Into a solution of 15 g. of oxide in 800 cc. of dry ether kept at $-10°$ was allowed to dribble one equivalent of phenyl magnesium bromide during the course of an hour. A yellowish white solid appeared. After another hour's stirring in the freezing mixture the contents of the flask were poured on iced acid and the ethereal layer treated as before. There was obtained 9 g. of pure product, besides some unchanged oxide and a rather unstable halogen compound which was not further investigated.

When a similar solution was allowed to stand at room temperature overnight instead of being decomposed immediately upon removal from the freezing mixture, no primary product could be isolated. Some yellowish white magnesium derivative was filtered and decomposed separately; it yielded the unstable halogen compound, melting at about 100° with vigorous decomposition. The filtrate, after being decomposed, was subjected to steam distillation. Much benzophenone was obtained, and the gummy polymer remained in the flask. From this and other observations we may conclude that cleavage of the primary magnesium derivative is not due to excess of Grignard reagent.

α-Phenyl-β-(diphenyl-hydroxy-methyl) Ethylene Oxide, 111.—The product obtained by the above procedures is very soluble in ether, moderately soluble in methyl alcohol, and difficultly soluble in petroleum ether. From a mixture of ether and petroleum ether it separates in clusters of large needles which melt at 129–130°. With methyl magnesium iodide it liberated 1.0 mole of gas and consumed 2.1 moles of reagent.

Anal. Calcd. for $C_{21}H_{18}O_2$: C, 83.4; H, 6.0. Found: C, 83.7; H, 5.9.

With excess phenyl magnesium bromide at $-10°$ for one hour, most of the substance was recovered unchanged; at room temperature, however, triphenyl carbinol was the only product which could be isolated. A sample maintained for one hour at 150° showed no evidence of decomposition, and the melting point was unaffected. The compound was not attacked by acetic anhydride, even on warming and allowing the solvent to evaporate over caustic alkali in a vacuum desiccator. Concentrated ammonium hydroxide alone, or in methyl alcohol, was also without effect.

Addition of Methyl Alcohol: **α,α,γ-Triphenyl-α,β-dihydroxy-γ-methoxy** Propane, **XIII.**—A solution of 5 g. of the primary product III in 70 cc. of absolute methyl alcohol containing 10 drops of concentrated hydrochloric acid was boiled for one hour. Dilution with water precipitated an oil which smelled strongly of benzaldehyde, but which deposited a mass of crystals when petroleum ether was added. The solid was filtered and washed with petroleum ether. The petroleum ether solution was concentrated and distilled with steam; the first fractions contained benzaldehyde, the latter fractions diphenylacetaldehyde, which was identified through its semicarbazone melting at 158–160" by comparison with a specimen at hand.

The solid can be obtained in much better yield by shaking at room temperature, thereby avoiding the destructive cleavage to benzaldehyde and diphenylacetaldehyde. The product is moderately soluble in acetone and ether, sparingly soluble in petroleum ether; it crystallizes from ether in clusters of prisms which melt at 154–155°. With methyl magnesium iodide it evolved 2.0 moles of gas and consumed 2.1 moles of reagent. Oxidized with chromic acid in glacial acetic acid it yielded methyl benzoate and benzophenone, identified by the odor and mixed melting point, respectively

Anal. Calcd. for $C_{22}H_{22}O_3$: C, 79.0; H, 6.6. Found: C, 78.3; H, 6.9.

Independent Synthesis of the Dihydroxy Ether: The Dimethyl Acetal of a-Hydroxy-β-methoxy-β-phenyl Propiophenone, XIV.—To a solution of 22 g. of sodium in 500 cc. of dry methyl alcohol which was cooled in a freezing mixture was added 170 g. of pure solid benzalacetophenone dibromide. The mixture was allowed to remain in the freezing mixture for five hours, then kept at nearly 0° in a refrigerator for three days. By this time all of the solid dibromide had disappeared but the very pale yellow solution was still slightly alkaline.

The solution was allowed to evaporate in an open dish. It left a residue composed of sodium bromide and colorless needles of an organic compound imbedded in a large quantity of pale yellow oil. This residue was dissolved in ether and water. The ethereal layer was thoroughly washed with water, dried over sodium sulfate, concentrated, and inoculated with the needles previously obtained. It gradually deposited 24 g. of the solid acetal, and 5 g. more was obtained by diluting the oily filtrate with low-boiling petroleum ether, and cooling it in a freezing mixture. The solid was thoroughly washed with petroleum ether and then recrystallized from dry methyl alcohol, from which it separates in stubby prisms with a brilliant luster. The melting point is 122". It is readily soluble in ether and acetone, moderately soluble in methyl alcohol, sparingly soluble in petroleum ether.

Anal. Calcd. for $C_{18}H_{22}O_4$: C, 71.5; H, 7.3. Pound: C, 71.2; H, 7.4.

Hydrolysis, Followed by Reaction with Phenyl Magnesium Bromide.—The acetal group is readily hydrolyzed to the corresponding ketone by dilute acid. Thus, 9 g. of acetal was shaken with 200 cc. of dry methyl alcohol containing 3 cc. of concentrated hydrochloric acid. After ten minutes the solution was diluted with water and extracted with ether. The ethereal solution was thoroughly washed with water, dried over calcium chloride to remove the last traces of water and alcohol, and evaporated to about 100 cc.

Since a preliminary experiment had failed to produce a crystalline ketone, the ethereal solution itself was added to an excess of phenyl magnesium bromide. A white precipitate formed and redissolved. The mixture was boiled gently for fifteen minutes and then poured into ice and hydrochloric acid. The ethereal layer deposited 8 g. of the dihydroxy ether—a quantitative yield.

Isomerization of the Oxido Carbinol: α,α-Diphenyl-β-(hydroxy-benzyl) Ethylene Oxide, IV.—A solution of 0.8 g. of potassium hydroxide in 2 cc. of water was added to a solution of 20 g. of the oxido carbinol in 400 cc. of methyl alcohol. The mixture was shaken for two days, during which all of the carbinol dissolved. One-fourth of the solution was then gradually diluted with ice water while the walls of the vessel were rubbed with a glass rod. It precipitated the new oxide in small prisms, hexagonal in outline, along with some unchanged oxido carbinol. Whether the latter was due to incomplete reaction or whether it indicates that the process is reversible has not yet been established. The yield of pure isomer from one-fourth of the solution was at least 3 g.

The new compound is very soluble in alcohol and in ether, sparingly soluble in petroleum ether. After two recrystallizations from ether–petroleum ether, the melting point was constant at 103°. The substance was recovered unchanged after being heated to 150°. In the machine it liberated 0.9 mole of gas and consumed 2.1 moles of reagent.

Anal. Calcd. for $C_{21}H_{18}O_2$: C, 83.4; H, 6.0. Found: C, 83.3; H, 6.2.

Oxidation to Benzoyl Diphenyl Ethylene Oxide 11.–A portion of the isomer was added to a warm solution of one equivalent of chromic acid in glacial acetic acid. As the mixture became green instantly, it was poured at once into water. The ethereal extract, after being washed with water and sodium carbonate, and dried over calcium chloride, was concentrated to a small volume. Crystals of the ketonic oxide, II, separated, and were identified by a mixed melting point with this substance, which is to be described later.

Reaction with Phenyl Magnesium Bromide.—The product from 2 g. of the oxido alcohol, after treating with an excess of phenyl Grignard reagent, was a yellowish mobile oil which showed no tendency to solidify. A fractional distillation with steam enabled us to separate first a diphenyl fraction; then an intermediate fraction containing diphenylacetaldehyde, which was identified as the semicarbazone; and finally benzhydrol, which crystallized in the aqueous distillate in fine needles, and was identified by a mixed melting point.

Reaction with Methyl Magnesium Iodide (Inverse).—A solution of 3 g. of the freshly recrystallized alcohol in absolute ether was cooled in ice and treated with 1.25 equivalents of methyl magnesium iodide. The mixture, which contained a yellow precipitate in a pale red solution, was boiled for twenty minutes and then decomposed with iced acid. The ethereal layer was washed with thiosulfate and water, evaporated, and fractionally distilled with steam. In the first fraction benzaldehyde was identified by its odor and by conversion into the phenyl hydrazone. In the last fraction diphenyl acetaldehyde was identified by means of its semicarbazone melting at 160–161°.

The residue left in the distilling flask was dissolved in ether. The dried ethereal solution deposited 0.7 g. of a sparingly soluble solid which crystallized from acetone–petroleum ether in needles melting at 128°.

Anal. Calcd. for $C_{21}H_{18}O_2$: C, 83.4; H, 60. Found: C, 83.4; H, 6.1.

According to the analysis this is still another isomer of oxido carbinol. In the "machine" it reacted with 2.2 moles of reagent and liberated 1.8 moles of gas, and it was recovered unchanged. Since it was neither affected by hydrochloric acid in methyl alcohol nor cleaved by methyl magnesium iodide, it is presumably an a-hydroxy ketone formed during the steam distillation from unchanged oxido alcohol

$$C_6H_5CHOHCH\underset{\diagdown O \diagup}{—}C(C_6H_5)_2 \longrightarrow C_6H_5CHOHCOCH(C_6H_5)_2$$

Autoxidation: The Peroxide, V.—A batch of 8.2 g. of the oxido alcohol freshly recrystallized from ether and petroleum ether was placed in a small glass dish covered with a watch glass. In the course of three hours, it developed a perceptible temperature and a strong odor of benzaldehyde. It was left to itself for five days and then well washed with ether. The residue—5 1 g.—was recrystallized from acetone. It separated in fine needles, sparingly soluble in alcohol, ether and acetone. It melts at about 160° with brisk decomposition.

Anal. Calcd. for $C_{21}H_{18}O_4$: C, 75.5; H, **5.4.** Found: C, 75.3; H, 5.6.

In the machine, 1 mole of the substance consumed 4.2 moles of reagent and liberated 1 mole of gas.

Thermal Decomposition.—One and one-half grams of the peroxide was distributed in eight boats placed end to end in a combustion tube. As each boat was heated at one point until the peroxide melted, decomposition started and spread through the boat. The decomposition products were collected in ether. From the ethereal solution water extracted formic acid, which was identified by its reducing action on mercuric oxide.[15] The ethereal solution was fractionally distilled with steam; the first fraction contained benzaldehyde—identified as its phenyl hydrazone—the later fractions benzophenone, which was identified by its melting point before and after mixing with a sample.

Reaction with Methyl Magnesium Iodide.—To a solution of methyl magnesium iodide containing 1 g. of magnesium was added 1.8 g. of the peroxide in the form of a finely ground solid. The solid dissolved with evolution of gas and precipitated a gum which disappeared after prolonged stirring. The clear colorless solution was then de-

---

[15] **Mulliken,** "Identification of Pure Organic Compounds," 1914, p. 83.

composed with iced acid, the ether extract washed with thiosulfate and water, dried and concentrated. It deposited a solid which after recrystallization from ether–petroleum ether melted at 94–95".

Anal. Calcd. for $C_{15}H_{16}O_2$: C, 79.0; H, 7.0 Found: C, 78.8; H, 7 1.

In the machine one mole of the substance reacted with two moles of methyl magnesium iodide, liberated two moles of gas, and was recovered after addition of water.

The composition, crystalline form and melting point indicated that the substance was diphenyl methyl glycol. This glycol was therefore synthesized by treating ethyl lactate with excess of phenyl magnesium bromide. A comparison of the two products proved their identity.

The mother liquors from the glycol, on evaporation, left an oil. From the amount of reagent consumed it was to be expected that this oil contained methyl phenyl carbinol. It was therefore oxidized with a slight excess of chromic acid in glacial acetic acid. The oxidation product, isolated in the usual manner, was acetophenone. It was identified by condensing it with m-nitro benzaldehyde and comparing the condensation product with a sample of m-nitro benzalacetophenone.

Preparation of Benzoyl Diphenyl Ethylene Oxide: **α-Bromo-β,β-diphenyl-β-hydroxy Propiophenone, I.**—To an ice-cold Grignard reagent prepared from 24 g. of magnesium and 140 g. of bromo benzene was added 85 g. of dibromo dibenzoylmethane. Considerable heat was evolved and a transient yellow color appeared with each addition of solid. After fifteen minutes' stirring at the ordinary temperature the mixture was poured into iced acid, and the precipitated bromohydrin filtered and washed with ether, in which it is sparingly soluble. For analysis a small sample was purified by recrystallization from chloroform and petroleum ether, from which it separated in colorless, rectangular plates. It melts, with effervescence, at about 180°.

Anal. Calcd. for $C_{21}H_{17}O_2Br$: C, 66.2; H, 4.5. Found: C, 66.3; H, 4.4.

Benzoyl Diphenyl Ethylene Oxide, II.—A methyl alcoholic solution of sodium methylate was added to a suspension of the bromohydrin until the solution was slightly alkaline and the yellow color permanent; the suspended material now consisted of the oxido ketone and sodium bromide. The mixture was acidified with *a* little acetic acid, the product collected on a filter, washed with methyl alcohol and water, and recrystallized from acetone. It separated in clusters of short acicular prisms and melted at 124–125°. It is sparingly soluble in cold ether, alcohol and acetone. The yield was very nearly quantitative.

Anal. Calcd. for $C_{21}H_{16}O_2$: C, 84.0; H, 5 3. Found: C, 84.2; H, 5.6.

With methyl magnesium iodide the oxide consumed two moles of reagent and liberated only a negligible quantity of gas

Reaction with Phenyl Magnesium Bromide.—Heat was evolved and a reddish-purple color developed when *2* g. of oxide was added to excess phenyl Grignard reagent at room temperature. The color soon faded to a light green, and after fifteen minutes the solution was decomposed with ice and acid. The ethereal solution, after being washed with water and dried over sodium sulfate, was concentrated, whereupon it deposited 0.8 g. of triphenyl carbinol The residue was distilled with steam; from the middle fractions, treated with semicarbazide hydrochloride and sodium acetate in alcohol, was obtained the semicarbazone of diphenyl acetaldehyde, melting at 158–160°. Nixed with a known sample it melted at 158–161°.

Reaction with Ethyl Magnesium Iodide.—The oxide was treated in the same way with an excess of ethyl Grignard reagent. The ethereal solution, after concentration, was distilled with steam, and diphenyl acetaldehyde identified in the second half of the distillate.

Reaction with Other Oxido Ketones.—The experiments with the oxides of benzalacetone, anisalacetophenone, and α-phenyl-*p*-nitrobenzalacetophenone need not be described in detail because, as explained in the introduction, they were performed for special reasons and the general procedure was the same as that which has been described under the oxide of benzalacetophenone.

II. Experiments with Glycidic and Glyoxylic Esters

At first we prepared glycidic esters by the very convenient method of **Claisen**,[9] but found that the products contained considerable quantities of acid amides, which complicated still further the problem of isolating pure substances. We therefore turned to the method of **Darzens**.[16] For the preparation of diphenyl glycidic ester the procedure was as follows.

Into a well-cooled mixture of 182 g. of benzophenone and 122.5 g. of chloro-ethyl acetate, 68 g. of finely divided dry sodium ethylate was introduced at such a rate that the temperature could be kept below 5°. The mixture was allowed to remain at room temperature for twelve hours, then heated to 100° for six hours. After acidification with acetic acid it was diluted with water, which dissolved the salts and precipitated the oily ester. This was extracted with ether, the ethereal solution washed and dried. A small portion of the ethereal solution, evaporated at this stage, left a residue of 4.8 g. of an oil which when distilled with steam yielded 3.9 g. of diphenyl glycolic ester, showing that about 75% of the ketone had been converted into the glycidic ester.

The rest of the ethereal solution was fractionally distilled under a pressure of 3–10 mm. The fraction boiling at 190° was again examined by distillation with steam. It contained some benzophenone, which appeared in the distillate, but no sparingly soluble glycolic ester could be found in the residue. Distillation therefore destroys the oxido ester.

Reaction with Phenyl Magnesium Bromide.—Since it was impossible to isolate the pure oxido ester, an ethereal solution of the crude ester was added to a large excess of phenyl magnesium bromide in the customary manner. The product was manipulated in the usual manner and the residue left after removing triphenyl carbinol was distilled with steam. The first fractions contained diphenyl, the later fractions diphenyl acetaldehyde, which was identified as its semicarbazone. The a-oxido ester, therefore, does not give products of the type described by Bardon and Ramart but is cleaved like the oxido ketones.

Diphenyl Glyoxylic Ester, VI.—Since the oil obtained by distilling the crude glycidic ester failed to solidify in a freezing mixture, a small quantity of it was hydrolyzed by the method of Pointet? The resulting sodium salt was converted into the silver salt, and from the silver salt the ester was regenerated by boiling it for three hours with ethyl iodide. The ester obtained in this manner was a solid. Large quantities of this same solid ester were then obtained by diluting the remainder of the oily distillate with ether and petroleum ether, cooling the solution in a freezing mixture and inoculating it with the solid. After repeated recrystallization from ether and petroleum ether the ester melted at 37°, and this melting point remained constant during five consecutive crystallizations. Pointet reported a melting point of 47°, but either this is a typographical error or else as Troell suggests Pointet's solid was benzophenone.

Anal. Calcd. for $C_{17}H_{16}O_3$: C, 76.1; H, 6.0. Found: C, 76.2; H, 6.2.

The ester crystallizes in prisms which are readily soluble in alcohol and in ether, moderately soluble in petroleum ether. With methyl iodide it evolved 0.3 mole of gas,

---

[16] Darzens, *Comfit. rend.*, 139, 1214 (1904); 141,766 (1905).

indicating a tendency toward enolization similar to that of phenyl benzhydryl ketone. In order to prove that the substance is in reality a glyoxylic ester, it was turned into a phenyl hydrazone and oxidized with alkaline hydrogen peroxide.

Phenylhydrazone.—A solution of the ester in alcohol containing phenyl hydrazine hydrochloride deposited the phenyl hydrazone at the ordinary temperature within half an hour. The hydrazone is moderately soluble in ethyl alcohol, from which it separates in yellow prisms melting at 99–100°.

Anal. Calcd. for $C_{23}H_{22}O_2N_2$: C, 77.1; H, 6.1. Found: C, 77.4; H, 6.3.

Oxidation.—To a solution of 1 g. of ester and 3 cc of 20% hydrogen peroxide in 25 cc. of ethyl alcohol, dilute aqueous sodium hydroxide was added drop by drop during the course of an hour until somewhat more than one equivalent had been added. After another hour the solution was diluted with water and extracted with ether to remove any unchanged ester. The alkaline solution was acidified and extracted with ether; the latter was washed with water, dried with calcium chloride and evaporated. The residue, crystallized from ether–petroleum ether, melted at 145–146°; diphenyl acetic acid melts at 146° (Pointet).

Saponification: Phenylhydrazone of Diphenyl Glyoxylic Acid.—As a control for the above oxidation, 1 g. of ester was treated in the same way in the absence of hydrogen peroxide and another acid melting at 110–115° obtained. This is diphenyl glyoxylic acid, of melting point 116° (Pointet), and not diphenyl glycidic ester as Pointet believed. It readily forms an alkali-soluble phenyl hydrazone which crystallizes from hot methyl alcohol in yellow needles and melts with decomposition at about 210° (when heated slowly) or at about 245' (instantaneously on a block).[17]

And. Calcd. for $C_{21}H_{18}O_2N_2$: C, 76.4; H, 5.4. Found: C, 76.4; H, 5.1.

The Methyl Ester: $(C_6H_5)_2CHCOCOOCH_3$.—The methyl ester was prepared in the hope that the methyl ester of phenyl glycidic acid—formed by condensing benzophenone with methyl chloro-acetate—might be obtained as a solid. All attempts to induce the crude condensation product to solidify were unsuccessful and distillation rearranged the glycidic into the glyoxylic ester. In order to get the latter to crystallize it likewise was necessary to secure a small quantity of solid for inoculation by methylating the acid through the silver salt. The ester boils at 175° under 5 mm., crystallizes from methyl alcohol in prisms, and melts at 75°.

Anal. Calcd. for $C_{16}H_{14}O_3$: C, 75.6; H, 5.5. Found: C, 75.8; H, 5.7.

Reaction with Phenyl Magnesium Bromide.—The reaction between the ethyl ester of diphenyl glyoxylic acid and phenyl magnesium bromide was investigated by Bardon and Ramart,[4] who thought, however, that they were dealing with the glycidic ester. They reported an ester alcohol melting at 130° and another product melting at 203–205' but identified neither of these substances.

Ethyl **α,β,β-Triphenyl-α-hydroxy** Propionate, **VII.**—An ethereal solution of 10 g. of the glyoxylic ester was added to an excess of phenyl magnesium bromide in an ice-bath, and the mixture was immediately poured into iced acid. The ethereal layer yielded 8 g. of a solid product and a small quantity of oil. A better yield (10 g.) of the same product was obtained by operating in an inverse manner. The hydroxy ester is moderately soluble in ether, from which it separates in nodules of minute needles melting at 118–120°.

Anal. Calcd. for $C_{23}H_{22}O_3$: C, 70.7; H, 6.4; OC_2H_5, 13.0. Found: C, 79.5; H, 6.4; OC_2H_5, 13.7.

α,β,β-Triphenyl-α-hydroxy Propiophenone, VIII, and **α,α,β,γ,γ-Pentaphenyl-α,β-**dihydroxy Propane, **IX.**—These two substances are always formed together when either

---

[17] *Cf.* Troell, Ref. 10, p. 2502, who gives 189° with decomposition.

the glyoxylic ester or the monohydroxy ester VII is added to a large excess of phenyl magnesium bromide, and the mixture is either allowed to remain for several days at the ordinary temperature or boiled for three or four hours, before it is decomposed with iced acid. In order to separate the mixture successfully it is necessary to proceed with great caution because the dihydroxyl compound is very readily cleaved into four other products, and when this happens the separation is almost hopeless. The most satisfactory procedure was as follows. A solution obtained by adding 20 g. of the hydroxy ester VII to an excess of phenyl magnesium bromide was boiled for three hours, then diluted with twice its volume of low-boiling petroleum ether and cooled in a freezing mixture for several hours. The top layer was treated separately with iced acid, but it contained little besides diphenyl and excess of phenyl magnesium bromide. The bottom layer was mixed with fresh ether, then likewise decomposed with iced acid. The ethereal solution was washed and dried, then allowed to evaporate in an open vessel. It left a pale yellow oil.

The oil was repeatedly extracted with low-boiling ether until the undissolved portion finally solidified. The solid was recrystallized from acetone and methyl alcohol and was thus readily purified. It crystallized in long truncated columns melting with decomposition at about 190°.

Anal. Calcd. for $C_{33}H_{28}O_2$: C, 86.8; H, 6.2. Found: C, 86.7; H, 6.3.

This substance is the glycol IX, as was established in the following manner. When it was treated with methyl magnesium iodide in the machine, it consumed two moles of reagent and liberated two moles of gas; therefore it contains two hydroxyl groups. When its solution in ethyl alcohol or, better, glacial acetic acid, was boiled for a few hours it decomposed, cleanly, into phenyl benzhydryl ketone and benzhydrol—both isolated and identified by comparison with samples in hand. And when it was kept a few degrees above its melting point for a short time it gave in addition to the two products already mentioned, smaller quantities of triphenyl ethyl alcohol and benzophenone, which were separated by fractional steam distillation and likewise identified by comparison with authentic samples.

$$\text{I}\quad (C_6H_5)_2CHC(C_6H_5)OHC(C_6H_5)_2OH \longrightarrow (C_6H_5)_2CHCOC_6H_5 + (C_6H_5)_2CHOH$$

$$\text{II}\quad (C_6H_5)_2CHC(C_6H_5)OHC(C_6H_5)_2OH \longrightarrow (C_6H_5)_2CHCHOHC_6H_5 + (C_6H_5)_2CO$$

The petroleum ether extracts were allowed to evaporate spontaneously. They gradually deposited along with a small quantity of the glycol another solid which separated in flat needles and after recrystallization from ether–petroleum ether melted at 123°.

Anal. Calcd. for $C_{27}H_{22}O_2$: C, 85.7; H, 5.8. Found: C, 85.7; H, 6.1.

This substance must be the hydroxy ketone VIII, because when it was boiled for three hours with a slight excess of phenyl magnesium bromide it was converted into the glycol IX.

The Glycolic Ester, X.—As was stated earlier, the crude glycidic ester, when distilled with steam, left a residue which solidified during the distillation. The solid was recrystallized from alcohol in fine lustrous needles melting at 130°.

Anal. Calcd. for $C_{17}H_{18}O_4$: C, 71.3; H, 6.3. Found: C, 71.6; H, 6.5.

The corresponding methyl ester, obtained in a similar manner, likewise crystallized in silky needles and melted at almost the same temperature as the ethyl ester, 130–131°. A mixture of the two, however, melted at 110°.

Anal. Calcd. for $C_{16}H_{16}O_4$: C, 70.6; H, 5.9. Found: C, 70.8; H, 5.9.

Summary

1. When organic magnesium compounds react with α-oxido ketones, they combine with the carbonyl group only. By operating at a low tem-

perature and decomposing the product immediately, it is possible to secure the corresponding oxido carbinol; otherwise, the unstable magnesium derivatives decompose spontaneously into magnesium derivatives of aldehydes, and ketones which may subsequently be transformed into tertiary alcohols.

2. Organic magnesium derivatives first transform α-oxido esters into a-oxido ketones; the final products are therefore the same as those obtained with these ketones. Other results have been reported but the substance used in these cases was an a-ketonic ester and not the supposed isomeric α-oxido ester.

3. Oxido carbinols are reactive substances which show unexpected properties.

STUDIES IN AUTO-OXIDATION REACTIONS. II. THE MECHANISM OF THE AUTO-OXIDATION OF CERTAIN ETHERS

BY NICHOLAS A. MILAS[1]

RECEIVED SEPTEMBER 22, 1930 PUBLISHED JANUARY 12, 1931

Introduction

In previous publications[2] from this Laboratory a general theory has been advocated, which, if properly applied, seems to account for the various phenomena and mechanism of auto-oxidation reactions. Briefly stated, the theory assumes the addition of molecular oxygen to compounds containing molecular valence electrons comparable to valence electrons of atoms. As a direct consequence of this theory, one would expect molecular oxygen to add directly onto the bivalent oxygen atom present in alcohols, ethers, ketones, aldehydes, etc., or onto the bivalent sulfur atom present in thio-alcohols, thio-ethers, thio-phenols, thio ketones, etc., or onto the trivalent nitrogen atom present in primary, secondary and tertiary amines, hydrazones and the like to form highly unstable dative peroxides which either rearrange or hydrolyze to yield other relatively more stable peroxides. Certain ethers were chosen for the present investigation because of the existence of diversity of opinion regarding the fundamental mechanism of their auto-oxidation.

The auto-oxidation of ethyl ether has been the subject of several investigations of which only two will be mentioned here. Clover[3] was the

---

[1] **Research Associate, Massachusetts Institute of Technology.**

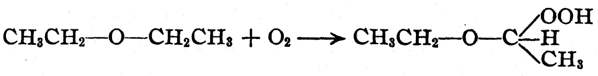
[3] **Clover,** *ibid.*, **44,** 1107 (1922).

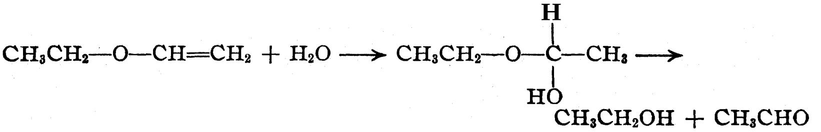
first to make a serious attempt to elucidate the mechanism of the auto-oxidation of ethyl ether. He proposed the mechanism



$$CH_3CH_2{-}O{-}CH_2CH_3 + O_2 \longrightarrow CH_3CH_2{-}O{-}C\begin{cases}OOH\\H\\CH_3\end{cases}$$

which was based on his claim to have isolated an ether peroxide having acidic properties. This claim, however, was later disputed by Wieland and Wingler,[4] who attributed the peroxidic properties of ethyl ether to "dioxy-ethylperoxide," which is assumed to be an addition product of one molecule of hydrogen peroxide to two molecules of acetaldehyde. To reconcile the oxidation of ethyl ether with Wieland's early views[5] on oxidation, Wieland and Wingler proposed a primary dehydrogenation of ethyl ether followed by the formation of hydrogen peroxide and vinyl ethyl ether with subsequent hydrolysis of the latter to form alcohol and acetaldehyde.

$$CH_3CH_2{-}O{-}CH_2CH_3 + O_2 \longrightarrow CH_3CH_2{-}O{-}CH{=}CH_2 + H_2O_2 \qquad (1)$$



$$CH_3CH_2{-}O{-}CH{=}CH_2 + H_2O \longrightarrow CH_3CH_2{-}O{-}\underset{HO}{\overset{H}{C}}{-}CH_3 \longrightarrow CH_3CH_2OH + CH_3CHO \qquad (2)$$

However, the dehydrogenation mechanism, as applied to the oxidation of ethers, seems to be in direct conflict with experimental evidence. It has already been shown elsewhere[2]" that the dehydrogenation theory is incapable of explaining true auto-oxidation reactions. The question, therefore, remains whether the oxidation of ethers fulfils the criteria of auto-oxidation reactions. This is answered in the affirmative in the experimental portion of this paper. The auto-oxidation of dibenzyl ether, for example, was found not only to be appreciably influenced by both negative and positive catalysts, but also to be capable of inducing the oxidation of substances otherwise inert to molecular oxygen.

Furthermore, the isolation of active organic peroxides from the oxidation of ethers makes the reaction of "active" hydrogen with molecular oxygen, rather than with these peroxides, very improbable. These peroxides, without doubt, ought to be far better hydrogen acceptors than molecular oxygen, since they liberate iodine instantly from a neutral solution of potassium iodide, which is relatively stable to molecular oxygen.

Besides, if vinyl ethers were to form during the oxidation of ethers, one would expect them to be oxidized by the active peroxides or peracids formed, leading to oxidation products different from those ordinarily found. Bergmann and Miekeley[6] have shown that vinyl ethyl ether is

[4] Wieland and Wingler, *Ann.*, 431, 317 (1923).

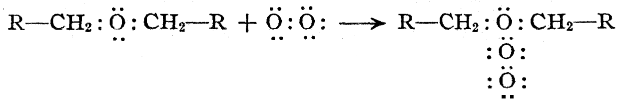
[5] Wieland, Ber., 45, 484, 685, 679, 2603 (1912).

[6] Bergmann and Miekeley, *ibid.*, 54, 2151 (1921).

easily oxidized by benzoperacid to a crystalline substance which hydrolyzes, in presence of mineral acids, to glycolic aldehyde and ethyl alcohol. No glycolic aldehyde has ever been isolated from the oxidation of ethyl ether.

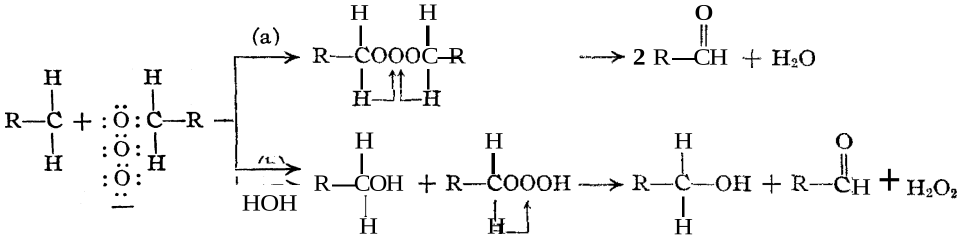
Finally, we have found that tertiary butyl methyl, tertiary butyl benzyl, dibenzyl and methyl cresol ethers, 1,4-dioxane, anisole and even diphenyl ether form peroxides upon oxidation, yet it is quite difficult to conceive a dehydrogenation mechanism for these oxidations.

One may very reasonably conclude, therefore, that the oxidation of ethers with molecular oxygen is a true auto-oxidation phenomenon, which, according to our view, should proceed through the primary addition of molecular oxygen onto the bivalent oxygen atom of the ethers, and could be expressed in general



$$R{-}CH_2:\ddot{\underset{..}{O}}:CH_2{-}R + \ddot{\underset{..}{O}}:\ddot{\underset{..}{O}}: \longrightarrow \begin{array}{c} R{-}CH_2:\ddot{O}:CH_2{-}R \\ :\ddot{O}: \\ :\ddot{\underset{..}{O}}: \end{array}$$

Such a dative or oxonium peroxide would be extremely unstable, but not improbable, since there exists considerable chemical evidence[7] to indicate that the oxygen atom in ethers is relatively unsaturated and can readily form oxonium compounds. The addition of molecular oxygen to ethers, as shown above, will induce a positive charge on the ether oxygen which will then have the tendency to attract toward it the electrons from the neighboring carbon atoms, leaving at least one of them positively charged. This displacement of electrons will cause a weakening of one of the linkages between the carbon atom and the ether oxygen, leading to the following possible changes



These reactions seem to account adequately for the initial products formed in the auto-oxidation of ethers. Reaction (b) seems to predominate although reaction (a) is indispensable to account for the products of reaction (b) appearing in the oxidation of very dry ethers.

The organic peroxide shown in reaction (b) seems to be identical with the primary peroxide formed in the auto-oxidation of alcohols.[8] More-

over, peroxides of this type exhibit properties similar to monoxyalkyl peroxides prepared by Woker[9] by mixing either formaldehyde or acetaldehyde with hydrogen peroxide preferably in the ratio of 1:1. This mixture yields with benzidine a blue color which is characteristic and is not produced by either the aldehyde or hydrogen peroxide separately. Quite recently King[10] has advanced the view that in deteriorated diethyl ether the main substance responsible for the peroxidic properties is monoxyethyl peroxide. Furthermore, our own experiments indicate that monoxyalkyl peroxides are formed as the primary decomposition products in the oxidation of ethers. These peroxides can further combine with free aldehydes to form dioxy-alkyl peroxides previously described by Nef[11] and by Wieland and Wingler.[4]

It may be mentioned here that during the oxidation of ethers side reactions seem to occur, which are responsible for the production of small quantities of esters and acids. These will not be considered in the present paper.

Experimental Part

The experimental part of this paper is divided into two sections: the first dealing with the oxidation of dibenzyl ether under the influence of various catalysts and the second with the oxidation of various ethers under the influence of ultraviolet radiation.

(1) Oxidation of Dibenzyl Ether.—This ether was chosen because preliminary experiments revealed that it has a higher rate of oxidation than any of the other ethers studied.[12] Moreover, the oxidation of this ether cannot be easily interpreted on the basis of the dehydrogenation theory.

The dibenzyl ether used was the C. P. quality furnished by the Eastman Kodak Company. This was further purified by shaking first with sodium carbonate solution to remove any benzoic acid present, then with sodium bisulfite containing potassium iodide to remove both the aldehyde and the peroxide present in the ether. The ether was finally washed with water, dried over anhydrous sodium sulfate and fractionated under reduced pressure in an atmosphere of pure nitrogen; the fraction boiling at 149.5 to 151.5° under 7 mm. pressure was collected and stored in a brown bottle under an atmosphere of nitrogen.

The experiments were performed in a shaking thermostat[13] at 40 ± 0.05°, and at a shaking speed of 248 complete strokes per minute. The thermostat consists of a Stanley insulated gallon jug fitted with a device in such a way as to permit thermoregulation while the thermostat is being shaken. This device (Fig. 1) consists of a coiled steel

[12] Except tertiary butyl benzyl, which was prepared long after the experiments had been performed with dibenzyl ether.

[13] This was built for the author by Mr. C. L. Gallagher of the Research Laboratory of Physical Chemistry.

tube of 0.8 mm. internal diameter about 36 cm. long and contains sixteen loops. On one end it is welded directly onto a steel mercury well which is fastened inside the thermostat, and on the other end, it is cemented to a capillary glass tube thereby permitting the necessary connections with the relay, etc.

Before each experiment the apparatus was evacuated by closing stopcocks 2 and 3; oxygen, which had been previously dried by passing it through concd. sulfuric acid and phosphorus pentoxide, was allowed to fill the entire apparatus, then by means of a 10-cc. calibrated pipet the sample of the ether (10.36 g.) was dropped into the reaction chamber by removing the ground-glass stopper A. The apparatus was once again evacuated, refilled with oxygen and the reaction allowed to proceed. The total oxygen absorption at any given time was corrected to standard conditions, then changed to cc. per mole of the ether. Figure 2 shows the total oxygen absorption per mole as plotted against time, while Fig. 3 shows the average oxygen absorption rate against time. The results of the experiments with picric acid and *p*-benzoquinone as negative catalysts are not shown on the plots because the absorption was so small that it was impossible to read it without making a large percentage of error. For the sake of comparison the total volume of oxygen absorbed in each experiment at the end of a period of 120 hours, and the total peroxide found expressed both in cc. of 0.02 N thiosulfate and in peroxide oxygen per mole of the ether are given in Table I. It may be seen that the total peroxide oxygen is only a small part of the total oxygen absorbed. This is due to the fact that comparatively large amounts of benzaldehyde and benzoic acid are also formed, which account for the total oxygen absorbed.

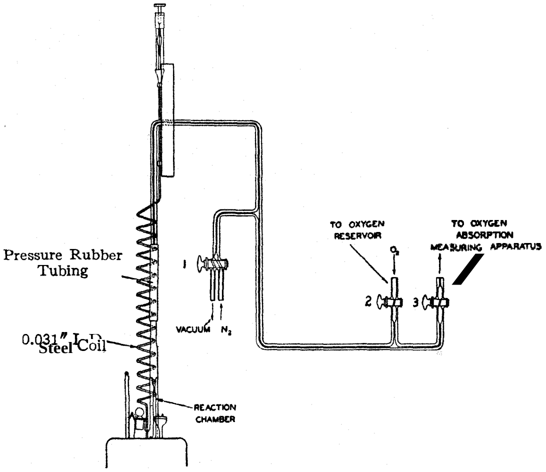

Fig. 1.—Diagram of flexible connection to shaking apparatus for oxygen absorption measurements.

TABLE I

A COMPARISON OF THE TOTAL OXYGEN ABSORBED WITH THE TOTAL PEROXIDE FOUND IN DIBENZYL ETHER

Catalyst	Catalyst, moles/mole of ether	Total O_2 absorbed, cc./mole ether	Total peroxide oxygen, cc./mole ether	Total peroxide in cc. *N*/50 thiosulfate/mole ether
Iodine	0.002	109		..
Benzoquinone	.002	65	...	
Picric acid	.002	30	3.2	29
Water	.010	1309	195.7	1747
Gold	.048	1172	134.7	1203
Silver	.088	1644	499.3	4458
Copper	.149	1745	212.0	1895
Mercury	.047	5233	498.0	4448
Iron	.172	1030	229.0	2044
Dibenzyl ether	...	650	109.0	977

For the titration of the peroxide the oxidized dibenzyl ether is removed from the catalyst, at the end of each experiment, by dissolving it in 30 cc. of pure benzene, the solution filtered and made up to a definite volume, an aliquot part of which is mixed in a special flask with 20 cc. of 5% solution of potassium iodide containing a few drops of freshly prepared starch emulsion and acidified with 5 cc. of glacial acetic acid After fifteen minutes of standing the liberated iodine is titrated against $N/50$ thiosulfate solution, and the flask evacuated and allowed to stand in the dark, with occasional shaking, for ten hours when the final titration is made. Blanks are used at every stage. Later, under the section of oxidized ethers of lower boiling point than dibenzyl, the vacuum treatment is omitted.

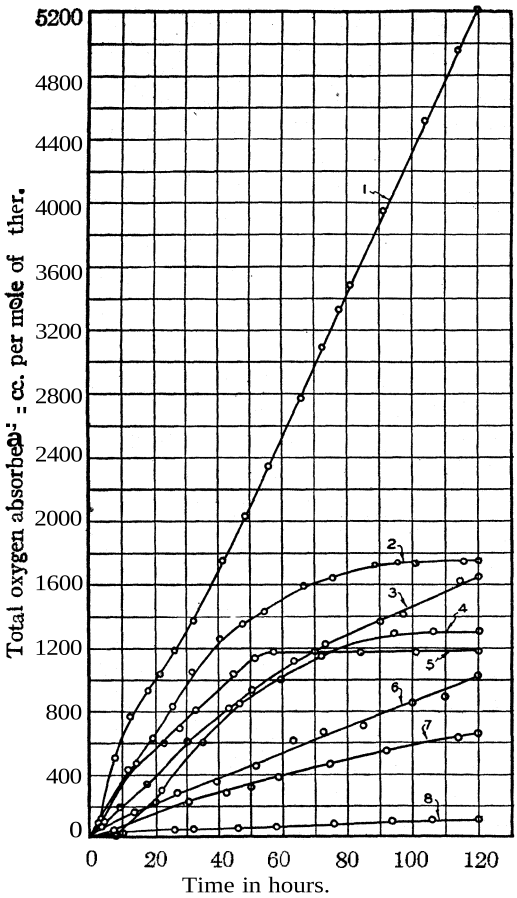

Fig. 2.—Effect of catalysts on the total oxygen absorption of dibenzyl ether. Curve 1, dibenzyl ether + Hg; Curve 2, dibenzyl ether + Cu; Curve 3, dibenzyl ether + Ag; Curve 4, dibenzyl ether + water; Curve 5, dibenzyl ether + Au; Curve 6, dibenzyl ether + Fe; Curve 7, dibenzyl ether alone; Curve 8, dibenzyl ether + I_2.

When a sample of dibenzyl ether in a quartz flask is exposed to ultraviolet light[14] for ten hours at the same temperature but without shaking, the amount of peroxide found corresponds to 1592 cc. of $N/50$ thiosulfate per mole. This is almost twice the peroxide found when the ether is oxidized in the dark for 120 hours.

Among the oxidation products of dibenzyl ether, monoxybenzyl peroxide has been detected by the benzidine reaction, which yielded a deep green color changing quickly to brown. Benzaldehyde was isolated as the derivative of p-nitrophenylhydrazine, m. p. 191°. Benzoic acid was also isolated, m. p. 120.5–121°. An attempt to isolate benzoperacid from the oxidation products by distillation failed because of the high boiling point of the ether, and small amounts of a polymer which is also formed during the oxidation interfered when other methods such as precipitation by an inert solvent were attempted.

It may be remarked here that the catalysts used were of the purest quality obtainable: gold was "Corona" gold purchased from the White Mfg. Co.; silver had been prepared in this Laboratory by the electrolytic precipitation method; iron was in

---

[14] For description of the method used, see Section 2.

the powder form prepared by the reduction of iron oxide with hydrogen;, mercury was purified in the usual manner; copper was used in the form of wire 3 to 4 mm. long previously polished and cleaned; iodine was of the pure "reagent" quality; picric acid of the C. P quality, while *p*-benzoquinone was part of a pure sample previously used in other investigations.

Discussion of Results.—From the results shown in Table I and those represented by the curves of Figs. 2 and 3, certain,significant conclusions may be drawn in regard to the auto-oxidation of dibenzyl ether.

Small quantities of inhibitors like iodine, picric acid and benzoquinone show a strong inhibitory action on the oxidation of dibenzyl ether. These substances have also been found to be excellent inhibitors in several auto-oxidation reactions.

Water in small quantities acts as a negative catalyst during the initial stages of the reaction, then as a positive catalyst as the reaction progressed.

Several metals which have been tried in small quantities show a definite acceleration effect. All metals studied were found to have undergone various degrees of oxidation, from a slight tarnish of gold to a complete oxidation of mercury. Silver, which is very resistant to atmospheric oxidation at 40°, was found oxidized to the extent of 2.35%. The results with copper seem to be at variance with those of Hewer,[15] who reports copper to have a retarding influence on the oxidation of ethyl ether.

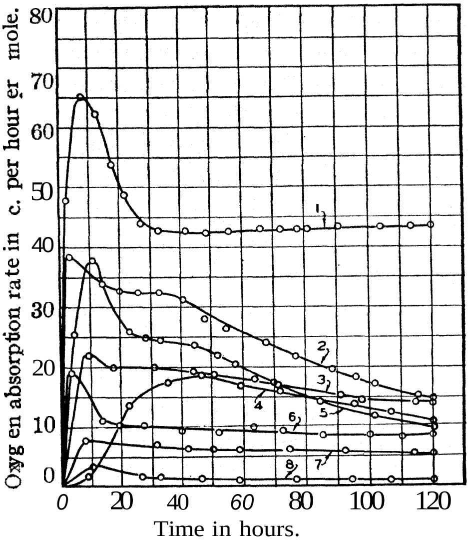

Fig. 3.—Effect of catalysts on oxygen absorption rate of dibenzyl ether. Curve 1, dibenzyl ether + Hg; Curve 2, dibenzyl ether + Cu; Curve 3, dibenzyl ether + Ag; Curve 4, dibenzyl ether + water; Curve 5, dibenzyl ether + Au; Curve 6, dibenzyl ether + Fe; Curve 7, dibenzyl ether alone; Curve 8, dibenzyl ether + I_2.

(2) Auto-Oxidation of Various Ethers under the Influence of Ultraviolet Radiation.—In the foregoing section mention was made of the marked effect of ultraviolet radiation on the auto-oxidation of dibenzyl ether. Similar and more pronounced effects have been observed with several other ethers, the results of which will be presently reported. 1,4-Dioxane, for example, yielded, after eighty hours of continuous exposure to oxygen, an amount of peroxide equivalent only to 6.8 cc. of *N*/50

---

[15] Hewer, Lancet, 216, 770 (1929); also quoted in Am. J. Pharm., 101, 840 (1929).

thiosulfate solution per mole, while on exposure to ultraviolet light the amount of peroxide formed for the same period of time was equivalent to 452 cc. of $N/50$ thiosulfate per mole of the ether.

The mechanism of the photochemical oxidation is not very well established at present, but our present results, which should be considered only preliminary, seem to indicate that it follows the same course as that of the oxidation in the dark. This view is particularly strengthened by the fact that the products formed in both reactions are not only identical but are those predicted by our theory. Furthermore, these facts stimulate the conclusion that the primary effect of ultraviolet radiation is to increase the energy content of the molecular valence electrons of the ether oxygen, thereby transforming the whole ether molecule from a relatively inert to a highly activated state. This view is in accordance with the general theory[2a] of auto-oxidation reactions recently proposed by the author. Thereby, the rate with which molecular oxygen combines with ethers to form oxonium peroxides will, presumably, depend not only on the nature of the original ether but also on the statistical average concentration of the activated ether and oxygen molecules present at any moment.

Experimental Procedure and Results

The reactions were carried out in a quartz vessel consisting of a bulb of 1000 cc. capacity and a neck 22 cm. long and 4 cm. in diameter. The neck was provided with an outer condenser jacket through which cold water was allowed to circulate during each reaction. A hollow ground-in pyrex stopper fitted onto the vessel served to connect the latter with a mercury manometer. Dry oxygen was introduced into the apparatus through a small side tube provided with a two-way stopcock and sealed onto one end of the manometer. The reaction vessel was suspended in an air-bath consisting of a rectangular well-insulated tinned iron box 23 X 23 × 36 cm., and ultraviolet light from a standard "Uviarc" lamp was allowed to fall horizontally only upon the bulb of the vessel through a side opening on the box of about the same size as the bulb. In all measurements the lamp was kept at a distance 35 cm. from the bulb. A very efficient fan driven by a high speed motor served to stir the air inside the box, thereby keeping the temperature at about 45 ± 1°.

There seem to be no data available in the literature to show the effect of ultraviolet radiation on the rate of peroxide formation during the oxidation of ethers. It was deemed advisable, therefore, in the present case, to follow the auto-oxidation of ethers by determining the peroxide formed with time of illumination. Although this method fails to account completely for the true rate of auto-oxidation, it affords an excellent semi-quantitative comparison of the tendency with which ethers oxidize.

One hundred cc. of freshly distilled ether, free from peroxide, was added to the quartz vessel after it had been evacuated and filled with pure oxygen. The reaction was then started and the time recorded when the "Uviarc" lamp was turned on. At the end of a definite period of illumination, usually ten hours, the lamp was turned off and the reaction mixture allowed to stand in the dark for one-half hour to acquire the temperature of the room (during this dark period the oxidation of ethers is extremely small, as compared with the photochemical oxidation, and could therefore be entirely neglected without introducing any serious error in the results), then pure oxygen was admitted into the apparatus until the pressure became equal to the atmospheric pressure; the stopper was then removed and by means of a 5-cc. calibrated pipet, samples of 5 cc. were pipetted into an acidified solution of potassium iodide and the iodine liberated titrated against $N/50$ thiosulfate. Best results were obtained when the potassium iodide solution was acidified, just before use, with glacial acetic acid. Blanks were used in every titration. Figure 4 shows the total amount of peroxide found in each of the nine ethers tried expressed in *cc.* of $N/50$ thiosulfate consumed per mole of each ether plotted against time of irradiation. Duplicate runs made with some of these ethers were found to check within 4 to 6%. In addition to these ethers, phenetole, anisole, *p*- and o-methyl cresol and diphenyl ether developed after forty hours of irradiation the following amounts of peroxide expressed in cc. of thiosulfate per mole of each ether: 110.5, 59, 140.4, 115 and 15 cc., respectively. No attempt was made to isolate any of the oxidation products from the aromatic ethers.

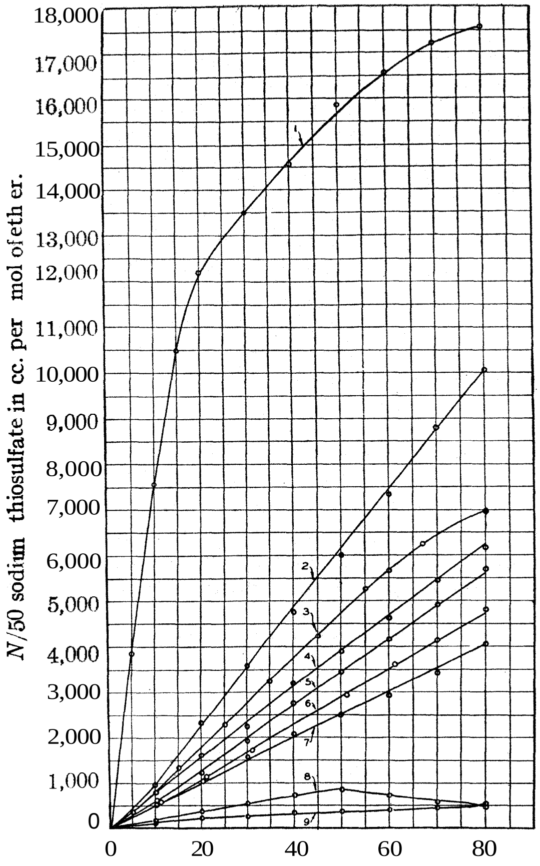

Fig. 4.—Effect of ultraviolet radiation on the oxidation of ethers: Curve 1, *tert.*-butyl benzyl; Curve 2, *sec.*-butyl ethyl; Curve 3, *tert.*-butyl ethyl; Curve 4, *n*-butyl ethyl, Curve 5, isobutyl ethyl; Curve 6, *tert.*-butyl n-propyl; Curve 7, n-dibutyl; Curve 8, 1,4-dioxane; Curve 9, *tert.*-butyl methyl.

Some interesting though only tentative conclusions, at present, seem to emerge from these results. With the majority of ethers studied the total peroxide formed increases, for long periods of time, proportionately with the time of irradiation. The groups to which the ether oxygen is attached exert a decided influence, just as it was anticipated, on the rate with which molecular oxygen adds on to this atom. In other words, the rate with which different ethers autooxidize, under the conditions of our experiments, bears a close relationship to their structure. It would be very interesting, however, to see if these relationships follow when the measurements are made using monochromatic radiation and the quantum yields determined. Such a method of approach is contemplated by the author.

Preparation and Purification of Materials

The following ethers have been prepared and purified in this Laboratory by Dr. George W. Rigby, and details will be found in his Dissertation:[7] *tert.*-butyl ethyl, *tert.*-butyl methyl, *tert.*-butyl n-propyl, n-butyl ethyl, isobutyl ethyl and *sec.*-butyl ethyl. All these ethers have been refractionated over metallic sodium just before use in order to destroy any peroxide that might have developed. The boiling points were found to agree very well with those determined by Dr. Rigby.

n-Dibutyl ether and 1,4-dioxane were the C. P. products purchased from the Eastman Kodak Company. Both of these ethers, but especially the latter, showed the presence of considerable amounts of peroxide and were further purified by fractionating over metallic sodium. It is quite interesting to note that 1,4-dioxane has been variously reported[16] to be indifferent to several oxidizing reagents, and consequently has been highly recommended as a solvent for molecular weight determinations.

Phenetole, anisole and diphenyl ether were also the C. P. products furnished by the Eastman Kodak Company, but were not further purified since they were found to contain only minute traces of peroxides and no aldehydes or phenols.

However, the methyl cresol ethers (Kahlbaum's C. P. quality) contained not only considerable amounts of peroxides, but also aldehydes and organic acids. These were removed and the ethers finally fractionated.

Tert.-butyl benzyl ether was synthesized, for the first time, by us and a brief description of its preparation here will not be irrelevant. Benzyl chloride was mixed with a large excess of sodium *tert.*-butylate and the mixture allowed to stand at room temperature for two months. At the end of this time the mixture was washed with water and the oil which had separated out was dried aver anhydrous sodium sulfate and fractionated, the fraction boiling, with a slight decomposition, at 205.6–208° (corr.) collected and used immediately in our reaction. The density of this ether was found to be d_4^{25} 0.9439. Metallic sodium reacts with it vigorously and therefore cannot be used for its purification. Concentrated hydrochloric acid reacts with this ether, yielding *tert.*-butyl chloride and benzyl chloride. It oxidizes in the dark, yielding monoxy-benzyl peroxide and *tert.*-butyl alcohol. Attempts to separate the peroxide in the pure form were not successful. Both benzaldehyde and benzoic acid have been isolated from its oxidation products.

TABLE II

BOILING POINTS OF ETHERS

Ether	B. p., °C.	Literature
Tert.-butyl methyl	55.3	54-55
Tert.-butyl ethyl	73.1	70
Tert.-butyl n-propyl	97.4	
Tert.-butyl benzyl	205.6–208	..
n-Butyl ethyl	92.3	91.4
n-Butyl n-butyl	142.2–143	140.9
Isobutyl ethyl	81.1	78–80
Sec.-butyl ethyl	81.2	..
1,4-Dioxane	100.9–101.1	101.2–101.4
Methyl o-cresol	170.1–171.6	171.3
Methyl *p*-cresol	175.5–176.0	176.5

No oxidation products of ethers other than the peroxides have been determined quantitatively. Attempts have been made, however, to iso-

---

[16] Anschiitz and Broeker, Ber., 59, 2844 (1926); Reid and Hofmann, *Ind.* Eng. Chem., 21, 695 (1929).

late and identify all the important products. Hydrogen peroxide was identified in the oxidation products of all ethers studied by the titanium sulfate test and by Jorissen's vanadic acid reagent.[17] All aliphatic oxidized ethers studied yielded a strong benzidine reaction, which has been ascribed by Woker,[9] Wieland and Wingler[4] and others to the presence of monoxy-alkyl peroxides. The aldehydes were identified by the preparation of their *p*-nitrophenylhydrazones, which were found to have melting points agreeing very well with those recorded in the literature. *Sec.*-butyl ethyl ether yielded in addition to acetaldehyde methyl ethyl ketone.

The hydrazone of glycolic aldehyde isolated from the oxidation products of 1,4-dioxane is actually an osazone first described by Wohl and Neuberg,[18] m. p. 311°. Dakin and Dudley[19] prepared it from glycolic acid, m. p. 302°, and Curtius[20] from glyoxal, m. p. 308°. Our product was recrystallized several times from hot pyridine into fine red needles, m. p. 308.7°. With this osazone alcoholic potash gives a greenish-blue color, changing to deep blue and slowly to violet and finally to reddish-brown. That the aldehyde formed during the oxidation of 1,4-dioxane was not glyoxal was proved by its failure to reduce ammoniacal silver nitrate solution and its positive reaction with Fehling's reagent.

Tert.-butyl alcohol was isolated as the *tert.*-butyl choride, b. p. 50–51°, from the oxidation products of all *tert.*-butyl ethers. Alcohols formed during the oxidation of the other ethers oxidized further and it was, therefore, impossible to isolate them as such.

Another oxidation product detected in small quantities by the mercuric chloride test in all ethers having either the methyl or ethyl groups is formic acid. This acid was also isolated from the oxidation products of 1,4-dioxane.

Isolation of Some Organic Peroxides.—Four of the oxidized ethers were washed with sodium carbonate solution, dried and the unchanged ether removed by distillation in a vacuum at temperatures varying from 0 to 70°, the receiver being cooled in a mixture of solid carbon dioxide and ether. Portions of the residue were then analyzed for active oxygen by the potassium iodide–thiosulfate method, and for the amount of aldehyde formed on hydrolysis in dilute sulfuric and subsequent distillation of the aldehyde by precipitation with *p*-nitrophenylhydrazine. Three trial determinations by the latter method with known samples of propionaldehyde gave recoveries of the aldehyde of 95.6, 94.3 and 95.2%.

The analytic data obtained are given in Table III. The calculated ratio of aldehyde to peroxide is based on the assumption that the first

i-$C_4H_9OC_2H_5$	$C_6H_{12}O_4$	10.81	10.58	1	0.68
	$C_6H_{14}O_4$	10.66	10.39	2	

These peroxides are all colorless oils which explode violently when heated directly in a flame and possess an odor resembling that of peracids. In ether solution they fail to give the benzidine or chromic acid reactions, but liberate iodine readily from a solution of potassium iodide and give a strong red color with *p*-amidodimethylaniline hydrochloride.

Inasmuch as the peroxide content differs only slightly in the two types of peroxides shown in the foregoing table, it was thought advisable to synthesize the dioxy-ethyl and dioxy-propyl peroxides and compare their behavior toward different reagents with that of the peroxides isolated from *tert.*-butyl ethyl and *tert.*-butyl n-propyl ethers.

The dioxy-propyl peroxide was prepared by allowing a 2:1 mixture of propionaldehyde and hydrogen peroxide in dry ether to stand at room temperature for twenty-four hours. Thereafter the mixture was treated and analyzed in the same manner employed above with the oxidized ethers. The percentage of active oxygen was found to be 10.10 as against 10.66 calculated for $C_6H_{14}O_4$, while the ratio of aldehyde to peroxide was 1.86:1 as against 2:1 calculated. This peroxide has a very disagreeable odor, fails to liberate iodine from neutral potassium iodide and gives only a very weak test with *p*-amidodimethylaniline hydrochloride. It clearly differs from the peroxide isolated from oxidized *tert.*-butyl n-propyl ether.

The dioxy-ethyl peroxide was also prepared in the same manner and was found to have in ether solution properties similar to dioxy-propyl but different from the peroxide isolated from *tert.*-butyl ethyl ether. An attempt to separate it in the pure form under the same experimental conditions applied to *tert.*-butyl ethyl ether failed to leave any residue for analysis.

It is now quite obvious, from the evidence presented, that the peroxides isolated from the oxidation products of four ethers are different from the monoxy-alkyl and dioxy-alkyl peroxides, and therefore might be considered as peresters of the type described. However, neither the monoxy- nor the dioxy-alkyl peroxides are to be excluded from the oxidation products of ethers.

The author takes this opportunity to express profound appreciation to Professor James F. Norris for his coöperation.

Summary

1. Evidence has been brought forward to show that the dehydrogenation theory of Wieland, as applied by Wieland and Wingler to the auto-oxidation of ethers, is untenable.

2. The oxonium peroxide theory, based on previous views of the author, has been proposed to explain the auto-oxidation of ethers.

3. The rate of oxygen absorption by dibenzyl ether has been determined at 40°, and the effect on this rate of the metals gold, silver, copper, iron and mercury, of water, and of iodine, picric acid and benzoquinone has been studied.

4. Ultraviolet radiation has been shown markedly to accelerate the oxidation of various ethers. The rate of peroxide formation under these conditions has been found to depend largely on the type of groups attached to the oxygen atom of the ether.

5. *Tert.*-butyl benzyl ether has been prepared for the first time.

6. The oxidation products of several of the ethers have been identified, and four peroxides have been isolated and shown to differ in properties from monoxy- and dioxy-alkyl peroxides.

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

THE PREPARATION OF NITROMETHANE

BY PETER P. PRITZL AND HOMER ADKINS

RECEIVED SEPTEMBER 25, 1930 PUBLISHED JANUARY 12, 1931

The reaction of a metallic nitrite with an alkyl halide produces varying proportions of the nitroparaffin and alkyl nitrite depending upon the particular metal, alkyl group and halogen involved. In continuing a study of this reaction,' the reaction of the salts of halogenated acids with sodium nitrite was investigated. It was found by Bolin in this Laboratory that methyl nitrite was not formed in detectable quantities by the reaction of sodium chloroacetate with sodium nitrite nor ethyl nitrite from sodium a-chloropropropionate. These observations led to attempts to determine what reactions reduced the yield of nitromethane to 35–38% of the theoretical in the standard method for the preparation of nitromethane.[2] Experiments were, therefore, made to ascertain to what extent the low yield of nitromethane was due (1) to mechanical losses, (2) to hydrolysis of chloroacetic acid, (3) to reduction of nitromethane by glycolic acid formed by this hydrolysis, (4) to unreacted sodium nitrite, and (5) to the condensation of nitromethane in the presence of alkali.

For the purposes of comparison the following standard procedure slightly modified from that of Whitmore and Whitmore was adopted. A 40% solution of sodium hydroxide (100–105 ml.) was slowly added with vigorous stirring to a mixture of 100 g. of chloroacetic acid and 100 g. of finely crushed ice until the mixture was just alkaline to phenolphthalein, the temperature being kept below 10". Seventy-three grams of sodium nitrite in 100 ml. of water was added and the mixture slowly heated during twenty-five to thirty minutes to 108–110°. Distillation of nitromethane began when the solution was at a temperature of about 87°. The nitromethane was separated from the water layer and the latter redistilled three to five times until the last distillation yielded approximately 4 ml. of water and 0.3 ml. of nitromethane. The combined fractions of nitromethane was dried over calcium chloride for twelve hours, poured off and distilled, the fraction at 98–101° being saved and weighed as nitromethane. Three successive trials of this method gave yields of 27.5, 26.6 and 26.7 g., the average being 41.6% of the theoretical.

The mechanical loss of nitromethane during the preparation was found to be from 4.9 to 5.1 g. or about 9.0%. This was determined by placing known weights (51 to 64 g.) of the compound in 200 ml. of water and recovering the nitromethane by distillation as in the standard procedure.

The percentage of hydrolysis of sodium chloroacetate under approximately the conditions to which it was subjected during its reaction with sodium nitrite was found to be 14.9%. In this determination 9.5 g. of chloroacetic acid was neutralized as in the standard procedure, and 8.4 g. of sodium bicarbonate and 10 ml. of water added. The mixture was then subjected for a time interval and at temperatures which had previously been determined to be approximately those that occurred in the actual preparation of

---

[1] Reynolds and Adkins, THIS JOURNAL, 51, 279 (1929).

[2] Whitmore and Whitmore, "Organic Syntheses," John Wiley and Sons, Inc., New York. 1923, Vol. III, p. 83.

nitromethane. The flask containing the reaction mixture was heated in a water-bath which was raised to a temperature of 90° in eight to nine minutes. The contents of the flask were kept at an average temperature of 90.4' for fifteen minutes, the variation being not more than ±1°. The contents of the flask were then cooled to room temperature in less than one minute. The amount of hydrolysis was calculated from the amount of sodium bicarbonate remaining in the flask. This was determined by the addition of an excess of standard hydrochloric acid, removal of the carbon dioxide by bubbling carbon dioxide-free air through the solution for twenty minutes and then titrating the excess acid. When sodium chloroacetate was subjected to the same conditions except that no sodium bicarbonate was used, the hydrolysis was found to be only 2 3%.

The sodium glycolate formed by hydrolysis apparently has little or no effect upon the preparation except in so far as its formation reduces the amount of sodium chloroacetate available for reaction with sodium nitrite. A reaction mixture to which sodium glycolate had been added gave a yield of 39.6% of nitromethane, which is only 1 or 2% less than the usual yield.

The amount of sodium nitrite remaining in the reaction flask after the distillation of the nitromethane in the standard procedure was found in two analyses to be 18.7 g. and 19.0 g. or an average of 25.8% of the amount originally used. This determination was made by utilizing the fact that ammonium nitrite decomposes to give nitrogen and water. Eighty grams of ammonium chloride and 100 ml. of water were added to the flask containing the residue to be analyzed. The flask was then attached to an apparatus so arranged that the mixture could be subjected to distillation and the evolved gases bubbled through sulfuric acid and sodium hydroxide. Nitrogen was liberated when the reaction flask was at a temperature of 108°. The yields of nitromethane in these two experiments were 45.7 and 41.9% of the theoretical amount. In each of the experiments 800 ± 10 ml. (24°, 740 mm.) of nitrogen was also evolved during the preparation and distillation of the nitromethane.

The method of analysis for sodium nitrite used above was shown to be reliable both for the analysis of solutions containing only sodium nitrite and those containing nitrogenous compounds resulting from the reaction of nitromethane in an alkaline solution. For example, when a solution containing 15.24 g. of sodium nitrite in 75 ml. of water was analyzed the volume of nitrogen obtained was 98.5% of the theoretical amount. In another test of the method of analysis, 15.23 g. of sodium nitrite, 55.5 g. of nitromethane and 84 g. of sodium bicarbonate were placed in 250 ml. of water. The nitromethane was distilled out in the usual way, the recovery being 72.1%. The residue thus containing the condensation products from 15.5 g. of nitromethane and 15.23 g. of sodium nitrite was analyzed for the nitrite. There was found 15.20 g. of nitrite or 99.9% of the amount originally placed in the mixture.

The formation of nitromethane from sodium nitrite and sodium chloroacetate is usually assumed to involve the following reactions as given by Whitmore and Whitmore

$$ClCH_2COONa + NaNO_2 = NO_2CH_2COONa + NaCl \qquad (I)$$

$$NO_2CH_2COONa + H_2O = CH_3NO_2 + NaHCO_3 \qquad (II)$$

These reactions do not explain the vigorous evolution of carbon dioxide that occurs during the preparation nor the highly colored products present during the reaction, nor the nitrogenous tar-like residue. According to Dunstan, Dyrnond and Goulding[3] nitromethane reacts in the presence of

---

[3] Dunstan and Dymond, *J. Chem. Soc.*, 59, 430 (1891); Dunstan and Goulding, *ibid.*, 77, 1262 (1900).

sodium bicarbonate to form methazonic acid, water and carbon dioxide, e. g.

$$2CH_3NO_2 + NaHCO_3 \longrightarrow HON{=}CHCH{=}N(O)ONa + CO_2 + 2H_2O \quad \text{(III)}$$

It seems almost certain that this reaction occurs during the preparation of nitromethane, for the conditions are almost identical with those under which methazonic acid has been prepared. The dry residue was found to explode on heating, which is in accord with the observations of Dunstan and Goulding.

A group of experiments was made to ascertain the extent to which nitromethane reacts in the presence of sodium bicarbonate. The weights of sodium bicarbonate (89 g.) and nitromethane (64.6 g.) which would be formed in the preparation according to Reaction II were placed in 260 ml. of water and distilled as in the actual preparation. An exothermic reaction began at 70°, nitromethane distilled over, and carbon dioxide was evolved. The solution went through the color changes from cherry-red to black which are characteristic of the reaction mixture in the preparation of nitromethane. The solution was gradually heated during twenty or twenty-five minutes up to 105–108° as in the preparation, and the recovery of nitromethane determined. The loss was in three experiments 21.5, 19.6 and 22.1 g., respectively, or an average loss of 32.6%. In this loss there is included the 9% mechanical loss referred to above, so that 23 to 24% of the nitromethane used underwent condensation, presumably to methazonic acid.

The fate of the sodium nitrite was thus completely accounted for in that about 50% was converted into nitromethane, of which about 8 to 9% was lost in manipulation, 23 to 24% was converted into methazonic acid and its condensation products and 25 to 26% remained in the residue. About 10% of the chloroacetic acid was unaccounted for but this is probably due to the impracticability of determining the extent of hydrolysis under exactly the conditions that exist in the reaction mixture. It is possible that some of it reacts with the condensation products of nitromethane.

Upon the basis of these experiments it seemed possible that the yield of nitromethane could be increased by reducing the alkalinity in the zone of reaction either by incompletely neutralizing the chloroacetic acid or by modifying the method of bringing the reactants together. An increase in the yield to 46% was actually obtained if the sodium nitrite solution was heated to 100–110° before the solution of sodium chloroacetate was added by way of a dropping funnel. In another experiment the same yield of 46% was obtained as by this method except that in this latter case the chloroacetic acid was only half neutralized.

The most effective way of increasing the yield of nitromethane was to use the method of adding the reactants described in the preceding paragraph and to increase the ratio of chloroacetic acid to sodium nitrite so as to insure the reaction of all of the sodium nitrite. When the salt from 100 g. of chloroacetic acid was allowed to react with 36.5 g. of sodium nitrite the yield of nitromethane based on the sodium nitrite was 65% of the theoretical amount. Yields up to 70% of the theoretical were obtained by using an excess of chloroacetic acid.

Summary

The reactions of sodium chloroacetate and sodium nitrite have been studied and it has been ascertained that in using molecular quantities of the reactants approximately 50% of the nitrite is converted into nitromethane, while about 24% of it gives nitromethane which undergoes further condensation to what is presumably the sodium salt of methazonic acid. About 26% of the sodium nitrite does not react, chiefly because 15% or more of the sodium chloroacetate undergoes hydrolysis to sodium glycolate. The formation of nitromethane may be increased to approximately 75% of the theoretical amount if a sufficient excess of sodium chloroacetate is used to insure the complete reaction of the sodium nitrite. The actual yields of nitromethane obtained were about 9% lower than those given above (50 and 75%) because of mechanical losses on the scale of operation used in obtaining them. The weight of nitromethane actually obtained may be increased by about 10% by modifying the standard method so that the sodium chloroacetate is introduced into the nitrite solution after the latter has been heated to the temperature of reaction.

A method is described for the determination of sodium nitrite in the presence of nitrates and methazonic acid and its condensation products.

GEOGRAPHIC LOCATION AND THE IODINE CONTENT OF THE THYROID GLAND

BY F. FENGER, R. H. ANDREW AND J. J. VOLLERTSEN

RECEIVED OCTOBER 6, 1930 PUBLISHED JANUARY 12, 1931

The biochemical literature contains but very limited data regarding seasonal fluctuations in any physiological function. We know that the thyroid gland needs iodine to render its secretion active. The amount of iodine in the gland consequently reveals its potency. Seidell and Fenger[1] have shown that a very marked seasonal variation exists in the percentage of iodine present in the healthy, normal thyroid glands of domestic animals. There is, in general, from two to three times as much iodine present in the glands during the summer and fall months as during the winter and spring seasons. The glands on which these conclusions were based were collected at Chicago and represented principally the middle central states.

As a result of an inquiry from Dr. W. L. Aycock of the Harvard Medical School, it was decided to investigate existing conditions in the northern and southern portions of the United States. Hog glands were selected

---

[1] Seidell and Fenger, J. *Biol. Chem.*, 13, 517 (1913), and Bulletin 96, Hygienic Laboratory, U. S. Public Health Service. 1914, p. 67.

because the hog is an omnivorous animal like the human race, and because the size of the hog thyroid remains constant throughout the seasons.

Approximately one pound of hog thyroid glands was collected weekly, with a few exceptions, for a period of one year at West Fargo, N. D., our most northern abattoir, and also at Fort Worth, Texas, our most southern plant. Immediately after dissection, the glands were frozen and shipped to Chicago in this condition. On arrival, the glands were thawed out, carefully freed from extraneous tissue and weighed. The glands were next finely minced and dehydrated in *vacuo* at low temperature (85°F.). The fat was removed by means of petroleum ether and the desiccated fat-free material powdered. On the finished powder we determined the ash, P_2O_5 and iodine. Lack of space permits only the showing of the iodine values.

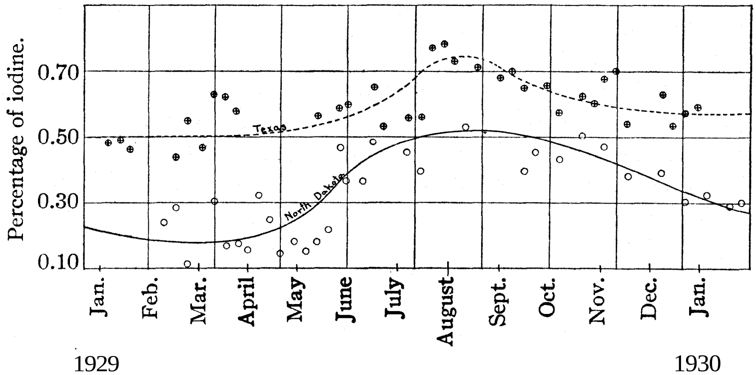

Fig. 1.—Seasonal variation in iodine content of hog thyroid glands from Texas and North Dakota, 1929–30.

Disregarding fluctuations due to the comparatively small number of glands constituting each weekly sample, it will be seen from the chart that both types of glands show seasonal variations in the form of a marked iodine increase during the summer months. The iodine level is higher in the southern than in the northern thyroids but the seasonal fluctuation is more pronounced in the northern glands. The yearly average for the Texas glands is 0.60% iodine with a maximum of 0.78% in August and a minimum of 0.44% in the latter part of February, while that of the North Dakota thyroid is only 0.32% iodine with a top peak at 0.53% in August and a low dip down to 0.13% early in March.

The weight of the fresh glands is not tabulated in this communication. It was found, however, that the fresh southern thyroids were smaller throughout the year and weighed approximately 20% less than the northern glands. The amount of thyroid iodine per unit of body weight is, in spite of this difference, considerably higher in the Texas hogs than in the North Dakota animals. The principal reason for this condition must be sought in the geographic location of the two collection points. The latitude of West Fargo is about 47° north and the winters are quite severe. Fort Worth is situated close to the thirty-third parallel and the winter months are comparatively mild.

Conclusions

Calculated on the desiccated fat-free basis, the yearly average for hog thyroid glands from North Dakota is 0.32% iodine, while that of Texas glands is 0.60% iodine.

The seasonal variation in the iodine content is most pronounced in the northern glands.

The higher iodine level of the Texas glands and the greater seasonal fluctuations of the North Dakota thyroids are attributed to the geographic location of the two states.

THE ACETYLATION OF ORTHO-HYDROXY ALDEHYDES

BY T. MALKIN AND M. NIERENSTEIN

RECEIVED OCTOBER 10, 1930 PUBLISHED JANUARY 12, 1931

Herzig and Wenzel[1] found that when phloroglucin aldehyde is heated with acetic anhydride and anhydrous sodium acetate, no trace of the corresponding coumarin was produced, and that the condensation product consisted mainly of 2,4,6-triacetoxybenzylidenediacetate (I), which melted at 155–156°. Later, Knoevenagel[2] showed that benzylidenediacetate formation is general to all aromatic aldehydes, being favored by rise of temperature. On the other hand, Pratt and Robinson[3] apparently succeeded in preparing for the first time triacetylphloroglucin aldehyde (II) by the interaction of phloroglucin aldehyde with acetic anhydride and anhydrous potassium carbonate. They found that during the reaction considerable heat was evolved and that the resulting product melted at 151°, a melting point subsequently raised to 156–157° by Robertson and Robinson.[4] The agreement between the melting points found by Herzig and Wenzel and Robertson and Robinson, respectively, for the two substances I and II seemed to us very striking, and since Robinson's triacetylphloroglucin aldehyde is an important starting material in the syntheses of a large number of the anthocyanidins,[5] we thought it desirable to

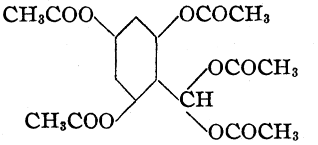
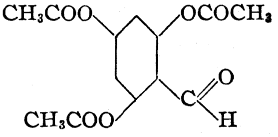
[5] See Pratt and Robinson, *J. Chem. Soc.*, 127, 1182 (1925); Malkin and Robinson, *ibid.*, 127, 1190 (1925); Gatewood and Robinson, *ibid.*, 1959 (1926); Nolan and Robinson *ibid.*, 1968 (1926); Robertson and Robinson, *ibid.*, 1710 (1927); Malkin and Nierenstein, *Ber.*, 61, 791 (1928).

re-investigate this material. Our results leave no doubt whatever that the so-called triacetylphloroglucin aldehyde (II) of Robinson and his co-workers is in fact the penta-acetate (I) of Herzig and Wenzel. This incidentally also offers an explanation for the analytical difficulties commented on by Pratt and Robinson, who found that their product did not give correct values for triacetylphloroglucin aldehyde (II) and assigned to it the empirical formula $C_{13}H_{12}O_7 + {}^1/_2H_2O$.[6]



I



II

In the present communication, a method for the preparation of triacetylphloroglucin aldehyde (II) is described, and this method has also been extended to the preparation of diacetyl-β-resorcylic aldehyde and acetylsalicylic aldehyde. All these aldehydes are smoothly acetylated in ethereal solution with acetic anhydride and anhydrous potassium carbonate in which manner all rise of temperature is controlled. That evolution of heat should be avoided is evident from the fact that if salicylic aldehyde is warmed for a few minutes with acetic anhydride and anhydrous potassium carbonate, 2-acetoxybenzylidenediacetate only is obtained. Cooling in ice does not, however, sufficiently retard the formation of benzylidenediacetate and leads, for example, in the case of phloroglucin aldehyde, to a quantitative yield of the penta-acetate (I) and not the triacetate (II).

The ease with which the formation of benzylidenediacetate takes place clearly accounts in our opinion for the low yields which are obtained when coumarin is prepared by the Perkin synthesis,[7] a fact well known to industry.[8]

The failure of Herzig and Wenzel to obtain 5,7-dihydroxycoumarin by the Perkin reaction is thus in harmony with the facile benzylidenediacetate formation of phloroglucin aldehyde, although Gattermann[9] states that this coumarin is formed by heating phloroglucin aldehyde, anhydrous sodium acetate and acetic anhydride in a sealed tube for five hours at 160–175°. Gattermann, however, draws attention to the fact that the deacetylated product shows no fluorescence in concentrated sulfuric acid, the character-

[6] The analytical data of Pratt and Robinson refer to the product melting at 151°, which was obviously impure penta-acetate (I). No analyses are recorded by Robertson and Robinson for their pure product (m. p. 156–157°).

[7] According to Simonis, "Die Cumarine," Stuttgart, 1916, p. 59, the yield of 37.5% recorded by Gnehm, *Ber.*, 14, 262 (1881), is the highest yield so far given in the literature for coumarin.

[8] See May, ***Perfumery Essential Oil Record,*** 16, *47* (1925).

[9] Gattermann, Ann., 357, 345 (1907).

istic property of 7-hydroxycoumarins. Gattermann's synthesis, therefore, still requires confirmation.

The application of the true o-acetoxy aldehydes in the syntheses of flavylium compounds is in progress, and is reserved for subsequent publications.

Experimental

Phloroglucin aldehyde and β-resorcylic aldehyde were prepared by Adams and Levinc's modification of the Gattermann reaction[10] and only those who have worked with the original Gattermann method can appreciate the advance for which Adams' modification stands. In our experience, however, the comparatively large excess of zinc cyanide as used by Adams and Levine is unnecessary and cleaner products are obtained when only a very slight excess over the theoretical is employed.

Acetyl-salicylic Aldehyde.—To a solution of 10 g. of salicylic aldehyde in 50 cc. of dry ether are added 15 g. of anhydrous potassium carbonate and 15 cc. of acetic anhydride, and the reaction mixture vigorously shaken for thirty minutes. The solution is then filtered on the pump and the residual solid washed several times with dry ether The residue left on evaporation of the ether is treated with water and the solid collected, The product crystallizes from ligroin (b. p. 60–80°) in needles which melt at 38°, in agreement with the melting point given in the literature.

2-Acetoxybenzylidenediacetate.—Ten grams of salicylic aldehyde dissolved in 30 cc. of acetic anhydride is warmed for a few minutes with 10 g. of anhydrous potassium carbonate. The oil formed on pouring into water and standing for some time is separated from the aqueous layer and dissolved in a little alcohol. On standing, thick prisms separate which on crystallization from alcohol melt at 107°. This product is identical with the "2-hydroxybenzylidenediacetate"(m p. 101°) of Perkin,[11] as already pointed out by Barbier[12] and Knoevenagel,[13] who give its melting point as 104–105" and 103°, respectively.

Diacetyl-β-resorcylic Aldehyde.—Three grams of β-resorcylic aldehyde, dissolved in 100 cc. of dry ether, was reacted on with 6 g. of anhydrous potassium carbonate and 10 cc. of acetic anhydride in the manner already described for the preparation of acetylsalicylic aldehyde. The crude product (3.5 g.) separated from absolute alcohol in colorless needles which melted at 69'. The alcoholic solution gives no coloration with ferric chloride.

Anal. Subs., 4.580, 5.101, 4.891 mg.: CO_2, 9.960, 11.150, 10.660 mg.; H_2O, 1.81, 2.12, 1.96 mg. Calcd. for $C_{11}H_{10}O_5$: C, 59.46; H, 4.50 Found: C, 59.31, 59.63. 59.45; H, 4.42, 4.65, 4.48.

Triacetylphloroglucin Aldehyde (II).—For the preparation of phloroglucin aldehyde in small quantities, the following slight modification of the original method of Adams and Levine was found to give excellent results. Into a solution of 2 g. of anhydrous phloroglucin in 25 cc. of dry ether containing, 1.2 g. of zinc cyanide, a good stream of dry hydrogen chloride is passed until the oil formed solidifies. After standing for two to three hours, the solid is collected, washed with ether, and the imide salt dissolved in 40 cc. of water and hydrolyzed on a water-bath. The solid (2 g.) obtained on cooling is collected and dissolved in ether, filtered from traces of a red-colored byproduct, and the ether evaporated. Phloroglucin aldehyde thus obtained crystallizes

in long cream-colored needles from water containing a trace of sulfur dioxide. As already recorded by Gattermann, the product has no definite melting point.

In the acetylation, 2.3 g. of phoroglucin aldehyde in 100 cc. of dry ether containing 7.5 g. of anhydrous potassium carbonate and 15 cc. of acetic anhydride are worked up in the manner already described. The crude solid (3 g.) crystallizes from alcohol in thick colorless prisms which melt at 101°. The alcoholic solution gives no coloration with ferric chloride.

Anal. Subs., 5.100, 4.869 mg.: CO_2, 10.420, 9.930 mg.; H_2O, 1.98, 1.85 mg. Subs., 5.333, 5.930 mg.: 5.68, 6.37 cc. of $N/100$ NaOH. Calcd. for $C_{13}H_{12}O_7$: C, 55.71, H, 4.29; CH_3CO, 46.07. Found: C, 55.74, 55.64; H, 4.34, 4.25; CH_3CO, 45.82, 46.21.

The 2,4,6-triacetoxybenzylidenediacetate (I), obtained by the method of Pratt and Robinson, melted at 157".

Anal. Subs., 4.979, 5.075 mg.: CO_2, 9.730, 9.930 mg.; H_2O, 2.06, 2.09 mg. Subs., 6.769, 6.181 mg.: 8.57, 7.81 cc. $N/100$ NaOH. Calcd. for $C_{13}H_{12}O_7$ (triacetylphloroglucin aldehyde): C, 55.71; H, 4.29; CH_3CO, 46.07. Calcd. for $C_{17}H_{18}O_{10}$ (2,4,6-triacetoxybenzylidenediacetate): C, 53.39; H, 4.71; CH_3CO, 56.27. Found: C, 53.30, 53.36; H, 4.63, 4.61; CH_3CO, 54.47, 54.36.

For the micro-acetyl estimations we are indebted to Dr. Arnulf Soltys and to Dr. M. Zacherl, which were carried out by them in Professor Pregl's laboratory, according to the Pregl–Soltys method.''

Summary

A general method for the acetylation of o-hydroxy-aldehydes is described. The acetylation is carried out with acetic anhydride and anhydrous potassium carbonate in the presence of ether, in which manner benzylidenediacetate formation is avoided.

A METHOD FOR THE DETERMINATION OF PEROXIDASE ACTIVITY[1]

BY JOHN D. GUTHRIE

RECEIVED OCTOBER 14, 1930 PUBLISHED JANUARY 12, 1931

A mixture of α-naphthol and *p*-phenylenediamine has frequently been used for both the qualitative and quantitative estimation of oxidase activity.[2] This depends on the oxidation of the reagent by atmospheric oxygen to form an indophenol, oxidase acting as the catalyst. In the estimation of peroxidase, hydrogen peroxide takes the place of oxygen in the reaction. The α-naphthol-*p*-phenylenediamine mixture has, however, usually been regarded as too sensitive for peroxidase, and other compounds

---

[14] Pregl, "Die Quantitative Organische Mikroanalyse," Berlin, Dritte Auflage, 1930, p. 216.

[1] Herman Frasch Foundation for Research in Agricultural Chemistry, Paper No. 13.

[2] H. M. Vernon, J. *Physiol.*, 42, 402–432 (1911).

have been used for its estimation, especially pyrogallol.[3] It is true that the α-naphthol–p-phenylenediamine reagent is too sensitive for peroxidase when used near the neutral point, but in more acid solutions the reaction is sufficiently slow to be followed quantitatively. Furthermore, catalase is inactive in acid solutions and its interference is, therefore, avoided.

In a previous paper[4] the α-naphthol–p-phenylenediamine reagent was used in a study of peroxidase in potatoes that had been treated with chemicals that break the rest period. The method used in this work gave relative values, only determinations made at the same time being comparable. The procedure has now been improved so that determinations made at different times may be compared.

Preparation of Substrate.—Prepare a citrate buffer, PH 4.5, by dissolving 21 g. of crystalline citric acid in 170 cc. of N sodium hydroxide and diluting to one liter. To 200 cc. of this add 200 cc. of water, 1 g. of p-phenylenediamine hydrochloride, and 20 cc. of 4% α-naphthol in 50% alcohol. Filter the solution.

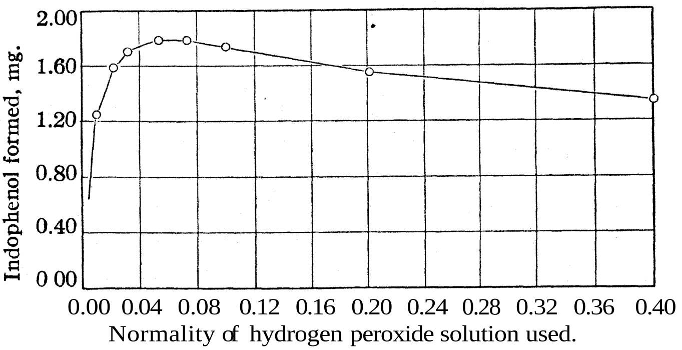

Fig. 1.—Showing the effect of using various hydrogen peroxide concentrations for the determination of peroxidase. Potato juice, 0.5 cc., was used in each determination.

The Method.—Place 25-cc. portions of the freshly prepared substrate in unlipped centrifuge tubes of about 80-cc. capacity. Place in a water-bath at 25° and allow to attain the temperature of the bath. Add 0.5 to 2.0 cc. of the juice or extract containing the enzyme, the amount depending on the peroxidase content. If the extract is very high in peroxidase, it will be necessary to make a known dilution before drawing the sample. Start the reaction by adding 5 cc. of $N/20$ hydrogen peroxide. When ten minutes have elapsed, stop the reaction by adding 5 cc. of 0.1% aqueous solution of potassium cyanide.

Remove from the bath and add 25 cc. of toluene. Stopper with a well fitting cork, shake vigorously and centrifuge. Pour off the clear layer of toluene, which now contains the indophenol, and compare it colorimetrically with the standard. It is usually desirable to run blank determinations on the reagents.

The Standard.—Prepare indophenol by adding 100 cc. of 2 N hydrogen peroxide and 2 cc. of 10% aqueous solution of $FeCl_3 \cdot 6H_2O$ to 800 cc. of the substrate. Allow to

---

[3] R. Willstatter and A. Stoll, *Ann.*, **416**, 21–64 (1918).

[4] F. E. Denny, L. P. Miller and J. D. Guthrie, *Am. J. Botany*, 17, 483–509 (1930).

stand overnight. Filter off the precipitated indophenol and purify it by crystallization from a 1:1 mixture of absolute alcohol and toluene.

To make the standard, dissolve 50 mg. of this preparation in 50 cc. of a warm 1:1 mixture of absolute alcohol and toluene. Add toluene to make the total volume one liter. The standard keeps well.

A solution of iodine in chloroform, 2 g. per liter, is also a satisfactory standard. When set at 20 mm. in the colorimeter, it is equivalent to a solution of 75 mg. of the indophenol per liter.

Effect of Hydrogen Peroxide Concentration.-Since Willstätter and Stoll[3] have shown that high concentrations of hydrogen peroxide are harmful to peroxidase, determinations were made using hydrogen peroxide solutions of various normalities. These solutions were standardized with potassium permanganate. The results are shown in Fig. 1. The optimum amount of hydrogen peroxide to use is found to be 5 cc. of $N/20$ solution.

Effect of Concentration of **Enzyme.**—The effect of using various amounts of potato juice is shown in Fig. *2*. The enzyme activity is linear with the concentration of enzyme up to an activity of about *4.0*. It is, therefore, recommended that extracts giving higher values be diluted before drawing the sample.

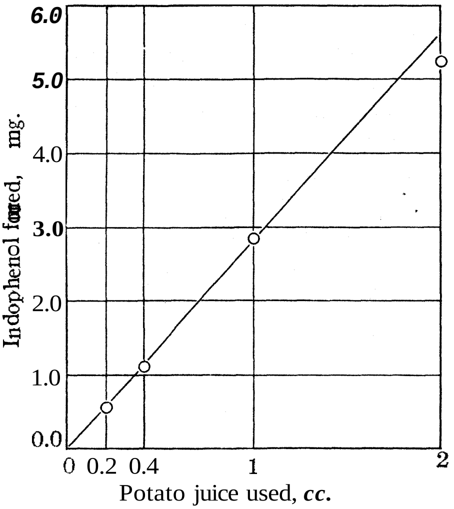

Fig. 2.—Showing the effect of various concentrations of peroxidase, obtained by the use of different volumes of potato juice.

Accuracy of Method.—Potato juice was diluted one-quarter and determinations were made using 2 cc. of the diluted juice. The average indophenol value was 1.48 mg. with an average error of ±0.03 mg.

Summary

A method for estimating peroxidase activity, based on the formation of indophenol from a mixture of *p*-phenylenediamine and a-naphthol in a citrate buffer of PH 4.5, is described.

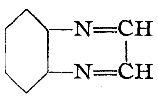
THE RELATION OF QUINOXALINE TO THE AMMONIA SYSTEM

BY F. W. BERGSTROM AND R. A. OGG, JR.

RECEIVED OCTOBER 23, 1930 PUBLISHED JANUARY 12, 1931

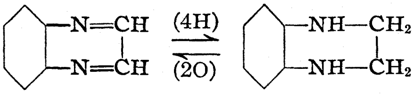
In a recent article[1] the structure of quinoline was discussed from the standpoint of the ammonia system of compounds of Franklin and co-workers, and it was there pointed out that this compound contains the ammono aldehyde grouping —CH=N—, and so should be expected to display properties analogous to those of aldehydes of the water system. In the present work it is desired to apply similar reasoning to the structure of another heterocyclic compound, quinoxaline, and to present experimental confirmation.

From the conventional formula for quinoxaline, A, it is seen that two adjacent ammono aldehyde groups are present in the molecule, and hence it is to be regarded formally as an ammono 1,2-dialdehyde, or ammonoglyoxal.[2] Therefore the properties of quinoxaline, in so far as they involve the heterocyclic ring, should be those of an ammono glyoxal. Some previously known reactions are in accord with this analogy. Thus quinoxaline is synthesized by the action of o-phenylenediamine on glyoxal,[3] a reaction which may be regarded as the ammonolysis of glyoxal by a substituted ammonia, the product being a substituted ammono glyoxal.



A

On reduction quinoxaline behaves as an ammono dialdehyde, yielding the corresponding ammono diprimary alcohol, 1,2,3,4-tetrahydroquinoxaline, which may be oxidized back to quinoxaline.[4]



Several new reactions of quinoxaline have been carried out, the results of which in the main substantiate still further the analogy between this compound and glyoxal.

Quinoxaline and Bisulfites.—Glyoxal behaves as a typical dialdehyde in uniting with two equivalents of acid sulfites. Similarly, quinoxaline has been found to add very readily two equivalents of sodium bisulfite, the solid addition product being easily decomposed by bases with regeneration of quinoxaline.

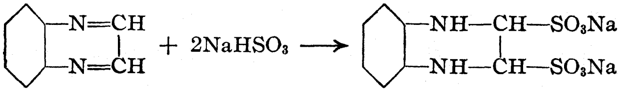
---

[1] Bergstrom and McAllister, THIS JOURNAL, 52, 2845 (1930).

[2] More correctly, it is to be regarded as an ammono dialdehyde diacetal, since the third valences of the nitrogen atoms are united to an o-phenylene group.

[3] Hinsberg, Ann., 237, 327 (1887).

[4] Merz and Ris, Ber., 20, 1191 (1887). See also Meisenheimer and Wieger, *J. prakt. Chem.*, [2] 102, 45-62 (1921).



Quinoxaline.—This was prepared by the method of Hinsberg[3] from glyoxal sodium bisulfite and o-phenylenediamine. The glyoxal was prepared by the method of Pollak,[5] and the o-phenylenediamine according to the method of Hinsberg and König.[6] The quinoxaline was obtained as a colorless crystalline mass, m. p. 32.0° (corr.),[7] and boiling at 229" (corr.) at 760 mm. It was very soluble in water and organic solvents.

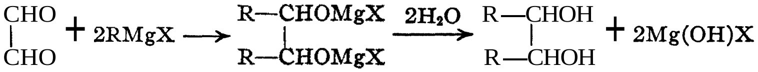
Quinoxaline Sodium **Bisulfite.**—Quinoxaline was added to a nearly saturated aqueous solution of slightly more than two equivalents of sodium bisulfite. Upon the addition of two volumes of ethyl alcohol, a very voluminous precipitate of fine white needles formed. This was filtered off, dissolved in a little water and reprecipitated with alcohol. Samples for analyses were dried in a vacuum over sulfuric acid.

Anal. Subs., 0.4839, 0.1667: Na_2SO_4, 0.2004, 0.0691. Calcd. for $C_8H_8O_6N_2S_2Na_2$: Na, 13.61. Found: Na, 13.41, 13.42.

The product decomposed on heating. By treatment with aqueous solutions of bases, quinoxaline and a neutral sulfite were formed. Acids caused evolution of sulfur dioxide.

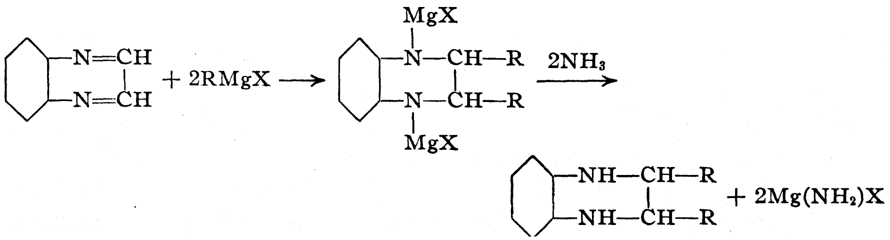
Quinoxaline reacted slowly with sulfurous acid, yielding some sulfuric acid, and an amorphous blue solid which was not further investigated.

Quinoxaline and the Grignard Reagent.—Monomeric glyoxal reacts with two equivalents of a Grignard reagent,[8] the product yielding on hydrolysis the corresponding *dl*-di-secondary alcohol.



$$\begin{matrix}\text{CHO}\\|\\\text{CHO}\end{matrix} + 2\text{RMgX} \longrightarrow \begin{matrix}\text{R—CHOMgX}\\|\\\text{R—CHOMgX}\end{matrix} \xrightarrow{2H_2O} \begin{matrix}\text{R—CHOH}\\|\\\text{R—CHOH}\end{matrix} + 2\text{Mg(OH)X}$$

Quinoxaline has been found to behave in precisely analogous fashion, giving as the final product the corresponding dl-ammono di-secondary alcohol,[8a] i. e., *dl*-1,2,3,4-tetrahydro-2,3-dialkyl-(or aryl)-quinoxaline, in good yield. dl-Tetrahydro-diphenyl- and *dl*-tetrahydro-dimethylquinoxalines were thus prepared, and the method is suggested for the synthesis of other homologs.



---

[5] Pollak, Monatsh., 15, 469 (1894).

[6] Hinsberg and König, Ber., 28, 2947 (1895).

[7] Ninsberg gives 27° as the melting point.

[8] Wren and Still, J. Chem. *Soc.*, 103, 1770 (1913).

[8a] Strictly speaking, if the phenylene group is taken into consideration in the naming, we should speak of the di-alkyltetrahydroquinoxalines as mixed ammono di-secondary alcoliol-dihydric phenols.

***dl*-1,2,3,4-Tetrahydro-2,3-diphenylquinoxaline.**—Three grams of quinoxaline in absolute ether was added slowly to ethereal phenylmagnesium bromide (2.2 equivalents) in an atmosphere of nitrogen. The reaction was immediate and vigorous, with precipitation of a semi solid dark brown addition compound. After two hours' standing this was decomposed by careful addition of liquid ammonia (water may also be used). The ammonia was evaporated and the product was extracted with ordinary ether, leaving a residue of ammono basic magnesium bromide. The ether solution was steam distilled, ether first coming over and finally a little diphenyl, the residue being a clear brown gum, vitreous when cold. It was treated with hot concentrated hydrochloric acid and the resulting solid hydrochloride was recrystallized from glacial acetic acid as fine white needles. This was then decomposed with hot aqueous ammonia, regenerating the free base as a colorless vitreous mass, very difficult to crystallize. It was obtained from alcohol as colorless plates, m. p. 106° (corr.). With alcoholic silver nitrate it gave a fine green color and a silver mirror. By acetylation with acetic anhydride and crystallization of the product from alcohol, fine white needles were obtained, m. p. 170° (corr.).

The above properties agree with those of dl-tetrahydro-diphenylquinoxaline, described by Hinsberg and König[9a] and Bennett and Gibson.[9b] A sample of this compound prepared by the method of Hinsberg and Konig proved to be identical with the above product. In particular, the diacetyl derivative from each melted at 170° (corr.), and gave the same mixed melting point, proving their identity: yield of *dl*-tetrahydro-diphenylquinoxaline by the Grignard reaction, 70% of the theoretical.

***dl*-1,2,3,4-Tetrahydro-2,3-dimethylquinoxaline.**—Three grams of quinoxaline in absolute ether was slowly added to ethereal methylmagnesium iodide (2.2 equivalents) in an atmosphere of nitrogen. The addition product settled out rapidly as a dark oil, and after an hour was decomposed with liquid ammonia as above. The product was extracted with ether, which was then evaporated off in a vacuum desiccator, leaving a partially crystalline red residue. This was dissolved in 25 cc. of hot alcohol and added to a solution of 2.8 g. of crystalline oxalic acid in 10 cc. of hot alcohol. After several hours in the cold, the copious crystalline precipitate (oxalate of the base) was filtered off, washed and recrystallized from alcohol. After filtration, the precipitate was decomposed with aqueous ammonia, the free base then being extracted from the solution with benzene. Evaporation of the benzene left a yellowish crystalline mass, which could be crystallized from ligroin or water as fine colorless plates, m. p. 101° (corr.). With aqueous ferric chloride a magnificent blue coloration was produced.

Gibson[10] gives 101° as the melting point of *dl*-1,2,3,4-tetrahydro-2,3-dimethylquinoxaline. A sample of this compound prepared by Gibson's method from 2,3-dimethylquinoxaline proved to be identical with the above product. Each melted sharply at 101° (corr.), as did a mixture of equal quantities, showing their identity. The yield of dl-tetrahydro-dimethylquinoxaline by the Grignard reaction was 50% of the theoretical.

Quinoxaline and Hydrocyanic Acid.—Glyoxal was found by Pollak[6] to react with two equivalents of hydrocyanic acid, yielding two optically isomeric dicyanohydrins, the dinitriles of dl-tartaric and meso-tartaric acid, respectively.

Quinoxaline has been found to behave in similar fashion, adding two equivalents of hydrogen cyanide to give only one ammono dicyanohydrin,

---

[10] Gibson, *ibid.*, 342 (1927).

the hitherto unknown 1,2,3,4-tetrahydro-2,3-dicyanoquinoxaline in accordance with the equation

I 
(The optical constitution of this substance was not determined.) This substance was shown to be a secondary diamine, but attempts to saponify it to the corresponding acid were fruitless.

1,2,3,4-Tetrahydrodicyanoquinoxaline.—Ten grams of pure quinoxaline, 7 g. (3.4 equivalents) of anhydrous hydrogen cyanide,[11] and 20 cc. of absolute alcohol were sealed in a bomb tube, which was then heated for two hours at 100" and allowed to stand overnight. The resulting clear yellowish solution was transferred to a beaker and evaporated to dryness in a vacuum desiccator, leaving a crystalline residue. This was extracted twice with carbon tetrachloride (to remove unchanged quinoxaline), and the residue was recrystallized once from water. It was finally purified by precipitation from saturated ether solution by the addition of several volumes of carbon tetrachloride. The crystals so obtained were white prismatic needles, odorless and tasteless, very soluble in alcohol and hot water, moderately soluble in ether, slightly soluble in benzene and cold water and insoluble in carbon tetrachloride. The substance melted at 168.5" (corr.) without appreciable decomposition, but the liquid decomposed above 200°.

Anal. Subs., 0.1416, 0.1455: CO_2, 0.3388, 0.3480; H_2O, 0.0574, 0.0603. Subs. 0.1023, 0.1060: 0.09537 *N* HCl (Kjeldahl), 23.16, 24.00 cc. Calcd. for $C_{10}H_8N_4$: C, 65.19; H, 4.39; N, 30.42. Found: C, 65.25, 65.22; H, 4.54, 4.64; N, 30.25, 30.25.

The yield was about 30%, irrespective of the time of heating. Apparently an equilibrium between quinoxaline, hydrogen cyanide and the addition compound was reached.

The compound did not dissolve in dilute acids and bases. A water solution yielded with nitrous acid an immediate yellow precipitate which gave the Liebermann reaction. The diacetyl derivative was prepared by heating with excess acetic anhydride at 100°. The remaining anhydride was decomposed with alcohol, and the ethyl acetate was removed by evaporation. The gummy residue was dissolved in alcohol and reprecipitated with water. Several repetitions of this process gave colorless prisms, m. p. 93.5" (corr.), very soluble in alcohol, but insoluble in water.

Anal. Subs., 0.0927, 0.0618: 0.09537 N HCl (Kjeldahl), 15.10, 9.95 cc. Calcd. for $C_{14}H_{12}N_4O_2$: N, 20.90. Found: N, 21.76, 21.51.

Attempts to saponify tetrahydro-dicyanoquinoxaline were unsuccessful. Strong bases decomposed it into metal cyanide and quinoxaline, as did a solution of two equivalents of potassium amide in liquid ammonia. Heating with strong hydrochloric acid caused decomposition to a dark tarry mass.

Oxidation of Quinoxaline

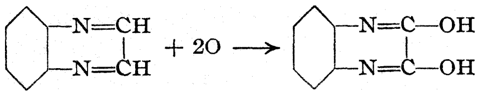
Glyoxal is readily oxidized, first to glyoxalic and then to oxalic acid. Quinoxaline was reported by Hinsberg[3] to be resistant to chromic acid, while Gabriel and Sonn[12] found that alkaline permanganate solutions disrupted the benzene ring, yielding a pyrazine-dicarboxylic acid. In the present investigation it was found that by the action of a suitable agent, such as ammonium persulfate, quinoxaline undergoes an oxidation analogous to

---

[11] "Organic Syntheses," John Wiley and Sons, Inc., New York, **1927**, Vol. VII, p. 50.

[12] Gabriel and Sonn, *Ber.*, 40, 4850 (1907).

that of glyoxal, yielding an o-phenylene ester of a mixed aquo-ammono oxalic acid, *i. e.*, 2,3-dihydroxyquinoxaline.



2,3-Dihydroxyquinoxaline.—With warm ammoniacal silver nitrate solutions quinoxaline gave a fine silver mirror, but for convenience in isolating the reaction product recourse was had to ammonium persulfate as the oxidizing agent: 1.3 g. of quinoxaline and 15 g. of ammonium persulfate were dissolved in 50 cc. of water, which was then slowly heated to boiling. The solution gradually turned red and deposited a slight brown precipitate. After a few minutes it was cooled and filtered. The filtrate, after evaporation to a small bulk, was nearly neutralized with aqueous ammonia. The resulting precipitate was recrystallized from water, in the form of fine white needles, melting above 300°. This product was shown to be 2,3dihydroxyquinoxaline[13] by converting it into 2,3-dichloroquinoxaline.[14] The substance was heated with excess phosphorus pentachloride at 180° for a few minutes. The melt was decomposed with ice and washed with water. Extraction of the residue with benzene and evaporation of the latter gave a white solid. This was recrystallized from petroleum ether, appearing as fine white needles, m. p. 149.8° (corr.). This substance was 2,3-dichloroquinoxaline, as was shown by the unaltered melting point when it was mixed with a sample of pure 2,3-dichloroquinoxaline, m. p. 149.8° (corr.), prepared by the method of Hinsberg and Pollak.[14] The yield of dihydroxyquinoxaline was about 30% of the theoretical.

Attempts to nitridize quinoxaline in liquid ammonia solution with iodine or ammonium azide were unsuccessful.

Quinoxaline and Potassium Amide.—In the presence of bases glyoxal undergoes an internal Cannizzaro reaction, yielding glycolic acid. Quinoxaline might be expected to undergo an analogous reaction with ammono bases, such as potassium amide, in liquid ammonia, but this was not found to be the case. The reaction of quinoxaline with potassium amide in liquid ammonia apparently follows a complex course, which has not been definitely established. When small amounts (less than one equivalent) of potassium amide were used, the quinoxaline was converted into a viscous, resinous substance. It is suggested that this may be the result of a polymerization of the quinoxaline induced by the ammono base. When two or more equivalents of potassium amide were used, two products were obtained, a dark tarry substance, and a white crystalline precipitate. The latter upon hydrolysis yielded potassium hydroxide and an organic compound which appeared to be fluorubin, described by Hinsberg and Schwantes.[15] Fluorubin is to be regarded as a derivative of ammono oxalic acid, and as a nitridation product of quinoxaline. Inasmuch as no gaseous hydrogen was obtained, equivalent reduction must have taken place, and it is suggested

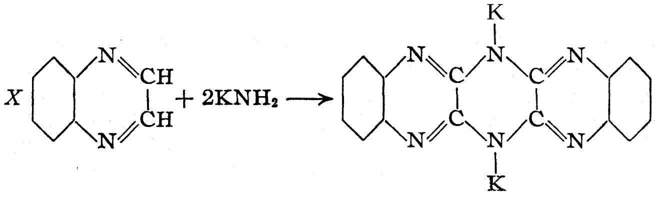
---

[13] Bladin, *Ber.*, 18, 674 (1885).

[14] Hinsberg and Pollak, *ibid.*, 29, 784 (1896). 2-Hydroxyquinoxaline also yields 2,3-dichloroquinoxaline on fusion with phosphorus pentachloride [Motylewski, ibid., 41, 800 (1908)]. However, 2-hydroxyquinoxaline melts at 269°, whereas the compound obtained melted above 300°.

[15] Himsberg and Schwantes, *ibid.*, 36, 4048 (1903).

that the tarry product may have been a polymerized reduced quinoxaline. It appears at least probable that an external Cannizzaro reaction[16] took place, whose results may be expressed by the following equation, although it is to be emphasized that this is not definitely proved.



+ an equivalent quantity of reduced quinoxaline

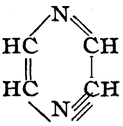
Dipotassium salt of fluorubin

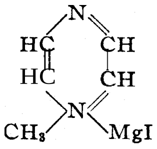
The technique described by Franklin[17] was used in the study of this reaction.

When quinoxaline was treated in liquid ammonia[18] with less than one equivalent of potassium amide, it immediately turned to a dark viscous substance, very soluble in ammonia. No definite compound could be isolated from the mixture. When two or more equivalents of potassium amide were used, the first reaction was the formation of a heavy yellow crystalline precipitate. After a few hours' standing the solution turned deep red and the precipitate became light and voluminous. It was white but very difficult to wash free of the red color. On hydrolysis of the carefully washed salt, a fluorescent green solution and a yellow powder were obtained. The solution proved to contain potassium hydroxide. The yellow powder was washed and dried. It melted above 350° and was insoluble in organic solvents. However, it dissolved in aqueous alkalies to give fluorescent green solutions, and in acids to give intense red fluorescent solutions. These properties agree with those of fluorubin, described by Hinsberg and Schwantes.[15]

Anal. Subs., 0.1234: 0.09537 *N* HCl (Kjeldahl), 26.50 cc. Calcd. for $C_{16}H_{10}N_6$ (fluorubin): N, 29.38. Found: N, 28.69.

The residue from the washings of the salt was a dark tarry substance, from which no pure compounds could be isolated. It is to be noted that mild reduction of quinoxaline leads to complex products.[4]





C

Pyrazine.—It was thought possible that pyraeine, B, which also is formally an ammono glyoxal, might undergo reactions similar to those described for quinoxaline. This, however, was not the case. Pyrazine[19] did not add bisulfites or hydrogen cyanide.[20] With ethereal methyl magnesium iodide, it gave a curdy brown precipitate, probably of the constitution *C*, which yielded no alkyl pyrazine on ammonolysis.

---

[16] That is, a reaction similar to the conversion of benzaldehyde to benzyl alcohol and benzoic acid.

[17] Franklin, *J. Phys. Chem.*, **24**, 81 (1920); Strain, This Journal, 49, 1995 (1927).

[18] Quinoxaline is only slightly soluble in liquid ammonia at −33°, but is miscible with it in all proportions at room temperature.

[19] This compound was prepared by the method of Wolff and Marburg, *Ann.*, **363**, 169 (1908).

[20] That is, under the same conditions in which quinoxaline adds sodium acid sulfite or hydrocyanic acid.

Pyrazine was not attacked by iodine in liquid ammonia, although it is to be noted that it can be oxidized in water solution.[21]

Potassium amide in liquid ammonia reacts with pyrazine to form an opaque dirty green solution from which no definite products were isolated.

Discussion

The experimental evidence presented in this article shows the striking analogy between the reactions of glyoxal and those of quinoxaline, substantiating the consideration of the latter as a substituted ammono glyoxal. The usefulness of the ammonia system viewpoint in the study of this and similar heterocyclic compounds is evident. It is intended to show in a later communication how derivatives of quinoxaline may be studied in the same manner.

A point of interest is that in the reactions presented here quinoxaline showed a reactivity more resembling that of an open-chain aldimine than that of a cyclic compound. (Compare the relative inertness of naphthalene, quinoline, etc.) This would seem to indicate definitely the presence of two true double bonds in the heterocyclic ring of quinoxaline.

Summary

1. The behavior of quinoxaline as an ammono glyoxal has been demonstrated by several new reactions. Thus it has been found to add two equivalents of bisulfites, Grignard reagents and hydrogen cyanide, and to undergo oxidation to o-phenylene oxamide. Quinoxaline has been found to react with potassium amide, probably in the sense of the Cannizzaro reaction.

2. **A** new method for the preparation of *dl*-1,2,3,4-tetrahydro-2,3-dialkyl (or diaryl) quinoxalines has been discovered.

3. The following new compounds have been prepared: quinoxaline sodium bisulfite and 1,2,3,4-tetrahydro-2,3-dicyanoquinoxaline.

STUDIES OF CONJUGATED SYSTEMS. VI. THE PREPARATION OF THE GEOMETRIC ISOMERS OF METHYLSTYRYLCARBINOL AND OF PHENYLBUTADIENE

BY IRVING E. MUSKAT AND MARGARET HERRMAN

RECEIVED OCTOBER 24, 1930 PUBLISHED JANUARY 12, 1931

In the course of an investigation on the addition reactions of conjugated systems we had occasion to study the preparation and properties of phenylbutadiene. In our early work with this hydrocarbon[1] we encountered considerable difficulty in obtaining consistent results. The yields of phenylbutadiene were at times very good, while again, with the same procedure and under apparently identical conditions, we failed to obtain any of the desired product. A search of the literature revealed that other investigators had encountered similar difficulties.[2] We therefore undertook a thorough study of the preparation of this hydrocarbon with the result that we were able to isolate the geometric isomers of both methylstyrylcarbinol and of phenylbutadiene and have determined the conditions under which to obtain either.

Phenylbutadiene was first prepared by Liebermann[8] by distilling allo-cinnamylidene-acetic acid under diminished pressure. He obtained a very low yield of this hydrocarbon, which distilled at 86° under 11 mm. pressure, and which absorbed two moles of bromine to give a tetrabromide. In a later paper he reported an improved method for the preparation of the same compound by heating cinnamylidene-malonic acid with quinoline.[4] A phenylbutadiene with the same properties was then prepared by Klages,[5] who treated cinnamic aldehyde with methylmagnesium iodide and dehydrated the methylstyrylcarbinol that was formed. Doebner[6] prepared a different phenylbutadiene by the dry distillation of cinnamyl-acrylic acid with barium hydroxide. This phenylbutadiene distilled at 120° under 10 mm. pressure and crystallized to a solid, m. p. 22°. It did not react with bromine, and this led Doebner to assign to it a cyclic structure to indicate its saturated nature.

[6] Doebner, *ibid.*, 35,2129 (1902); *ibid.*, 36, 4318 (1903).

In 1904 Carl von der Heide[7] modified Klages' method for the preparation of phenylhutadiene, which modification has been used more or less satisfactorily ever since. His method is as follows: "To a solution of methylmagnesium bromide (prepared from 30 g. of magnesium) add drop by drop 100 g. of cinnamic aldehyde (instead of the theoretical 160 g.). After standing for twelve hours, decompose under strong cooling with 30% sulfuric acid, wash the ethereal solution with soda and water, dry and distil in a vacuum."

In our earlier work we used essentially the same procedure as that given by Carl von der Heide and obtained, as was stated above, inconsistent results. In order to ascertain the cause of our difficulties we have studied this reaction from every angle, varying every factor that might have some influence on the course of the reaction. The concentration of the Grignard reagent, the temperature at which the reaction occurred, and the rate of addition of the cinnamic aldehyde to the Grignard reagent were varied over a wide range without an appreciable effect on the products of the reaction It was then discovered that the products obtained depended entirely on the decomposition of the intermediate Grignard addition compound and the treatment of the reaction product before distillation.

The intermediate Grignard addition compound was prepared according to the method described by Muskat and Ludeman[1] by treating cinnamic aldehyde with methylmagnesium bromide. If this intermediate Grignard addition compound, to which we shall refer as B, is decomposed with dilute acid and the acid is very carefully washed out of the ethereal solution before distillation, then a new methylstyrylcarbinol is formed which resists dehydration to a marked degree. The structure of this carbinol was proved by ozonization. This *new* methylstyrylcarbinol, although it has nearly the same boiling point as the methylstyrylcarbinol reported by Klages, is decidedly different. *Kluges'* carbinol easily loses water, even on standing for a short time (frequently during distillation if a trace of acid is present), to give the ordinary phenylbutadiene, b. p. 86° under 11 mm. pressure.[2] The *new* carbinol has been kept for many months without the slightest decomposition. Only very strong dehydrating agents will dehydrate it to give, however, a *new* phenylbutadiene, b. p. 76° under 11 mm. pressure. That the two carbinols are true geometric isomers and not structural isomers was definitely established by the reduction of the two carbinols to give the same dihydro derivative, and by the results of an investigation of the chemical properties of the two carbinols, to be presented in a later paper.

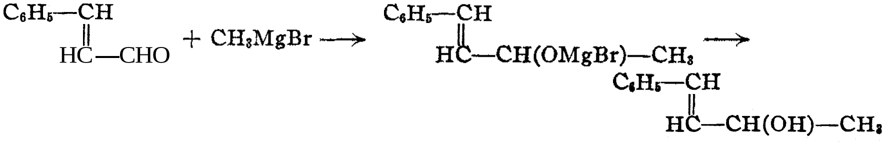
If the intermediate B is decomposed with a large excess of 30% sulfuric acid and the acid is carefully washed out of the ethereal solution of the carbinol before distillation, then the new carbinol described above is

---

[7] Carl von der Heide, *Ber.*, 37. 2101 (1904).

formed. However, if the acid is not washed out of the carbinol before distillation, a good yield of the ordinary phenylbutadiene is obtained.

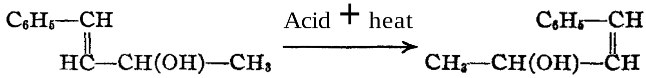
It thus appears that the new carbinol is the normal reaction product of cinnamic aldehyde with methylmagnesium bromide. Inasmuch as cinnamic aldehyde is commonly supposed to have the *trans* configuration,[8] the new carbinol would be represented with the *trans* structure, since the preparation of the carbinol does not involve the double bond which is responsible for the geometric isomerism.



$$\begin{matrix} C_6H_5{-}CH \\ \| \\ HC{-}CHO \end{matrix} + CH_3MgBr \longrightarrow \begin{matrix} C_6H_5{-}CH \\ \| \\ HC{-}CH(OMgBr){-}CH_3 \end{matrix} \longrightarrow \begin{matrix} C_6H_5{-}CH \\ \| \\ HC{-}CH(OH){-}CH_3 \end{matrix}$$

This *trans* structure of the new carbinol was further confirmed by comparing the rates of catalytic hydrogenation of the two carbinols.[9] (It was found that Klages' carbinol[10] was reduced at a faster rate than the new carbinol and according to Paal,[11] who showed that the *cis* isomer is always reduced more rapidly than the *trans* isomer, it would seem that the new carbinol has the *trans* configuration.) This has been confirmed in a similar manner by a study of the relative rates of oxidation of the two carbinols.

If the new *trans* carbinol is treated with dilute acids or even 30% sulfuric acid without heating, then it is neither rearranged to Klages' carbinol nor is it dehydrated to give phenylbutadiene. However, if some of the acid is allowed to remain dissolved in the carbinol, then on distillation it is partially rearranged to Klages' carbinol which, if 30% sulfuric acid has been used, loses water to give ordinary phenylbutadiene. We must then conclude that on warming with acids the *trans* carbinol is rearranged to the *cis* isomer.



$$\begin{matrix} C_6H_5{-}CH \\ \| \\ HC{-}CH(OH){-}CH_3 \end{matrix} \xrightarrow{\text{Acid + heat}} \begin{matrix} C_6H_5{-}CH \\ \| \\ CH_3{-}CH(OH){-}CH \end{matrix}$$

On standing, or in the presence of a dehydrating agent, the *cis* carbinol loses water readily to give Klages' phenylbutadiene, b. p. 86° under 11 mm. pressure. This phenylbutadiene must then have the corresponding *cis* structure.

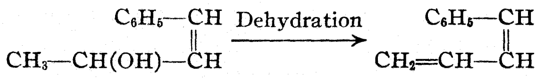
---

[8] See M. Bourguel, Bull. *soc. chim.*, [4] **45**, 1066 (1929), who has recently prepared the cis isomer of cinnamic aldehyde by the catalytic reduction of the corresponding acetylene derivative. It is planned to prepare a quantity of this new *cis*-cinnamic aldehyde, treat as above with methylmagnesium bromide and determine whether Klages' carbinol is the normal reaction product of this isomer.

[9] This work will be reported in a paper that is to follow.

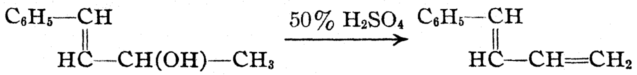
[10] Evidence to be given in the following paper leads us to believe that the carbinol reported by Klages was in reality a mixture of the two geometric isomers. However, we shall use the term "Klages' carbinol" to refer to that carbinol which easily loses water to form the ordinary phenylbutadiene.

[11] Paal, *Ber.*, 60, 1221 (1927); *ibid.*, 63, 766 (1930).



$$\begin{array}{r}C_6H_5\text{—}CH\\ \|\\ CH_3\text{—}CH(OH)\text{—}CH\end{array}\xrightarrow{\text{Dehydration}}\begin{array}{r}C_6H_5\text{—}CH\\ \|\\ CH_2{=}CH\text{—}CH\end{array}$$

If the *trans* carbinol is treated with a very strong dehydrating agent, such as 50% sulfuric acid, a molecule of water is lost to give a new phenylbutadiene, b. p. 76° under 11 mm. pressure. This must therefore have the corresponding *trans* structure.



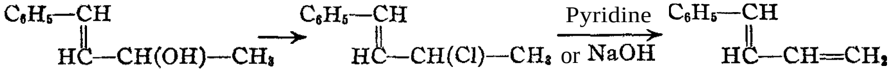
$$\begin{array}{l}C_6H_5\text{—}CH\\ \quad\;\|\\ \quad HC\text{—}CH(OH)\text{—}CH_3\end{array}\xrightarrow{50\%\ H_2SO_4}\begin{array}{l}C_6H_5\text{—}CH\\ \quad\;\|\\ \quad HC\text{—}CH{=}CH_2\end{array}$$

The *cis* and *trans* structures of the two phenylbutadienes as well as the carbinols have been confirmed by the relative rates of catalytic hydrogenation and of oxidation of the two isomers. In each case the isomer to which we have assigned the *cis* structure was hydrogenated more rapidly and oxidized more rapidly than was the *trans* isomer.[9] If the higher boiling *cis* phenylbutadiene is allowed to stand overnight with a trace of acid and then directly distilled, the lower boiling *trans* phenylbutadiene is formed. Obviously the acid rearranges the *cis* phenylbutadiene to the *trans* isomer, while it rearranges the *trans* methylstyrylcarbinol to the cis isomer.

$$\begin{array}{r}C_6H_5\text{—}CH\\ \|\\ CH_2{=}CH\text{—}CH\end{array}\xrightarrow{\text{[redacted]}}\begin{array}{l}C_6H_5\text{—}CH\\ \quad\;\|\\ \quad HC\text{—}CH{=}CH_2\end{array}$$

If methylmagnesium iodide is used to react with cinnamic aldehyde instead of methylmagnesium bromide the conditions are somewhat different. These details are described in the experimental part.

The new *trans* phenylbutadiene can be prepared by treating the tmn: carbinol with dry hydrogen chloride in anhydrous ether solution to form an almost quantitative yield of the chloride. The chloride may now be refluxed for several hours with pyridine or shaken for twenty-four hours with a 5% sodium hydroxide solution at room temperature, either of which removes one mole of hydrogen chloride to give the new *trans* phenylbutadiene in an almost quantitative yield.



$$\begin{array}{l}C_6H_5\text{—}CH\\ \quad\;\|\\ \quad HC\text{—}CH(OH)\text{—}CH_3\end{array}\longrightarrow\begin{array}{l}C_6H_5\text{—}CH\\ \quad\;\|\\ \quad HC\text{—}CH(Cl)\text{—}CH_3\end{array}\xrightarrow[\text{or NaOH}]{\text{Pyridine}}\begin{array}{l}C_6H_5\text{—}CH\\ \quad\;\|\\ \quad HC\text{—}CH{=}CH_2\end{array}$$

In the experimental part the method for the preparation of each of the methylstyrylcarbinols and of the phenylbutadienes will be given in detail.

It is interesting to note that the most striking chemical difference between the two methylstyrylcarbinols lies in the fact that they differ in the ease with which water is lost to give the corresponding phenylbutadiene; yet the geometric difference, the *cis–trans* isomerism, has apparently nothing to do with the tendency to lose water. It is at once clear why cis maleic acid should lose water easily to give an anhydride while the *trans* fumaric should not, but it is difficult to understand why there should be any difference in the ease with which water is lost from the two methylstyrylcarbinols, since the part of the molecule affected supposedly has nothing to do with the geometric isomerism. It may be that the phenyl group in the *cis* position has a loosening influence on the hydrogen atoms of the methyl group. This suggestion finds some support in the fact that the hydroxyl group of the *trans* carbinol seems to be fully as reactive as the hydroxyl group of the *cis* carbinol, and therefore the difference in the ease of eliminating water from the two carbinols must depend on the hydrogen atoms of the methyl group.

Experimental Part[12]

The Preparation of the Intermediate Grignard Addition Compound B.—The intermediate Grignard addition compound was prepared according to the method of Muskat and Ludeman.[1] "Methylmagnesium bromide is prepared in the usual manner from 40 g. of methyl bromide and 10 g. of magnesium. The manipulation is much easier and the loss is much less if the methyl bromide is allowed to pass into the ether suspension of the magnesium turnings as a gas from a cylinder instead of added as a liquid (b. p. 4.5°) through a dropping funnel. Thirty grams of cinnamic aldehyde (free of cinnamic acid and dried over calcium oxide) is allowed to drop in slowly, the reaction flask being immersed in an ice–salt mixture during the process. The theoretical amount of cinnamic aldehyde (53 g.) is not used, for only part of the cinnamic aldehyde combines with the Grignard reagent; the rest polymerizes to a resin. . . . ." In this work we used three times the quantities of the reagents given above, and the addition compound was allowed to stand overnight before decomposition. The Grignard addition compound prepared in this way will be referred to as B.

Decomposition of the Intermediate Grignard Addition Compound B

(a) With Dilute Acids. The Preparation of *Trans* **Methylstyrylcarbinol.**—The intermediate Grignard addition compound B was decomposed with sufficient dilute (about 10%) acid (sulfuric, hydrochloric or acetic acid may be used) to dissolve the magnesium hydroxide. The decomposition was effected by gradually pouring the intermediate B into a large flask containing a mixture of ice and dilute acid. A mechanical stirrer was used to keep the mixture in constant agitation and thus avoid localized heating. The decomposition mixture was extracted with ether, the ethereal solution very carefully washed free from acid, dried over anhydrous sodium sulfate, and the ether removed by vaporization. When subjected to distillation under diminished pressure, the residual oil, with the exception of a small fraction, distilled over completely at 117° under 4 mm. pressure. Its boiling point was determined at several pressures: 116.5° at 3.5 mm., 117.5° at 5 mm., 123° at 7.5 mm. pressure. It is a stable compound and may be kept for many months without the slightest decomposition. Its refractive index at 31° is 1.5550.

Anal. Calcd. for $C_{10}H_{12}O$: C, 81.03; H, 8.16. Found: C, 81.02, 81.03; H, 8.20, 8.21. Calcd. for $C_{10}H_{12}O$: mol. wt., 148.09. Found: mol. wt., 149.1.

The method of preparation and the above analyses indicate that the compound is methylstyrylcarbinol, $C_6H_5—CH=CH—CH(OH)—CH_3$; however, its chemical and physical properties are at variance with those of the methylstyrylcarbinol reported

---

[12] The authors wish to express their appreciation to Mr. Charles Marshall for his aid in the preparation of some of these compounds.

by Klages.6 That it really is a methylstyrylcarbinol was proved by subjecting it to ozonization. The carbinol (10 g.) was dissolved in chloroform and a current of ozonized oxygen was bubbled through the solution for several hours. An ozonizer similar to the one described by Harries[13] was used. After the ozonization was complete the chloroform was removed by vaporization under reduced pressure and the residual viscous ozonide was decomposed with water. To insure the complete decomposition of the ozonide it was warmed on the water-bath for a short time. The mixture consisted of aldehydes and acids and was separated into its components by extracting the alkaline solution several times with ether. The ethereal solution was dried and the ether removed by vaporization. A solid (0.9 g.) remained which melted at 120°. It was crystallized once from water and melted at 122°, the melting point of benzoic acid. A mixture with pure benzoic acid also melted at 122°. The water extract gave a positive Uffelman test for lactic acid, the second oxidation fragment of the carbinol.

The ethereal solution of the aldehydes was again washed with alkali and the ether was removed by vaporization. The residue, an oil, was treated with an aqueous solution of semicarbazide hydrochloride in the usual manner. A semicarbazone (8.8 g.) was precipitated after a time. This was removed and dried. It melted at 209°. It was recrystallized several times from alcohol and melted at 214°, the melting point of the semicarbazone of benzaldehyde. When it was mixed with the synthesized product the melting point of the mixture was not lowered. This corresponds to a 90.8% yield of benzaldehyde.

It is of paramount importance for the preparation of this *trans* methylstyrylcarbinol to wash all traces of acids from the ethereal solution of the carbinol before distillation. It is also better to use anhydrous sodium sulfate rather than calcium chloride to dry the ethereal solution, since frequently traces of acid may be introduced by the calcium chloride.

The above preparation was repeated except that the acid was not washed out of the ethereal solution of the carbinol before distillation On distilling the residual oil a mixture of the *trans* carbinol and a small amount of Klages' *cis* carbinol was obtained. The presence of the latter was indicated by the fact that the distillate became cloudy shortly after distillation. The cloudiness is due to the water split from the *cis* carbinol The ready loss of water is a characteristic property of this compound. Frequently during distillation a portion of the *cis* carbinol will decompose to give phenylbutadiene and droplets of water. We must therefore conclude that the *trans* carbinol rearranges to the *cis* carbinol when it is warmed in the presence of acid.

That this rearrangement is due to the warming with acid and not merely to the presence of acid was confirmed in the following manner. The pure *trans* carbinol was shaken with 30% sulfuric acid at room temperature (about 25°) for twelve hours. It was then divided into two portions. The first portion was extracted with ether, the ethereal solution was very carefully washed free from acid, dried over anhydrous sodium sulfate, and the ether was removed by vaporization. The residual oil distilled over completely at 117° under 4 mm. pressure without the slightest indication of the presence of any *cis* carbinol. The second portion was worked up in exactly the same way except that the acid was not all washed out of the carbinol before distillation. During the distillation of the residual oil a great deal of water was split out and a mixture of phenylbutadiene, *cis* carbinol, droplets of water and some *trans* carbinol distilled over. This proves conclusively that it is necessary to warm the *trans* carbinol with acid to cause a rearrangement to take place.

(b) With Water.—The intermediate B was hydrolyzed with water, the hydrolysis product was extracted with ether, the ethereal solution dried over anhydrous sodium

---

[13] Houben–Weyl, "Die Methoden der Organischen Chemie," 1924, Vol. III, p. 276.

sulfate, and the ether removed by vaporization. When subjected to distillation under diminished pressure, the residual oil, with the exception of a very small fraction, distilled at 117° under 4 mm. pressure. It was identical with the *trans* carbinol described above.

The yield of the carbinol is much less and the manipulation more difficult by this method than by the method described above using dilute acids to decompose the intermediate B, since the magnesium hydroxide, which results from the hydrolysis of the intermediate B, frequently forms a stable emulsion with the ethereal solution of the carbinol.

(c) With 30% Sulfuric Acid. The Preparation of Ordinary *Cis* **Phenylbutadiene.**—The intermediate B was decomposed with 30% sulfuric acid exactly as described in (a). The decomposition mixture was extracted with ether, the ethereal solution very carefully washed free from acid, dried over anhydrous sodium sulfate, and the ether removed by vaporization. When subjected to distillation under diminished pressure the residual oil, with the exception of a small fraction, distilled over at 117° under 4 mm. pressure. It was identical with the *trans* carbinol described in (a).

The above preparation was repeated except that the acid was not washed out of the ethereal solution of the carbinol before distillation. On distilling the residual oil a mixture of the ordinary phenylbutadiene, the *trans* and *cis* carbinols and droplets of water was obtained. A considerable portion of the oil distilled at 204° under 3 mm. pressure, which is the boiling point of the dimer of phenylbutadiene. It was observed that whenever the *cis* phenylbutadiene was formed in the course of such a reaction, polymerization occurred to a marked degree.

In order to obtain a good yield of phenylbutadiene the following procedure was used. The intermediate B was poured into a beaker containing a liter of 30% sulfuric acid and no effort was made to keep the reaction cold. It was allowed to stand in contact with the acid overnight. The decomposition product was then extracted with ether, the ethereal solution washed several times with water and dried over anhydrous sodium sulfate overnight. The ether was then removed by vaporization and the residual oil subjected to distillation under reduced pressure. A 60% yield of phenylbutadiene boiling at 86° under 11 mm. pressure, was obtained. It was identical with the phenylbutadiene reported by Klages. Its refractive index at 28° is 1.5950.

It may be well to emphasize the following points in this method for the preparation of *cis* phenylbutadiene. If the intermediate B is decomposed with 30% sulfuric acid under strong cooling and continuous stirring and all of the acid is washed out of the ethereal solution before distillation, then the *trans* methylstyrylcarbinol is formed. If the intermediate B is decomposed with 30% sulfuric acid and no effort is made to cool the reaction or to keep it agitated to prevent localized heating, then the heat of the reaction in the presence of the acid is sufficient to rearrange the *trans* to the *cis* carbinol. Once rearrangement has taken place then the length of contact with the drying agent becomes of paramount importance. If the acid is washed out of the ethereal solution, and the solution is dried but a short time, the *cis* carbinol is the main product of the reaction. If, however, the acid is not washed out, then some decomposition occurs and phenylbutadiene, *cis* carbinol and water result. If the acid is washed out of the ethereal solution after the above rearrangement and the solution is dried overnight, then *cis* phenylbutadiene is obtained. If the acid is not washed out of the ethereal solution and the solution is dried overnight, then on distillation the *cis* phenylbutadiene may be rearranged into the *trans* phenylbutadiene, as will be shown later in the paper.

(d) With 50% Sulfuric Acid. The Preparation of *Trans* **Phenylbutadiene.**—The intermediate B was decomposed with 50% sulfuric acid in a manner entirely analogous to that described in (a). The residual oil was distilled under diminished pressure. A small amount of oil distilled at 76° under 11 mm. pressure and a dark viscous mass remained in the distilling flask. The oil was analyzed and proved to be a lower-boiling phenylbutadiene. Its refractive index at 28° is 1.5920.

Anal. Calcd. for $C_{10}H_{10}$: C, 92.25; H, 7.75. Found: C, 92.11, 92.21; H, 8.09, 7.90. Calcd. for $C_{10}H_{10}$: mol. wt., 130.08. Found: mol. wt., 132.2.

That it is the *trans* isomer of phenylbutadiene was shown by a study of its chemical reactions, which will be presented in a later paper.

The new *trans* phenylbutadiene can be prepared in a good yield by either of the two following methods.

(1) The *trans* carbinol was dissolved in anhydrous ether and dry hydrogen chloride gas was passed in until no more was absorbed. The flask was immersed in an ice-bath during the reaction. The ethereal solution was washed with dilute alkali to remove the excess acid and then with water until neutral. It was dried over anhydrous sodium sulfate and the ether was removed by vaporization. Upon distillation of the residual oil under diminished pressure, an almost quantitative yield of a light yellow oil distilled at 104° under 6 mm. pressure. It is quite stable and may be kept for several weeks with but little decomposition.

Anal. Calcd. for $C_{10}H_{11}Cl$: Cl, 21.29. Found: Cl, 21.17, 21.21.

The chloride has the structure  $\begin{array}{l} C_6H_5\text{—}CH \\ \quad\ \| \\ HC\text{—}CHCl\text{—}CH_3 \end{array}$. A thorough study of the chemical reactions of this chloride has been made and these will be presented in a later paper.

The chloride was refluxed for several hours with five volumes of pyridine. The reaction mixture was taken up in ether and washed thoroughly with water to remove the pyridine. The ethereal solution was dried over anhydrous sodium sulfate and the ether was removed by vaporization. When subjected to distillation under diminished pressure, the residual oil distilled over almost completely at 76° under 11 mm. pressure, the boiling point of the *trans* phenylbutadiene.

The chloride may be converted into the *trans* phenylbutadiene by shaking for twenty-four hours with approximately twice the theoretical amount of 5% sodium hydroxide. The reaction mixture is extracted with ether, the ether solution washed until neutral, dried over anhydrous sodium sulfate and the ether removed by vaporization. Upon distillation of the residual oil *an* almost quantitative yield of *trans* phenylbutadiene is obtained.

(2) The *trans* phenylbutadiene may be prepared by rearranging the *cis* phenylbutadiene. The rearrangement may be effected by allowing the *cis* phenylbutadiene to stand overnight with a trace of acid. A few pieces of calcium chloride moistened with dilute hydrochloric acid are added to the *cis* phenylbutadiene and, after standing overnight, the compound is distilled under reduced pressure. The lower-boiling *trans* phenylbutadiene distils at 76° under 11 mm. pressure. The yield is quantitative.

The Preparation of the Intermediate Grignard Addition Compound I.—The intermediate Grignard addition compound I is prepared in exactly the same manner as the intermediate Grignard addition compound B, except that methylmagnesium iodide is used in place of methylmagnesium bromide. The intermediate I is much less soluble in ether than is the intermediate B.

Decomposition of the Intermediate Grignard Addition Compound I.—The intermediate I was decomposed with dilute sulfuric acid in a manner entirely analogous to that described above for the corresponding methylmagnesium bromide intermediate B. The decomposition mixture was extracted with ether and the ethereal solution was washed with sulfurous acid to reduce the iodine that was set free. The intermediate

I may be decomposed directly with a saturated solution of sulfurous acid and thus avoid the preliminary treatment with dilute acid. After all of the iodine had been removed the ethereal solution was washed with water until neutral. A large number of washings were required to remove all of the sulfurous acid. The ethereal solution was dried over sodium sulfate and the ether removed by vaporization. When subjected to distillation under reduced pressure, the residual oil distilled over almost completely at 117° under 4 mm. pressure. It was identical with the *trans* carbinol described above.

The Preparation of *Cis* **Methylstyrylcarbinol.**—The above preparation was repeated except that the ethereal solution of the carbinol was washed only twice with water before distillation, thus leaving some of the sulfurous acid in solution. On distilling the residual oil, the cis methylstyrylcarbinol was obtained, b. p. 144° under 21 mm. pressure. It was identified by its characteristic tendency to lose water.

Anal. Calcd. for $C_{10}H_{12}O$: C, 81.03; H, 8.16. Found: C, 81.12, 81.10; H, 8.30, 8.27. Calcd. for $C_{11}H_{12}O$: mol. wt., 148.09. Found: mol. wt., 150.0.

This method is the most reliable for the preparation of *cis* methylstyrylcarbinol. Its refractive index at 31° is 1.5536.

If the above method of preparation is repeated and none of the acid is washed out, then on distilling the residual oil a small yield of the trans phenylbutadiene is obtained, and a dark viscous polymer remains in the distilling flask.

Summary

1. The isolation of the geometric isomers of methylstyrylcarbinol have been given and their geometric structures determined.
2. The isolation of a new geometric isomer of phenylbutadiene is given.
3. The geometric structures of the two isomeric phenylbutadienes were determined.
4. Methods for the preparation of each of the geometric isomers of methylstyrylcarbinol and of phenylbutadiene are described.
5. Methods of rearranging the above geometric isomers are given.

STUDIES OF CONJUGATED SYSTEMS.
VII. THE CHEMICAL REACTIONS OF THE GEOMETRIC ISOMERS OF METHYLSTYRYLCARBINOL

BY IRVING E. MUSKAT AND MARGARET HERRMAN

RECEIVED OCTOBER 24, 1930 PUBLISHED JANUARY 12, 1931

In the preceding article[1] we gave a detailed description of the methods of preparation of the geometric isomers of methylstyrylcarbinol and of the corresponding phenylbutadienes. The present paper contains the results of an investigation of the chemical reactions of the two geometric isomers of methylstyrylcarbinol.

The reactions studied have been of two general types: *i. e.*, reactions of the hydroxyl group, and reactions involving the double bond. In the

---

[1] Muskat and Herrman, THIS JOURNAL, 53, 252 (1931).

following pages we shall present, under these two heads, a comparison of the behavior of the two geometric isomers of methylstyrylcarbinol.

I. Reactions of the Hydroxyl Group

Klages[2] reported the preparation of the phenylurethan, m. p. 94°, of his *cis* carbinol. We have been unable to duplicate his results with the pure *cis* carbinol, although the *trans* carbinol does give a quantitative yield of a phenylurethan of the same melting point and apparently of the same crystalline structure. Therefore it seems evident to us that the results reported by Klages were obtained on a mixture of the two carbinols rather than from the pure compound. It must be remembered that Klages was not aware of the existence of the *trans* isomer of methylstyrylcarbinol

Burton[3] also reported a phenylurethan, m. p. 94°, from methylstyrylcarbinol prepared by Klages' method. In addition Burton reported the preparation from his carbinol of an acetate which is identical with the acetate we prepared from the *trans* carbinol. The *cis* carbinol is dehydrated under the conditions used to prepare the acetate of the *trans* carbinol. This is confirmatory evidence for our previous statement that the urethan reported by Klages resulted from the *trans* carbinol. It is significant that the previous investigators of methylstyrylcarbinol, who were unaware of the existence of geometric isomers of methylstyrylcarbinol, frequently purified their product in such a manner as to remove any *cis* carbinol present in the mixture they first obtained.

The *trans* carbinol, when treated with dry hydrogen chloride in anhydrous ether solution, reacts to form a *trans* chloride,  $\begin{array}{l} \quad C_6H_5{-}CH \\ \quad\quad\ \| \\ \quad HC{-}CHCl{-}CH_3 \end{array}$, b. p. 104° under 6 mm. pressure. Under the same conditions the *cis* carbinol reacts with hydrogen chloride to form a *cis* chloride,  $\begin{array}{r} C_6H_5{-}CH \\ \| \\ CH_3{-}CHCl{-}CH \end{array}$, b. p. 108° under 6 mm. pressure. Klages[2] has reported the preparation in a similar manner of *a* chloride from his methylstyrylcarbinol, but he stated that the chloride was so unstable that he was able neither to distil it nor to obtain even an approximate analysis. We have found that if all of the excess hydrogen chloride is not washed out of the ethereal solution of the chloride before distillation, then the chloride decomposes during distillation. However, if the acid is carefully washed out, then the chlorides of either of the carbinols may be distilled without the slightest decomposition. It is interesting to note that hydrogen chloride did not add to the double bond of either of the carbinols. The chloride obtained from the *cis* carbinol was found to be identical with the chloride obtained from the addition of hydrogen chloride to the *cis* phenylbutadiene.[4]

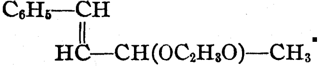
---

[2] Klages, *Ber.*, 35, 2649 (1902).

[3] Burton, *J. Chem. Soc.*, 132, 455 (1929).

[4] To be reported in a later paper.

The *trans* chloride was refluxed with a 10% solution of sodium acetate for several hours. A product was obtained which distilled at 118° under 4 mm. pressure, and which was identified as the acetate,



$$\begin{array}{l}C_6H_5\text{—}CH\\ \quad \| \\ \quad HC\text{—}CH(OC_2H_3O)\text{—}CH_3\end{array}$$

. This acetate is identical with the acetate prepared directly from the *trans* carbinol as given above. A condensation product of the *trans* carbinol was also obtained. This condensation product will be referred to later in the paper.

When the *trans* chloride was refluxed with silver oxide until all of the chloride had reacted, a small amount of the *trans* phenylbutadiene, b. p. 76° under 11 mm. pressure, was obtained with a preponderance of the polymer of this phenylbutadiene, b. p. 194° under 3 mm. pressure.

The *trans* chloride was refluxed with about five times its volume of pyridine for several hours. An almost quantitative yield of the *trans* phenylbutadiene, b. p. 76° under 11 mm. pressure, was obtained. Under the same conditions the *cis* chloride gave about 40% of the *cis* phenyl butadiene, b. p. 86° under 11 mm. pressure, the rest being polymerized to the dimer.

The *trans* chloride was shaken with two moles of 5% sodium hydroxide for approximately twenty-four hours. An almost quantitative yield of the *trans* phenylbutadiene was obtained. Under the same conditions the *cis* chloride gave a very small amount of the cis phenylbutadiene, the rest being polymerized to the dimer.

The reactions of the carbinols with varied concentrations of sulfuric acid to cause rearrangement or dehydration have been amply discussed in the preceding paper.'

In addition to these reactions of the hydroxyl group of the carbinols it has been observed that on heating the *trans* carbinol, condensation occurs with the elimination of one mole of water from two moles of the carbinol. The condensation product distils over at 200° under 6 mm. pressure. It may have either of the following structures (the geometric isomerism will not be indicated).

$$C_6H_5CH{=}CH\text{—}CH(CH_3)\text{—}COH(CH_3)\text{—}CH{=}CHC_6H_5$$

I

$$C_6H_5CH{=}CH\text{—}CH(CH_3)\text{—}CH_2\text{—}CHOH\text{—}CH{=}CHC_6H_5$$

II

On ozonization it was possible to isolate 76 3% of benzaldehyde calculated on the basis of two moles of benzaldehyde for each mole of the condensation product. This proves that the condensation did not involve the double bonds. The condensation product also formed a tetrabromide, m. p. 179°, which confirms the above conclusion. Structure I is favored due to the fact that the hydrogen atoms of the terminal methyl group of the *trans* carbinol are very unreactive. No effort was made to distinguish between the two structures. Under the same conditions the *cis* carbinol decomposed to give water and the dimer of phenylbutadiene.

II. Reactions Involving the Double Bond

An effort was made to prepare the dibromide addition compounds of the two carbinols. The conditions of bromination were widely varied but in every case decomposition occurred with the elimination of water and the formation of the tetrabromide of phenylbutadiene.

The catalytic hydrogenation of the two carbinols by means of the Adams method[5] was studied. The products of reduction of the two carbinols were found to be identical. The compound proved to be 3-hydroxy-1-phenylbutane, $C_6H_5—CH_2—CH_2—CH(OH)—CH_3$, which was identified by means of its boiling point, 105° under 6 mm. pressure, and the melting point of its phenylurethan, 114°. The identity of the reduction products of the two carbinols was definitely established by comparing the melting points of their phenylurethans.

3-Hydroxy-1-phenylbutane has been prepared before by the reduction with sodium amalgam of benzalacetone[6] and of benzylacetone.[7] Since alkaline reagents are known to cause rearrangements of such compounds, we synthesized the 3-hydroxy-1-phenylbutane by the condensation of hydrocinnamic aldehyde with methylmagnesium bromide. The 3-hydroxy-1-phenylbutane prepared in this way was identical with that reported in the literature.

The relative rates of catalytic hydrogenation of the two carbinols were determined. An apparatus designed by Muskat and Knapp[8] for the study of the rates of catalytic hydrogenation of unsaturated compounds was used. The apparatus was so designed that the pressure of the hydrogen always remained constant while the volume of the hydrogen varied. Under the same experimental conditions and with equal weights of catalyst from the same batch, the *cis* carbinol was hydrogenated more rapidly than was the *trans* carbinol. This is in perfect agreement with the work of Paal,[9] who has shown, after a detailed study of a large number of geometric isomers, that the *cis* compound is always more rapidly hydrogenated than is the corresponding *trans* isomer. Complete experimental data and graphs for the hydrogenation of each of the carbinols will be given in the Experimental Part.

The oxidation of the two carbinols with perbenzoic acid was studied. It was found that under the same experimental conditions the *cis* carbinol

[8] To be published soon.

[9] Paal, Ber., 60, 1221 (1927); *ibid.*, *63*, 766 (1030).

was oxidized more rapidly than was the *trans* carbinol. This same difference was also observed in the rate of oxidation with perbenzoic acid of the two geometric isomers of phenylbutadiene.[8] This suggests that it might be possible to use the relative rates of oxidation with perbenzoic acid as a means of distinguishing between geometric isomers.

Both Böeseken[10] and Meerwein[11] have attempted to calculate the velocity constants for the oxidation of unsaturated compounds by means of perbenzoic acid. They have concluded from their results that the oxidation follows a second order reaction. These conclusions seem to us to be not wholly warranted since the data show a decided decrease in the second order reaction constant as the oxidation proceeds. Thus, for the oxidation of pinene, Meerwein has calculated the following values for the second order reaction constant K

Minutes	5	10	20	40	60
$K \times 10^3$	1573	1138	985	866	845

It appears to us that these oxidation reactions are not properly expressed by the equation for a second order reaction.

We have calculated the velocity constants for the oxidation experiments reported here. After calculating K for a first, second and third order reaction, it became quite obvious that the oxidation of methylstyrylcarbinol is best expressed by the equation for a third order reaction. K_3 is remarkably constant for this type of work and is well within the experimental limits of error.

The exact significance that may be attached to this is still uncertain. It seems that the rate of oxidation of an unsaturated compound with perbenzoic acid is proportional to the concentration of the unsaturated compound and to the square of the concentration of the perbenzoic acid. Further work on the oxidation of unsaturated compounds by means of perbenzoic acid and also of peracetic acid is contemplated.

The oxides of each of the carbinols were isolated. They had approximately the same boiling points: the oxide of the *trans* carbinol distilled at 118° under 4 mm. pressure, while the oxide of the *cis* carbinol distilled at 117° under 3.5 mm. pressure. The oxide of the *trans* carbinol was prepared in larger quantity in order to study its chemical properties. A number of attempts were made to break the oxide linkage but with no success. It was heated for several hours with 2 N sulfuric acid, and in place of the expected trihydroxyphenylbutane a condensation product was obtained which was formed by the elimination of one mole of water from two moles of the oxide of the *trans* carbinol. The condensation product distilled at 200° under 4-mm. pressure. It may have either of the following two structures (the geometric isomerism will not be indicated).

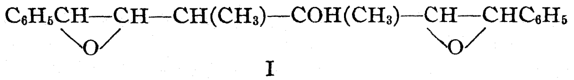
[11] Meerwein, *J. prakt. Chem.*, **113**, 24 (1926).



$$C_6H_5\underset{\diagdown O \diagup}{CH\text{—}CH}\text{—}CH(CH_3)\text{—}COH(CH_3)\text{—}\underset{\diagdown O \diagup}{CH\text{—}CH}C_6H_5$$

I

$$C_6H_5\underset{\diagdown O \diagup}{CH\text{—}CH}\text{—}CH(CH_3)\text{—}CH_2\text{—}CHOH\text{—}\underset{\diagdown O \diagup}{CH\text{—}CH}C_6H_5$$

II

For the same reasons given above for the condensation product of the *trans* carbinol, we favor Structure I. The same condensation product was obtained on heating the oxide with dilute sulfuric acid in a bomb tube for several hours at 150°.

Dry hydrogen chloride was passed into an ethereal solution of the oxide of the *trans* carbinol. The hydroxyl group of the carbinol was attacked but the oxide linkage remained intact.

The oxide of the carbinol was heated for several hours with dilute alkali. No reaction occurred and the original oxide was'isolated.

Dry ammonia gas was bubbled through an alcoholic solution of the oxide for several hours but no reaction occurred.

This remarkable stability of the oxide linkage casts some doubt as to the presence of such a linkage in the molecule. It may be that the oxide had rearranged to a ketone in a manner normal to ethylene oxides.

$$C_6H_5\text{—}\underset{\diagdown O \diagup}{CH\text{—}CH}\text{—}CHOH\text{—}CH_3 \longrightarrow C_6H_5\text{—}CH_2\text{—}CO\text{—}CHOH\text{—}CH_3$$

It is interesting to note that different samples of the pure oxide always gave typical ketonic color reactions but every effort to prepare a derivative of such a ketone failed.

The oxide of stilbene has been found to show very much the same stability as does the oxide of the *trans* carbinol. However, the oxide of stilbene could not have undergone a rearrangement to the ketone

$$C_6H_5\text{—}\underset{\diagdown O \diagup}{CH\text{—}CH}\text{—}C_6H_5 \longrightarrow C_6H_5\text{—}CH_2\text{—}CO\text{—}C_6H_5$$

desoxybenzoin, for the properties of the two are decidedly different.

An effort was made to oxidize the methylstyrylcarbinols with potassium chlorate and osmic acid but with no success.

Experimental Part

The two methylstyrylcarbinols were prepared according to the method described in the preceding article by Muskat and Herrman.[1]

I. Reactions of the Hydroxyl Group

(a) **Phenylurethan.**—The phenylurethan of the *trans* methylstyrylcarbinol was prepared as follows. Equimolar quantities of the carbinol and of phenyl isocyanate, each dissolved in a small amount of dry ligroin, were mixed together and the solution was allowed to stand. In a few hours an oily layer settled out and crystals slowly formed in the oil. After several days the oil was completely transformed into a yellowish crystalline mass. The ligroin was poured off and the crystals were dissolved in hot benzene. After filtration the benzene was removed by vaporization. The light yellow crystalline deposit which remained was purified by several recrystallizations from hot alcohol. The pure, white crystals melted at 94°.

Anal. Calcd. for $C_{17}H_{17}O_2N$: C, **76.36;** H, **6.41;** N, **5.24.** Found: C, **76.42, 76.45; H, 6.74, 6.68; N, 5.29, 5.29.**

If the *cis* carbinol is treated in a similar manner with phenyl isocyanate, water is eliminated, and the phenyl isocyanate is converted to the crystalline carbanilide, m. p. 235°, which is insoluble in benzene. No trace of a phenylurethan could be detected.

(b) Acetate.—The acetate of the *trans* carbinol was prepared according to Burton's[3] method, by refluxing **10** g. of the carbinol with **15** cc. of acetic anhydride for six hours. An acetate which distilled at 141–144° under **15** mm. pressure, was obtained.

Anal. Calcd. for $C_{12}H_{14}O_2$: C, **75.8;** H, **7.4.** Found: C, **75.67, 75.25;** H, **7.61, 7.57.**

It appears from these results that Burton had the *trans* carbinol but was not aware of it.

Under the same conditions the cis carbinol is dehydrated to give a preponderance of the dimer of phenylbutadiene. This was proved by analysis of the product.

(c) Chloride.—The *trans* carbinol was dissolved in approximately twice its volume of anhydrous ether, and dry hydrogen chloride was allowed to pass in until it ceased to be absorbed. The flask was immersed in an ice-bath during the reaction. The ethereal solution was then thoroughly washed with water to remove all of the acid, dried over anhydrous sodium sulfate, and the ether removed by vaporization. When subjected to distillation under diminished pressure, the residual oil, with the exception of a small fraction, distilled over completely at **104°** under *6* mm. pressure.

Anal. Calcd. for $C_{10}H_{11}Cl$: **Cl, 21.29.** Found: **Cl, 21.21, 21.17.**

Under the same conditions the *cis* carbinol reacted with hydrogen chloride to give an almost quantitative yield of a chloride which distilled at 108° under 6 mm. pressure.

Anal. Calcd. for $C_{10}H_{11}Cl$: **Cl, 21.29.** Found: **Cl, 21.29, 21.43.**

It should be emphasized that for the preparation of either of the chlorides it is essential to remove all traces of acid before distillation. If any acid remains the chlorides decompose on distillation to give a tarry residue.

The *trans* chloride was refluxed with a 10% solution of sodium acetate. The reaction mixture was then extracted with ether, the ethereal solution dried over anhydrous sodium sulfate, and the ether removed by vaporization. The residual oil was distilled under diminished pressure. Two fractions were collected: (1) b. p. 118° under **4** mm. pressure, **(2)** b. p. 200° under 6 mm. pressure. These fractions were analyzed: **(1)** proved to be the acetate of the *trans* carbinol which was described above, while **(2)** was a condensation product of the *trans* carbinol which will be described later in the paper.

The *trans* chloride was refluxed with a water suspension of silver oxide until all of the chloride had reacted. The reaction mixture was then extracted 'with ether and worked up in the usual manner as described above. Two fractions were collected: **(1) b.** p. 76° under **11** mm. pressure and **(2)** b. p. **194"** under **3 mm.** pressure. Fraction 1, of which but a small amount was obtained, proved to be the *trans* phenylbutadiene, while fraction *(2)* was the polymer of the *trans* phenylbutadiene. These compounds were identified by analyses.

The *trans* chloride was refluxed with about five times its volume of dry pyridine for several hours. The reaction mixture was then taken up in ether, and the ethereal solution was thoroughly washed with water to remove all of the pyridine. The ethereal solution was dried over anhydrous sodium sulfate, and the ether was removed by vaporization. When subjected to distillation under diminished pressure, the residual oil, with the exception of a small fraction, distilled over completely at 76° under 11 mm. pressure, the boiling point of the *trans* phenylbutadiene. It was further identified by analysis.

The *cis* chloride was treated with pyridine in an analogous manner and yielded about 40% of the *cis* phenylbutadiene, b. p. 86° under 11 mm. pressure. The remainder was polymerized to the dimer, b. p. 205° under 10 mm. pressure. Both compounds were further identified by analyses.

The *trans* chloride was shaken with twice the theoretical amount of 5% sodium hydroxide for approximately twenty-four hours. The mixture was then extracted with ether, the ethereal solution thoroughly washed with water to remove the excess alkali, dried over anhydrous sodium sulfate, and the ether was removed by vaporization. The residual oil distilled almost completely at 76° under 11 mm. pressure, which is the boiling point of the *trans* phenylbutadiene.

When treated with alkali under the same conditions, the *cis* carbinol gave a very small yield of the *cis* phenylbutadiene, b. p. 86° under 11 mm. pressure, and the remainder was polymerized to the dimer. Both compounds were further identified by analyses.

(d) Condensation.—The *trans* methylstyrylcarbinol was heated to a temperature of 180° under atmospheric pressure. Droplets of water were formed on the sides of the reaction vessel and the mass became viscous and assumed a dark brown color. The viscous mass was extracted with ether, the ethereal solution dried over sodium sulfate, and the ether was removed by vaporization. The residual oil was distilled under diminished pressure. After a small amount of unchanged carbinol distilled over, the temperature rose quickly to 200°, at which point the bulk of the material distilled over under 6 mm. pressure.

Anal. Calcd. for $C_{20}H_{22}O$: C, 86.27; H, 7.97. Found: C, 86.38, 86.17; H, 8.18, 7.76. Calcd. for $C_{20}H_{22}O$: mol. wt., 278.17. Found: mol. wt., 282.3.

The condensation product was ozonized in a manner entirely analogous to that described for the *trans* methylstyrylcarbinol in the preceding paper.[1] Five grams of the condensation product gave 2.3 g. of the semicarbazone of benzaldehyde and 1.6 g. of benzoic acid. This corresponds to a 76.3% yield of benzaldehyde on the basis of two moles of benzaldehyde for each mole of the condensation product.

A chloroform solution of the condensation product was treated with two moles of bromine, also in chloroform solution. This solution was completely decolorized, but no further absorption followed the addition of a few more drops of bromine solution. The chloroform was removed and the residual solid mass was recrystallized several times from hot ligroin. The pure bromide melted at 179°.

Anal. Calcd. for $C_{20}H_{22}OBr_4$: Br, 53.47. Found: Br, 53.55, **53.35.**

II. Reactions Involving the Double Bond

(a) **Bromination.**—A number of attempts to prepare a dibromide addition compound of the two carbinols were made but with no success. In every case decomposition occurred with the elimination of water, resulting in the formation of the tetrabromide of phenylbutadiene. This was identified by its melting point, 146°, and the melting point of a mixture with a sample of known origin. In one experiment the carbinol (in an open weighing bottle) was placed in a desiccator containing an equivalent amount of bromine, also contained in a weighing bottle. The desiccator was closed and the bromine, which vaporized slowly, reacted with the carbinol. Even under such mild conditions, decomposition of the carbinol occurred, with the formation of the tetrabromide of phenylbutadiene.

(b) Catalytic Hydrogenation.—Each of the two carbinols was hydrogenated catalytically by the Adams method.[5] The catalyst was prepared in the manner described by Adams and methyl alcohol was used as the solvent. After the hydrogenation was complete, the catalyst was removed by filtration, and the filtered solution was subjected to distillation under diminished pressure. The methyl alcohol was first removed, after which, in each instance, the temperature rose to 105° under 6 mm. pressure, and the remainder distilled over completely at this temperature.

Anal. Calcd. for $C_{10}H_{14}O$: C, 79.94; H, 9.4. Found: C, 79.91, 79.79; H, 9.34, 9.76.

The phenylurethan of each of the reduced carbinols was prepared by merely adding an equivalent weight of phenyl isocyanate to the pure reduction products and allowing to stand for a few hours. In each case the solution solidified completely. After several recrystallizations from alcohol, the pure crystals melted at 113°, as did a mixture of the two. This proved the identity of the reduction products of the two carbinols.

The 3-hydroxy-1-phenylbutane was synthesized by condensing hydrocinnamic aldehyde with methylmagnesium bromide and decomposing the resulting addition compound with dilute acid, in a manner entirely analogous to that described by Muskat and Herrman[1] for the preparation of the *trans* carbinol. The 3-hydroxy-1-phenylbutane, prepared in this manner, also distilled at 105° under 6 mm. pressure, and gave a phenylurethan which melted at 113° and did not lower the melting point of the above phenyl urethans when mixed with it.

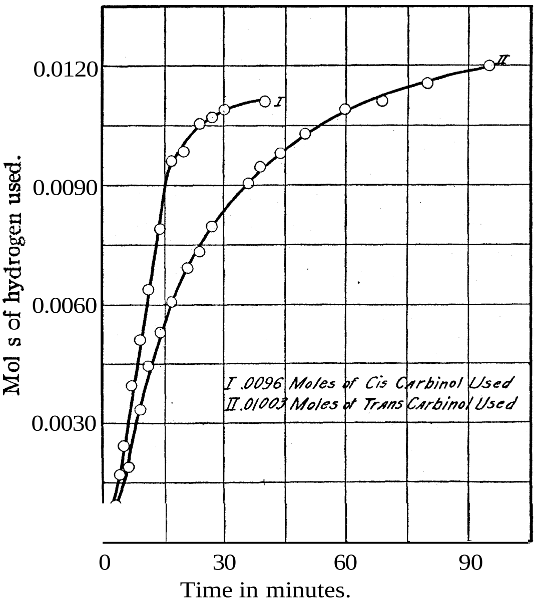


Fig. 1.—50 cc. of glacial acetic acid used as solvent.

(c) The Relative Rate of Catalytic Hydrogenation of the Two Isomeric Carbinols.—The apparatus and method used in determining the rates of catalytic hydrogenation will be described in detail in a paper to be published soon by Muskat and Knapp.

Ten-milligram portions of the same batch of the catalyst were used in all of the experiments. The barometric pressure was 747 mm. and the temperature was 29° except in the case of the *trans* methylstyrylcarbinol in glacial acetic acid, where it was 744 mm. and the temperature 27°. The excess pressure in every case was 88 cm. The experimental data obtained are given graphically in Figs. 1 and 2.

(d) Oxidation of the Methylstyrylcarbinols with Perbenzoic Acid.—Each of the two isomeric carbinols was oxidized with perbenzoic acid. The perbenzoic acid was prepared according to the method of Tiffeneau.[12] The carbinols, dissolved in chloroform, were treated with a chloroform solution of perbenzoic acid following the method

---

[12] "Organic Syntheses," John Wiley and Sons, Inc., New York, 1928, Vol. VIII, p. 30.

first used by Prileshajew[13] for the oxidation of unsaturated compounds. The rate of oxidation was easily followed by the usual iodimetric titration. The rates of oxidation of the two carbinols were determined at different temperatures and with different concentrations of perbenzoic acid. A blank on the perbenzoic acid was always run concurrently with each of the oxidation experiments. Only those runs are included here in which the blank was negligible. At definite time intervals 2 cc. of the solution was removed, added to an acidified solution of potassium iodide, and the liberated iodine was titrated with standard sodium thiosulfate solution.

Previous investigators, who determined the rate of oxidation of unsaturated compounds by means of perbenzoic acid, have experienced considerable difficulty in obtaining reproducible results. Thus Boeseken and Blumberger[14] state that some unknown catalytic effect influenced the rate of oxidation. They state further that oxidation occurs more readily with perbenzoic acid that has been allowed to age than with freshly prepared perbenzoic acid. Meerwein,[15] on the other hand, reports directly conflicting results. During our study of the rate of oxidation of the two carbinols we were able to prove conclusively that the inconsistent results first obtained were not due, in this particular case, to any variation in the perbenzoic acid but rather to the method of titration. When the sample (2 cc.) that was taken out for titration was added to the dilute acetic acid solution of potassium iodide, iodine was set free. If this mixture is allowed to stand before titration, the iodine is absorbed by the unsaturated compound and a much lower titer is obtained. For unsaturated compounds that are but slowly oxidized, such a lowering of the titer may easily change the data by 100%. Consequently in all of the data given here the iodine that was set free was immediately titrated. If this precaution was taken it was easily possible to duplicate our results. The graphs for the oxidation of the two isomeric methylstyryl carbinols are given in Fig. 3.

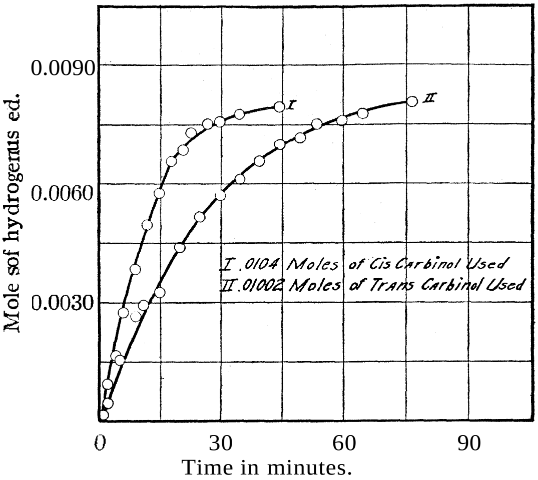

Fig. 2.—50 cc. of CH_3OH used as solvent.

We have calculated the velocity constants for the oxidation experiments reported here. Since the initial molar concentrations of the perbenzoic acid and of the carbinols were very nearly equal, we were able to use the following set of equations for the determination of the velocity constants.

$$\text{First order:} \quad K_1 = \frac{2.303}{t} \log \frac{A}{(A - x)}$$

---

Summary

1. The chemical reactions of the two geometric isomers of methylstyrylcarbinol were studied. These studies included the reactions involving the hydroxyl group and the double bond The differences in the reactivity of the two carbinols were noted in each case.

2. The relative rates of catalytic hydrogenation of the two isomeric carbinols were determined. The *cis* carbinol was reduced more rapidly than the corresponding *trans* carbinol.

3. The relative rates of oxidation of the two isomeric carbinols by means of perbenzoic acid were determined. The *cis* carbinol was oxidized more rapidly than the corresponding *trans* carbinol.

4. The velocity constants for these oxidation reactions were calculated and it was found that the rate of oxidation of the two carbinols is best expressed by the equation for a third order reaction.

5. The oxides of the two carbinols were prepared and their reactions studied.

ADDITION OF PHENOLS TO THE ETHYLENIC LINKAGE.[1] REACTION MECHANISM AND SYNTHESIS OF CERTAIN PHENOLIC ETHERS

BY JOSEPH B. NIEDERL AND SAMUEL NATELSON

RECEIVED OCTOBER 25, 1930 PUBLISHED JANUARY 12, 1931

Theoretical Part

Isolated cases of reactions between phenols and unsaturated compounds have been reported before. Isoprene,[2] cinnamic acid,[3] cyclohexene,[4] isoamylene, styrene[5] and acetylene[6] have been condensed with phenol type compounds under the influence of mineral acid with the formation of the corresponding substituted phenol in most cases.

In 1925 Niederl[7] showed that acetone condenses with phenols and that the resulting compounds could also be obtained by the interaction of unsaturated ketones with phenols. The reaction was shown to be an addition of the phenol to the unsaturated ketone.[8] This reaction was then systematically studied and it was found that the following types of unsaturated compounds would condense with phenols: alcohols,[9] ethers,[10] esters,[11] aldehydes,[12] ketones,[13] acids,[14] nitriles, amines, halides and ethylene oxide.[15]

The purpose of the present research was to continue the work on into the unsaturated hydrocarbon series in order to study the products obtained

[15] Work is now in progress at New York University.

with a view toward a probable mechanism for all these condensation reactions with phenols.

β-Amylene and di-isobutylene were treated with phenol and the cresols in the presence of sulfuric acid. The corresponding ethers were obtained. The following mechanism is offered for this reaction, taking the reaction between β-amylene and m-cresol as an example.

It is first assumed that sulfuric acid is added to the unsaturation of amylene.[16] An ester would be formed of the structure

$$CH_3CH_2CH{=}CHCH_3 + H_2SO_4 = CH_3CH_2CH_2CH(CH_3)OSO_3H$$

Since condensation took place, it could only have taken place in one of two ways: either in the formation of a five carbon substituted phenol, or in an elimination of sulfuric acid with the formation of an amyl cresyl ether

$$CH_3CH_2CH_2CH(CH_3)\boxed{OSO_3H + H}OC_6H_4(CH_3) = CH_3CH_2CH_2CH(CH_3)OC_6H_4(CH_3)$$

This ether had not been reported in the literature up to this time and the proof of its structure was therefore undertaken. It was synthesized according to the Williamson method.[17] The resulting compound was shown to be identical with the ether obtained using the condensation method.

It appears from the work accomplished that the condensation of unsaturated ketones, alcohols, ethers, esters, aldehydes, acids and hydrocarbons (where the reactions are carried out at higher temperatures) takes a different course than the condensation of unsaturated hydrocarbons with phenols in the cold, substituted phenols being obtained in the first case and ethers in the latter. An explanation was then sought which would harmonize these differences. Claisen[18] and others[19] have shown that alkyl phenyl ethers with a negative group in the alkyl radical are prone to rearrange upon heating or, more rapidly, in the presence of mineral acid or zinc chloride. The formation of substituted phenols upon condensation of unsaturated alcohols, ethers, esters, aldehydes, ketones and acids with phenols can now be better explained. Addition of sulfuric acid is first assumed and then elimination of the acid with the formation of an ether. Ethers of these types, as mentioned above, have been shown to rearrange rapidly, especially in the presence of mineral acids. Under the conditions of the experiment, therefore, the ether was not isolated, but the substituted phenol was obtained.

In the condensation of amylene and di-isobutylene with phenols in the cold, ethers were formed with a saturated alkyl group. These are known

to be stable and will not rearrange except under unusual conditions. It was therefore of interest to see whether these long-chain ethers would rearrange at higher temperatures. This would explain the substituted phenols obtained by Konig and Schrauth, by condensing unsaturated hydrocarbons at higher temperatures. o-Cresyl di-isobutyl ether was therefore gently refluxed for five hours in the presence of a mixture of zinc chloride and hydrochloric acid. A crystalline solid was obtained which was shown to be di-isobutyl o-cresol

$$(CH_3)C_6H_4OC_8H_{17} \xrightarrow{\text{Rearrangement}} (CH_3)C_6H_3(C_8H_{17})OH$$

The mechanism then proposed for all these condensations of unsaturated compounds with phenols would constitute an addition of hydrogen sulfate to the ethylenic linkage and a subsequent elimination of the acid with the formation of an ether. This ether in the case of saturated alkyl chains is stable and will not rearrange. In the case of more negative or heavier groups, rearrangement takes place with the formation of the corresponding substituted phenol.

Experimental Part

Condensation Method.—The method followed in these condensations is based upon work reported in earlier articles.[20]

One molecular weight of the cresol or phenol was weighed into a 500-cc. Erlenmeyer flask. To this was added one mole of the unsaturated hydrocarbon, care being taken to avoid excessive evaporation. The flask was well corked and the contents shaken until complete solution had taken place. The mixture was surrounded by an ice and salt bath and allowed to come to zero degrees. Ninety-eight grams of sulfuric acid was weighed out and transferred to a buret. Two drops of sulfuric acid were carefully added. The cork was replaced and the flask thoroughly shaken, keeping the whole immersed in the freezing mixture. The remaining sulfuric acid was then added drop by drop with constant stirring and shaking. At no time was the temperature allowed to go over zero degrees. If this precaution is not observed side reactions are favored and a marked decrease in the yield is noticed. After half of the sulfuric acid has been added further addition does not increase the temperature greatly and the remainder can be added fairly rapidly.

The flask was then stoppered with a cork through whose bore was placed a calcium chloride drying tube to exclude moisture and to allow any gases formed to escape. The mixture, which was almost colorless and mobile at first, turned a pink, brown or red color on standing, dependent upon the phenol or cresol used, and assumed a heavy viscous appearance. The flask was allowed to remain in the bath until the ice had melted, and then after shaking was allowed to stand for one week at room temperature with occasional shaking. The viscosity seemed to increase slowly until it reached a constant value after four or five days.

The mixture was loosened from the walls of the vessel with ice water. Five molar, ice cold, sodium hydroxide was then added until the whole solution was just alkaline. On standing an oil separated at the top of the liquid. This was removed in a separatory funnel. In some cases it was more convenient to extract with ether and then evaporate the ether on a water-bath.

---

[20] Niederl, THIS JOURNAL, 50, 2230 (1928); 51, 2426 (1929).

The separate oil was washed twice with 50-cc. portions of dilute alkali (5%). It was then washed with two 50-cc. portions of saturated salt solution and then with 25 cc. of distilled water.

The liquid was dried over anhydrous potassium carbonate overnight, then transferred to an Erlenmeyer flask and a few bright pieces of sodium were introduced. After being left overnight effervescence ceased and the liquid was then distilled over a small piece of sodium. This precaution was necessary to remove the last traces of cresol or amyl alcohol, which may have been formed in the reaction as a by-product. The distillate thus obtained was then fractionated several times.

s-Amyl *m*-Cresyl Ether, 2-m-Cresoxypentane, $CH_3CH_2CH_2CH(CH_3)OC_6H_4(CH_3)$.—This compound was obtained by applying the above method to amylene (b. p. 35–37°) and m-cresol. The fraction first collected was between 210–245°. Upon redistillation most of the liquid came over between 235–238°. The material was a clear mobile liquid which had a faint aromatic odor: b. p. 238° (uncorr.); n_D^{21} 1.500; sp. gr. 0.920 (20").

Anal. Calcd. for $C_{12}H_{18}O$: C, 80.89; H, 10.11; mol. wt. 178. Found: C, 80.57; H, 10.77; mol. wt. 179.6.

The above ether was nitrated, using the following method: 20 cc. of concentrated sulfuric acid was mixed with 1 cc. of the condensation product. Concentrated nitric acid was added drop by drop until the vigorous reaction had ceased; 5 cc. was added in excess and the whole warmed on a water-bath until brown fumes ceased to be given off.

The reaction mixture was then poured into 200 cc. of water, when a yellowish-brown precipitate came out on standing. The precipitate was washed with water, a limited quantity of dilute sodium bicarbonate solution and then again with small portions of water. The brown mass was dried on a porous plate and recrystallized from 75% alcohol.

The material on recrystallization gave dark brown needles melting at 106°, which was shown to be trinitro-m-cresol. This product is probably formed on hydrolysis of the ether by the sulfuric acid and then nitration of the freed cresol.

Anal. Calcd. for $C_7H_5N_3O_7$: N, 17.29. Found: N, 17.01.

s-Amyl m-cresyl ether was also prepared by the following method:[21] 14 g. of sodium was dissolved in 200 cc. of absolute ethyl alcohol in a three-necked flask fitted with a reflux condenser. While the last bit of sodium was dissolving, 65 g. of m-cresol was added through a dropping funnel. The whole was refluxed for twenty minutes. Through the same dropping funnel extending below the level of the liquid, amyl bromide prepared by the method of Wurtz[16] was added drop by drop with constant refluxing. After all the halide had been added, refluxing was continued for two hours more. Sodium bromide separated out in less than twenty minutes and the flame had to be kept low to avoid excessive bumping. At the end of two hours the flask was allowed to cool and its content filtered with suction from the separated sodium bromide. The filtrate was put in a distilling flask and the alcohol distilled off.

The oil was separated from more sodium bromide, which had come out, by extraction with ether. The ether extract was washed with dilute sodium hydroxide solution, then with water and dried over calcium chloride. It was next treated with metallic sodium to remove any alcohol or cresol still left. The ether was evaporated and the oil fractionated. The major portion came over between 234–238°: b. p. 238" (uncorr.); n_D^{21} 1.496; sp. gr. 0.915 (20°).

Anal. Calcd. for $C_{12}H_{18}O$: C, 80.89; H, 10.11. Found: C, 80.82; H, 10.11.

On nitrating, as described before, trinitro-m-cresol was also obtained.

By applying the procedure given for amylene and m-cresol to phenol and the other cresols the following products were obtained.

---

[21] Williamson, J. *Chem. Soc.*, 4, 106 (1851).

***s*-Amyl *p*-Cresyl** Ether, **2-*p*-Cresoxypentane,** $CH_3CH_2CH_2CH(CH_3)OC_6H_4(CH_3)$.—The crude product distilled between 220–240°. This on careful redistillation gave a product which boiled fairly constantly between 223–225"; b. p. 225 (uncorr.); sp. gr. 0.920 (20°); n_D^{21} 1.505.

***s*-Amyl** o-Cresyl Ether, 2-o-Cresoxypentane, $CH_3CH_2CH_2CH(CH_3)OC_6H_4(CH_3)$.—The crude product distilled between 210–240°. On fractionation most of the material came over between 231–234"; b. p. 234°; n_D^{21} 1.493; sp. gr. 0.915 (20°).

The application of the condensation process to di-isobutylene, phenol and the cresols yielded the following products.

Di-isobutyl Phenyl Ether, **2,2,4-Trimethyl-4-phenoxypentane,** $CH_3C(CH_3)_2CH_2C(CH_3)_2OC_6H_5$.—The material obtained was a clear, colorless liquid which solidified to needle-like crystals on prolonged cooling in an ice and salt bath. The material distilled with slight decomposition at atmospheric pressure. It distilled at 190° at 40 mm.; m. p. 12°; b. p. 258° (760 mm.); 190" (40 mm.); sp. *gr.* 0.950 (20°); n_D^{21} 1.510.

Anal. Calcd. for $C_{14}H_{22}O$: C, 81.55; H, 10.68. Found: C, 80.49; H, 10.47.

By applying the Williamson method to di-isobutyl bromide prepared by the method of Kondakow[22] and sodium phenolate, an ether was obtained which showed the following physical constants: m. p. 11°; b. p. 193° (40 mm.); n_D^{21} 1.505; sp. *gr.* 0.930 (20").

On nitration of di-isobutyl phenyl ether after the method described under amyl-*m*-cresyl ether, a product was obtained which melted at 120° and was shown to be picric acid by a mixed melting point. This product was obtained from both the condensation product and the synthesized ether.

p-Cresyl Di-isobutyl Ether, **2,2,4-Trimethyl-4-*p*-cresoxypentane,** $CH_3C(CH_3)_2CH_2C(CH_3)_2OC_6H_4(CH_3)$.—A clear liquid was obtained which was purified by fractionation: b. p. 272° (uncorr.); n_D^{21} 1.470; sp. gr. 0.889 (20°).

Anal. Calcd. for $C_{15}H_{24}O$: C, 81.82; H, 10.91. Found: C, 81.65; H, 10.91.

m-Cresyl **Di-isobutyl** Ether, **2,2,4-Trimethyl-4-*m*-cresoxypentane,** $CH_3C(CH_3)_2CH_2C(CH_3)_2OC_6H_4(CH_3)$.—The crude oil distilled from 250–275". On fractionation the portion from 269–273° was collected; b. p. 273° (uncorr.); sp. gr. 0.895 (20°); n_D^{21} 1.476.

Anal. Calcd. for $C_{15}H_{24}O$: C, 81.82; H, 10.91. Found: C, 81.99; H, 11.12.

Di-isobutyl o-Cresyl Ether, **2,2,4-Trimethyl-4-*o*-cresoxypentane,** $CH_3C(CH_3)_2CH_2C(CH_3)_2OC_6H_4(CH_3)$.—B. p. 271" (uncorr.); m. p. 6° (uncorr.); sp. gr. 0.881 (20"); n_D^{21} 1.472.

Di-isobutyl *o*-Cresol, $CH_3C(CH_3)_2CH_2C(CH_3)_2C_6H_3(CH_3)OH$.—Hydrogen chloride was bubbled through 20 g. of di-isobutyl o-cresyl ether at zero degrees until 0.5 g. increase in weight was observed; 1 g. of anhydrous zinc chloride was added and the whole heated in an oil-bath to 200° for five hours. The mixture was steam distilled. An oil separated out which solidified to needle-like crystals on cooling. The phenolic properties of the compound are illustrated by its reaction with aqueous sodium hydroxide solution (formation of a soap-like sodium salt, soluble in water with difficulty) and of its alcoholic solution with ferric chloride with the formation of a transient green color; m. p. 49–50" (uncorr.).

Anal. Calcd. for $C_{15}H_{24}O$: C, 81.82; H, 10.91. Found: C, 82.17; H, 10.37.

Summary

The condensation of unsaturated hydrocarbons with phenolic type compounds was carried out. Ethers were obtained. This work, therefore, affords a method of preparing certain alkyl phenyl ethers.

---

[22] Kondakow, J. *prakt.* Chem., [2] *54*, 450 (1897).

A mechanism was proposed not only for this condensation reaction but also for all similar condensation reactions between compounds containing the ethylenic linkage and phenols in the presence of sulfuric acid.

Further work, as to the condensation possibilities of unsaturated hydrocarbons, mono- and di-olefins, alcohols, (esters, ethers), aldehydes (acetals) and ketones, acids, nitriles, amines and halides with mono- and polyhydroxy phenols is being carried out.

NEONICOTINE AND ISOMERIC PYRIDYLPIPERIDINES[1]

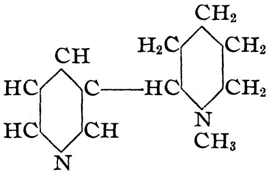
BY C. R. SMITH

RECEIVED OCTOBER 27, 1930 PUBLISHED JANUARY 12, 1931

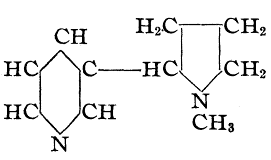
In a previous publication[2] on the interaction of sodium, pyridine and oxygen, the principal products isolated by the procedure outlined were γ,γ-, α,α-, β,γ- and β,β-dipyridyls. Later work has shown that, in addition to these compounds, there are formed water-insoluble bases boiling between 200 and 270°, richer in hydrogen than the dipyridyls, and a water-soluble base of especial interest which has been isolated and identified as β-pyridyl-α-piperidine. This compound has been called "neonicotine" because of its resemblance to nicotine in chemical structure and its toxicity to aphids and other soft-bodied insects.[3]

Neonicotine, $C_{10}H_{14}N_2$, resembles nicotine in structure more than does any of the other isomeric pyridylpiperidines. It is the only one of the pyridylpiperidines that has yet been prepared which shows any marked toxicity to insects.

A comparison of the formulas of neonicotine and nicotine reveals the similarity in structure. The N-methylneonicotine is shown in Formula I for comparison with nicotine (II)



Methylneonicotine I



Nicotine II

---

[1] Presented as a part of the Insecticide Symposium before the Division of Agricultural and Food Chemistry at the 79th Meeting of the American Chemical Society, Atlanta, Georgia, April 7 to 11, 1930.

[2] C. R. Smith, THIS JOURNAL, 46,414 (1924).

[3] Toxicity results are to be reported elsewhere in a joint publication with Dr. C. H. Richardson and H. H. Shepard.

Pictet and Rotschky[4] reported the alkaloids nicotelline, nicoteine and nicotimine, in addition to nicotine, as being present in the tobacco plant. They suggested that nicotelline, $C_{10}H_8N_2$, was possibly an unknown dipyridyl. This must be incorrect since all the dipyridyls are now known, and the properties of nicotelline do not agree with any of them. Nicotimine, $C_{10}H_{14}N_2$ was described as an oil boiling at 250–255°, forming a picrate which crystallizes in thick prisms melting at 163°. It was suggested that nicotimine might be β-pyridyl-α-piperidine, which is the constitution ascribed by the author to neonicotine. Neonicotine boils at 280–282°, forms a picrate which melts at 213° (corr.) and crystallizes from water in prismatic needles. The two substances are evidently different.

There are nine possible pyridylpiperidines. The γ,γ-derivative, called isonicotine, was first prepared by Weidel and Russo.[5] The β,β-derivative, nicotidine, was prepared by Skraup and Vortmann.[6]

To these are now added the α,α, one β,γ and the two α,β-derivatives (one of which is neonicotine) prepared in this study.

Attempts to synthesize neonicotine directly from α,β-dipyridyl have usually resulted in the production of α-pyridyl-β-piperidine or isoneonicotine. It is plausible to assume that neonicotine is formed in the sodium, pyridine and oxygen reaction by some secondary reduction of α,β-dipyridyl, in spite of the fact that the author has been unable actually to separate and identify that dipyridyl. But this failure might well be ascribed to its complete reduction or the difficulties encountered in its detection. Also, attempts to increase the yield of neonicotine by the preliminary addition of α,β-dipyridyl to the sodium reaction have not as yet succeeded.

Weidel and Russo, using a different sodium–pyridine reaction, reported the presence of isonicotine. There is no indication according to the author's method of any pyridylpiperidine other than neonicotine being formed. If present, certain of these, including isonicotine, would undoubtedly appear in the neonicotine fraction as separated by the methods used.

Neonicotine has been shown to be a reduced α,β-dipyridyl because reduction with hydrogen using platinum as catalyst leads to α,β-dipiperidyl. Tin and hydrochloric acid reduction of α,β-dipyridyl leads to the formation of isoneonicotine, which is shown to be α-pyridyl-β-piperidine because it readily forms picolinic acid on oxidation with alkaline permanganate. Neonicotine would be expected to oxidize to nicotinic acid but seems to be oxidized to an intermediate product which resists complete oxidation to the acid: This oxidation will be still further studied. All the pyridylpiperidines that have been prepared except isonicotine are liquids which fume in air more readily than the dipyridyls. When warmed their odor

---

[4] Pictet and Rotschky, Ber., 34, 696 (1901).

[5] Weidel and Russo, Monatsh., 3, 851 (1882).

[6] Skraup and Vortmann, *ibid.*, 4, 597 (1883).

is usually suffocating, suggesting nicotine to a certain extent. The freshly distilled oil on standing develops a sperm-like odor. Isonicotine, however, has a pleasant odor (resembling commercial opium according to Weidel and Russo). The hydrochlorides of the pyridylpiperidines are hygroscopic and are soluble in alcohol, whereas those of the dipyridyls and dipiperidyls are insoluble. The bases themselves are soluble in water in all proportions and are not extracted by ether unless strongly alkaline. When completely dried all are soluble in ether. α-Pyridyl-α-piperidine is the most soluble in ether; neonicotine is the most difficult to extract from alkaline media.

The pyridylpiperidines undergo some decomposition on distillation at atmospheric pressure, whereas the dipyridyls and dipiperidyls are unaffected. The picrates of the pyridylpiperidines crystallize well from hot water and melt with little or no decomposition, thus differing from the dipiperidyls, which usually decompose before the melting point is reached (α,β-dipiperidyl is excepted). Their nitroso derivatives all appear to be non-crystalline except nitroso-isonicotine, and are of little use in identification but may be used in freeing the pyridylpiperidines from the dipyridyls. This separation can also be effected satisfactorily by the absolute alcohol–hydrochloric acid method as used for neonicotine.

The tin reduction method of preparing the pyridylpiperidines is not satisfactory except in the case of isonicotine. Experiments that have been made with sodium reduction show that in all probability reduction to dipiperidyl is never complete but that some hexahydro product is formed along with considerable unaltered dipyridyl and tar. New methods of reduction are being tried in the hope of obtaining better yields and purer products with less manipulation.

Experimental

Isolation of Neonicotine.—Twenty-five grams of sodium, cut in thin slices, was treated with 700 cc. of dry pyridine (b. p. 115°) at room temperature for twenty-four hours or longer until the sodium had completely reacted, forming sodium dipyridine. The mixture was then digested for ten hours at 115°, cooled, and oxidized with dry oxygen at 90° until the black color had completely changed to brown with no lumps remaining. Twenty-five cubic centimeters of water and 400 cc. of ether were then added to the mixture, which was maintained at a temperature below the boiling point of ether. After standing, the sodium hydroxide tarry liquor slowly settled out, permitting decantation of the pyridine–ether layer. Fresh quantities of ether were added to the residue until it was essentially free of pyridine and soluble oils. After the pyridine and ether were removed by distillation from an oil-bath, the oil residue was distilled in a vacuum until a slight decomposition and darkening of the distillate was apparent. The dipyridyl mixture containing the neonicotine was next treated with an excess of hydrochloric acid and evaporated with 95% alcohol to separate γ,γ-dipyridyl dihydrochloride. After the dihydrochloride was filtered off, fresh additions of 95% alcohol were made and evaporation repeated until nearly all the γ,γ-dipyridyl had been removed. The alcohol was next removed from the filtrate by evaporation, and the bases were freed by caustic soda. Most of the oily layer was removed mechanically and the remainder extracted with ether. The combined oil and ether extractions were dried with solid caustic and distilled in a vacuum, the water, pyridine and alcohol in the first part of the distillation being rejected. The distilled oil was dissolved in ether, and the water-soluble dipyridyls and neonicotine were washed out with several small portions of water. The ether contained principally α,α-dipyridyl and the oils boiling below 270" contained a little β,γ-dipyridyl, and some unidentified oils boiling above 305°.

The water-soluble oils and neonicotine were evaporated with a slight excess of hydrochloric acid to low volume, freed by caustic soda, and dried in ethereal solution. The ether was removed and the oils were distilled in *vacuo*. In order to remove the water-soluble dipyridyl, principally the β,γ, the distillate was dissolved in absolute alcohol and then absolute alcohol saturated with dry hydrochloric acid gas was added to precipitate the dipyridyls. In all about 300 cc. of alcohol was required, and complete precipitation was insured by passing hydrochloric acid gas through the mixture. The filtrate was evaporated until the alcohol was removed and the impure neonicotine was then liberated with caustic soda.

The neonicotine was extracted with ether only when completely dried with lumps of caustic soda or potash. The ether was removed and the residue containing neonicotine distilled first in vacuum to remove traces of water, pyridine, etc., and then under atmospheric pressure, being collected between 275 and 285°. In order further to purify the neonicotine it was necessary to form the picrate first in alcohol solution and to recrystallize it from water. The neonicotine picrate formed prismatic needles melting at 213° (corr.). The base obtained from the picrate after careful drying boiled at 280–281° at 775 mm. pressure.

Neonicotine picrate is very insoluble in 95% alcohol, but digestion with several portions of boiling alcohol probably dissolves contaminating dipyridyl picrates from the impure picrate, causing it to become hard instead of oily. Water is excellent for recrystallizing the neonicotine picrate as well as all the other picrates of the pyridylpiperidines.

The first impure preparations of neonicotine that were prepared analyzed low in hydrogen, but as the methods of separation were improved the hydrogen content reached 7.9 to 8.8%. Considerable difficulty was encountered in low carbon determinations but this was overcome by using platinum asbestos catalyst and burning slowly in oxygen.

Anal. Calcd. for $C_{10}H_{14}N_2$: C, 74.07; H, 8.64; N, 17.33. Found: C, 73.69; 7421; H, 8.30, 7.94; N (Dumas), 17.7.

Reduction of Neonicotine.—Neonicotine was hydrogenated in dilute hydrochloric acid solution, with the Adams–Vorhees platinum catalyst. The theoretical for 6H is 3.7%; the absorption found ranged between 3.9 and 4.0%. The filtered solution was concentrated, the base liberated and extracted with alcohol–ether mixture, and a weighed portion of the purified base was titrated with standard acid. The results agreed closely with the titration of dipiperidyl.

Neonicotine obtained from the picrate was reduced with hydrogen and the boiling point of the dipiperidyl was found to be 269–270°, the same as α,β-dipiperidyl. The nitroso derivative of the dipiperidyl melted at 88°. The melting point was unchanged when the substance was mixed with pure dinitroso-α,β-dipiperidyl (m. p. 88°). The dipiperidyl picrate melted at 225° and was unchanged by admixture of α,β-dipiperidyl picrate. Neonicotine is thus shown to be a hexahydro-α,β-dipyridyl. It might be rither β-pyridyl-α-piperidine or α-pyridyl-β-piperidine.

α,β-Dipyridyl.—The preparation of α,β-dipyridyl followed the procedure previously described[7] except that it has been very much simplified by the elimination of the

---

[7] C. R. Smith, THIS JOURNAL, 52, 397 (1930).

lead acetate precipitation which was followed by hydrogen sulfide to remove the lead. In the improved method the solution of the potassium dicarboxylate of the α,β-dipyridyl, after filtration of the manganese dioxide, is evaporated to low volume and acidulated with hydrochloric acid until congo-red paper is just turned blue. This assures the proper hydrogen-ion concentration to precipitate quantitatively the dicarboxylic acid If too much acid is used, alkali may be added, followed carefully by acid until the indicator just changes color. The precipitated acid can be obtained very pure by dissolving in boiling water, decolorizing with carbon and evaporating to low volume.

Reduction of **α,β-Dipyridyl.**—When α,β-dipyridyl was reduced with tin and hydrochloric acid, it was found that only a part was reduced to the hexahydro compound. In the reduction experiments four to five parts of tin were used to one of dipyridyl in a large excess of hydrochloric acid. After removal of the hydrochloric acid by evaporation on the steam-bath, the addition of water always disclosed an insoluble portion of double chloride of tin and unreduced α,β-dipyridyl. These precipitates can be filtered off and reduced with additional quantities of tin and acid although the author preferred to reject all insoluble fractions formed at first or during subsequent removal of the tin with hydrogen sulfide. The α,β-dipyridyl was often recovered from the insoluble precipitates by adding alkali and extracting with ether and used for later reductions. When free from tin the hydrochloric acid solution turned wine-red on evaporation. The addition of caustic potash produced an orange-red color and liberated the base, which was extracted with ether containing alcohol. The extract was evaporated and the residue distilled under reduced pressure. The distillate was dissolved in ether, and the reduced product was washed out with a small quantity of water. The reduced product was recovered by adding alkali and extracting with ether–alcohol, followed by evaporation of the solvent and distillation. The product thus obtained should be either neonicotine or isoneonicotine. Results show that the product obtained by the tin reduction of α,β-dipyridyl is probably isoneonicotine and is α-pyridyl-β-piperidine.

Isoneonicotine picrate melted at 217–218° (corr.); neonicotine picrate melted at 212–213°. A mixture of the two melted at 200°. When isoneonicotine was oxidized with potassium permanganate, the only acid produced was picolinic acid. Neonicotine was at first readily oxidized by permanganate but then seemed to resist further oxidation so that the expected nicotinic acid was not found. The permanganate oxidation of neonicotine and its alkyl derivatives will be studied further.

Isoneonicotine boils at 282° (760 mm) with partial decomposition. Its odor is similar to that of neonicotine.

α,α-Pyridyl-piperidyl.—α,α-Dipyridyl was reduced with tin and hydrochloric acid, four parts of tin to one of dipyridyl. Heat was applied toward the end of the reaction to dissolve the tin completely. Considerable insoluble double chloride of tin and unreduced dipyridyl was formed and removed by filtration. Filtration was also used to eliminate it when it was formed during the removal of the hydrochloric acid by evaporation and of the tin with hydrogen sulfide. When free from tin, the acid solution of the α,α-pyridylpiperidine turns green on evaporation. Addition of alkali turns the solution purple and liberates the base, which was extracted by ether. The base, after removal of the ether, was distilled under reduced pressure. It still contains some α,α-dipyridyl and other contaminating oil, which can be removed by petroleum ether extraction of the aqueous solution. The free base finally obtained has a sperm-like odor similar to neonicotine. It boiled at 265–266° (756 mm.).

Anal. Calcd. for $C_{10}H_{14}N_2$: C, 74.07; H, 8.64. Found: C, 73.97; H, 8.71.

α,α-Pipyridylpiperidine forms a picrate melting at 187°, crystallizing from water in small prisms. The nitroso derivative was formed as an insoluble oil. After extraction by ether and evaporation of the solvent it remained an oil and was not further studied.

Isonicotine (**γ-Pyridyl-γ-piperidine**).—Isonicotine was first prepared by Weidel and Russo. The author prepared several lots of 30 g. each by hydrochloric acid reduction of γ,γ-dipyridyl, rejecting all insoluble double chlorides formed during the isolation of the base. The reduction of γ,γ-dipyridyl by this method appears to be more readily effected than the reduction of any of the other dipyridyls tried.

Isonicotine was obtained as a pleasant smelling substance quite different in odor from the other pyridylpiperidines studied, which have more of a sperm- and nicotine-like odor. It distilled water white in a partial vacuum, solidifying to a hard mass of crystals melting at about 80° as described by Weidel and Russo. After several distillations in a partial vacuum to remove all water, isonicotine begins to boil at 292° under atmospheric pressure. The thermometer slowly rises during the distillation because of polymerization, and a residue is left in the flask. Evidently 292" is the proper boiling point (Weidel and Russo gave it as far above 260°). Isonicotine forms a picrate, crystallizing from water in prismatic needles which melt at 215–218° with evolution of gas.

When treated in concentrated solutions with sodium nitrite and dilute hydrochloric acid, the nitroso derivative separated as an oil, which was extracted with ether. The evaporation of the ether leaves the nitroso derivative, which crystallizes. After reaystallization from dilute alcohol it was found to melt at 112°.

The methylation of isonicotine by means of dimethyl sulfate, methyl iodide or potassium methyl sulfate always resulted in complete failure. The first two reagents caused the formation of nothing but tar even when the reaction was very carefully moderated. The potassium methyl sulfate did not react at all.

Nicotidine.[8]—The reduction of β,β-dipyridyl with tin and hydrochloric acid was found to be very incomplete. More than 80% of the dipyridyl was recovered as the hydrochloride after the removal of the tin and the addition of absolute alcohol. β,β-Dipyridyl seems to resist reduction more than any of the other dipyridyls tried (α,γ not available).

The reduction of β,β-dipyridyl with sodium and absolute alcohol was also tried. Eight grams of dipyridyl dissolved in 300 cc. of absolute alcohol was reduced with 15 g. of sodium. Examination of the reduced base showed considerable unaltered dipyridyl along with nicotidine. Treatment with absolute alcohol and hydrochloric acid was used to remove dipyridyl and dipiperidyl. The nicotidine distilled at 284–285° and is a viscous oil with an odor similar to that of neonicotine. The product was not pure, as shown by the character of the picrate first formed. Several recrystallizations were required to obtain a product melting at about 206°.

β-Pyridyl-γ-piperidine.—β,γ-Dipyridyl seems to be more readily reduced than α,α-, β,β- or α,β-dipyridyl but less readily than γ,γ-dipyridyl. The usual insoluble double salt did not appear until the acid was evaporated to low volume and the residue diluted with water. The combined insoluble precipitates contained about 30% of the original dipyridyl. The reduced oil fraction was shown still to be impure by the appearance and melting point of the picrate obtained after precipitation in alcoholic solution and recrystallization from water. The picrate consisted largely of leaflets mixed with needles and melted around 233° after darkening around 210°. The product was finally purified through the nitroso derivative, which separated as an oil and was extracted with ether. After decomposition with concentrated hydrochloric acid, liberation of the base with alkali, and distillation under reduced pressure, the resulting oil formed a picrate in long fern-like needles. The recrystallized product melted with slight darkening at 240° and appeared to be a uniform product.

The reduction product of this dipyridyl proved to be β-pyridyl-γ-piperidine because it gave only nicotine acid on oxidation with potassium permanganate.

Anal. Calcd. for $C_{10}H_{14}N_2$: C, 74.07; H, 8.64. Found: C, 73.87, 74.20; H, 8.67, 8.82.

Summary

1. Neonicotine (β-pyridyl-α-piperidine) was separated from the products obtained in the author's sodium–pyridine–oxygen reaction. Nicotimine, isolated by Pictet and Rotschky from the nicotine alkaloids and tentatively identified by them as the same product, is probably different.

2. The reduction of γ,γ-, β,γ-, α,α- and β,β-dipyridyls by tin and hydrochloric acid results in varying yields of the corresponding pyridylpiperidines. The ease of reduction is probably greatest with γ,γ, diminishing in the order given, β,β being the least easily reduced.

3. Attempted synthesis of neonicotine from α,β-dipyridyl usually resulted in isoneonicotine but further study is to be made to accomplish this end successfully.

THE α,α'-DIMETHYLSUBERIC AND α,α'-DIBROMO-α,α'-DIMETHYLSUBERIC ACIDS

BY CATHERINE CASSELS STEELE[1]

RECEIVED OCTOBER 27, 1930 PUBLISHED JANUARY 12, 1931

Satisfactory methods for the preparation of tetramethylene bromide (1,4-dibromobutane) have not been available until recent years, with the result that, although several α,α'-dialkyl substituted adipic[2] and pimelic[3] acids have been synthesized, the corresponding derivatives of suberic acid (1,6-hexane-dicarboxylic acid) are unknown. Perkin[4] used a crude mixture of tetra- and pentamethylene bromides on the sodium salt of malonic ester, but obtained from the action of the tetramethylene bromide only the closed chain compound, ethyl 1,1-pentamethylene-dicarboxylate. In the preparation of the dialkyl acids, one molecular proportion of the bromide was condensed with one of the sodium salt of malonic ester to give two products; one was the ester of a closed chain acid[5] and the other the ester of a straight chain tetracarboxylic acid.[6] The latter results from the action of one mole of bromide on two moles of malonic ester.

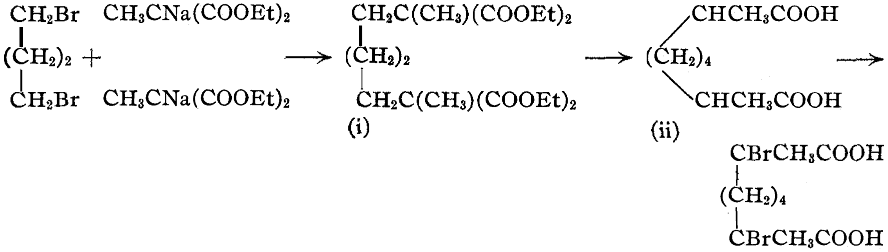
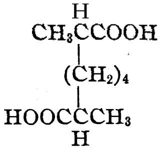
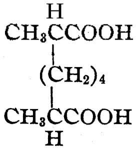
The esters of the straight chain tetracarboxylic acids were then alkylated in the α,α'-positions by treating the disodium salt with an alkyl bromide.[3] Hydrolysis of this product and heating to split off carbon dioxide gave the α,α'-substituted dibasic acids.[2,3] A simpler method was used by Perkin[7] in the preparation of α,α'-di-isobutylpimelic acid, in which he condensed trimethylene bromide with 2 moles of isobutylmalonic diethyl ester. The only other use made of this method in such syntheses was in the preparation of α,α'-dimethyladipic acid from ethylene bromide and monomethylmalonic diethyl ester.[8]



In the present investigation one molecular proportion of tetramethylene bromide was condensed with two of sodiomethylmalonic diethyl ester to give ethyl dimethylhexane-tetracarboxylate (i) in 40% yield. Hydrolysis of the ester gave the tetracarboxylic acid and on heating the latter to 240° α,α'-dimethylsuberic acid (ii) was obtained. This acid was found to exist in two isomeric forms, with melting points of 132–133° and 91–92°, respectively. One of these must be a racemic mixture (dl), and the other an internally compensated (or *meso*) form.



(*dl*)



(*meso*)

No attempt has yet been made to distinguish between the two forms.

The α,α'-disubstituted adipic acids exist in two forms;[2] of the corresponding pimelic series[9] only α,α'-dimethoxypimelic acid has been separated, by crystallization of the amide.[10] α,α'-Dibromosuberic acid,[11] prepared by the bromination of suberic acid, and α,α'-dimethoxysuberic acid[11] both exist in two forms, and α,α'-dimethoxyazelaic acid[11] was separated through the amides.

[10] Hassell and Ingold, *ibid.*, 129, 1470 (1926).

[11] Goss and Ingold, *ibid.*, 129, 1473 (1926).

The fact that a dialkyl suberic acid also exists in two forms seems to indicate that the abnormality in the pimelic series is due to mechanical difficulty in separating the two isomers, and not to the existence of only one form of alkyl derivative, although it is surprising that six dialkyl derivatives, and the dibenzyl, dibenzal and dibromopimelic acids were all isolated as single compounds.

Bromination of α,α'-dimethylsuberic acid should result in an α,α'-dibromo-α,α'-dimethylsuberic acid. Treatment with red phosphorus and bromine, a method used successfully on suberic acid by Hell and Gantter,[12] surprisingly did not give the expected compound, but a mixture of partially brominated products, some of which were unsaturated. The dibromide, however, was obtained by the action of bromine on the acid chloride, as in the bromination of suberic acid by Ingold.[11]

Both forms of α,α'-dimethylsuberic acid gave as the main product a dibromo acid, m. p. 200–210° *ex* ethyl acetate and although in both cases the crude mixture melted about 185°, a distinct crystalline second form was not obtained.

The original goal of this investigation was the preparation of *cis*-1,2-dimethylcyclohexane-1,2-dicarboxylic anhydride. This compound ought to be identical with deoxycantharidin, which is obtained from the naturally occurring drug cantharidin by the action of hydrogen bromide and subsequent reduction of this "dibromide" with zinc and acetic acid.[13] Coffey[14] prepared *cis*-cyclohexane-1,2-diacetic anhydride and *cis*-1,2-dimethylcyclohexane-4,5-dicarboxylic anhydride, these being the structures for deoxycantharidin derived from the other two possible formulas assigned to cantharidin. He found neither of these identical with the deoxycantharidin derived from the natural product but recorded no synthesis of the 1,2-dicarboxylic anhydride. In this work it was hoped to obtain it from dibromodimethylsuberic acid by the elimination of bromine and consequent formation of a cyclohexane ring, but treatment of both the bromo acid and its dimethyl ester with copper bronze or molecular silver met with no success.

Experimental Part

Preparation of Tetramethylene Bromide.—The simplest method recorded in the literature is that of Müller,[15] who passed hydrogen bromide into tetramethylene glycol at 80°, using Böeseken's[16] preparation of the latter by the reduction of diethyl succinate with sodium and alcohol. The glycol has been made in this Laboratory according to this method, with the modification that, after removal of the alcohol and toluene by distillation in steam, the residue was extracted continuously for forty-eight hours with

ether and the glycol distilled, b. p. 148° (30 mm.). The bromination was carried out in a manner analogous to the preparation of trimethylene bromide[17] except that the mixture was refluxed for eight hours instead of three. A 70% yield of distilled bromide was obtained, b. p. 106–110° (30 mm.)

Monomethylmalonic Diethyl Ester.—The action of either methyl iodide[18] or methyl bromide[19] on sodio-malonic ester gives a product which one cannot say with certainty is not contaminated with malonic or dimethylmalonic ester. Zane and Ingold[20] purified the product by hydrolysis, crystallization of the acid, and re-esterscation. The method employed in this work was to convert ethyl a-bromopropionate to ethyl α-cyanopropionate, and to hydrolyze the nitrile. Zelinsky[21] treated ethyl a-bromopropionate in absolute alcohol with potassium cyanide, heated and agitated the mixture with hot air for six hours and obtained a yield of 18% a-cyano ester; the main product of the reaction was dimethylcyanosuccinic ester. It was found by making a series of runs, using a steam-bath and a mechanical stirrer, that an optimum time existed for the yield of ethyl a-eyanopropionate and a correspondingly small amount of the succinic ester; the yield, based on the amount of a-bromo ester actually used in the reaction, was obtained as high as 43%.

To a boiling suspension of 144 g. of potassium cyanide in 195 g. of absolute alcohol was added, as rapidly as possible, 387 g. of ethyl α-bromopropionate (b. p. 158°), the mixture being mechanically stirred after about one-third of the ester had been added. Boiling was then continued for nine and a half hours, the mixture was cooled, filtered and the filtrate and washings poured into 2 liters of water. The oily product was washed and distilled under atmospheric pressure with the use of a 25–30 cm. fractionating column, when the following fractions were obtained

155–170°	Unreacted a-bromo ester	154 g.
170–185°	Intermediate fraction	10 g.
195–205°	Ethyl a-cyanopropionate	70.5 g.

A second distillation of the cyano ester gave a boiling range of 197–198°, the residue being succinic ester.

Hydrolysis and esterification of the nitrile were accomplished in one operation.[22] A cold, thoroughly agitated solution of 127 g. of ethyl α-cyanopropionate in 196 g. of 95% ethyl alcohol was treated gradually with 196 g. of concd. sulfuric acid, then gently refluxed for seven hours, cooled and poured into 2 liters of water. The oily layer was washed with dilute sodium carbonate solution, and on distillation gave 118 g. (93%), b. p. 104–105° (27 mm.).

Ethyl **Dimethylhexane-tetracarboxylate.**—23.8 g. of metallic sodium was added to a solution of 180.5 g. of monomethylmalonic diethyl ester in 1 liter of absolute alcohol (magnesium dried) contained in a 3-liter, 3-necked flask fitted with a mechanical stirrer, condenser and dropping funnel. The mixture was warmed until a clear solution was obtained,[23] then treated with 112 g. of tetramethylene bromide, and refluxed for eighteen

[23] The sodium salt of methylmalonic diethyl ester is practically insoluble in toluene, so the use of this solvent, which was tried first, was discontinued.

hours. The alcoholic solution, decanted from the sodium bromide, and the washings were distilled to remove most of the alcohol; the residue, poured into water, gave an oil which, after being washed with water, was separated into the following fractions by distillation

90–125° (30 mm.)	35 g. water and unchanged ester
150–160° (6 mm.)	61.5 g. (a)
210–217" (6 mm.)	83 g. (b)

(a) is 3-butenyl monomethylmalonic diethyl ester,[24] and (b) is the required dimethylhexane-tetracarboxylate (40% yield).

Anal. Calcd. for $C_{20}H_{34}O_8$: C, 59.7; H, 8.45. Found: C, 59.53; H, 8.37.

Dimethylhexane-tetracarboxylic Acid and α,α'-Dimethylsuberic Acid.—Eighty-two grams of the ester [(b) above] was hydrolyzed by boiling with 90 g. of potassium hydroxide in 1 liter of 95% alcohol for fifteen hours with mechanical stirring. The solution, diluted with water, was taken to dryness in an evaporating dish, the residue taken up in the minimum amount of water, and refluxed for four hours with 180 cc. of concd. hydrochloric acid. Dilution with water and evaporation to dryness gave a mixture of potassium chloride and the tetrabasic acid, 58 g. (calcd. 60 g.) of the latter being isolated by five extractions with ether. It was not purified further, but heated in a metal-bath at 240° for twenty minutes (or until all the carbon dioxide was expelled), giving 38 g. (calcd. 41 g.) of crude dibasic acid.

The Two Isomeric Forms of Dimethylsuberic Acid.—The following method of separating the isomers was adopted. The dibasic acid was extracted five times with boiling water, the aqueous solutions decanted off the dark, oily material, and filtered hot through ordinary filter paper. The first fractions which separated had melting points in the range 100–118° (18 g. from 38 g. of crude) and these on five recrystallizations from boiling water gave small, colorless plates with constant m. p. 132–133° (first form). Second fractions from the original extracts gave similarly an additional 1 g.

Anal. Calcd. for $C_{10}H_{18}O_4$: C, 59.4; H, 8.91. Found: C, 59.34; H, 8.79.

The other isomer was isolated from the fractions melting below 100" by first washing out oily material with cold ligroin, then dissolving in boiling ligroin and filtering from any insoluble material. The solution on cooling deposited crystals which on two recrystallizations gave 3.5 g. of small, glistening prisms, m. p. 91–92" (second form).

Anal. Calcd. for $C_{10}H_{18}O_4$: neut. equiv., 101. Found: 102.4.

Dimethylsuberic Diethyl Ester.—Forty grams of the crude acid was esterified in the usual manner; 43 g. of the diethyl ester was obtained (84%), b. p. 178–185° (25 mm.).

Bromination of α,α'-Dimethylsuberic Acid, First Form.—(a) An intimate mixture of 5 g. of acid (m. p. 132–133°) and 0.5 g. of red phosphorus was allowed to stand overnight with 6 cc. of bromine, then warmed gently and air blown through to remove excess bromine. On addition of water and warming to decompose the acid halide, partial carbonization took place and no pure compound was isolated.

(b) Eleven grams of the acid, 1.2 g. of red phosphorus and 12 cc. of bromine were allowed to stand overnight, then treated slowly with methyl alcohol; the solution was poured into a large volume of water, and extracted with ether. On distillation, the following fractions were obtained

(i) and (ii) did not decolorize permanganate immediately, but were oxidized by it on standing. (iii) decolorized permanganate immediately.

(c) **α,α'-Dibromo-α,α'-dimethylsuberic Dimethyl Ester.**—Thirteen grams of the acid of m. p. 132–133° was warmed with 11.2 cc. of thionyl chloride in a flask fitted with a ground-in water condenser until there was no further reaction; 10.4 cc. of bromine was then added gradually, the mixture kept hot on the steam-bath for eight hours, then cooled and treated with absolute methyl alcohol. On distillation 19.5 g. of ester was obtained (78%), b. p. 216–219° (30 mm.). It was colorless when freshly distilled, but turned brown on exposure to air.

(d) **α,α'-Dibromo-α,α'-dimethylsuberic Acid.**—Three grams of acid of m. p. 132–133° was treated as above with thionyl chloride and bromine. After standing overnight it was warmed with about 50 cc. of water until all the sirup had decomposed to a hard, crystalline mass. This was filtered off and washed with water: yield, 3.8 g., m. p. 177–193° with decomposition.

Anal. Calcd. for $C_{10}H_{16}O_4Br_2$: Br, 44.4. Found for crude acid: Br, 46.9.

On two recrystallizations from ethyl acetate the acid had the constant m. p. 200–201°. The original mother liquor, when taken to dryness, gave 1 *g.* of partially crystalline material which could not be recrystallized from any of the ordinary solvents.

Second Form. Bromination of Second Form of Dimethylsuberic Acid.—Two and one-half grams (m. p. 91–92°) was brominated in the manner outlined above. The crude product consisted of 3.9 g. of m. p. 194–196°, and on recrystallization from ethyl acetate 2 g. was obtained, m. p. 200–201"; this gave a mixed melting point with the acid melting at 200–201° from (d) of 200–201°. The initial mother liquors gave 1.2 g. of sirupy material on evaporation to dryness.

Anal. Calcd. for $C_{10}H_{16}O_4Br_2$: Br, 44.4. Found for pure acid: Br, 44.4.

Attempts at **Ring Closure.**—(a) A mixture of 10 g of copper bronze and 18.6 g. of ester on heating to 140° appeared to boil suddenly and evolved copious fumes. When the mass was cooled, extracted with alcohol and distilled, only low-boiling fractions were obtained and no definite compound was isolated

(b) When a suspension of copper bronze in a solution of 2 g. of the acid in nitrobenzene was heated to 160°, the liquid darkened and the copper lost its luster. Heating was continued at this temperature for an hour, with addition of more copper at intervals, the mixture cooled, filtered and most of the solvent removed by distillation. Precipitation from the residue with petroleum ether (b. p. 40–60°) gave a sirupy product which could not be induced to crystallize.

(c) A solution of 2 g. of the acid in 35 cc. of acetone was shaken for twenty-four hours with 1.6 g. of molecular silver, then filtered and the filtrate taken to dryness. On one recrystallization from ethyl acetate, the material had the melting point 200–201°, gave a positive test for bromine, and a mixed melting point with the starting material (m. p. 200–201°) was exactly the same.

The author wishes to record her indebtedness and thanks to Professor Roger Adams, at whose suggestion this work was undertaken, and with whose help and criticism it was carried out.

Summary

1. Tetramethylene bromide was prepared by the action of a solution of hydrobromic acid and sulfuric acid on tetramethylene glycol. Monomethylmalonic diethyl ester was prepared from ethyl a-cyanopropionate, and the conditions for the maximum yield of the latter product from α-bromopropionate were elaborated.

2. Methylmalonic ester and tetramethylene bromide were condensed to give ethyl dimethylhexane-tetracarboxylate, which on hydrolysis and decomposition at 240° gave α,α'-dimethylsuberic acid.

3. α,α'-Dimethylsuberic acid exists in two isomeric forms, both of which were isolated pure. Bromination of either acid gave as the principal product one and the same α,α'-dibromo-α,α'-dimethylsuberic acid.

4. Attempts to form a cyclohexane ring by removal of bromine with copper bronze and molecular silver were unsuccessful.

URBANA, ILLINOIS

SYNTHESIS AND PYROLYSIS OF METHYLALLENE AND ETHYLACETYLENE[1]

BY CHARLES D. HURD[2] AND RICHARD N. MEINERT[3]

RECEIVED NOVEMBER 3, 1930 PUBLISHED JANUARY 12, 1931

The only previous mention of methylallene in the literature is its synthesis in 1888 by Norton and Noyes.[4] They listed its boiling point at 19° and prepared its tetrabromide. The synthesis was effected through "butyric chloral" by the following steps

$$CH_3—CHCl—CCl_2—CHO \xrightarrow{Zn(C_2H_5)_2} CH_3CHClCCl_2CH_2OH \xrightarrow{PCl_5}$$

$$CH_3CHClCCl_2CH_2Cl \xrightarrow{Zn \times Cu} CH_3—CH{=}C{=}CH_2$$

Since that time a few general methods of synthesis for allenes have been developed, none of which, however, has received application in the synthesis of methylallene. Bouis' general method[5] seemed to possess definite advantages and was therefore selected.

Crotonaldehyde was the starting point in the synthesis. It was reduced

to crotyl alcohol, which, in turn, was changed into crotyl bromide. On bromination the latter yielded 1,2,3-tribromobutane. Treatment of this with potassium hydroxide gave rise to 2,3-dibromo-1-butene which, on treatment with zinc dust suspended in ethyl alcohol, yielded methylallene. The steps in this synthesis are

$$CH_3CH{=}CHCHO \longrightarrow CH_3CH{=}CHCH_2OH \longrightarrow CH_3CH{=}CHCH_2Br \longrightarrow$$
$$CH_3CHBrCHBrCH_2Br \longrightarrow CH_3CHBrCBr{=}CH_2 \longrightarrow CH_3{-}CH{=}C{=}CH_2$$

The boiling point of methylallene was found to be 10.3° instead of 19" as was reported by Norton and Noyes. This boiling point was obtained with a standardized thermometer, using a vacuum-jacketed spiral column having a cooling cup at the top of the column so that a drip-back could be maintained. From this, it seems that the older value is in error, possibly due to superheating of the vapor. Other physical constants of methylallene were also determined, as no values for the density or the refractive index have been previously recorded.

No mention of 2,3-dibromo-1-butene is made in the literature. For this reason it was studied in some detail. Methylallene tetrabromide was mentioned in Norton and Noyes' paper but none of its properties was listed. Therefore, it was synthesized, analyzed and its physical properties determined. It was prepared both by bromination of methylallene and by bromination of 2,3-dibromo-1-butene.

Comparison of the Pyrolysis of Allene and **Methylallene.**—It was found that methylallene resembles allene in its mode of pyrolysis. At temperatures from 500 to 550°, a complete decomposition was effected in thirty-six seconds and three-fourths of the methylallene was converted into liquids of a polymeric nature. Some tarry material and a little carbon were deposited on the walls of the reaction tube.

The liquids were separated as efficiently as possible into fractions containing but one polymer. The lowest boiling fraction was obtained in a state of fairly high purity. It boiled at 110–115° and a molecular weight determination showed that it was a dimer of methylallene. Attempts to prove its structure by permanganate oxidation or by ozonization were not fruitful.

Inasmuch as allene was found[6] to pyrolyze 66 and 81% in fifty-five and eighty-six seconds, it is evident that it is more resistant to heat than methylallene which was almost completely altered in thirty-six seconds. Although the gaseous products from both allene and methylallene were the lesser products of the reaction, it is interesting to note that methylallene, even with its considerably shorter contact time, gave more than twice the volume of gaseous products. As compared with 77–132 cc. of gas from each liter of allene pyrolyzed, methylallene gave rise to 235–308 cc. Evidently the methyl group is the responsible factor, for much of the

---

[6] Meinert and Hurd, THIS JOURNAL, 52, 4540 (1930).

increased volume was due to methane. Paraffin hydrocarbons made up about half of the total volume of the gases, and the n in C_nH_{2n+2} was considerably nearer unity in the gases from methylallene.

There is another interesting difference between allene and its homolog. Whereas the former is isomeric with only one member of the acetylene series, methylallene is isomeric with two, namely with ethylacetylene and dimethylacetylene. In addition, butadiene-1,3 is also isomeric. Of these three, ethylacetylene would be analyzed with acetylene as "acetylenes" with the alkaline potassium iodomercurate reagent. Dimethylacetylene and butadiene would be taken up in the 82.5% sulfuric acid pipet, if not in the 62.5% pipet. Such a mixture of propylene, allene, butadiene and dimethylacetylene would defy identification with the present methods of analysis, but since the total quantity of these gases was small it is evident that such transformations, even if present, must be very minor effects.

Ethylacetylene.—Ethylacetylene has been prepared by several workers, but there is no record of its pyrolysis. Both Reboul's and Lespieau's methods[7] of preparation are open to the criticism that the ethylacetylene might be contaminated with methylallene. In the former method hydrogen bromide is detached from 2-bromo-1-butene by alcoholic potassium hydroxide. In the latter method, two moles of hydrogen bromide are detached from 1,2-dibromobutane. Picon's method,[8] wherein ethyl iodide is made to react with sodium acetylide in liquid ammonia, is not open to this objection. Therefore this method, or rather a modification of it, was used in the present study. It was found that diethyl sulfate could be substituted for the much more expensive ethyl iodide. Both methods were tried and it was found that the reaction proceeded more smoothly when the sulfate was used than when the iodide was employed. The equation is

$$NaC{\equiv}CH + (C_2H_5)_2SO_4 \longrightarrow C_2H_5C{\equiv}CH + Na(C_2H_5)SO_4$$

A similar synthesis of methylacetylene, using sodium acetylide and dimethyl sulfate, has been described recently.[6] There is every reason to believe that this reaction with alkyl sulfates is general. No doubt alkyl *p*-toluenesulfonates could also be used with success.

The boiling point of the ethylacetylene, made by the diethyl sulfate procedure, was 8.5°. This is in agreement with Picon, who also reported 8.5°, but contradicts the work of Reboul, who reported 14–14.5°, and also contradicts the work of Lespieau, who reported 18°.

The relationship between allene and methylacetylene has been shown previously[e] to be a predictable one on the basis of the three-carbon system inasmuch as methylacetylene pyrolyzed into allene. In the present study we were interested to see if ethylacetylene and methylallene bore a

---

[7] Reboul, *Compt. rend..* 113, 591 (1891); Lespieau, *Ann. chim.,* [8] *27,* 146 (1912).

[8] Picon, *Compt. rend., 158,* 1184 (1914).

similar relationship, in which case an equation to represent it would be: $CH_3CH_2C{\equiv}CH \longrightarrow CH_3CH{=}C{=}CH_2$. The reverse change, that of methylallene into ethylacetylene, has been brought about[9] by heating with sodium,

When ethylacetylene was pyrolyzed, it was found that liquids were not so abundantly formed as was the case with methylacetylene. At 580 and 600° only one-third of the gas pyrolyzed appeared as liquids. Comparatively large amounts of gaseous products were formed. Thus, at 600° there were formed from each liter of ethylacetylene pyrolyzed the following amounts of gases: 94 cc. of acetylenes, of which less than a fifth was methylacetylene; 70 cc. of propylene, with possibly a small admixture of allene; 108 cc. of ethylene; 170 cc. of hydrogen, and 435 cc. of paraffins, practically all of which was methane. This total volume of 883 cc. of gas is a little more than double the volume obtained when a temperature of 550° was employed. However, the 403 cc. in the latter case is considerably in excess of the 308 cc. which was produced from ethylallene under almost duplicate conditions. Ethylacetylene was quite stable at 500° using a contact time of thirty-five seconds. Only 23% of it underwent pyrolysis. However, the pyrolysis was practically 100% at 580°.

The liquids obtained were separated into fractions with difficulty, owing to the small amount available. They were shown to be not aromatic in type. Their resemblance to the liquids obtained from the allenes and from methylacetylene was striking, but no definite polymers were identified. Although the refractive index data were of the same order of magnitude as the data from the corresponding fractions obtained from methylallene, the agreement was not close enough to warrant a claim that the two liquids were identical. Certainly, however, they were similar.

Experimental Part

Crotonaldehyde was reduced to crotyl alcohol with ethoxymagnesium chloride using the method of Meerwein.[10] This was converted in 68% yield into crotyl bromide[11] by interaction with 48% hydrobromic acid.

1,2,3-Tribromobutane.—Bromine (80 cc., dried with concd. sulfuric acid) was slowly dropped into a cold and rapidly-stirred solution of 203 g. of crotyl bromide in 300 cc. of carbon tetrachloride. The details for this preparation of tribromobutane were analogous to those for the preparation of 1,2,3-tribromopropane (by adding bromine to allyl bromide) which are given in "Organic Syntheses."[12] The tribromobutane thus produced was twice distilled at 14 mm. The yield was 95% of the theoretical. At 14 mm. it boiled at 100–101° and at 20° its index of refraction was 1.5680. Charon[13]

reported the b. p. to be 113–114° at 21 mm. Delaby[14] reported the b. p. at 19 mm. to be 110–113" and the index of refraction, n_{D}^{15} 1.569.

2,3-Dibromo-1-butene.—In a one-liter balloon flask were placed 419 g. of 1,2,3-tribromobutane, 20 cc. of water and 100 g. of sodium hydroxide. The flask was connected to an efficient condenser by a wide bent tube and a receiving flask was fitted to the condenser by means of an adapter. The receiver was immersed in a bath of ice water. The contents of the flask were heated directly with a small, slightly luminous flame which was directed by the hand against the flask with a rotary motion. The flask was shaken from time to time, and gradually the alkaline layer became emulsified as the reaction progressed. The reaction proceeded very rapidly at first and developed considerable heat, enough in fact to cause spontaneous distillation of some of the product. After the first rapid reaction had subsided, the flask was again heated until all the liquid had distilled over, after which the solid material in the flask was strongly heated until no more distillate was obtained. The bromide in the receiving flask was washed with water, and the bromide layer separated from the water layer. The 2,3-dibromo-1-butene, which contained some unchanged tribromobutane, was then distilled under reduced pressure. The fraction boiling in the range of 85–90° at 40 mm. was collected. The residue, consisting of unchanged tribromobutane, was saved to be worked up with sodium hydroxide after a sufficient amount had accumulated from several runs. The fraction consisting of the dibromobutene with a small amount of the tribromobutane was redistilled; b. p. 75° at 20 mm. The small amount of residue was combined with the previous residues. The yield was 86%. Analyses of the dibromobutene and of the methylallene tetrabromide which follows were performed by Mr. Forrest Pilgrim.

Anal. Subs., 0.2212: AgBr, 0.3875. Calcd. for $C_4H_6Br_2$: Br, 74.72. Found: Br, 74.55.

The physical constants were found to be as follows: density, d_4^{20} 1.8881, index of refraction, $n_{\mathrm{D}}^{2.8}$ 1.5556; n_{D}^{20} 1.5464; $n_{\mathrm{D}}^{26.5}$ 1.5430. The change of the index of refraction with change of temperature, $dn_{\mathrm{D}}/dT = -0.00053$; at 20 mm., the boiling point was 75".

Preparation of Methylallene Tetrabromide.—Fifty grams of 2,3-dibromo-1-butene was added to an equal volume of dry carbon tetrachloride, and the calculated amount of bromide was added slowly. The reaction was slow in starting. As a matter of fact it was necessary to warm the flask gently to start the reaction but after once started it became so exothermic that it was necessary to cool the reacting mixture. When all of the bromine had been added, the solvent was removed and the methylallene tetrabromide was distilled at reduced pressure. The distillate was redistilled, only the middle portion being retained for the determination of the constants.

Anal. Subs., 0.2218: AgBr, 0.4463. Calcd. for $C_4H_6Br_4$: Br, 85.53. Found: Br, 85.63.

The physical constants were found to be as follows: melting point, −2°; b. p. at 7 mm., 97.5"; specific gravity, d_4^{20}, 2.510 (the average of 2.5097 and 2.5103); index of refraction at 3.6°, 1.6152 and at 20.0". 1.6070. From these data, $dn_{\mathrm{D}}/dT = -0.00050$.

The only previous mention of this compound is in the paper of Norton and Noyes in 1888. Therein it was stated to be prepared from methylallene and bromine, and it was stated not to solidify at −17°. In determining the melting point it was found in the present work that the bromide had to be cooled to −40° until solidification occurred, but with a little of the solid material in contact with the liquid bromide, it could be solidified at −2°, and melted within half a degree of this point.

Preparation of **Methylallene.**—A one-liter, three-necked flask was fitted with a

---

[14] Delaby, *Compt. rend.,* 176, 589 (1923). These values are used in "International Critical Tables," Vol. I, p. 186.

reflux condenser inclined at an angle of 45°, a dropping funnel, and a tube reaching nearly to the bottom of the flask, so that an inert gas could be used to flush out the apparatus. A delivery tube leading from the top of the condenser was fitted to a 100-cc. distilling flask which served as a trap and was kept at a temperature of 30° by a water-bath. A spiral condenser and receiver was fitted to the side arm of the trap flask. This condenser-receiver was kept at a temperature of −12° by ice and salt. The receiver was so arranged that the condensed liquid could be blown into a bottle for storage without removing any connections. The main reaction flask was heated with a water-bath.

Ethyl alcohol (300 cc.) and zinc dust (160 g.) were placed in the reaction flask. The 2,3-dibromo-1-butene (131 g.) was added slowly through the dropping funnel, during which time the alcohol in the flask was kept boiling vigorously. The methylallene all passed over into the condenser and was liquefied. There was a small amount of alcohol which collected in the trap. The reflux condenser was kept at 35–40° in order to retain the alcohol but at the same time to permit the methylallene to escape. After all of the bromide had been added, the alcohol in the flask was boiled for several minutes and carbon dioxide was bubbled through to sweep out all of the methylallene. The crude material thus obtained was fractionated, using the spiral column previously described. The yield was 72%, calculated on the basis of the pure, distilled methylallene.

The physical properties of the liquid methylallene were as follows: b. p. 10.3"; d_4^0 0.676; $n_{\mathrm{D}}^{1.3}$ 1.4205.

Pyrolysis

Apparatus.—The apparatus used in the pyrolysis of both methylallene and ethylacetylene was the same as has been described by the authors in a previous paper,[15] except for the manner in which the hydrocarbon was introduced into the system. The liquefied hydrocarbon was placed in a 25-cc. water-jacketed buret. The buret was attached by means of a rubber stopper to a 100-cc. distilling flask immersed in a bath at 35°. This served as a vaporizing chamber, and the gas was then led from the side arm of the distilling flask through the flowmeter and manometer connections into the reaction chamber as previously described. A spiral condenser which was immersed in a bath at −15° served to condense any unchanged methylallene which came off with the exit gases.

The exit gaseous mixture was analyzed by the method of Hurd and Spence.[16] Of supplementary interest, it was found that methylallene resembles propylene very decidedly in its rate of absorption in sulfuric acid solutions. Neither of these gases is appreciably soluble in the 62.5% sulfuric acid solution or in the alkaline potassium iodomercurate reagent. In 82.5% sulfuric acid, methylallene and propylene are absorbed at about the same rate. This rate is about 1.2 times faster than the rate for allene. It is interesting to note that in dilute acetic acid allene is absorbed about three times more rapidly than propylene. With a 2:1 solution of glacial acetic acid and water (in an Orsat pipet), 8.2 cc. of methylallene dissolved in two minutes, whereas only 2.7 cc. of propylene was absorbed. The same ratio held in more dilute solutions. For purposes of analysis of allene–propylene mixtures by this method, a ratio considerably greater than 3:1 would be required.

Pyrolysis of **Methylallene.**—The data obtained in four experiments are given in Table I.

In the first run, the off-gas consisted almost entirely of the carbon dioxide

---

Paraffins	..	122.0	145.0	173.4

used to fill the system at the start of the experiment. No analysis of the remainder of this gas was made.

Reference to Table I shows that the reaction leading to the formation of liquids of high boiling point was the major effect in this pyrolysis. This was also the case with allene. The gaseous products were relatively unimportant, with the exception of the paraffin hydrocarbons which were present to the extent of 12–17% of the volume of methylallene pyrolyzed. Some carbon was deposited in the reaction tube.

The liquids which were obtained when methylallene was pyrolyzed were fractionally distilled using a 100-cc. Claisen flask which was equipped with a Vigreux column. The higher-boiling fraction was distilled under reduced pressure. The following fractions were obtained:

Fraction	B. p., °C.	n_D	Weight, g.
A	30–42	....	1.3
B	42–75	....	0.7
C	75–135	1.4815	6.6
D	135–200	1.4978	9.1
E	100-200 (33 mm.)	1.547	8.6
Residue			10.7

The residue was a very viscous, rubbery material that partially solidified on cooling.

Fraction A was shown to contain considerable unchanged methylallene by preparing the bromide. A mixture of the di- and tetrabromides was obtained as is always the case, and this was fractionally distilled in so far as the small volume would permit. The first portion boiled at 120–130° at 40 mm. and had a refractive index of 1.5408 at 26.5'. If pure, 2,3-dibromo-1-butene has a refractive index of 1.5430 at 26.5'. The second portion boiled at 150–160° at 40 mm. and had a refractive index of 1.5905 at 27.5'; $n_D^{27.5}$ for pure methylallene tetrabromide is 1.6033. The first portion was evidently the dibromide and the second was largely the tetrabromide of methylallene, with a small amount of the dibromide as an impurity. No solid tetrabromide was produced, which fact speaks for the absence of butadiene tetrabromide in this material.

Portion C of the liquids was purified by distillation. It was perfectly clear and had an odor resembling that of kerosene. The boiling point was 110–115° and the refractive index 1.4758 at 27°. The molecular weight of this sample was determined by the Victor Meyer method.

Mol. *wt.* Subs., 0.1582, 0.0809: cc. of gas formed, 41.7 at 26°, 752.7 mm.; 18.4 at 29°, 748.3 mm. (measured over water). Mol. wt. found: 97.7, 116. Mean, 105.9. Calculated mol. wt. of C_8H_{12}: 108.

This, together with the boiling point and the refractive index, shows that fraction C is a dimer of methylallene or perhaps a mixture of several dimers, inasmuch as several are possible.

Preparation of Ethylacetylene.—Thirty-six grams of sodium was dissolved in about 500 cc. of liquid ammonia. Then acetylene was passed into the solution till the blue color, characteristic of sodium in liquid ammonia, had disappeared. Following this, 230 g. of diethyl sulfate was added slowly, keeping the flask at −60°. Essentially the apparatus and procedure was identical to the one which has been recently described for the synthesis of methylacetylene[17] from dimethyl sulfate and sodium acetylide. The preparation of ethylacetylene by this method proceeded even more smoothly than the preparation of methylacetylene.

The ethylacetylene was liquefied and fractionally distilled, using a low-pitched, vacuum-jacketed spiral[18] column. It boiled at 8.5°, which is in agreement with the value found by Picon. The yield of the pure, redistilled ethylacetylene was 97.5 g. which represents a yield of 60%, based on the equation $Et_2SO_4 + HC\equiv CNa \longrightarrow EtC\equiv CH + NaEtSO_4$.

Pyrolysis of Ethylacetylene.—The ethylacetylene was pyrolyzed, using the same apparatus that was used for the methylallene experiments. In this case the spiral condenser-receiver was kept at a temperature of $-20°$ so that all of the ethylacetylene which was not changed in the hot zone would be condensed and prevented from passing into the gas collection bottle along with the off-gas from the reaction. The data are given in Table II.

The off-gas from Runs 3 and 4 was combined and had a total volume of 11,200 cc. It was passed slowly through a spiral condenser and receiver maintained at a temperature of $-78°$ by a bath of acetone and solid carbon dioxide. About 2 cc. of liquid condensed. This was allowed to vaporize into two fractions by placing the receiver first in an ice-bath and collecting all the gas that came off at this temperature, and then allowing the receiver to warm up to room temperature and collecting this gas. The first fraction consisted of 500 cc. of gas, and the second fraction was also 500 cc. of gas. These two fractions (A and B) gave the following results upon analysis

Fraction	A	B
Acetylenes, %	16.2	41.6
Gas soluble in 82.5% H_2SO_4, %	32.4	47.2
Ethylene, %	12.2	0.0
Carbon dioxide, %	6.5	2.1

From this it can be calculated that the following volumes of substances were present in the two fractions

	A	B
Acetylenes, cc.	81	208
Gas soluble in 82.5% H_2SO_4, cc.	162	236
Ethylene, cc.	61	...

Since the total volume of gas treated in the experiment was 11,200 cc. by adding together the amounts from fractions A and B, it is possible to account for 289 cc. or 2.6% of acetylenes, 398 cc. or 3.5% of hydrocarbons absorbed in 82.5% sulfuric acid and 61 cc. or 0.56% of ethylene. Reference to Table II makes it evident that only about one-fourth of the total acetylenes present in the gas had condensed at −78°. Since methylacetylene boils at −23.8' and ethylacetylene at +8.5°, the uncondensed acetylenes must represent ordinary acetylene (C_2H_2). The fact that a small amount of ethylene, which boils at −103°, was condensed makes it appear probable that some acetylene, which boils at −81°, would also condense. Hence the acetylenes found in fraction A are probably C_2H_2 for the most part.

About one-third of all the hydrocarbons from the pyrolysis which were absorbed in 82.4% sulfuric acid were condensed at −78°. This would certainly include any allene or methylallene which might be present, and would include much propylene as well, which boils at −50°.

In order to ascertain whether there was any methylallene present, all of the acetylenes were removed from a portion of sample B, and the gas which remained was placed in a cylinder inverted in a bath at −5° which completely surrounded it. There was no liquefaction as witnessed by the fact that there was no contraction in volume. Hence the gas of fraction B which was absorbed in 82.5% sulfuric acid could not have been methylallene, nor could any appreciable amounts of dimethylacetylene or butadiene-1,3 have been present. It may have been either allene or propylene. However, taking into account the velocity of the pyrolysis of allene at temperatures above 550°, it is doubtful if any allene would be found in the off-gas from these experiments.

Referring again to Table II, these conclusions indicate that at least 80% of the gases listed as acetylenes consist of acetylene, C_2H_2, the remainder being methylacetylene. The gases absorbed in 82.5% sulfuric acid are considered to be almost entirely propylene, with possibly small amounts of allene, but with no methylallene.

Liquids.—The liquids obtained in the pyrolysis of ethylacetylene were all combined and fractionally distilled. The refractive indices of the various fractions were determined, with these results.

Fraction	Weight, g.	B. p., °C.	n_D^{24}
A	0.5	30–65	....
B	1.0	65–100	1.4720
C	2.0	100–135	1.4925
D	5.0	135–200	1.5242
Residue	8.5		

Fractions B and C were combined and redistilled, and a fraction boiling from 110 to 120° was taken. Its refractive index was 1.4905. The boiling points were not sharp for the different fractions, and the temperature ascended gradually throughout the distillation with no indication of a pure compound distilling over. The very small volume of these fractions made it impossible to purify them further by distillation methods.

The odors and colors of the fractions were very similar to those obtained in the pyrolysis of allene, and especially of methylacetylene. A comparison of the index of refraction data of the corresponding fractions of the liquids obtained from ethylacetylene and methylacetylene shows a marked similarity. They are no doubt compounds of the same type, and there are some indications that some of the same liquids are present from both substances.

Summary

2,3-Dibromo-1-butene and 1,2,2,3-tetrabromobutane have been prepared and their physical properties determined. Methylallene has been prepared in a state of purity and its density and refractive index determined. A new synthesis for ethylacetylene has been developed.

It has been shown that methylallene polymerizes when pyrolyzed, and the presence of a dimer among the polymerization products has been demonstrated. In addition to the polymers, methane, ethane, ethylene, hydrogen, propylene and allene are formed in small amounts.

In the pyrolysis of ethylacetylene it has been shown that from one-third to one-half of the material was converted into liquids which resembled the liquids formed from methylallene, allene and methylacetylene. In addition to the liquids, there were produced paraffinhydrocarbons, hydrogen,

ethylene and propylene in the ratio approximately of 9:3:2:2, as well as small amounts of acetylene, methylacetylene and allene.

INDICATIONS OF GLUCOSE IN MILK[1]

BY CARRELL H. WHITNAH

RECEIVED NOVEMBER 3, 1930 PUBLISHED JANUARY 12, 1931

The work here reported was started by a request from the Dairy Department to determine if a large increase in the blood sugar of cows would cause the appearance of glucose in the milk. The samples of milk were furnished by the Dairy Department in connection with various projects in which the Department of Chemistry is cooperating.

The milk of lot number one was a composite from all herds supplying milk to the Dairy Department. That of lot number seven was taken separately from three of these herds. The other lots were individual milkings from each of three cows over the intervals indicated.

The official polarimetric method[2] for estimating milk sugar was modified to facilitate the estimation of small amounts of glucose in milk. Fifty cc. of milk was clarified, without further dilution, with 2.5 cc. of official mercuric nitrate solution. The mixture was filtered after standing for five minutes and the rotation of the filtrate measured at 20° in a 20-cm. water-jacketed tube.

Fermentation with yeast, as applied by Raymond and Blanco[3] to other material, was tried as a method of removing any glucose in the milk. To determine whether this method was practicable, 0.5% of glucose was added to a sample of milk, the rotation of which was previously shown not to be changed by treatment with yeast. The extra rotation due to the added glucose was completely removed from 50-cc. samples of this sweetened milk by contact with 3 g. of yeast at 30° in between fifteen and thirty minutes, or with 1 g. of yeast in less than two hours. Samples treated with 3 g. of yeast showed no further change on standing for two hours with the yeast. It was therefore concluded that all the glucose and none of the lactose was removed, and that one hour would be a suitable time for the fermentation.

The yeast was prepared from Fleischmann's baker's yeast by washing and centrifuging five times.[4] The last wash water was found to be clear and free from reducing sugars.

Analyses of 275 samples of milk showed decrease of rotation, after treating 50-cc. portions with 3 g. of yeast for one hour, varying from zero, in 20 cases, to a decrease corresponding to 0.35% of glucose in the milk. In eleven other samples the rotation was observed to increase from 0.01 to 0.07% of the original rotation on treatment with yeast. It is, at present, uncertain whether these apparent increases should be accepted

as real and what significance should be given them. The sensitiveness and reliability of the determinations are indicated by the fact that of 566 duplicate determinations 443 checked as closely as the polariscope could be read, *i.* e., less than 0.002% sugar while the average variation in all duplicates was only 0 008%. Thus the method seems sensitive enough to make significant all the measurements reported.

Removal of glucose on treatment with yeast is considered to be the cause of decrease in rotation; first because glucose is generally considered[6] to be the precursor in the blood of the lactose in the milk, and second, because glucose is known to be readily fermented by yeast[6] either in aqueous solutions or in blood.

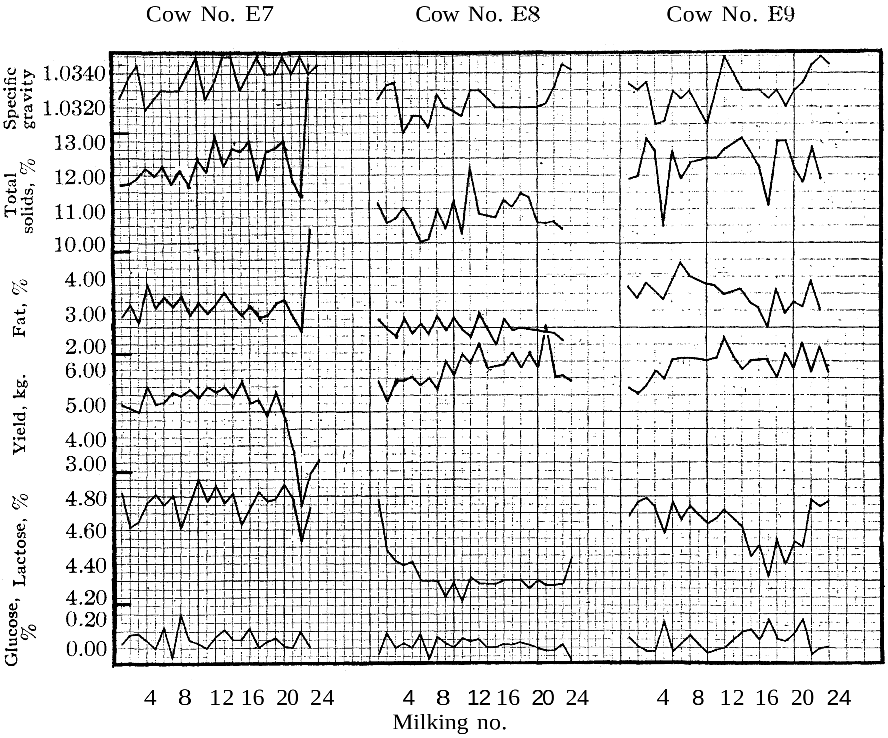

Fig. 1.

Table I shows variations in the glucose content of milk calculated from changes in specific rotation due to fermentation with yeast. The third lot is the only long interval in which all samples apparently contained glucose. This was in the spring shortly after the cows had been turned out to pasture. The observations in the following three lots were on cows receiving dry feed only.

Table II and Fig. 1 indicate simultaneous values in percentage of apparent glucose, percentage of lactose, yield, percentage of fat, percentage of

Summary

A method for estimating small amounts of glucose in milk has been developed, which depends on selective fermentation of the glucose and measurement of the rotary power of fermented and unfermented milk.

Changes in rotary power corresponding to glucose percentages varying from zero to 0.35% of glucose have been found in normal cow's milk.

THE IDENTIFICATION OF PHENOLS

BY C. FREDERICK KOELSCH

RECEIVED NOVEMBER 3, 1930 PUBLISHED JANUARY 12, 1931

Reagents which have been recommended for the identification of phenols are diphenylcarbamine chloride,[1] *p*-nitrobenzyl bromide[2] and 3,5-dinitrobenzoyl chloride.[3] Since none of these reagents in the hands of the inexperienced student has given entirely satisfactory results, the characterization of phenols by the use of chloro-acetic acid has been developed in this Laboratory.

Chloro-acetic acid reacts smoothly with phenols in aqueous sodium hydroxide giving good yields of the sodium salts of aryloxyacetic acids. The acids themselves are crystalline solids easily purified by recrystallization from water. One gram of a phenol furnishes an amount of the derivative sufficient for the determination of its neutral equivalent, often a valuable aid in identification, in addition to its melting point.

The experimental procedure is quite simple. To a mixture of 1.0 g. of the phenol with 3.5 ml. of 33% sodium hydroxide is added 2.5 ml. of a 50% chloro-acetic acid solution; if necessary, a little water is added to dissolve the sodium salt of the phenol. The test-tube containing the solution is stoppered loosely and heated for one hour in a gently boiling water-bath. The solution is cooled, diluted, acidified to congo red with a mineral acid, and extracted once with ether. The ether extract is washed once with a little water, and the aryloxyacetic acid is removed by washing with dilute

sodium carbonate solution. Acidification of this extract gives the free acid, which is recrystallized from water.

The accompanying table contains the data which have been observed on the aryloxyacetic acids prepared in this Laboratory. Those acids for which no reference is given are new compounds. As was expected,[4] no nitrophenoxyacetic acids were isolated when o- or *p*-nitrophenols were used, and the yield was unsatisfactory when m-nitrophenol was used.

GLUCURONIC ACID, A CONSTITUENT OF THE GUM OF ROOT NODULE BACTERIA[1]

BY E. W. HOPKINS, W. H. PETERSON AND E. B. FRED

RECEIVED NOVEMBER 6, 1930 PUBLISHED JANUARY 12, 1931

In a previous paper[2] data were presented which demonstrated that glucose is a product of hydrolysis of the gums produced by the bacteria of red clover, alfalfa and pea, and that uronic acid is also a constituent of these gums and comprises from 4.1 to **25.3%** of the weight of the gum. Besides the analytical data, qualitative tests indicated the presence of a uronic acid. When the gum hydrolysate was neutralized with barium hydroxide and poured into ethyl alcohol, a precipitate formed which possessed reducing properties, left a considerable ash on ignition, and gave a strong uronic acid test with naphthoresorcinol. The uronic acid did not yield mucic acid when oxidized with nitric acid and hence was not galacturonic acid.

The nature of the unknown uronic acid has been investigated more thoroughly and, on the basis of the evidence which will be presented in this paper, it is concluded that the unknown acid is glucuronic.

Experimental

Identification of the Uronic Acid.—The gum was produced by pure cultures of pea and red clover bacteria, and was prepared as described in a previous paper.[2] The dried gum was taken into solution with 5% (by weight) sulfuric acid, and was hydrolyzed by heating for two hours in an autoclave at fifteen pounds steam pressure. After neutralizing the hot solution with barium carbonate, the barium sulfate was filtered off and well washed. The filtrate was concentrated to about one-tenth of the original volume and poured into four volumes of 95% alcohol. The precipitate which formed was filtered off. The filtrate was concentrated to a small volume and a second precipitate was obtained by pouring into alcohol. The combined precipitates of crude uronic acid were taken into solution in a small volume of water and an excess of sulfuric acid was added. Upon pouring this solution into four volumes of 95% alcohol, a precipitate of inorganic impurities formed. The alcohol was removed by evaporation and the sulfuric acid precipitated with barium hydroxide. The filtrate from the barium sulfate was neutralized at the boiling point with barium hydroxide in order to insure the complete neutralization of any uronic acid lactone. The solution was then decolorized, concentrated and the barium salt of the uronic acid precipitated with alcohol. The product still retained a slightly yellow color, but it was sufficiently pure for the preparation of the osazone derivative.

The *p*-bromophenylhydrazone of glucuronic acid has been used by Neuberg[3] as a means of identification, but Goldschmiedt and Zerner[4] reported difficulty in the purification of this derivative, and found that the alkaline earth salts of glucuronic acid furnished a better starting material for the preparation of a suitable derivative. They

[4] G. Goldschmiedt and E. Zerner, *Monatsh*, **33,** 1217 (1912).

prepared the *p*-bromophenylosazone and found this compound could he readily purified and that it gave nitrogen and base analyses which checked well with the calculated values. The use of this derivative as a means of identification possessed particular advantages in our work since the separation and purification of free uronic acid from its salt can be accomplished only with considerable loss of material. Therefore the *p*-bromophenylosazone of the barium salt of the uronic acid was prepared and the melting point and the barium and nitrogen contents of this derivative were determined.

Uronic Acid of Preparation 6 (Gum from Red Clover Nodule Bacteria).—The gum was hydrolyzed and the barium salt of the uronic acid purified by the methods already described. This purified barium salt was used in the preparation of the p-bromophenylhydrazine derivative, as follows: barium salt of the uronic acid 1 part, p-bromophenylhydrazine hydrochloride 3 parts, barium acetate 4 parts and water 70 parts. The mixture was heated for two minutes in a boiling water-bath, shaken well, and rapidly filtered. The turbid yellow filtrate was treated with 3 cc. of glacial acetic acid, and again heated in a boiling water-bath. After ten to twenty minutes' heating yellow crystals began to separate. Further crops of crystals were obtained by continued heating, but the melting point of these later crops varied but little from that of the first. The crystals were filtered off, washed well with water, and with boiling absolute ethyl alcohol. The melting point of the derivative was 216". Goldschmiedt and Zerner give the melting point of the p-bromophenylosazone of barium glucuronate as 215–217°. The same derivative of glucuronic acid was prepared and its melting point found to be 216°.[5] The melting point of a mixture of the known derivative with the unknown was the same as that of the derivatives separately, 216".

The osazone was analyzed for nitrogen and barium by the micro methods of Pregl.[6]

Anal. Subs., 6.090 mg.: N_2, 0.504 cc. (24°, 746 mm.). Subs., 7.335 mg.: $BaSO_4$, 1.430 mg. Calcd. for $(C_{18}H_{17}O_5N_4Br_2)_2Ba$: N, 9.37; Ba, 11.49. Found: N, 9.35; Ba, 11.47.

Uronic Acid Preparation 8 (Gum from Pea Nodule Bacteria).—The gum was hydrolyzed, the barium salt of the uronic acid was purified, and the p-bromophenylosazone prepared in the manner already described. The melting point of the preparation was 216" and no depression in the melting point of the same derivative of glucuronic acid occurred when the two were mixed together. Analyses for nitrogen and barium gave the following results.

Anal. Subs., 7.300 mg.: N_2, 0.615 cc. (24°, 746 mm.). Subs., 4.960 mg.: $BaSO_4$, 0.980 mg. Calcd. for $(C_{18}H_{17}O_5N_4Br_2)_2Ba$: N, 9.37; Ba, 11.49. Found: N, 9.52; Ba, 11.62.

The melting point and the barium and the nitrogen content of the p-bromophenylosazone agree with those of the same derivative of glucuronic acid.

Further Evidence of the Identity of the Sugar Produced by Hydrolysis of the Gum.—In a previous paper[Z] it was reported that the sugar constituent of the gums was glucose, as was indicated by fermentation tests and the melting point of the phenylosazones. In the preparation of the glucuronic acid considered in this paper, the sugar obtained on hydrolysis was a matter of minor concern, but since material was available, it seemed worth while again to determine the identity of the sugar.

Sugar of Preparation 8 (Gum from Pea Nodule Bacteria).—After concentra-

---

[5] The authors desire to express their gratitude to Dr. Armand J. Quick of the Cornell University Medical College for placing at their disposal the glucuronic acid used in this test.

[6] The authors are indebted to Professor Karl Paul Link of the Agricultural Chemistry Department for the micro analyses given in this paper.

tion of the sugar solution to a small volume, glacial acetic acid was added. Crystallization of the sugar took place rapidly and the sugar was purified by recrystallization from acetic acid. The pure product was dried thoroughly in a vacuum oven and a polarization of the sugar made: 0.5005 g. was dissolved in water and after adding a drop of strong ammonia the volume was made up to 25 cc. The rotation in a 200-mm. tube at 24.5" was found to be +6.1° Ventzke; specific rotation: found, +52.7°, required for d-glucose, +52.7°.[7]

The phenylosazone was prepared and was found to have a melting point of 204". The nitrogen content of the phenylosazone was as follows.

Anal. Subs., 4.515 mg.: N_2, 0.6566 cc. (24°, 741.7 mm.). Calcd. for $C_{18}H_{22}N_4O_4$: N, 15.65. Found: N, 16.25.

Although the nitrogen content of the phenylosazone does not agree as well with the calculated value as is desirable in a good derivative, the other evidence presented, i. e., the specific rotation of the crystallized sugar, and the results of the fermentation tests reported in the previous paper[2] give clear evidence that the sugar is glucose.

Sugar of Preparation 6 (Gum from Red Clover Nodule Bacteria).—An attempt was made to crystallize the sugar obtained by hydrolysis of this preparation, but without success. One of the solutions was clarified with basic lead acetate and another was dehydrated in vacuo and the friable residue taken up in absolute methyl alcohol, but both treatments failed to remove some substance which interfered with crystallization. The phenylosazone, however, was prepared without difficulty. The melting point of the osazone was 204°. Analysis gave the following figures for nitrogen.

Anal. Subs., 4.100 mg.: N_2, 0.5831 cc. (24°, 741.7 mm.). Calcd. for $C_{18}H_{22}N_4O_4$: N, 15.65. Found: N, 15.89.

The nitrogen content of this osazone is within the limits of error usual in such preparations. This evidence together with the results of the fermentation tests previously reported[2] indicates that here, as in the pea gum, glucose is a constituent of the gum.

Discussion

Although glucose and glucuronic acid were the products of hydrolysis of both pea and red clover gums, it does not appear that these two gums are identical chemical entities. Certain differences between them were observed. Less reducing sugar as glucose was obtained from pea gum than from the red clover gum. After fermentation of the sugars by yeast and bacteria, the hydrolysate of pea gum contained a larger amount of unfermentable reducing substance. A further point of difference was evidenced by the unsuccessful attempts to crystallize the sugar of red clover gum in contrast to the comparative ease with which crystallization of the pea gum sugar took place. Thus, when considered from the point of view of their hydrolytic products, there are differences in the gums in spite of their apparent similarity. These products of hydrolysis are the same as those obtained by Heidelberger and associates[8] from the soluble specific substance of Type III Pneumococcus. However, these workers found in the

---

hydrolytic products an aldobionic acid precipitable by basic lead acetate. Since in our work the sugar solution was purified by repeated precipitation with 95% ethyl alcohol, such an acid might have been overlooked. Ehrlich and von Sommerfeld[9] report a di-uronic acid obtained by the hydrolysis of pectinic acid. This acid appeared as an insoluble mass in the hydrolysate. In our work a very small amount of insoluble matter was observed in the acid solution after hydrolysis and this material apparently did possess acidic properties. However, the method of hydrolysis used was more drastic than that employed by either Heidelberger and Goebel or Ehrlich and von Sommerfeld, as it was desired to obtain only the products of complete hydrolysis. If compounds of either of these types were present, they must have constituted only a small part of the products of hydrolysis.

Summary

Glucuronic acid has been identified as a constituent of the gum produced by the root nodule bacteria of pea and red clover. The gum was subjected to acid hydrolysis and the glucuronic acid separated from the hydrolysis products as the barium salt. The *p*-bromophenylosazone of this salt had the melting point and the barium and the nitrogen content required for this derivative of glucuronic acid.

The sugar produced by hydrolysis of the gum of the pea bacteria was crystallized, and its specific rotation agreed with that of glucose. In the case of the sugar from the gum of the red clover bacteria, crystallization could not be effected. However, the phenylosazone of this sugar possessed the melting point and the nitrogen content required for phenylglucosazone.

THE MIGRATION OF ACYL FROM SULFUR TO NITROGEN

BY H. P. LANKELMA AND ALBERT E. KNAUF

RECEIVED NOVEMBER 6, 1930 PUBLISHED JANUARY 12, 1931

The work of Raiford,[1] from a study of sixteen different substituted *o*-aminophenols, has shown that when the radicals acetyl and benzoyl are introduced, identical diacyl derivatives are obtained regardless of the order of introduction. This clearly involves a migration of acyl between oxygen and nitrogen during acylation. The present investigation was undertaken to determine whether a similar migration of the radicals acetyl and benzoyl would take place between sulfur and nitrogen in an o-aminothiophenol.

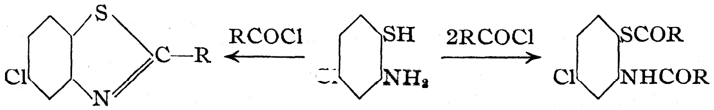
The base employed, 2-amino-4-chloro-thiophenol is readily prepared and isolated in the form of the hydrochloride, by reducing 4,4′-dichloro-2,2′-

---

[9] F. Ehrlich and R. von Sommerfeld, *Biochem.* Z., 168, 263 (1926).

[1] See papers of Raiford, THIS JOURNAL (1919–1926).

dinitrodiphenyldisulfide with tin and hydrochloric acid. The acylation of the hydrochloride in dimethylaniline, with acetic anhydride or benzoyl chloride easily could be controlled to give either the diacyl derivative or benzothiazole. Heating the mixture at the temperature of tha water-bath gave a smooth conversion to the diacyl derivative; upon boiling the mixture, however, only benzothiazole was obtained.[2]



2-Benzoylamino-4-chlorothiophenol and 2-acetylamino-4-chloro-thiophenol, upon drying for several hours in a desiccator or upon recrystallization from alcohol, were completely converted into the corresponding benzothiazoles.[3] Hofmann[4] prepared 2-phenylbenzothiazole by heating *o*-aminothiophenol hydrochloride with benzoyl chloride. He called attention to the probable formation of the N-benzoyl derivative as an intermediate product but did not isolate it. Reissert[5] upon saponifying 2-benzoylaminophenyl thiobenzoate obtained a product which upon recrystallization from alcohol proved to be 2-phenyl-benzothiazole. He reports no melting point for the crude product. It is probable that the initial product was the N-benzoyl derivative, which upon recrystallization formed the benzothiazole.

2-Benzoylamino-4-chlorothiophenol gave upon treatment with acetyl chloride a different diacyl derivative from that obtained by treating 2-acetylamino-4-chlorothiophenol with benzoyl chloride. This shows that no migration of acyl occurs during acylation.

Saponification of the two isomeric benzoyl acetyl derivatives gave the same product, 2-benzoylamino-4-chlorothiophenol, which was identified in one case as the corresponding benzothiazole. This shows that the benzoyl radical displaces acetyl from nitrogen upon saponification of 2-acetylamino-4-chlorophenyl thiobenzoate.

Experimental

2-Amino-4-chlorothiophenol Hydrochloride.—4,4′-Dichloro-2,2′-dinitrodiphenyldisulfide prepared by the method of Blanksma[6] was suspended in five times its weight of alcohol and reduced with tin and hydrochloric acid. The best yields were obtained by stirring the mixture at a temperature of about 70°. Above this temperature a por-

---

[2] A further study of the acylation of this base has been made and will be reported in a later communication.

[3] Mills and Whitworth, *J. Chem. Soc.*, 2738 (1927), have found that 2-cinnamoylaminothiophenol may be recrystallized from alcohol unchanged.

tion of the aminothiophenol was further reduced, with the liberation of hydrogen sulfide. The resulting solution was filtered, the filtrate evaporated to about one-third its volume, and the hot solution treated with an equal volume of concentrated hydrochloric acid. Upon cooling, the hydrochloride separated out, contaminated with tin salts. It was purified by reprecipitation from alcohol with hydrochloric acid. It separated in firm colorless or straw colored needles; yield, 55–60%.[7] That this product is 2-amino-4-chlorothiophenol hydrochloride was shown by the fact that it is soluble in cold aqueous alkali, and by the analysis for sulfur.

Anal. Calcd. for $C_6H_8NCl_2S$: S, 16.34. Found: S, 16.27.

The hydrochloride was converted into the free base by the action of an excess of ammonium carbonate solution. The free base separated as a light yellow precipitate, m. p. 198–201° with decomposition.8 Upon oxidation with ferric chloride it is converted into 4,4′-dichlorodi-*o*-thioaniline, m. p. 118–119°.[9] The free base is very rapidly oxidized by the air to the alkali-insoluble disulfide.

2-Phenyl-5-chlorobenzothiazole.—One gram of 2-amino-4-chlorothiophenol hydrochloride was dissolved in 8 cc. of dimethylaniline and 1.2 g. of benzoyl chloride added. The mixture was boiled for thirty minutes. The thiazole was precipitated with dilute hydrochloric acid. It separated as colorless plates, insoluble in dilute alkali; yield, 1.2 g. Upon recrystallization from alcohol it separated in small colorless plates of m. p. 139°.

Anal. Calcd. for $C_{13}H_8NClS$: S, 13.05. Found: S, 13.26.

2-Methyl-5-chlorobenzothiazole.—This product resulted when the hydrochloride was treated with acetic anhydride by the method described above. The benzothiazole was extracted from the acidified solution with ether. One gram of hydrochloride gave 0.5 g. of benzothiazole, m. p. 65–67°. Upon recrystallization from alcohol it separated in thin colorless plates melting at 68–69°.

Anal. Calcd. for C_8H_6NClS: S, 17.45. Found: S, 17.36.

2-Benzoylamino-4-chlorophenyl **Thiobenzoate.**—A mixture of 1 g. of 4-chloro-2-aminothiophenol hydrochloride, 1.8 g. of benzoyl chloride and 5 cc. of dimethylaniline was heated on a water-bath for ten minutes. The dibenzoyl derivative was precipitated by hydrochloric acid; 1.35 g. of product melting at 140–154° was obtained. It was recrystallized from a mixture of benzene and alcohol from which it separated in colorless plates of m. p. 158–159°.

Anal. Calcd. for $C_{20}H_{14}SNClO_2$: S, 8.72. Found: S, 9.07.

2-Benzoylamino-4-chlorothiophenol.—0.74 g. of 2-benzoylamino-4-chlorophenyl thiobenzoate was saponified by allowing it to stand at room temperature with an excess of potassium hydroxide in alcohol. Upon diluting with water and acidifying, the monobenzoyl derivative separated as a crystalline white solid, which upon drying melted at 105–106°; yield, 0.45 g. This compound was soluble in dilute aqueous sodium hydroxide and was precipitated unchanged on acidifying.

Anal. Calcd. for $C_{13}H_{10}ONClS$: S, 12.11. Found: S, 12.29.

Upon recrystallization from alcohol or ether this substance was completely converted into the alkali insoluble 2-phenyl-5-chlorobenzothiazole, m. p. 139".

2-Acetylamino-4-chlorophenyl **Thioacetate.**—One and four-tenths grams of 2-amino-4-chlorothiophenol hydrochloride and 2.0 cc. of acetic anhydride were treated

---

[7] The hydrochloride has a pronounced vesicant action upon the skin.

[8] Hodgson and Wilson, J. Chem. *Soc.*, **127**, 443 (1925), report 120° as the melting point.

[9] Hodgson and Wilson, Ref. 8, report a melting point of 116° for this substance.

as described under benzoylation of the base: 1.4 g. of product melting at 149–150° was obtained. It was recrystallized from alcohol, from which it separated as soft white needles melting at 150–151°.

Anal. Calcd. for $C_{10}H_{10}O_2NCl$: S, 13.17. Found: S, 12.90.

2-Acetylamino-4-chlorothiophenol.—One gram of 2-acetylamino-4-chlorophenyl thioacetate upon saponification with potassium hydroxide in alcohol gave 0.6 g. of monoacetyl derivative, m. p. 92–94°. This product was soluble in dilute sodium hydroxide solution and was precipitated unchanged on acidifying.

Anal. Calcd. for C_8H_8ONClS: S, 15.90. Found: S, 15.74.

This substance upon recrystallizing from alcohol separated in colorless plates, m. p. 68–69°. When melted with a sample of 2-methyl-4-chlorobenzothiazole the mixture melted without depression.

2-Acetylamino-4-chlorophenyl **Thiobenzoate.**—0.72 g. of 2-acetylamino-4-chlorothiophenol upon benzoylation in dimethylaniline with 0.70 g. of benzoyl chloride gave 1.05 g. of product melting at 137–142". Upon recrystallization from alcohol it separated in soft colorless needles of m. p. 141–142°.

Anal. Calcd. for $C_{15}H_{12}O_2NClS$: S, 10.49. Found: S, 10.55.

2-Benzoylamino-4-chlorophenyl Thioacetate.—0.58 g. of 2-benzoylamino-4-chlorothiophenol and 1.0 g. of acetyl chloride were dissolved in a few drops of dimethylaniline and the mixture heated for ten minutes on a water-bath. Upon acidifying, the diacyl derivative was precipitated: 0.55 g. of product melting at 108–116° was obtained. Upon recrystallization from alcohol it separated as long colorless needles melting at 129–130°. A mixture of this material with the isomeric 2-acetylamino-4-chlorophenyl thiobenzoate melted at 108–116°, showing that they are different substances.

Anal. Calcd. for $C_{15}H_{12}O_2NClS$: S, 10.49. Found: S, 10.84.

Saponification of **2-Acetylamino-4-chlorophenyl Thiobenzoate.**—Eight-tenths gram of this substance was saponified with excess potassium hydroxide in alcohol. The monoacyl derivative obtained melted at 60–90° and was soluble in cold aqueous sodium hydroxide. Upon recrystallization from alcohol it melted at 138–139°. When melted with a sample of 2-phenyl-5-chlorobenzothiazole, m. p. 139°, the mixture melted at 138–139°, showing the identity of the two substances.

Saponification of 2-Benzoylamino-4-chlorophenyl **Thiobenzoate.**—0.46 g. of this substance upon saponifying with excess potassium hydroxide in alcohol gave 0.16 g. of product melting at 89–93°. Upon purifying by reprecipitating from aqueous sodium hydroxide it melted at 100–102°. A mixture of this product with 2-benzoylamino-4-chlorothiophenol melted without depression.

Summary

1. N-Acyl derivatives of 2-amino-4-chloro-thiophenol have been prepared. These lose water very readily to form the corresponding benzothiazoles.

2. No rearrangement of acetyl and benzoyl between sulfur and nitrogen occurs upon acylation of the N-acyl derivative of the o-aminothiophenol. This is unlike the typical behavior of an o-aminophenol.

3. Upon saponification of 2-acetylamino-4-chlorophenyl thiobenzoate a migration of benzoyl from sulfur to nitrogen occurs.

DEGUELIN. I. THE PREPARATION, PURIFICATION AND PROPERTIES OF DEGUELIN, A CONSTITUENT OF CERTAIN TROPICAL FISH-POISONING PLANTS

BY E. P. CLARK

RECEIVED NOVEMBER 7, 1930 PUBLISHED JANUARY 12, 1931

In two recently published reports concerning the constituents of some tropical fish-poisoning plants[1,2] attention was directed to a pale green substance which crystallizes in rod-like plates and melts at 171°. This material, which is highly toxic to fish, is an active constituent of derris and cubé roots, the leaves of *Cracca (Tephrosia) vogelii* and the roots of *Cracca (Tephrosia) toxicaria*.

For purposes of convenience the compound has been termed deguelin, derived from *Deguelia*, the generic name, which, under the American code of botanical nomenclature, supersedes that of derris.

Although deguelin occurs abundantly in cubé and derris roots, its preparation in a chemically pure condition is accomplished with difficulty, which fact has seriously limited the supply of material for study. However, with the information now available it is possible to state that deguelin is a dimethoxylactone, $C_{23}H_{22}O_6$. Some derivatives of the substance have been prepared and, in a preliminary way, its effectiveness as an insecticide has been investigated[3] This communication describes the procedure used in the preparation and purification of the compound, records some of its chemical and physical properties and presents the data upon which the statements regarding its composition and nature have been based.

Deguelin occurs in the non-crystallizable extractives of the four previously mentioned plant materials. Apparently, however, it exists in some form of combination, since it and the constituents with which it is associated are obtained only when the non-crystalline material, dissolved preferably in methyl or ethyl alcohol, is treated with an alkali. In many of the common solvents, the solubilities of all the constituents, including deguelin, are essentially the same, rendering the purification of any one of the substances difficult.

Deguelin showed no optical activity, but it may have existed in the plant in an optically active state and the drastic alkali treatment might have caused racemization. This point has not yet been studied.

When deguelin was first prepared it was purified by repeated recrystallization until it had a constant melting point of 165°. This material was optically uniform, and analytical data showed the composition indicated

---

[1] Clark, *Science*, 71, 396 (1930).

[2] Clark, THIS JOURNAL, 52, 2461 (1930).

[3] Davidson, *J. Econ. Entomol.*, 23, 877 (1930).

by its formula to be constant. Later, in purifying another lot, the melting point constantly dropped until 165° was reached. Upon further recrystallization the melting point rose until at 171° it was constant. Both preparations, that is, the compound melting at 171° and that melting at 165°, had identical optical properties and gave identical analytical data. After obtaining the substance melting at 171° it has been impossible, so far, to obtain a pure sample melting at 165°. The melting point of 171° has, therefore, been recorded for the material.

A reaction of deguelin useful in permitting an attack upon the molecule is its oxidation with potassium ferricyanide. Under properly controlled conditions the reaction proceeds smoothly, yielding a yellow compound, dehydrodeguelin, $C_{23}H_{20}O_6$. On further oxidation with chromic acid, this substance forms dehydrodeguelone, $C_{23}H_{18}O_7$. This is interpreted as indicating an oxidation of a methylene to a carbonyl group.

Dehydrodeguelin reacts with alcoholic potassium hydroxide, forming a phenolic monocarboxylic acid, $C_{23}H_{24}O_8$. The reaction shows the presence in the molecule of a lactone group, but since it involves the addition of two moles of water instead of one, as would be expected, the reaction is abnormal and is analogous to the results obtained by Butenandt with dehydrorotenone.[4]

Evidence of a phenolic hydroxyl group in this acid, which has been designated as deguelic acid, was given by the claret color developed when an alcoholic solution of the acid was treated with ferric chloride. Attempts to form a crystalline acetyl derivative of the acid by using acetic anhydride and sodium acetate were unsuccessful. Instead, ring closure and dehydration occurred, resulting in the regeneration of the mother substance, dehydrodeguelin.

Further work upon this insecticide is in progress.

Experimental

The rotenone in a concentrated ethereal extract of derris root was removed by crystallization, and the mother liquors were concentrated to a thick sirup, practically free from ether; 100 g. of this material was dissolved in 300 cc. of hot methanol and treated with 20 cc. of aqueous 10% solution of sodium hydroxide. In a short time crystallization began and after twenty-four hours 27.5 g. of crude product was removed. This material was a mixture of several substances, three of which predominated, namely, toxicarol, deguelin and tephrosin.

A rough separation of toxicarol was obtained as follows. The crude mixture was dissolved in the minimum quantity of boiling chloroform. The solution was filtered through norit, and again heated to its boiling point. Twelve volumes of boiling alcohol were then added. The solution was vigorously boiled until it was practically free from chloroform, and by that time most of the toxicarol had separated. The crystals filtered from the boiling solution consisted of 10 g. of impure toxicarol. As the mother liquors cooled, 5 g. of light yellow crystals separated, whose melting point was around 168°. This fraction, which is richest in deguelin, was subjected to fractional crystalliza-

---

[4] Butenandt, *Ann.*, 464, 372 (1928).

tion from boiling 95% alcohol. As purification proceeded the melting point generally dropped somewhat and then rose eventually to 171°.

The substance crystallizes in plate-like rods many of which are six-sided. Its indices of refraction are: η_α, 1.570; η_β, 1.590 (common) and η_γ, $>$ 1.739 both ±0.003. The extinction is inclined, and the elongation is negative. Most of the crystals do not extinguish sharply when examined in parallel polarized light with crossed nicols.[5]

Anal. Calcd. for $C_{23}H_{22}O_6$: C, 70.03; H, 5.63; OCH_3 (2), 15.7. Found: C, 69.99; H, 5.63; OCH_3, 15.8.

There is much deguelin in the impure toxicarol and in the mother liquors from the crystalline material used for fractionation. However, the difficulty involved in separating it as such is too great for it to be of practical value. Some of the deguelin fractions obtained after roughly removing toxicarol may have melting points higher or even lower than 168, depending largely upon the quality of the derris root employed.

Deguelin from Cubé Root.—The non-crystallizable extractives from cubé root when treated with sodium hydroxide in the manner just outlined yield principally a mixture of deguelin and tephrosin. There is also a small quantity of a yellow substance present, but deguelin is much more readily obtained pure from cubé than from the crystalline mixture derived from derris root. Also, sodium carbonate may be substituted for sodium hydroxide to induce the crystallization of the mixture of compounds under discussion. With sodium carbonate crystallization is generally slower, and the two main constituents separate in large crystals, enabling one to make a rough mechanical separation, and thereby simplifying the purification of deguelin. The following experiment is representative of what may be obtained with a good specimen of cubé roots.

Rotenone mother liquors from 5.2 kg. of cubé roots were concentrated to a thick sirup. This material, which weighed 560 g., was dissolved in 11 liters of hot methanol, and 55 g. of dry sodium carbonate was added. The mixture was stirred occasionally for an hour and then allowed to crystallize for two days. The product was removed by filtration and washed first with methanol, and then with water to remove the excess of sodium carbonate. Upon suspending the mixture in methanol, tephrosin, which consisted of heavy prisms, quickly settled to the bottom of the container, and deguelin, in the form of thin plate-like rods, remained suspended sufficiently long to be decanted. The yield was 92 g. of crude tephrosin and 83 g. of deguelin. Upon concentrating the mother liquors under reduced pressure, 98 g. of a mixture of deguelin and tephrosin was obtained. Since this material was more valuable as a source of tephrosin, it was used for this purpose. The purity of the deguelin fraction was such that one recrystallization from *n*-butanol followed by two recrystallizations from ethanol gave a product whose melting point was 171° and which possessed the same optical properties recorded for deguelin from derris.

Dehydrodeguelin.—Ten grams of deguelin dissolved in 500 cc. of boiling ethanol was treated with 150 cc. of a hot aqueous solution of 18 g. of potassium ferricyanide and 2.8 g. of potassium hydroxide. The mixture was allowed to stand until the next day and then quickly diluted with 1.5 liters of water. Dehydrodeguelin separated as large yellow crystals. The residual organic material dispersed in the milky mother liquor was carefully decanted. The crystals were then washed with water by decantation, transferred to a filter and finally washed with methanol. The product was 5.4 g. of dehydrodeguelin, consisting of bright yellow pointed rods and needles whose melting point was 233°.

For preparative purposes dehydrodeguelin may be obtained by oxidizing crude

---

[5] The optical data recorded in this communication were determined by George L. Keenan of the Food, Drug and Insecticide Administration of the U. S. Department of Agriculture. Appreciation is gratefully acknowledged for this valuable cooperation.

deguelin from derris. For example, 50 g. of crude deguelin in 10-g. portions gave by the above described procedure 19.6 g. of pure dehydrodeguelin, whose melting point was 233°. The material was recrystallized from a chloroform solution by adding 5 volumes of methanol. The melting point and appearance did not change. The crystals have straight extinction and negative elongation. The refractive indices are: η_α, 1.635 (shown lengthwise); η_β, 1.687 (shown crosswise) and η_γ, higher than 1.74.

Anal. Calcd. for $C_{23}H_{20}O_6$: C, 70.39; H, 5.14; OCH_3 (2), 15.8. Found: C, 70.20; H, 5.17; OCH_3, 15.8.

Several preparations of this compound had a melting point of 228°, which was not altered by repeated recrystallization. The analytical and optical data, nevertheless, were identical with those of the specimens melting at 233°.

Dehydrodeguelone.—Two grams of dehydrodeguelin dissolved in 30 cc. of boiling acetic acid was oxidized with 15 cc. of a 10% acetic acid solution of crystalline sodium dichromate (theory requires 10 cc.). After five minutes three volumes of methanol were added, immediately causing 0.26 g. of the oxidation product to separate. It consisted of bright yellow rods which melted at 287° (corr.).

This compound was recrystallized from its solution in chloroform by adding eight volumes of hot ethanol. The material separated as groups of bright yellow slender rods which began to contract and darken at about 280° and melt at 292° (corr.). It showed inclined extinction and negative elongation. Its indices of refraction were η_α, 1.505; the β value was not determinable and the maximum (γ) value was greater than the refractive index of methylene iodide (η_D, 1.74). However, many of the rods matched this liquid.

Anal. Calcd. for $C_{23}H_{18}O_7$: C, 67.96; H, 4.47; OCH_3 (2), 15.3. Found: C, 67.80; H, 4.58; OCH_3, 15.5.

Deguelic Acid.—To a 10% alcoholic solution of potassium hydroxide, made by adding 30 cc. of an aqueous solution of 15 g. of the alkali to 120 cc. of 95% ethanol, 5 g. of dehydrodeguelin and 10 g. of zinc dust were added, and the mixture was gently boiled for thirty minutes. After the zinc had settled, the clear liquid was decanted and cooled by adding crushed ice. The flask containing the zinc dust was washed with water, and the liquid was filtered from the zinc and added to the main reaction mixture, which was then diluted to 750 cc. The solution was made acid to congo red with sulfuric acid and extracted with ether. The ethereal solution was washed with water, dried with sodium sulfate, concentrated to 75 cc. and allowed to crystallize. The yield was 2.2 g. Upon allowing the mother liquor to evaporate a second crop of crystals was obtained, giving in all a yield of 53–55% of the starting material. The crude acid had a melting point of 183–185°. It was recrystallized by dissolving 1 g. in 20 cc. of boiling ethanol and adding an equal volume of water. The yield was 95%, and the substance had a melting point of 188°. A second recrystallization gave a colorless preparation whose melting point was 189° (corr.). It consisted of rods, square plates and needles. The extinction was inclined, and the sign of elongation was positive: η_α, 1.520; η_β, occurring infrequently, was 1.665; η_γ, >1.74. The most significant optical feature possessed by the substance, observed with convergent polarized light (crossed nicols), was the frequent occurrence of interference figures with the optic axis inclined. Many such crystals or fragments do not extinguish readily with crossed nicols (parallel polarized light) but remain bright when the microscope stage is rotated.

Anal. Calcd. for $C_{23}H_{24}O_8$: mol. wt. 428.3; C, 64.47; H, 5.65; OCH_3 (2), 14.5. Found: acid equivalent, 424; C, 64.32; H, 5.78; OCH_3, 14.7.

Dehydrodeguelin from Deguelic Acid.—A mixture of 0.25 g. of dry sodium acetate, 1 g. of deguelic acid and 4 cc. of acetic anhydride was refluxed for fifteen minutes. The condenser was then disconnected, and about 3 cc. of the liquid was removed by distillation and the residue carefully treated with methanol to decompose the remaining anhydride. Finally 15 cc. of methanol was added, causing the crystallization of 0.24 g. of brown rods, whose melting point was 228°. The material was purified by filtering its chloroform solution through norit, evaporating the filtrate to a small volume and adding 10 volumes of methanol. The substance separated as irregular-shaped salmon-colored plates and rods, which melted at 232°. Recrystallization of the compound in the same manner gave a product whose melting point was 233° (corr.). When this preparation was mixed with an authentic sample of dehydrodeguelin, the melting point was not depressed. Also, oxidation with chromic acid gave dehydrodeguelone. In spite of these facts and the fact that the analytical data given below were the same as those for dehydrodeguelin, the optical properties of the material were not the same as those recorded for this compound. However, when a specimen of the substance was dissolved in chloroform and the solution treated with several volumes of methanol in which a few crystals of pure dehydrodeguelin were suspended, the material separated possessed the optical properties recorded for dehydrodeguelin.

Anal. Found: C, 70.40; H, 5.27; OCH_3, 15.9.

Summary

1. The preparation, purification, and some properties of deguelin, a constituent of several tropical fish-poisoning plants, are described.

2. Evidence is presented to show that deguelin is a dimethoxylactone, $C_{23}H_{22}O_6$.

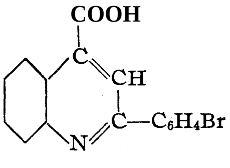
PREPARATION OF CERTAIN BROMINATED CINCHOPHENS

BY H. G. LINDWALL, J. BANDES AND I. WEINBERG

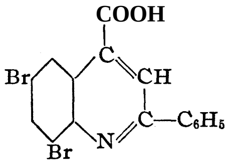
RECEIVED NOVEMBER 10, 1930 PUBLISHED JANUARY 12, 1931

It has been the purpose of this investigation to synthesize some brominated derivatives of cinchophen (2-phenylcinchoninic acid) in order to study later the physiological effects of the introduction of halogen. Condensations of 5,7-di-bromoisatin, as well as of isatin, with certain methyl ketones have been effected by means of the Pfitzinger[1] method.

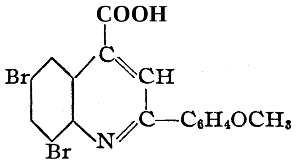
By the interaction of isatin and *p*-bromoacetophenone in the presence of potassium hydroxide in water and alcohol, 2-phenyl-4'-bromocinchoninic acid (I) was obtained. In the same manner, 5,7-dibromoisatin and acetophenone reacted to give 6,8-dibromo-2-phenylcinchoninic acid (11), while p-methoxyacetophenone and 5,7-dibromoisatin yielded 6,8-dibromo-2-phenyl-4'-methoxycinchoninic acid (III)



I



II



III

---

[1] Pfitzinger, J. *prakt. Chem.*, 56, 292 (1897).

The non-halogenated derivative corresponding to (III) (4′-methoxy-2-phenylcinchoninic acid) was first prepared by Ciusa and Lazzatto[2] by Döbner's method.[3] This compound may also be prepared conveniently by the Pfitzinger method from isatin and *p*-methoxyacetophenone.

In the preparation of the 5,7-dibromoisatin it was found convenient to use a method described in the experimental part, employing 95% ethyl alcohol as a medium. This method has the advantage of speed as well as of good yield.

Experimental Part

5,7-Dibromoisatin.—Three grams of isatin and 40 cc. of 95% ethyl alcohol were heated on a steam-bath until the isatin was completely dissolved. While the solution was still hot, bromine (7.5 g.) was added slowly, drop by drop, with slow stirring of the mixture. The dibromo isatin began to separate from the mixture almost immediately upon the addition of the first few drops of bromine. After complete addition of bromine, the mixture was cooled slowly at first and later in ice. The product, after having been washed with water and with alcohol, was recrystallized from alcohol. 5,7-Dibromoisatin crystallizes from alcohol in long orange-red needles melting at 248–250°; yield, 80%.

Preparation of Substituted Cinchoninic Acids.—The procedure for the synthesis of 4'-bromo-2-phenylcinchoninic acid illustrates the general procedure A mixture of 15 g. of isatin, 22.5 g. of *p*-bromoacetophenone, 122 cc. of ethyl alcohol and 60 cc. of 33% potassium hydroxide solution was refluxed for eight hours with stirring. The alcohol was removed by distillation and the excess *p*-bromoacetophenone by steam distillation. The residual aqueous solution was cooled, acidified with hydrochloric acid and filtered. The solid was washed with water, followed by ethyl alcohol, and was crystallized twice from ethyl acetate.

These cinchoninic acids, pale yellow needles, are practically insoluble in water, ether, cold alcohol and cold ethyl acetate, but readily soluble in hot alcohol and hot ethyl acetate. The yield of recrystallized product is about 65% of the theoretical amount.

TABLE I

SUBSTITUTED CINCHONINIC ACIDS

Cinchoninic acid	Formula	Reactants	M. p., °C.	Nitrogen, % Calcd.	Nitrogen, % Pound	Bromine, % Calcd.	Bromine, % Found
4'-Bromo-2-phenyl-	$C_{16}H_{10}O_2NBr$	Isatin and *p*-bromoacetophenone	239–340	4.27	4.18	24.36	24.00

THE PREPARATION OF AROMATIC MERCURIC CHLORIDES FROM AROMATIC DIAZONIUM CHLORIDES

BY ROBERT E. MCCLURE AND ALEXANDER LOWY

RECEIVED NOVEMBER 14, 1930 PUBLISHED JANUARY 12, 1931

In an investigation[1] by the authors upon the electrochemical reduction of benzenediazonium chloride to phenylhydrazine hydrochloride it was noted that another substance was formed when the mercury cathode was violently stirred. This product proved to be phenylmercuric chloride. A non-electrolytic experiment showed that the formation of the latter compound was purely a chemical reaction and may be represented by the following

$$C_6H_5N_2Cl + Hg \longrightarrow C_6H_5HgCl + N_2$$

This reaction appears somewhat similar to the Gattermann reaction and suggests the possible formation of an unstable phenylcupric halide. The nature of the reaction also suggested that other aromatic mercury compounds might be prepared in the same way. Further investigation confirmed this point of view and this paper describes the preparation of a number of these compounds.

Nesmejanow[2] prepared a number of aromatic mercury halides by the reaction

$$\text{Aryl } N_2Cl{\cdot}HgCl_2 + 2Cu \longrightarrow \text{Aryl } HgCl + N_2 + 2CuCl$$

Experimental

It was evident in this type of reaction that the state of division of the mercury would be an important factor. A number of the usual types of stirrers were tried but even at high speed failed to give more than a small amount of the phenylmercuric chloride. An anchor-shaped stirrer, made from 4-mm. glass tubing with prongs drawn out to capillary fineness and with an opening at the base, gave good results. This stirrer was used in all the experiments described. The bottom of the stirrer was immersed in the mercury with the capillary tips extending into the solution. A fine spray of mercury was thrown from the tips by centrifugal action.

A **Typical** Experiment.—Five grams of redistilled aniline was dissolved in 30 cc. of concentrated hydrochloric acid and 50 cc. of water. The solution was cooled to 0°

[2] Nesmejanow, *Ber.*, **62B**, 1010 (1929).

and diazotized in the usual manner.[3] The diazotized solution was made up to 200 cc. volume with distilled water. A 1.5-cm. layer of mercury was placed in a GOO-cc. beaker and the solution added. The beaker was placed in an ice-bath and the temperature maintained below 5° throughout the entire experiment. The mercury and solution were stirred at 1000 r. p. m. Immediately after the stirrer was started a gray foam formed and gradually rose to the top of the beaker, persisting throughout the experiment. After four hours a test with alkaline β-naphthol showed that only a trace of the diazonium chloride remained. The stirring was stopped and the solution filtered through a Buchner funnel. The residue consisted of finely divided globules of mercury, which would not readily coalesce, and a fine grayish precipitate. The residue was boiled for several minutes with 100 *cc.* of water, which caused the mercury to coalesce. The precipitate was washed away from the mercury, filtered and dried by suction After drying, the residue was extracted with several portions of hot acetone, **300** cc. in all. After two recrystallizations 8 g. of white leaf-like crystals was obtained. This product readily sublimed to white leaflets, melting point 251°, which agrees with that given in the literature for phenylmercuric chloride.[4] The compound was further identified by treating with sodium iodide in cold acetone solution,[5] the phenylmercuric iodide resulting: melting point 265°.[6]

A number of aromatic mercuric chlorides have been prepared by the same type of reaction. The apparatus used and the procedure were as described in the typical experiment. The results are given in Table I.

TABLE I

RESULTS OF EXPERIMENTS

Amines diazotized, 6 g	**Product, -mercuric chloride**	**Solvent for purification**	Yield, g	Yield, %	**M** p , °C	M p.,[4] °C
Aniline	Phenyl-	Acetone	8	45	251	251
p-Toluidine	*p*-Tolyl-	Acetone	8	52	233	233 5
o-Toluidine	o-Tolyl-	Ethanol	11	72	146	146
2-Amino-1,4-dimethyl-benzene	2,5-Dimethylphenyl-	Ethanol	9	64	182.5	183
or-Naphthylamine	α-Naphthyl-	Benzene	2 5	**20**	188 5	189

Instead of using the mechanically divided mercury produced by stirring, black precipitated mercury was used. This was precipitated from mercuric chloride by stannous chloride and carefully washed until free of chlorides. This was rapidly stirred with the benzenediazonium chloride and a 20% yield of phenylmercuric chloride was obtained.

Further work is being conducted upon this reaction at the present time.

Summary

1. A method for the preparation of aromatic mercuric chlorides by the action of finely divided mercury upon the corresponding aromatic diazonium chloride has been developed.

SILICA GEL AS A CATALYST IN THE PREPARATION OF NITRILES[1]

BY JAMES A. MITCHELL[2] AND E. EMMET REID

RECEIVED NOVEMBER 14, 1930 PUBLISHED JANUARY 12, 1931

Previous investigations have shown that silica gel is an excellent catalyst for certain dehydrating reactions involving organic compounds. Milligan, Chappell and Reid[3] showed it to be an extraordinarily good esterification catalyst; Brown and Reid studied its application in the alkylation of ammonia and dehydration of alcohols[4] and also in the alkylation of aniline.[5]

The catalytic dehydration of the nascent amide formed from acetic acid and ammonia, according to the equation

$$CH_3COOH + NH_3 = CH_3CN + 2H_2O$$

in the presence of thoria and alumina, has been studied by Van Epps and Reid.[6] They found that an 85% yield of nitrile could be obtained at 500° with the better catalyst, alumina. They reported that no nitrile was obtained by passing ethyl acetate and ammonia over alumina, while Mailhe[7] obtained nitriles from esters and ammonia with both thoria and alumina.

This reaction has been investigated in the presence of silica gel.

Results

We have found that silica gel is a more efficient catalyst than either thoria or alumina in the preparation of nitriles from acids and ammonia. Using acetic acid and an excess of ammonia, as the temperature of operation is raised the percentage conversion to acetonitrile increases until at 500–525° a maximum is reached (practically quantitative). Increasing the temperature to 550° results in a decreased yield and increasing it to 575° lowers the yield still further. It appears that operation at tempera-

---

tures above 500° fouls the catalyst, for after such treatment runs at lower temperatures gave low yields.

If the temperature of operation was not allowed to rise above 500° the catalyst was very slightly discolored and its activity continued unimpaired almost indefinitely, even after repeated heating and cooling in air.[8]

In every case when the temperature of operation was above 500° a noticeable quantity of a white solid formed in the condenser when distilling the lower (water) layer of the product. The higher the temperature the greater was the yield of this material. It was identified as ammonium carbonate. It is reasonable to suppose that even at temperatures of 500° or lower some ammonium carbonate is formed—which may account, in part, for the salting out of the nitrile to form the upper layer. The acetic acid not converted to nitrile or amide is, of course, in the lower layer in the form of ammonium acetate, and is also efficient as a salting out agent.

A rough calculation of the velocity of passage of the reactants through the catalyst in the case of acetonitrile shows that when the time of contact is twenty-five seconds at 500°, the percentage conversion is 95% (practically quantitative) and only 60% when the rate of flow of the reactants is twice as fast.

The results obtained show that highly purified gel and commercial gel are of the same order of activity.

All the aliphatic acids from acetic to heptoic, with an excess of ammonia, produce large yields of nitriles. The yield from lauric acid is decidedly lower and no nitrile has been obtained from palmitic acid. High yields of nitriles are also obtained from phenylacetic and hydrocinnamic acids.

With all the acids except acetic and isovaleric the catalyst blackens readily at temperatures of 500° or lower and loses its activity in most cases very gradually with use.

The yields of isovaleronitrile, above 90%, offer a rather surprising contrast with the yield of n-valeronitrile, which never exceeded 80%. The difference can hardly be ascribed to any difference in thermal stability of the two acids and, as the nitriles are relatively more stable than the acids, the results may indicate that the formation of nitrile from the isovaleric acid is much more rapid than from the normal acid.

In passing an ester with an excess of ammonia over silica gel the initial percentage conversion to nitrile is high, approximately the same as with the acid. The catalyst, however, in contrast with the acid reaction, is rapidly fouled. Aside from the greater instability of the ester as compared with the acid, the fouling of the catalyst might be partially explained by the decomposition products of the alcohol formed in the ester reaction.

---

[8] With thoria and alumina the catalytic efficiency has been shown to fall off fairly rapidly with use.

Brown and Reid[9] have shown that large amounts of aldehyde are formed in passing butyl alcohol over silica gel. Our experience indicates that silica gel is rapidly fouled in any reaction involving the presence of aldehyde, probably due to the formation of polymerization products.

In passing ethyl benzoate and ammonia over silica gel, ammonium benzoate was obtained as one of the products of the reaction. In this instance we are dealing, after the initial reaction (1), with two competing reactions

$$C_6H_5COOC_2H_5 + NH_3 \rightleftharpoons C_6H_5CONH_2 + C_2H_5OH \qquad (1)$$

$$C_6H_5CONH_2 \rightleftharpoons C_6H_5CN\ 4\ H_2O \qquad (2)$$

$$C_6H_5CONH_2 + H_2O \rightleftharpoons C_6H_5COOH + NH_3 \qquad (3)$$

The fouling of the catalyst has been found to favor Reaction **3** (*i. e.*, more ammonium benzoate is formed) and decrease the yield of nitrile, Reaction 2. If the catalyst is effective in the establishment of both equilibria (2) and (3), it is only reasonable to expect that if it becomes less effective in one reaction it will also become less effective in the other. Two alternative explanations of the experimental result are possible: first, either the gel is such *an effective catalyst* for the establishment of equilibrium, **(3)** that partial fouling hardly impairs its activity, or, second, the hydration of the amide and dehydration of the ammonium salt, (3), is *independent of the catalyst* and merely involves a thermal equilibrium. As less amide is converted to the nitrile more is available for hydrolysis to the acid and ammonia.

In order to ascertain which of these two explanations is correct, benzamide was hydrolyzed in sealed tubes with and without silica gel. The gel had no effect on the rate of hydrolysis. Similar experiments using ammonium acetate showed that silica gel has no influence on the rate of formation of the amide.

It is evident, therefore, that silica gel affects only the second reaction, in the conversion of acids and ammonia to nitriles.

It is, of course, a well-known fact that ammonium salts of the aliphatic acids are easily dehydrated to the amide by the application of heat. Boehner and Andrews[10] and Boehner and Ward[11] have shown that various large-surface catalysts are active in the dehydration of amides. In our experiments in which amides were swept over silica gel by a current of air or nitrogen at temperatures above 400° very high yields of nitriles were obtained.

Experimental

Apparatus and Procedure.—The horizontal tube furnace used was similar to that described by Kramer and Reid.[12]

---

[9] Brown and Reid, *J. Phys. Chem.*, 28, 1080 (1924).

[10] Boehner and Andrews, THIS JOURNAL, **38,** 2503 (1916).

[11] Boehner and Ward, ibid., **38,** *2505* (1916).

[12] Kramer and Reid, *ibid.*, 43, 880 (1921).

The catalyst, 100 g. of silica gel, was placed in a pyrex tube approximately 56 cm. by *23* mm. and activated by heating for four or five hours at 210° in a slow current of dried air, gradually raising the temperature to that desired in the experiment, while continuing the current of dried air.

An accurately measured quantity of acid (or ester) was passed through a dropping arrangement, the flow of which could be regulated by means of a glass rod ground in the tip, and introduced directly by a capillary into an atmosphere of ammonia, over the gel. The ammonia was passed through a calibrated flowmeter and led in through a separate tube ending a little short of the end of the capillary tube. An excess of ammonia was always used

The temperature was read from a thermometer placed between the catalyst tube and the wall of the furnace and kept constant within 1°. Temperatures above 500° were read with a thermocouple.

The gases after leaving the catalyst were led through a condenser, cooled by very cold water, and thence into a receiver, which in the case of acetonitrile was immersed in an ice–salt bath. The excess ammonia was allowed to escape.

The product invariably separated into two layers—the upper layer being practically pure nitrile and ammonia. The nitrile is salted out by ammonium acetate and ammonium carbonate. The lower layer in the case of the soluble nitriles also contained considerable nitrile.

Analysis.—Van Epps and Reid[6] estimated acetonitrile by fractional distillation. The product obtained, however, cannot be freed completely from ammonia, even after refluxing for some time.

The following analytical method proved very satisfactory. The two layers from the run were separated and distilled separately from a Claisen flask with an extended neck and the distillates collected up to 90°. The combined distillate from both layers was weighed and entered as product. The acetonitrile present was determined as follows. An accurately weighed sample of the product (about 0.5 g.) was sealed in a glass tube with *2* cc. of 18 N sulfuric acid and heated at 150° for two and one-half to three hours. The tube contents, after hydrolysis, were carefully washed into a *50-cc.* volumetric flask. A 5-cc. aliquot was titrated for total acidity with 0.1 N sodium hydroxide with phenolphthalein as an indicator, using throughout carbon dioxide-free water. A similar 5-cc. aliquot was heated in a porcelain dish on a water-bath for one and one-half hours, frequently washing down the sides of the dish with distilled water. The acetic acid formed by the hydrolysis of the nitrile was volatilized, leaving the excess sulfuric acid behind. The residue was titrated as before. The difference in the titers, of course, represents the acetic acid present—whence the acetonitrile in the product can be calculated. The estimation of propionitrile was effected in much the same manner. The two-layer product from the run was saturated with potassium carbonate. This effectively salted out the nitrile (an aqueous solution of propionitrile saturated with potassium carbonate retains in solution only about 0.02 g. per cc.). The upper layer was separated, distilled, and the fraction boiling between 90–98" analyzed as before.

Several similar analyses were run on butyronitrile, but this and the higher nitriles were easily purified and quickly freed of ammonia by distillation. Accordingly the higher nitriles were purified and estimated by fractional distillation.

Catalyst.—The catalyst used for the most part was ordinary 8–14 mesh commercial gel.[13] A purified gel catalyst was prepared by refluxing a sample of the commercial gel for several hours with concentrated nitric acid and subsequently cleaned by continued washing with distilled water until it was snow-white and acid free. A portion of the

---

[13] Kindly furnished by Professor W. A. Patrick.

gel purified in this manner was further purified by electrolysis, until entirely freed of electrolyte.[14]

Materials.—The acetic acid was C. P. glacial acetic acid. The propionic, butyric and caproic[15] acids were technical materials carefully purified by distillation through a precision fractionating column. The isovaleric, lauric, palmitic and phenylacetic acids, butyl acetate and ethyl benzoate employed were the purest materials obtainable from the Eastman Kodak Company. The normal valeric acid used was prepared by the Grignard reaction from n-butyl bromide and carbon dioxide and purified by distillation through a fractionating column. Normal heptoic acid was prepared by oxidizing heptaldehyde with chromic acid mixture, separating the product formed and purifying by fractionation through a column.

Hydrocinnamic acid was prepared by completely reducing pure cinnamic acid with amalgamated zinc according to the method of Clemmensen[16] and recrystallizing the product from water until an accurate, sharp melting point was obtained.

n-Butyl n-butyrate was prepared by the oxidation and esterification of n-butyl alcohol with sulfuric–chromic acid.[17]

The Preparation of Nitriles from Acids

Acetonitrile (Methyl Cyanide).—The effect of variation of temperature on the yield of nitrile is indicated in the first section of Table I.

Variation in the rate of flow of the two reactants was studied and the results are tabulated in Section II, Table I. Keeping the temperature constant at 500° it is evident, as is to be expected, that the time of contact with the catalyst is a factor of considerable importance. Increasing the rate of flow of either the acid or ammonia results in a decreased yield.

The results obtained in using a highly purified sample of the same gel are indicated in the third section of Table I. It is evident that similar yields of nitriles are obtained.

Each section of the table represents the results from a fresh charge of catalyst.

The two-layer product from the run was always water white without the least discoloration.

Propionitrile (Ethyl Cyanide).—The product, which always separated into two layers, was almost colorless, although several times a slight yellow coloration was apparent. After salting out with potassium carbonate, the upper layer upon distillation was quickly freed of ammonia and the boiling point rose rapidly to 95°. The fraction was taken between 90–98'—the major portion distilled between 95–97°. The propionitrile occasionally smelled faintly of ammonia, generally not at all, and the analyses showed a high degree of purity (98%).

Lauronitrile (n-Undecyl Cyanide).—Ninety grams of lauric acid was passed over commercial gel at 500° with an excess of ammonia. The rate of flow was comparable with those of the other experiments. The acid was kept molten by surrounding the dropping apparatus with a "chimney," through which a current of hot air was passed. The temperature was kept constant (65°) to insure an even flow of acid.

A fair amount of solid material was obtained in the product, which seemed to consist of the amide, and the ammonium salt of the acid.

The liquid product was washed with water and distilled under 98 mm. pressure. The larger part of the material distilled at 192–195°; yield of nitrile, 46.0 g. (55%).

Palmitic acid was passed over silica gel at 500° with an excess of ammonia. The acid was kept molten and at a temperature of 90°, using the same technique as with the lauric acid. The product was distilled under diminished pressure. The major portion distilled within 1.5 of 265° under 32 mm. pressure. It appeared to be a mixture of the amide and the acid. The product after several recrystallizations was still very impure and melted sluggishly around 40°. No noticeable amount of nitrile was obtained.

Phenylacetonitrile (Benzyl Cyanide).—One hundred and fifty grams of phenylacetic acid was passed over commercial gel at 500° with an excess of ammonia at a rate comparable to those in the previous experiments. The acid in the dropping arrangement was kept molten and at a temperature of 90° as before. The product separated into two layers. The upper (nitrile) layer was separated and distilled under vacuum. The product was almost pure nitrile. That fraction boiling between 128.5–129.5' at 31 mm. was entered as nitrile; yield, **112** g. (87%). The gel was completely blackened after use, but was still active.

Phenylpropionitrile (Phenylethyl Cyanide).—One hundred and twenty-three grams of hydrocinnamic acid was passed over commercial gel at 500° with an excess of ammonia, using the same technique as in the previous experiments with solid acids. The upper layer was distilled as before, practically all of it distilling at 141–142° at **25** mm.; yield of nitrile, 87 g. (81%).

The Preparation of Nitriles from Esters

Acetonitrile from n-Butyl Acetate.—The results obtained upon passing n-butyl acetate over commercial gel with an excess of ammonia are indicated in Table IV. Each space in the table indicates a change in catalyst.

TABLE IV

ACETONITRILE FROM n-BUTYL ACETATE

Temp., °C.	Ester used, g.	Time of expt., min.	Rate of flow of ammonia, cc./min.	Product		Yield, %
				Amount, g.	Purity, %	
500	21.8	64	95	9.64	70	87
444	21.8	47	100	9.80	65	82
400	21.8	77	95	10.50	59	80
400	21.8	81	90	10.22	46	61
370	45.3	129	90	11.17	59	41

370	43.6	120	90	12.00	52	40
400	43.6	120	85	14.57	52	49
455	43.6	112	95	15.82	61	63
465	43.6	123	105	14.60	55	52

The two layers of the product, highly colored and fluorescent, were separated and each distilled up to 85°. The material was analyzed for nitrile in the same manner as was the product obtained from acetic acid. At **500"** the efficiency of the catalyst decreased rapidly. At lower temperatures the life of the catalyst was longer, but its decline was still marked.

n-Butyronitrile from n-Butyl *n*-**Butyrate.**—Here again it is evident that good yields of nitrile are obtainable with a fresh catalyst, but the efficiency drops off rapidly with use (Table V, Section I).

Benzonitrile from Ethyl Benzoate.—As the use of benzoic acid was precluded by the type of apparatus employed, ethyl benzoate was passed over silica gel with an excess of ammonia gas. The formation of nitrile from the ester may be taken as sufficient indication that it is also obtainable from the acid. The results of experiments with ethyl benzoate are noted in Table V, Section II. It is apparent that favorable yields may be obtained. The catalyst, as with the other esters, is rapidly fouled.

The product invariably separated into two layers. The lower (nitrile) layer was distilled. The boiling point rapidly rose to 190° and practically all of the layer boiled between 190–195°. This fraction was taken as nitrile.

It was observed that during the experiments a considerable quantity of white solid collected in the condenser. As the catalyst was used and its efficiency decreased, the yield of this material increased. These crystals, upon examination, proved to be ammonium benzoate.

The Influence of Silica Gel on the Amide-Ammonium Salt Equilibrium.—Exactly weighed quantities of purified benzamide (0.3–0.4 g.) and a weighed quantity of water (about 1.1 g.—a large excess of water was used to force the hydrolysis of the amide) were sealed in pyrex tubes, half of the tubes containing about 0.5 g. of activated silica gel. Pairs of tubes with and without gel were heated at varying periods at 300'. The mixture of benzamide and ammonium benzoate was analyzed by the method outlined by Reid.[18] No difference was observed in the rate of hydrolysis of the amide, with or without gel.

Similar experiments were performed using ammonium acetate (at 150°). The rate of formation of acetamide was the same, with and without the gel.

---

[18] Reid. *Am.* Chem. *J.*, 44, 76 (1910).

A solution of 100 g. of ammonium carbonate in 200 cc. of glacial acetic acid was divided into two equal portions, 5 g. of activated silica gel being added to one of them. These were refluxed side by side and at suitable intervals exact portions drawn off from each and analyzed. The rate of formation of amide was the same in both cases.

Summary

The formation of nitriles from acid or ester vapors mixed with an excess of ammonia in the presence of silica gel has been studied.

From the acids the following yields were obtained: methyl cyanide, 95%; ethyl cyanide, **85%;** n-propyl cyanide, 90%; n-butyl cyanide, 80%; isobutyl cyanide, 94%; n-pentyl cyanide, 90%; n-hexyl cyanide, 93%; *n*-undecyl cyanide, 55%; benzyl cyanide, 87%; phenylethyl cyanide, 81%. No cyanide was obtained from palmitic acid.

From the esters the following yields were obtained: methyl cyanide, 87%; n-propyl cyanide, 75%; phenyl cyanide, 77%.

The life of the catalyst is long in the case of the acids and short in the case of the esters.

The optimum operating temperature for the reaction is 500°.

The catalyst is only active in dehydrating amides, and is not effective in the establishment of the ammonia–acid, amide–water equilibrium.

Silica gel is by far the best catalyst for the reaction that has, as yet, been studied.

THE DECOMPOSITION OF KETONES IN THE PRESENCE OF SILICA GEL

BY JAMES A. MITCHELL AND E. EMMET REID

RECEIVED NOVEMBER 14, 1930 PUBLISHED JANUARY 12, 1931

The decomposition of ketones in the presence of various dehydrating catalysts has been rather widely studied. Acetone has received the most attention, the condensation products being particularly well investigated.

Acetone kept for a long time over lime or aluminum chloride is transformed into mesityl oxide and phorone.[1] By passing acetone vapors over catalysts heated at a suitable temperature, thoria and alumina usually being employed, mesityl oxide, phorone, etc., have been obtained.[2] Ipatiew

and Petrow[3] reported that mesitylene is the main product formed in heating acetone with dehydrating catalysts at high temperatures and pressures. Greene[4] produced hexamethylbenzene, hut no mesitylene, by heating acetone with zinc chloride. Reckleben and Scheiber[5] prepared hexamethylbenzene by leading a mixture of acetone and methyl alcohol over alumina at 400° and assumed that the mechanism of the reaction involved the intermediate formation of mesitylene. Contrary to this, Senderens[2e] reported that no mesitylene is formed from acetone with alumina.

Mesitylene, mesityl oxide, phorone, etc., are produced by distilling acetone with reagents such as sulfuric acid,[6] or boron trifluoride.[7] Heated with acetic anhydride, mesityl oxide is produced.[8] The formation of mesityl oxide is not confined to "dehydrating catalysts;" nickel, for example, yields this product.[9]

The gaseous products from the decomposition of acetone have received some little attention. With alumina Senderens[2e] reports the formation of a little gas at 400° which is an equal mixture of carbon dioxide and monoxide and ethylene. Adkins[1] says that "pure acetone passed over heated freshly prepared alumina forms condensation products, only about 60% of the acetone passing through unchanged. No gaseous products are formed." With copper–alumina at 650° Mailhe[10] obtained a gas containing 15% carbon monoxide, 30% methane and 55% hydrogen. Jacobsen[11] reported the formation of aromatic hydrocarbons, among them triethylbenzene, by treatment of methyl ethyl ketone with sulfuric acid but later work has shown that homologs of mesityl oxide and phorone only are produced by the catalytic condensation of methyl ethyl ketone.[12] Petrow[13] has shown that under conditions of high temperature and pressure homologs of mesityl oxide and isophorone are formed with only a trace of triethylbenzene.

Acetophenone condenses to s-triphenylbenzene in the presence of various catalytic agents at room temperature;[14] or simply by long refluxing.[15]

Under conditions of high temperature and pressure, with alumina, triphenylbenzene, among numerous other materials, is produced.[16]

In the present investigation the decomposition of acetone, methyl ethyl ketone, and acetophenone has been studied in the presence of silica gel—particularly in connection with the condensation products formed.

Results

At atmospheric pressure and a temperature of 400–550° in the presence of silica gel the main condensation product of acetone is mesitylene, with a relatively small proportion of mesityl oxide, phorone, etc. At 500° a 17% yield of mesitylene is obtained. Silica gel seems to be the only dehydrating catalyst which in the gaseous phase converts acetone to mesitylene at ordinary pressures. Under conditions of high temperature and pressure silica gel also acts as an effective condensation catalyst. These conditions, however, favor the formation of high-boiling ketonic condensation products at the expense of low-boiling products including mesitylene. It is to be expected that high pressure would disfavor the mesitylene reaction since in this there is an increase in the number of molecules.

The method described here is advantageous for the preparation of mesitylene. The latter is readily isolated from the condensation product by washing with water and 70% alcohol, drying over calcium chloride and distilling, the fraction boiling between 130–190° being collected. The light-yellow oil thus obtained may be dried over sodium, which also effectively removes ketonic impurities, and subsequent fractionation yields a pure white oil of a high degree of purity.

The primary products in the homogeneous unimolecular decomposition of acetone are ketene and methane. The ketene then decomposes bimolecularly to ethylene and carbon monoxide.[17] In the presence of silica gel at 460° the highest percentage yield of ketene produced was 4.4%, 65% of the acetone used being decomposed. The gas evolved at this temperature contained 9% carbon monoxide, 17% methane, 28% carbon dioxide, 40% unsaturated hydrocarbon and 3% hydrogen. These facts show that the homogeneous decomposition of acetone in the presence of silica gel is taking place to only a minor extent at the temperature employed.

The presence of a small amount of methylacetylene in the gaseous products would indicate that the mechanism of the formation of mesitylene is dehydration of the acetone to methylacetylene and polymerization of the latter. Sabatier and Kubota[18] have assumed that the formation of mesitylene from allyl alcohol involves the intermediate formation of

[16] Ipatiew and Petrow, *Ber.*, 60, 1956 (1927).

[17] Rice and Vollrath, *Proc. Nat. Acad. Sci.*, 15, 702 (1929).

[18] Sabatier and Kubota, *Compt. rend.*, 173, 17 (1921).

methylacetylene. The fact that acetone passed over magnesium powder at a red heat produces magnesium methylacetylide[19] shows that such a decomposition may occur.

Experiments so far, however, have not substantiated this deduction, for upon passing methylacetylene, produced from alcoholic potassium hydroxide and propylene bromide, over silica gel at temperatures between 400–500°, no mesitylene was isolated from the condensation product.

Methyl ethyl ketone does not condense to triethylbenzene in the presence of silica gel. Ketonic condensation products only are produced. This is in agreement with facts concerning the liquid phase condensation of the ketone—although sulfuric acid is effective in condensing acetone to mesitylene it will not convert methyl ethyl ketone to triethylbenzene. Furthermore, a comparison of the gaseous decomposition products of acetone and methyl ethyl ketone indicates that the two reactions are of a strikingly different nature.

Acetophenone, in the presence of silica gel, condenses in a manner similar to acetone, s-triphenylbenzene being formed.

Experimental

The apparatus employed was similar to that used in the work described in the preceding article.[20] The catalyst was 100 g. of activated silica gel.

Acetone Condensation Products.—An examination of the condensation product indicated that it consisted for the most part of water, unchanged acetone and mesitylene with small proportions of mesityl oxide, phorone, etc. An idea of the relative amounts of the constituents may be obtained by the results of a typical first fractionation (run at 430°): total condensation product 14 g.: 110–160°, 2 g.; 160–170°, 7 g.; 170–180°, 2 g.

The product from the acetone was washed with water, the upper layer separated, dried over calcium chloride, and distilled in a long-necked Claisen flask. The boiling point rose rapidly to 160° and the fraction boiling between 160 and 170° was taken as mesitylene.

The mesitylene was identified as the trinitro derivative.[21] Nitration of the fractions below and above 160–170° showed that they contained considerable mesitylene.

Although the mesitylene fraction was taken between a fairly wide range, ten degrees, the fact that the lower and higher fractions contained considerable of the hydrocarbon would indicate that it is not over-estimated—although, undoubtedly, the ten degree fraction is not pure mesitylene. The yields of mesitylene are indicated in Table I.

TABLE I

YIELDS OF MESITYLENE

Temp., °C.	Acetone used, g.	Rate of flow, cc./min.	Yield, g.	Yield, %
430	80	0.90	4.30	7.8
450	80	.75	6.65	12.0
500	40	...	3.82	13.9
500	40	.75	4.72	17.2
500	40	.75	3.40	12.4
500	120	1.00	10.40	12.6
500	120	0.75	11.71	14.2
500	80	.65	7.60	13.8
550	80	.75	6.59	11.9

Condensation products other than mesitylene were further fractionated and examined. The results are summarized in Table II.

TABLE II

OTHER CONDENSATION PRODUCTS

Fraction	Density, 25/25 Determined	Density, 25/25 Ipatiew and Petrow	Chief constituent	Density, 25/25 Pure compound
127–131°	0.828	0.828	Mesityl oxide	0.854
162–167°	.861	.857	Mesitylene	.862
192–200°	.891	.871	Phorone	.877
205–210°	.918	.896	Isophorone	.925
248–253°	.941	.922	Xylitone	$.936_4^{16}$

Mesityl oxide was further identified as the semicarbazone. Attempts to prepare the bromination product of the phorone (liquid) and the semicarbazone of the isophorone fractions were unsuccessful.

The mesitylene and xylitone fractions were only slightly soluble in 70% alcohol, while the others were readily soluble.

Experiments were performed under conditions of high temperature and pressure with silica gel, using the technique and equipment described by Herndon and Reid,[22] the products being treated as in the experiments at atmospheric pressure. The results of the first fractionation of the product obtained (50 cc. of acetone was heated for two hours with 5 g. of activated gel in bombs of 100-cc. capacity) are as follows

	At 350°, g.	At 400°, g.	At 350° without catalyst, g.
Acetone used	160	192	160
Fraction 100–160°	11	7	4
Fraction 160–170°	10	5	1
Fraction 170–220°	6	13	2
Residue	13	20	4

At 350° a small amount of gaseous products was formed.

[22] Herndon and Reid, THIS JOURNAL, 50, 3065 (1928).

Unchanged Acetone and Ketene.—Unchanged acetone and ketene were estimated as follows. A suitable aliquot of the aqueous condensation product, collected in two traps immersed in ice–salt baths and washed into a volumetric flask, was titrated with standard sodium hydroxide for acetic acid and from this the proportion of ketene calculated. Any ketene escaping the receivers was bubbled into a flask containing hot water (to decrease the solubility of the carbon dioxide) and estimated as before by titration. The unchanged acetone was determined by adding an excess of hydroxylamine hydrochloride to a second aliquot part and titrating the liberated hydrochloric acid with standard sodium hydroxide,[23] a correction being made for the acetic acid formed from the ketene.

Gaseous Products.—The gaseous products from the reaction were analyzed in an Orsat–Williams apparatus—the gases being collected over water saturated with the gas. Representative analyses of the gases produced are indicated in Table IV. Saturated hydrocarbon was calculated as methane.

TABLE IV

REPRESENTATIVE ANALYSES

Temp., °C.	*Acetone,* *g.*	*Rate of flow,* cc./min.	*Gas* evol., *cc.*	*Percentages*				
				CO_2	Unsat.	*CO*	H_2	CH_4
400	20.0	0.66	550	24.0	46.6	7.4	0	16.7
470	6.0	.66	400	28.0	40.0	9.2	3.2	17.0
450	8.0	.66	460	27.0	45.2	7.4	2.6	11.9
500	4.0	.66	350	26.8	44.7	7.5	3.0	
500	4.0	.66	400	25.0	43.5	8.7	2.7	

The presence of an acetylene hydrocarbon was thus shown: (1) a white precipitate was formed with mercuric sulfate acidified with sulfuric acid, (2) a cuprous salt was formed, soluble in ammoniacal ammonium chloride

---

[23] Allen, "Commercial Organic **Analysis,**" 5th ed., 1923, Vol. I, p. 124.

(cuprous methylacetylide), (3) a silver salt was produced upon passing the gas through ammoniacal silver nitrate. The salts were decomposed by hydrochloric acid, evolving an unpleasant smelling gas.

Methyl Ethyl Ketone Condensation Products.—Upon passing the ketone over silica gel at 500° an oil insoluble in water, comparable in amount to that produced by acetone, was obtained.

From 140 g. of methyl ethyl ketone over 100 g. of commercial gel, at 500°, at the rate of 1.2 cc. per minute the following fractions were obtained: 110–145°, 1.9 g.; 145–160°, 1.2 g.; 160–170°, 0.8 g.; 170–210°, 1.6 g.; 210–220°, 1.5 g.; 220–300°, 4.9 g.; residue 5 g.

Heating 160 g. of the ketone in bombs, as in the acetone experiments, at 350° for two hours yielded the following fractions of condensation product, very little gas being formed: 110–150°, 1.2 g.; 150–170°, 8.5 g.; 170–205°, 7.5 g.; 205–225°, 3.5 g.; residue, 10 g. After further fractionation densities were determined:

Temp., °C.	Density 25/25 Determined	Density 25/25 Petrow	Chief constituent
160-167	0.854	0.8534	*Homo-mesityl oxide (peppermint-like odor)*
205-220	.877	.9048	*Homo-phorone*
238-248	.919	.9435	*Homo-isophorone*
260-270	.939	.9492[a]	*Homo-isophorone*

[a] Density 20/4, Ekeley and Howe.

Any triethylbenzene obtained would be in the second fraction. Repeated attempts to nitrate portions of this material with a mixture of equal parts of nitric and sulfuric acids (heating for twenty minutes) were futile. In a few cases a few crystals, too few to handle, were obtained. Unsuccessful attempts were made to nitrate all fractions of the product.

Most of the product was soluble in 70% alcohol, which also indicates that the product consists mostly of ketonic substances similar to mesityl oxide and phorone.

Unchanged methyl ethyl ketone was estimated as in the acetone experiments. The results at 500° using 3.94 g. of the ketone are summarized.

Time, min.	Ketone undecomposed	% Decomposition
18.5	1.29	67.2
16.0	1.27	67.6
17.0	1.39	64.7
17.5	1.34	66.1

Gaseous Products.—The results of the analyses of the gaseous products are indicated in Table V.

Acetophenone.—Passing 156 g. of acetophenone over 100 g. of commercial gel at 500°, at the rate of 0.5 cc. per minute, produced 12 g. of s-triphenylbenzene (9.8% yield).

The product from the acetophenone experiments was distilled directly

TABLE V

RESULTS OF ANALYSES

Temp., °C.	Ketone used, *g*	Rate of flow, *cc* /min.	Gas evol , *cc*	Percentages				
				CO_2	Unsat.	CO	H_2	CH4
500	4.05	0.66	275	15 5	15	12	2 2	30
500	405	.66	300	222	17.3	16.5		
				20.2	164			

until unchanged acetophenone was almost completely removed, The residue was washed with 90% alcohol, dissolved in benzene, filtered, the benzene removed by evaporation and the product taken up in ether. By spontaneous evaporation large, dark yellow crystals were obtained; these were removed while a good deal of mother liquor was still present, washed with dilute alcohol, and recrystallized from acetic acid. Several recrystallizations yielded a pure sample of triphenylbenzene, which was further identified as the monobromo derivative.

Upon heating acetophenone in the bombs at 350° a great variety of products was obtained. No triphenylbenzene was isolated from the viscous high-boiling fraction following the procedure previously described or after fractionation of the material under high vacuum.

Summary

1. The principal condensation product of acetone, in the presence of silica gel at 400–550°, is mesitylene. This is the only catalyst that has effected this reaction at atmospheric pressure. The yields of rnesitylene are comparable to those obtained by any other method.
2. It is suggested that the mechanism of the reaction involves dehydration of acetone to methylacetylene with subsequent polymerization of the latter to mesitylene. Experiments so far, however, have not substantiated this.
3. An analogous reaction does not take place with methyl ethyl ketone to an appreciable extent.
4. An analogous reaction takes place with acetophenone, yielding *s*-triphenylbenzene.

THE DECOMPOSITION OF ACETIC ACID IN THE PRESENCE OF SILICA GEL

BY JAMES A. MITCHELL AND E. EMMET REID

RECEIVED NOVEMBER 14, 1930 PUBLISHED JANUARY 12, 1931

The decomposition of acetic acid under the influence of various basic dehydrating catalysts has been well investigated, particularly in connection with the production of acetone, an excellent example of an "intermediate compound" catalytic reaction.

Chemically inert catalysts have been studied to some extent. Nef[1] observed that a high percentage of carbon monoxide was formed when acetic acid was passed over pumice at 500° and identified acetone as a minor product. Finely divided copper is also effective in converting acetic acid to acetone.[2] Senderens and Aboulenc,[3] upon passing acetic acid over charcoal, found that the gases produced contained 21.5% carbon dioxide and 35.5% carbon monoxide. The liquid product contained traces of ketone and aldehyde. Senderens[4] observed that when acetic acid was passed over precipitated silica, at 420°, among other materials, a gas was produced containing 90% carbon dioxide.

Kultashev and Kudryasheva[5] reported that over charcoal at 300° appreciable decomposition of acetic acid occurred, increasing with rise in temperature, acetone and methane being two of the products.

Results

In passing acetic acid over silica gel the maximum yield of acetone is obtained at 430–460° (about 29%). Above this temperature the increased amount of acetone decomposed more than offsets the increased amount of acetone formed. Above 400° appreciable decomposition of the acetone formed becomes noticeable. A small amount of an insoluble oil is obtained similar to that produced in the decomposition of pure acetone. Results are summarized in Table I.

In Experiments 19–24 aqueous acetic acid was used. It is evident that with aqueous acid a greater proportion of the decomposed acid is obtained as acetone. This would indicate that the proportion of water vapor present influences the rate of decomposition of the acetone—in accord with the results of Kultashev and Kudryasheva.[5] In Experiments 25–26 the same catalyst was used with glacial acetic acid.

The acid used in each experiment was 5.114 g. Experiments 1–9, using commercial gel, catalyst **A,** cover a larger number of experiments and the last results therefore represent those obtained after considerable use of the catalyst. In Experiments 10–18 a fresh charge of commercial gel was used, catalyst B. In Experiments 19–24 aqueous acetic acid was used; 19 and 20 contained 4.0%; 21–23, 8.0%; 24, 2.0% water by weight. Experiments 25 and 26 were run on the same catalyst using glacial acetic acid. Experiments 27-31 were run on a sample of electrolytically purified gel after a short period of activation, namely, one hour at 200° and one hour at 450°, catalyst C. Experiments 32–34 were run on purified gel after the usual period of activation, catalyst D.

Purified gel and commercial gel are equally effective catalysts in the formation of acetone (Experiments 32–34).

Experiments 27–31, using gel activated for a short time, clearly indicate that the conditions of activation of the catalyst considerably influence its activity. Experiments 27–29 show that as the rate of passage of the acid is increased, although the actual yield of acetone is decreased, the yield based on the acid decomposed is increased—hurrying the material through the tube greatly decreases the amount of acetone decomposed.

The activity of the catalyst slowly decreased with use as appears from the results of Experiments 1–9, which cover a catalyst that had been used for quite a time. In this connection it is interesting to note that the gel is almost immediately blackened in this reaction, while in the nitrile reaction—using ammonia and acetic acid—at the same temperatures,[6] blackening of the gel takes place very slowly. The shining, jet-black gel is so completely impregnated with carbon that it cannot be burned out except on the outer surface at a red heat in a current of oxygen.

It is possible for acetic acid to decompose in two ways, in both of which carbon dioxide is produced

$$2CH_3COOH = CH_3COCH_3 + CO_2 + H_2O$$
$$CH_3COOH = CH_4 + CO_2$$

The results indicated in Table II, which involve the precise determination of carbon dioxide liberated in the reaction, clearly indicate that not all of the carbon dioxide liberated is obtained from the acetone reaction—some is obtained from the splitting of acetic acid into methane and carbon dioxide.

TABLE II

RESULTS OF EXPERIMENTS

No.	Catalyst	Temp., °C.	Weight of carbon dioxide, g.
1	A	400	0 880
2		450	1.116
3		450	1.206
4		450	1.161
5	B	500	1.508
6		500	1.130
7	C	300	0.000
8		350	.050
9		380	.386
10		400	.428
11	D	450	.580
12		500	1.285
13		500	1.046

Acetic acid (4.78 g. in each experiment) was passed over the gel at the rate of 0.2 cc. a minute. In order to make a correction for any carbon dioxide liberated in the decomposition of the acetone formed, blanks were run on pure acetone and the following corrections were subtracted from the amount of carbon dioxide found: at 400°, 0.024 g.; 450°, 0.044 g.; 500°, 0.054 g. The values given in the table are these corrected values.

---

[6] Mitchell and Reid, **THIS JOURNAL**, 53, 321 (1931).

Experiment 6 was run after a large amount of acid (100 cc.) had been passed over the gel of Experiment 5.

Considering average results, a summary is made in the following table.

Temp., °C.	Acetone obtained, %	Methane produced if no acetone decomposed. %	HAc actually decomposed, %	Decomp. acid to acetone, %
400	14	18	37	65
450	28	19	65	85
500	24	28	81	90

The figures under "acetone obtained" are taken from Column 6 of Table I. Those in the next column are calculated from Table II by assuming that no acetone is decomposed after it has once been formed—the carbon dioxide corresponding to 14, 28 and 24% acetone being subtracted from the total carbon dioxide evolved, the remainder indicating the methane produced. It is evident that the sum of the figures of the second and third columns should equal the amount of acetic acid known to be decomposed, which was determined by titration (Table I). The difference between this sum and the acetic acid actually decomposed and the fact that the acetone reaction involves two molecules of acetic acid, whereas the methane reaction involves only one, makes it possible to estimate the amount of acetone decomposed under the conditions of the experiments and also, of course, the extent of the methane reaction.[7]

The conclusion is reached that 40 to 60% of the acetone originally formed in the reaction is decomposed—more, of course, being decomposed at the higher temperature. The acetone reaction is the predominant one. The estimate of the fraction of decomposed acid that is converted to acetone is given in the last column of the table.

This is in fair accord with the observation that acetone is decomposed to a similar extent in the presence of silica gel, using comparable rates of flow.

A comparison of the analyses of the gaseous products in the passage of acetic acid (Table 111), and acetone[8] over silica gel clearly indicates that the methane reaction is occurring to some extent—and the results agree in a general way with conclusions already deduced. Moreover, the analysis of the gases from acetic acid shows (1) that at lower temperatures the gas is richer in carbon dioxide (less acetone is decomposed), (2) that the amount of carbon dioxide evolved (and therefore acetone formed) decreases as the catalyst is used. Experiment 6, Table II, which was run on the

---

[7] The decomposition into ketene and water would probably not occur to any great extent at these temperatures—Hurd and Martin, THIS JOURNAL, 51, 3614 (1929). Any attempt to estimate the extent of this reaction by isolating the ketene, or estimating acetic anhydride formed, would be meaningless as ketene is also formed from the decomposition of the acetone. In fact, it may not be unreasonable to suppose that the formation of acetone is the intermediate step in the decomposition of acetic acid to ketene.

[8] Mitchell and Reid, *ibid.*, 53, **330** (1931).

same catalyst as in 5, passing 100 cc. of acid between experiments, precisely confirms this observation.

TABLE III

EXPERIMENTAL DATA

Temp., °C.	Acid used, g.	Rate of flow cc./min.	Gas evol., cc.	Percentage of— CO_2	Unsat.	CO	O_2	H_2	CH_4

500	2.10	.80	..	38.0	3.8	25.6	0.2	9.4	22.7
425	5.25	.56	175	63.0	8.5	6.5			20.0
460	3.15	.50	375	45.5	5.0	9.5			

Senderens' analysis[4] of the gaseous product obtained in passing acetic acid over precipitated silica, at 420°, indicated that it consisted of 90% carbon dioxide, and as the other 10%, consisting of carbon monoxide and a little ethylene, could be considered as decomposition products of the acetone produced, he concluded that the methane reaction did not occur.

The fact that silica gel, a chemically inert catalyst, is so effective in the conversion of acetic acid to acetone (85% of the acetic acid decomposed being converted into acetone) is hardly to be expected from the intermediate compound theory.

Experimental

The apparatus employed was similar to that described in the preceding article.[8] The catalyst, 100 g. of silica gel, was activated by heating for three hours at 210° and three hours at 450–500° in a slow current of air, dried with calcium chloride. A weighed quantity of the acid was passed through the dropping arrangement, through a capillary, and thence over the gel, through a condenser cooled by a rapid current of water and the product collected in a receiver immersed in carbon dioxide snow. An all-glass apparatus was employed—eliminating all rubber connections as well as "pockets" in which acid or product might be trapped. After passing the acetic acid over the catalyst the apparatus was swept out with nitrogen. The product was washed into a 50-cc. volumetric flask, a 2-cc. aliquot titrated for acetone by Messinger's method[9] and a 5-cc. aliquot titrated for unchanged acid with standard sodium hydroxide.

The exact determinations of carbon dioxide were made by passing the gases evolved from a weighed portion of acid through a condenser, an ice–salt trap, a small bubble tube containing water, a carbon dioxide snow–acetone trap, drying tubes and weighed soda-lime tubes. The tubes were brought to constant weight before and after the run, using a current of dried nitrogen.

---

[9] Scott, "Standard Methods of Chemical Analysis," Vol. II, p. 1537, 1922.

The gas produced was analyzed in an Orsat–Williams apparatus, being collected over water previously saturated with the gas. The saturated hydrocarbon was calculated as methane.

Summary

The decomposition of acetic acid in the presence of silica gel at a temperature range of 400–500° has been studied.

Silica gel is an effective catalyst for the conversion of acetic acid to acetone. At least 85% of the acetic acid decomposed in the presence of silica gel produces acetone.

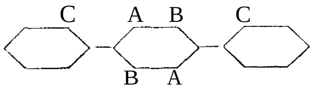
STEREOCHEMISTRY OF DIPHENYLBENZENES. MESO AND RACEMIC 2,5-DI-(3-BROMO-2,4,6-TRIMETHYLPHENYL)-3,6-DIBROMOHYDROQUINONES AND THE CORRESPONDING QUINONES. XII.[1]

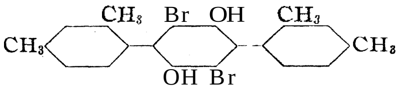
By P. R. Shildneck[2] and Roger Adams

Received November 17, 1930 Published January 12, 1931

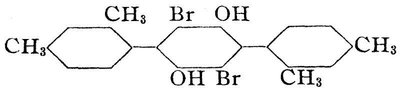
The possibility for the existence of a meso and a racemic modification of substituted 1,4-diphenylbenzenes of type (I) was demonstrated by isolation of two stereoisomeric 2,4-di-*m*-xylyl-3,6-dibromohydroquinones (IIa and IIb).[1b]



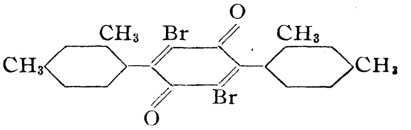
I



IIa



IIb



III

The two compounds formed two individual series of derivatives but oxidized to the same quinone (III). The quinone, in turn, upon reduction always gave a mixture of the two hydroquinones (IIa and IIb).

It was pointed out in the article describing these substances that on the basis of x-ray data and on the assumption that the quinone ring was essen-

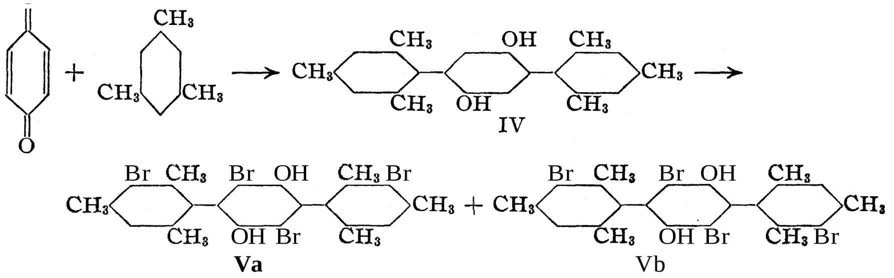
[2] This communication is a portion of a thesis submitted by P. K. Shildneck in partial fulfilment of the requirements for the Degree of Doctor of Philosophy in Chemistry at the University of Illinois.

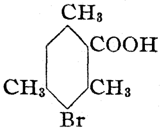
tially similar in character to the benzene ring, it might not be expected that two quinones would exist. The interference values indicated that in the quinone, although there would be collision between the methyl and the bromine groups, there would be none between the methyl and C=O groups and therefore free rotation would not be prevented.

In this investigation the study of diphenylbenzenes has been extended in order to demonstrate that isomerism of this type is general. Compounds have been selected which have at each of the linkages of the benzene rings, the four ortho positions substituted. Under these conditions not only should two stereoisomers exist as found in the trisubstituted compounds but if the proper groups are present, x-ray data lead to the conclusion that two stereoisomeric quinones are possible. Results have fully substantiated these predictions.

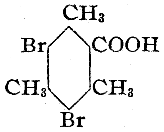
Mesitylene was added to *p*-benzoquinone and the resulting dimesitylhydroquinone (IV) was treated with four moles of bromine. Two isomeric tetrabromo compounds (Va and Vb) were readily isolated, each of which formed a characteristic diacetate. Although by the method of bromination (bromine in chloroform) it was very unlikely that two bromines could have entered a single mesitylene nucleus, nevertheless further information concerning the positions of the bromines in the two forms seemed desirable in order to be certain that two stereoisomeric compounds were in hand. Each of the two tetrabromo derivatives was oxidized with hydrogen peroxide and sodium hydroxide. There was formed first a deeply colored solution of quinone which gradually, after a long period of time, became nearly colorless. There was isolated as a result monobromomesitylcarboxylic acid (VI) in each instance. If the four bromines were not distributed with two in the inner ring and one in each of the outer rings in each molecule, part of the product should have been dibromomesitylcarboxylic acid (VII). No trace of this latter compound was found. Monobromomesitylcarboxylic acid and dibromomesitylcarboxylic acid were prepared by other methods and the latter was shown to be distinctly less soluble in water than the former. As a consequence the presence of any dibromo compound in a mixture of mono and dibromo should easily have been detected. The



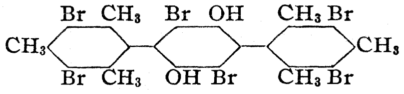
monobromo compound, however, was essentially pure as received from the reaction mixture, though the yield was low, as might be expected from an oxidation reaction of this type.



VI



VII

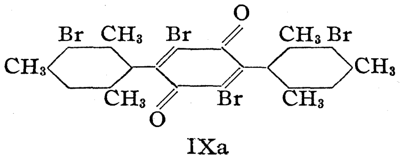


VIII

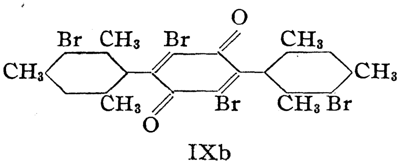
The two isomeric tetrabromohydroquinone derivatives (Va and Vb) upon treatment with liquid bromine yielded the same hexabromo derivative (VIII). This is of interest since it confirms the fact that the stereoisomers will exist only if each of the two end rings is asymmetrically substituted. The hexahromo derivative was then oxidized with hydrogen peroxide and sodium hydroxide. The reaction progressed in a fashion similar to the analogous oxidations of the two isomeric tetrabromo derivatives and pure dibromomesitylcarboxylic acid was isolated. Moreover, the hexabromo compound readily forms a diacetate and on oxidation the corresponding quinone.

All attempts to prepare the hexabromo derivative other than by the action of liquid bromine on the finely powdered tetrabromo derivatives failed. Likewise all attempts to prepare dibromomesitylcarboxylic acid by bromination of the monobromomesitylcarboxylic acid in solvents such as chloroform, carbon tetrachloride and glacial acetic acid failed. It was readily prepared by treating the solid monobromomesitylcarboxylic acid with liquid bromine. These facts indicate the unlikelihood of two bromines entering the mesitylene nucleus when the dimesitylhydroquinone was brominated in chloroform solution and further substantiate the contention that the two isomeric tetrabromo derivatives are stereoisomeric.

These two tetrabromodimesitylhydroquinones are of significance, not only because they represent a second example of stereoisomerism in the diphenylbenzene series, but because, unlike the two dibromodixylylhydroquinones which on oxidation give the same quinone, each upon oxidation yields an individual quinone (IXa and IXb). The two quinones differ from each other in solubility, melting point and other properties. The



IXa



IXb

two quinones are, in turn, readily reduced back quantitatively each to its respective hydroquinone (Va and Vb). These two quinones, therefore, represent the first instance in which isomerism of the diphenyl type has been discovered in molecules containing two rings one or the other of which is not a benzene nucleus. Which of the two quinones or hydroquinones is the meso and which the racemic is yet to be determined.

Experimental

2,5-Dimesitylhydroquinone (IV).[3]—In a 1-liter three-necked flask equipped with a mechanical stirrer and thermometer and surrounded with a freezing mixture of ice and salt was placed 700 cc of mesitylene (b. p. 164–168°). Stirring was started and when the temperature reached 0°, 150 g. of finely powdered anhydrous aluminum chloride was added at once. The suspension developed a deep red color.

Thirty grams of finely pulverized dry *p*-benzoquinone (purified by steam distillation) was added in 1-g. portions as rapidly as possible without permitting the temperature to rise above 5°. The well-stirred mixture became noticeably viscous and the original red color changed to brown. Stirring was continued for fifteen minutes longer and then 20 g. more of quinone was added as before, keeping the temperature below 5°. The mixture then became so viscous that continued stirring soon rolled up balls of brown gummy material in the excess mesitylene. Stirring was continued for three hours thereafter and then the flask with its contents was permitted to come slowly to room temperature overnight.

The excess mesitylene was decanted and the semi-solid residue decomposed in a mixture of 300 cc. of concentrated hydrochloric acid, 500 cc. of water and 500 g. of ice. The nearly white product was filtered with suction and washed with 3 N hydrochloric acid followed by hot water. The weight of air-dried crude product amounted to 40 g. Two crystallizations (with norite) from benzene gave 30 g. of pure white crystalline material melting at 225–226° (corr.).

The mesitylene was separated from the filtrate, combined with that previously decanted and steam distilled. In this way 600 cc. of pure mesitylene boiling at 164–168° was recovered. A residue of 45 g. of tarry material from the mesitylene and the mother liquors from the crystallizations yielded an additional 12 g. of pure material, making a total yield of 42 g.

Anal. Calcd. for $C_{24}H_{26}O_2$: C, 83.19; H, 7.57. Found: C, 82.97; H, 7.63.

Stereoisomeric **2,5-Di-(3-bromo-2,4,6-trimethylphenyl)-3,6-dibromohydroquinones (Va)** and (Vb). Form (α).—In a 500-cc. three-necked flask equipped with a thermometer, reflux condenser and 250-cc. separatory funnel was placed 25 g. of 2,5-dimesitylhydroquinone and 75 cc. of chloroform. The mixture was heated to effect solution. The solution was allowed to cool to 50° and through the separatory funnel was then added a solution of 52 g. of bromine in 150 cc. of chloroform dropwise at such a rate that the temperature was maintained at 50–60°. At first the solution decolorized after each drop of bromine and heat was evolved. After about one-fourth of the bromine had been added the rate of absorption became slower and the temperature dropped. The reaction mixture was then gently refluxed and the remainder of the bromine added over a period of one hour. Refluxing was continued for one hour longer, during which time a heavy, crystalline precipitate appeared.

The reflux condenser was tilted dowuward and all but a few cc. of the chloroform distilled off; 250 cc. of fresh chloroform was added and distilled off as before, this time distilling to dryness on the steam-bath. The dry yellowish solid material in the flask was dissolved in 2 liters of acetone by refluxing for one-half hour. Then 2 g. of norite and 0.5 g. of powdered stannous chloride were added and refluxing was continued for

---

[3] This compound was first made and analyzed by W. W. Moyer and described in his Ph.D. dissertation at the University of Illinois, June, 1929.

fifteen minutes longer. After a rapid filtration, the product separated on cooling. It was twice recrystallized from acetone, when it was obtained pure in the form of large rectangular prisms containing acetone of crystallization. The crystals effloresced to a white powder which when dry melted at 334–335° (corr.) with slight decomposition.

The filtrate from the original acetone crystallization was concentrated to 750 cc. and again cooled to room temperature. The crop of white prisms was filtered off (weight 2.5 g.) and the filtrate again concentrated to 250 cc. Upon cooling to room temperature and standing for several hours a third crop (1 g.) of white prisms was obtained. The two crops were combined and crystallized from 200 cc. of fresh acetone. About 2.8 g. of the α-form melting at 331–333° (corr.) was thus obtained.

Form (β).—The above filtrate of 250 cc. containing the more soluble material, was cooled to −10° in a freezing mixture. A white, fluffy precipitate appeared, quite different in appearance from the dense, granular less-soluble material. So soluble was this second material that it was found necessary to crystallize it from a mixture of acetone and water. For that purpose the acetone solution (250 cc.) was boiled for a few minutes with 1 g. of norite and 0.5 g. of powdered stannous chloride under the reflux, quickly filtered, heated again to boiling and hot water added a few cc. at a time until a permanent turbidity remained. Even from the hot solution a heavy precipitate of minute, shining flakes gradually appeared. The mixture was cooled to 0° and filtered. The crystalline precipitate was washed with 50% alcohol and dried. The yield amounted to 13 g. and the material melted at 292–294° (corr.).

The filtrate from this last crystallization was again heated to boiling and hot water added to the turbidity point as before. An additional 4.5 g. of product melting at 290–293° (corr.) was thus obtained. The last filtrate poured into an equal volume of water yielded 1.5 g. of less pure product.

The first two fractions were combined and recrystallized from a mixture of acetone and water as previously described, using, however. only 125 cc. of acetone. Thus 14.5 g. of pure material melting constant at 294–295° was obtained.

Analysis of substance melting at 334–335°: a-form (Parr bomb). Calcd. for $C_{24}H_{22}O_2Br_4$: Br, 48.31. Found: Br, 48.16.

Analysis of substance melting at 294–295°: β-form (Parr bomb). Calcd. for $C_{24}H_{22}O_2Br_4$: Br, 48.31. Found: Br, 48.10.

The difference in solubility in acetone of the a-form and β-form is marked. A conservative estimate would place the ratio of solubilities in acetone at room temperature at fifty to one. There is also a similar difference in solubility in ethyl alcohol and toluene. Both of the forms crystallize from 95% ethyl alcohol in colorless flat prisms. From toluene the more soluble β-form crystallizes readily in long, slender needles, while the less soluble a-form dissolves with difficulty in boiling toluene and crystallizes with equal difficulty in very short needles.

2,5-Di-(3-bromo-2,4,6-trimethylphenyl)-3,6-dibromohydroquinone Diacetate (or-Form).—A solution of 5.0 g. of the higher-melting tetrabromohydroquinone (α-form) was made in 25 cc. of boiling pyridine. To this was added 25 cc. of acetic anhydride and the mixture was refluxed for thirty minutes. A white crystalline precipitate appeared during the refluxing. The mixture was then cooled, filtered, and washed with water. Upon purification from 85 cc. of pyridine a yield of 4.7 g. of small white prisms melting at 285–286° (corr.) without decomposition was obtained.

Anal. (Parr bomb). Calcd. for $C_{28}H_{26}O_4Br_4$: Br, 42.87. Found: Br, 42.70.

2,5-Di-(3-bromo-2,4,6-trimethylphenyl)-3,6-dibromohydroquinone Diacetate (β-Form).—This substance was made in the same way as the acetate of the a-form using **5** g. of the a-hydroquinone, **10** cc. of acetic anhydride and **5** cc. of boiling pyridine. Crystallization of the 5 g. of crude reaction product from 10 cc. of pyridine yielded a pure compound melting at 237–238° (corr.) without decomposition.

The solubility of this diacetate in boiling pyridine is from eight to ten times greater than that of the diacetate of the a-form.

Anal. (Parr bomb). Calcd. for $C_{28}H_{26}O_4Br_4$: Br, **42.87.** Found: Br, **42.81.**

Stereoisomeric **2,5-Di-(3-bromo-2,4,6-trimethylphenyl)-3,6-dibromoquinones (IXa)** and **(IXb).** a-Form.—A solution of **5.0** g. of the a-form of the hydroquinone in 1-liter of boiling 95% ethyl alcohol was treated with **5** g. of benzoquinone and the mixture refluxed for one-half hour. During this time the orange, crystalline a-quinone appeared. After distilling **750** cc. of alcohol from the reaction mixture on the steam-bath, it was cooled and filtered. The product was washed free of benzoquinone with two 15-cc. portions of cold ethyl alcohol and dried in air. The yield amounted to **4.6** g. of product which melted at 295–296° with decomposition. Recrystallization from toluene did not alter the melting point. The quinone was readily soluble in cold pyridine, moderately soluble in hot toluene, sparingly in boiling ethyl alcohol and insoluble in boiling methyl alcohol.

Anal. (Parr bomb). Calcd. for $C_{24}H_{20}O_2Br_4$: Br, **48.44,** Found: Br, **48.27.**

β-Form.—The oxidation was carried out in a manner similar to that of the a-form, except that for **5** g. of the lower-melting β-hydroquinone only **350** cc. of boiling **95%** ethyl alcohol and **5** g. of benzoquinone were used. About **200** cc. of alcohol was removed as the orange product crystallized. The yield was **4.6** g. and melted at 284–285° with decomposition. Recrystallization from toluene did not alter the melting point.

In appearance this quinone resembles the other. The two have approximately equal solubilities in toluene and both crystallize readily from that solvent in small orange prisms. **A** difference in solubility was found in ethyl alcohol, the β-quinone being the more soluble. Likewise in methyl alcohol the β-quinone was found sparingly soluble in boiling solvent whereas the a-quinone was practically insoluble in boiling methyl alcohol.

Anal. (Parr bomb). Calcd. for $C_{24}H_{20}O_2Br_4$: Br, **48.44.** Found: Br, **48.22.**

Reduction of a- and **β-Quinones.**—A solution of **2.0** g. of the a- or β-quinone in 10 cc. of boiling pyridine was treated with finely powdered stannous chloride until the pyridine solution became colorless. The reaction mixture was then thrown into excess of **3** *N* hydrochloric acid, warmed and filtered. The product was washed free of acid with water and air-dried. The yield was quantitative and amounted to **2.0** g.

The crude product from the α-quinone reduction was dissolved in **200** cc. of boiling acetone, filtered and concentrated to **100** cc. The solution was rapidly chilled in a freezing mixture and allowed to stand for one hour; **1.8** g. of a fine, white crystalline material was filtered off and air-dried. The substance melted at 334–335° (corr.) with slight decomposition and showed no depression in melting point when mixed with the original a-hydroquinone. The filtrate from the crystallization yielded about **0.2** g. of product which melted about **5** to **7°** lower.

The crude product from the β-quinone was recrystallized from acetone and water and gave white crystals melting at 294–295° with slight decomposition. **A** mixed melting point with the original β-hydroquinone showed no depression.

Oxidation of the a-Quinone with Hydrogen Peroxide and Sodium Hydroxide to **Monobromomesitylcarboxylic** Acid **(VI).**—The first step in the oxidation of the hydroquinones is the formation of quinones, consequently the complete oxidations were carried out with the quinones. To a solution of 6 0 g of the a-quinone in 250 cc. of 95% ethyl alcohol was added a cold solution of 50 g. of sodium hydroxide in 125 cc. of water. The mixture was stirred mechanically and 125 cc. of 30% hydrogen peroxide was slowly added. The flask was surrounded with running water to maintain the temperature at 10–20".

The quinone slowly went into a dark red solution, which changed to a light red in the course of six to eight hours. During the course of forty hours more the red color of the solution faded to a light pink and considerable sodium acetate crystallized out.

A cold solution of 25 g of sodium hydroxide in 50 cc. of water was added, plus 50 cc. more of 30% hydrogen peroxide and the reaction mixture stirred for twenty-four hours longer at room temperature. More sodium acetate crystallized out but the solution did not completely decolorize.

The sodium acetate was filtered off. To the filtrate was added 1 liter of water and an equal volume distilled off in order to remove the alcohol. The remaining pink solution was acidified with concd. hydrochloric acid. The mixture, which at this point contains a yellow flocculent precipitate, was diluted to a volume of 2 liters with water, boiled for a few minutes, then quickly filtered. From the clear colorless filtrate long silky needles appeared upon cooling. The filtrate was chilled to 0° and the white needles were filtered and dried. The yield amounted to 0 75 g. The crude product after three recrystallizations from water melted constantly at 168° (corr.).

Anal. (Parr bomb.) Calcd. for $C_{10}H_{11}O_2Br$: Br, 32.89. Found: Br, 32.81. Calcd. for $C_6H(CH_3)_3BrCOOH$: neut. equiv., 243. Found: 245.

Oxidation of the β-**Quinone** with Hydrogen Peroxide and Sodium Hydroxide to **Monobromomesitylcarboxylic Acid, (VI).**—Five grams of the β-quinone was oxidized in exactly the same manner as the α-quinone. The product was worked up in the same manner. There was isolated 0.80 g. of long silky needles which after three recrystallizations from water melted constantly at 168° (corr.). A mixed melting point with the acid obtained from the oxidation of the α-quinone showed no depression.

Anal. (Parr bomb). Calcd. for $C_{10}H_{11}O_2Br$: Br, 32.89. Found: Br, 33.02. Calcd. for $C_6H(CH_3)_3BrCOOH$: neut. equiv., 243. Found: 245.

Monobromomesitylcarboxylic Acid, **(VI).**—In a 1-liter, 3-necked flask equipped with a mercury-sealed mechanical stirrer, a dropping funnel and a reflux condenser, were placed 130.5 g. of mesitylcarboxylic acid,[4] 1 g. of iron filings and 250 cc. of carbon tetrachloride. One hundred thirty-five grams of bromine was placed in the dropping funnel, the stirrer started, the flask heated to an oil-bath temperature of 120–130°, and the bromine run in over a period of one-half hour. Stirring and heating were continued for an additional half hour, then the mixture was cooled and filtered. The product was treated with a solution of 200 cc. of hydrochloric acid in 300 cc. of water, again filtered, dissolved in an excess of 5% sodium hydroxide, filtered and the free acid obtained by acidifying this solution with hydrochloric acid. The product was recrystallized from carbon tetrachloride or better 50% alcohol and melted when pure at 168°. The yield was 112 g.

Anal. Calcd. for $C_{10}H_{11}O_2Br$: Br, 32.88. Found: Br, 32.40. Calcd. for $C_{10}H_{11}O_2Br$: neut. equiv., 243. Found: 244.

2,5-Di-(3,5-dibromo-2,4,6-trimethylphenyl)-3,6-dibromohydroquinone, (VIII).—Efforts were made to brominate further the ***a***- and β-forms of the tetrabromohydroquinones (Va) and (Vb) in chloroform, carbon tetrachloride and glacial acetic acid solutions without success. Liquid bromine gave the desired result?.

---

[4] Made according to the method of Bamford and Simonsen, J. Chem. *Soc.*, 97, 1906 (1910).

(A) Bromination of the **α-Hydroquinone.—Five** grams of the finely powdered a-hydroquinone was placed in a 500-cc. Kjeldahl flask and 15 cc. of liquid bromine added. After standing for six hours the excess bromine was removed with air and the light yellow solid residue in the flask was washed with 5% sodium bisulfite solution, filtered and washed with water. The air-dried product (6.2 g.) was then dissolved in 60 cc. of hot pyridine and refluxed for a few minutes with 1 g. of norite and 0.25 g. of powdered stannous chloride. White granular crystalline material was obtained which was recrystallized from 50 cc. of fresh pyridine. The yield of product from this second crystallization amounted to 4.0 g. and the substance melted constantly at 395–398° (obs.) on the Bloc Maquenne.

Anal. (Parr bomb). Calcd. for $C_{24}H_{20}O_2Br_6$: Br, 58.51. Found: Br, 58.24.

(B) Bromination of the **β-Hydroquinone.—Five** grams of the β-hydroquinone was brominated in exactly the same manner as the α-hydroquinone. The reaction product was purified in the same way; 4.1 g. of purified product melting at 395–398° (obs.) on the Bloc Maquenne was obtained. A mixed melting point with the brominated a-hydroquinone showed no depression.

Anal. (Parr bomb). Calcd. for $C_{24}H_{20}O_2Br_6$: Br, 58.51. Found: Br, 58.19.

In order to make certain of no mistake, the bromination products of both the α- and @-hydroquinones were kept separate and converted independently to the diacetates and quinones. In each case identical products resulted.

2,5-Di-(3,5-dibromo-2,4,6-trimethylphenyl)-3,6-dibromohydroquinone **Diacetate.**—One gram of the hexabromo compound from the α- or β-tetrabromo compound was acetylated by refluxing with 10 cc. of pyridine and 10 cc. of acetic anhydride for thirty minutes. During the refluxing period the product crystallized from the boiling reaction solvent. The mixture was cooled and the crystalline precipitate filtered, washed with a few cc. of cold acetone and air-dried. The yield amounted to 1.05 g. After recrystallization from 15 cc. of boiling pyridine, 0.85 g. of pure white crystalline material melting sharply at 297° (corr.) was obtained.

Anal. (Parr bomb). Calcd. for $C_{28}H_{24}O_4Br_6$: Br, 53.06. Found: Br, 52.91.

2,5-Di-(3,5-dibromo-2,4,6-trimethylphenyl)-3,6-dibromoquinone.—One-half gram of the hexabromohydroquinone (produced either from the a- or β-tetrabromo compound) and 1250 cc. of 95% ethyl alcohol were refluxed until all was dissolved. Then 2.0 g. of benzoquinone was added, refluxing continued for one-half hour, and 1 liter of alcohol distilled off on the steam-bath.

The light orange-colored quinone crystallized during the distillation. The mixture remaining in the distilling flask was cooled and filtered. The product was washed free of benzoquinone with two 10-cc. portions of cold ethyl alcohol. The yield of air-dried product amounted to 0.48 g.

The quinone crystallized in the pure state from the alcohol reaction mixture and melted constantly at 390–393° (obs.) on the Bloc Maquenne. It was found to be soluble in hot pyridine and hot toluene and could be recrystallized readily from the latter.

Anal. (Parr bomb). Calcd. for $C_{24}H_{18}O_2Br_6$: Br, 58.64. Found: Br, 58.36.

Stannous chloride immediately decolorized the yellow pyridine solution, which after pouring into excess 3 N hydrochloric acid and crystallizing the white product from pyridine yielded the original hydroquinone melting at 395–398° on the Bloc Maquenne.

Oxidation of **2,5-Di-(3,5-dibromo-2,4,6-trimethylphenyl)-3,6-dibromohydroquinone** with Hydrogen Peroxide and Sodium Hydroxide to **Dibromomesitylcarboxylic** Acid, **(VII).—In** a 1-liter round-bottomed flask were placed 2.0 g. of the hexabromohydroquinone, 150 cc. of 95% ethyl alcohol and a cold solution of 20 g. of sodium hydroxide in 50 cc. of water. The mixture was stirred mechanically and immediately acquired a deep red color. After thirty minutes stirring, 100 cc. of water was added and the mixture stirred for two hours at 50°. It was then cooled to 20° and 50 cc. of 30% hydrogen peroxide stirred in. The flask was kept cooled to 10–20°.

Upon addition of the hydrogen peroxide the original dark red color of the mixture changed to a light red over a period of four to six hours. Stirring was continued at the same temperature for forty-eight hours. Sodium acetate crystallized out and the color of the reaction mixture changed to a pink. At this point a solution of 10 g. of sodium hydroxide in 25 cc. of water and 25 cc. more of 30% hydrogen peroxide were added

After an additional twenty-four hours of stirring at room temperature the sodium acetate was filtered from the pale pink solution and 500 cc. of water added to the filtrate. An equal volume (500 cc.) of water was distilled off to remove the excess ethyl alcohol. The residual solution was acidified with hydrochloric acid. The mixture, which at this point contained a yellowish flocculent precipitate, was diluted with water to a volume of 4 liters, brought to a boil and held there for a few minutes. It was then quickly filtered. Upon cooling the filtrate deposited a small crop of short white needles. The yield was 0.18 g. The melting point of this material, after recrystallization from 5 cc. of 50% ethyl alcohol, was constant at 210–211° (corr.). The yield was 0.11 g. of minute shining plates.

The substance was found to be soluble in 5% sodium bicarbonate solution, from which it was precipitated with hydrochloric acid as a white solid.

Anal. (Parr bomb). Calcd. for $C_{10}H_{10}O_2Br_2$: Br, 49.68. Found: Br, 49.50.

Dibromomesitylcarboxylic Acid, (VII).—In a test-tube 3.0 g. of monobromomesitvlcarboxvlic acid was treated with 5 cc. of liquid bromine at room temperature. The contents of the tube were then washed out with saturated sodium bisulfite solution and the collected light yellow solid residue washed with cold water. The yield of crude product amounted to 4.2 g. (air-dried).

The crude material was dissolved in 20 cc. of 95% ethyl alcohol and water added at the boil until a permanent turbidity appeared. Shining colorless plates appeared upon cooling. After one recrystallization from dilute (about 50%) ethyl alcohol the yield was 3.0 g of shining flakes melting constantly at 211° (corr.).

A mixed melting point with the acid obtained from the alkaline hydrogen peroxide oxidation of the hexabromohydroquinone showed no depression.

Anal. (Parr bomb). Calcd. for $C_{10}H_{10}O_2Br_2$: Br, 49.68. Found: Br, 49.83. Calcd. for $C_6(CH_3)_3Br_2COOH$: neut. equiv., 322. Found: 321.

Summary

1. Meso and racemic forms of 2,5-di-(3-bromo-2,4,6-trimethylphenyl)-3,6-dibromohydroquinones have been prepared. These were synthesized by brominating 2,5-dimesitylhydroquinone which in turn is readily formed by the addition of mesitylene to *p*-benzoquinone.

2. The two stereoisomeric compounds form characteristic diacetates and quinones. These latter compounds represent the first examples of the diphenyl type of isomers in compounds which have one of the rings not a benzene nucleus.

3. Each of the two 2,5-di-(3-bromo-2,4,6-trimethylphenyl)-3,6-dibromohydroquinones may be oxidized with hydrogen peroxide and sodium hydroxide to monobromomesitylcarboxylic acid,

4. The two hydroquinones may be brominated to the same hexabromo derivative, 2,5-di-(3,5-dibromo-2,4,6-trimethylphenyl)-3,6-dibromohydroquinone, thus indicating that symmetry in the end rings eliminates the stereoisomerism.

5. The hexabromo compound just mentioned forms a characteristic diacetate and quinone. Moreover, it is oxidized by sodium hydroxide and hydrogen peroxide to dibromomesitylcarboxylic acid.

THE REACTJON BETWEEN CERTAIN ORGANIC SULFUR COMPOUNDS AND SODIUM IN LIQUID AMMONIA[1]

BY F. E. WILLIAMS WITH E. GEBAUER-FUELNEGG

RECEIVED NOVEMBER 17, 1930 PUBLISHED JANUARY 12, 1931

In connection with certain investigations on the sulfur compounds in crude untreated petroleum, it was found necessary to determine the effect of sodium on some simple organic sulfur compounds. Sulfides, disulfides and mercaptans were chosen for this study, since they are representative of divalent sulfur compounds which are supposed to exist in crude petroleum.

Very little work has been done on the effect of sodium on these types of sulfur compounds. Moses and Reid[2] found that organic sulfides are unattacked by sodium in ether even after standing for three months. Disulfides are converted into the corresponding mercaptans.

Kraus and White,[3] using a solution of sodium in liquid ammonia, converted diphenyl sulfide into benzene and sodium sulfide. No other reaction products were isolated. Apparently, the solution of sodium in liquid ammonia is more reactive than the ether–sodium system. We found this idea borne out in the present investigation.

With the three types of compounds studied, sulfides, disulfides and mercaptans, sodium might be expected to react in liquid ammonia, at least in two ways: first, it might carry the reduction to completion, yielding as

---

[1] The investigation was carried out in 1928–1929 under a grant from the American Petroleum Institute, and specified as Project 17.

[2] Moses and Reid, THIS JOURNAL, 48, 776 (1926).

[3] Kraus and White, *ibid.*, 45, 775 (1923). We repeated Kraus' work on the reaction between diphenyl sulfide and sodium in liquid ammonia. Four experiments were made, two in which the procedure was identical with that described in the experimental part, and two in which the diphenyl sulfide was dropped into a solution of sodium in liquid ammonia as Kraus carried out the reaction. Our results were the same in all four experiments. A deep red solution was obtained when reaction was complete. The solid reaction product was a brown powder which ignited when exposed to moist air for a few minutes. Thiophenol and aniline were the only products identified. Benzene and sodium sulfide were watched for closely, since Kraus reported these, but we were unable to detect either compound.

final products sodium sulfide, hydrocarbons or amines or both; or second, the reduction might stop at an intermediate stage, forming sodium mercaptides, and hydrocarbons, or amines, or both.

So far as our present investigations show, only the second cotrrse is followed. Aliphatic sulfides are reduced to the corresponding mercaptides, and hydrocarbons, according to the equation

$$R_2S + 2Na + NH_3 = RSNa + NaNH_2 + RH$$

Disulfides are formed by oxidation of niercaptans. Treatment. with a reducing agent should reform the mercaptans. This was found to be the case as indicated by the general equation

$$R_2S_2 + 2Na = 2RSNa$$

Mercaptans, being weak acids, react with liquid ammonia to form slightly soluble, white crystalline ammonium mercaptides. If to a liquid ammonia solution of a mercaptide, sodium is added, the ammonium mercaptides are decomposed with the formation of sodium mercaptides, and the evolution of one-half mole of hydrogen

$$RSNH_4 + Na = RSNa + NH_3 + {}^1/_2\,H_2$$

Experimental

Materials.—The liquid ammonia was the regular commercial grade dried over sodium. The mercaptans, sulfides and disulfides were Eastman C. P. products.

Apparatus.—A new type of reaction chamber was designed for this investigation (see accompanying diagram). It was equipped with a mercury-sealed stirrer and connections for collecting gaseous reaction products.

Procedure.—Five grams of the compound under investigation was placed in the thoroughly dried reaction chamber, the stirrer placed in position and the two spiral exit tubes closed with two soda lime tubes. The reaction tube was then submerged slowly in the Dewar flask containing crude liquid ammonia. A stream of dried air was bubbled through the latter to cool it below the boiling point of liquid ammonia. One of the soda lime tubes was then removed and the exit tube of a small tank containing ammonia dried over sodium was connected by means of rubber tubing. A slow stream of gaseous ammonia was then run into the reaction chamber, where it condensed onto the sulfur compound and partially dissolved it. When 75 cc. of liquid ammonia had been condensed, the ammonia stream was stopped, but the connection allowed to stand. The remaining soda lime tube was then connected through a Bunsen valve to the gasometer.

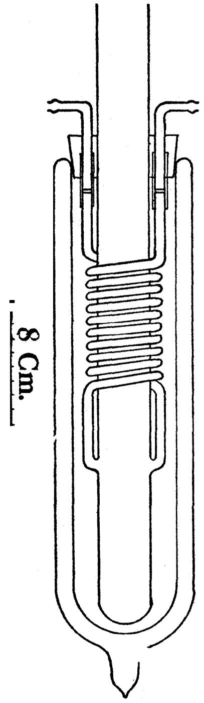

Fig. 1.

Stirring was then started, and clean sodium in the form of wire one-eighth inch in diameter and as long was dropped in, two pieces at a time. When the blue color had disappeared, another portion was added, and this was continued until the blue color remained permanent for two hours. At the end of this time the residual gaseous products were flushed into the gasometer with a fairly rapid stream of gaseous ammonia, the stirrer then quickly removed and the reaction chamber stoppered. Both exit tubes were connected to soda lime tubes and the reaction chamber set back into the Dewar flask from which the liquid ammonia had been removed. This precaution was necessary to prevent ebullition of the ammonia, which would force solid reaction products into the exit tubes. After about twelve hours, all of the ammonia had evaporated and a white crystalline product remained. This was scraped out, rapidly pulverized and preserved in a vacuum desiccator.

Sulfur was determined by oxidation with sodium peroxide in a Parr bomb and precipitated as barium sulfate.

Sodamide was determined by decomposing the sample with 10% sodium hydroxide solution, distilling the ammonia into standard acid as in the Kjeldahl method for nitrogen.

The gaseous products were analyzed by the conventional methods.

Aliphatic Sulfides

The reaction between n-propyl sulfide and n-heptyl sulfide and sodium in liquid ammonia was studied qualitatively with the following results: n-propyl sulfide yields n-propyl sodium mercaptide, sodamide and propane.

Normal heptyl sulfide crystallized when dropped into liquid ammonia and the solid appeared very insoluble. The reaction with sodium was very slow, but after fifty-five hours sufficient reaction had taken place to permit the identification of n-heptyl sodium mercaptide and sodamide. The amount of hydrocarbons produced was too small for identification and was mixed with unreacted organic sulfide.

Neither of these reactions produced a trace of sodium sulfide; the reaction always stopped with the formation of mercaptide.

Sodium sulfide was tested for in both alkaline and acid solutions. In the former case, a dilute sodium plumbite solution was mixed with a dilute solution of the solid reaction product. Not the slightest trace of black lead sulfide was produced.

To test for sodium sulfide in acid solution, a dilute solution of the solid reaction product, acidified with dilute hydrochloric acid, was treated with a few drops of lead acetate solution. No darkening of the solution or precipitation of black lead sulfide was noticeable.

Of a semi-quantitative nature was the study of the reaction between ethyl sulfide and sodium in liquid ammonia. The results of two representative runs are given in Table I. These values were calculated on the assumption of the ratio

$$1\ C_2H_5SNa:1\ NaNH_2:1\ C_2H_6$$

The yields of sodamide and ethane conform closely to the above ratio and suggest the following equation for the reaction

$$[C_2H_5]_2S + 2Na + NH_3 = C_2H_5SNa + NaNH_2 + C_2H_6$$

The ratio $C_2H_5SNa:NaNH_2$ 1 probably arises from a concomitant reaction

$$2\ [C_2H_5]_2S + 2Na = 2C_2H_5SNa + C_4H_{10}$$

Butane was not identified, however.

TABLE I

RESULTS OF REPRESENTATIVE RUNS

Run	Residue, g.	Wt. calcd., g.	Sulfur, %	Calcd. S, %	Extent of reaction
I	5.93	5.71	23.3	25.9	93.4
II	6.75	5.71	23.9	25.9	93.4

Run	Sodamide, %	Calcd., %	Extent of reaction
I	23.4	31.7	76.7
II	21.4	31.4	67.9

Run	Gas [N. T. P.], liters	Ethane, %	Found	Calcd.	Extent
I	1.04	79.1	0.83	1.04	79.1
II	0.99	72.3	0.71	1.04	69.6

Aliphatic Disulfides

The reaction between sodium and aliphatic disulfides in liquid ammonia was studied with ethyl, n-propyl and iso-amyl disulfides. The procedure was identical with that for the sulfides.

Qualitative examination of the reaction product showed that the alkyl sodium mercaptide was the only sulfur compound present, so the amount of mercaptide present was determined from the sulfur content of the solid product. The results for the three disulfides are tabulated in Table II.

TABLE II

Run	Residue, g.	Calcd. wt., g.	S, %	Calcd., %	Yield, %
		ETHYL DISULFIDE			
I	6.90	6.83	36.8	38.0	97.8
II	6.91	6.83	36.0	38.0	95.4
		n-PROPYL DISULFIDE			
I	6.47	6.20	31.9	32.6	102
II	6.38	6.20	32.0	32.6	102
		ISO-AMYL DISULFIDE			
I	5.85	5.55	24.0	25.4	99.5
II	5.93	5.55	23.8	25.4	99.9

Aliphatic Mercaptans

When mercaptans[4] are treated with liquid ammonia, slightly soluble white crystalline ammonium mercaptides are precipitated. When sodium is added to such a solution, a rapid reaction ensues with the formation of sodium mercaptides and the evolution of hydrogen, a reaction analogous to the reaction between ammonium bromide and sodium in liquid ammonia solutions.

$$NH_4Br + Na = NaBr + NH_3 + {}^1/_2\, H_2$$
$$RSNH_4 + Na = RSNa + NH_3 + {}^1/_2\, H_2$$

---

[4] For the analogous reaction with thiophenols, see Ref. 3,

Summary

1. Aliphatic sulfides react with sodium in liquid ammonia chiefly according to the equation

$$R_2S + 2Na + NH_3 = RSNa + NaNH_2 + RH$$

2. Under the same conditions, aliphatic disulfides are reduced quantitatively to the corresponding mercaptides

$$R_2S_2 + 2Na = 2RSNa$$

3. Aliphatic mercaptans react as follows

$$RSH + NH3 = RSNH_4$$
$$RSNH_4 + Na = RSNa + NH_3 + {}^1/_2H_2$$

4. No sodium sulfide is produced in any of these reactions; the reaction stops with the formation of mercaptide.

THE OXIDATION OF "TRI-ISOBUTYLENE" BY OZONE

BY ROBERT J. McCUBBIN

RECEIVED NOVEMBER 24, 1930 PUBLISHED JANUARY 12, 1931

The preparation of the so-called tri-isobutylene was first described in detail by Butlerow,[1] who dissolved isobutylene in a cold mixture of five parts of sulfuric acid to one part of water. The resulting oil boiled at 177.5–179° (749 mm.) and had a specific gravity of 0.774 at 0°. Dichromate oxidation yielded carbon dioxide, trimethylacetic acid, acetic acid, an acid $C_{11}H_{22}O_2$, acetone, and a neutral oil. The acid $C_{11}H_{22}O_2$ distilled at 266° and melted at 66–70'. The neutral oil had a boiling range of 100–220°, reacted with phosphorus trichloride and sodium, but did not reduce Tollens' reagent. In order to explain the formation of the solid acid Butlerow assumed the structure of the hydrocarbon to be $[(CH_3)_3C]_2{=}C(CH_3)_2$. He stated that the oxidation might first involve a pinacolone rearrangement with the formation of $[(CH_3)_3C]_2C(CH_3)COCH_3$. Further oxidation of this compound would result in the production of $[(CH_3)_3C]_2C(CH_3)COOH$, which would account for a solid acid having the formula $C_{11}H_{22}O_2$.

In a recent communication[2] the author described the preparation of diisobutylene, the method of treating it with ozone, and the products resulting from the hydrolysis of the ozonide. In the work with tri-isobutylene a very similar procedure was followed.

Preparation of Tri-isobutylene.—Seven hundred fifty ml. of sulfuric acid and 250 ml. of water were mixed and cooled to about 5°. Then one liter of tertiary butyl

---

[1] Butlerow, *Ber.*, 12, 1482 (1879).

[2] McCubbin and Adkins, THIS JOURNAL, 52, 2547 (1930).

alcohol was slowly added with constant shaking, care being taken to keep the temperature between 20 and 25'. The mixture was allowed to stand for about twelve hours and the oil layer removed. It was washed with dilute sodium hydroxide solution, dried over calcium chloride and fractionated twice over sodium, using a Widmer column. The yield of olefin, b. p. 175.5–179° (740 mm.), was 60-65%.

Formation and Hydrolysis of **Ozonide.**—Eighty-four grams (0.5 mole) of tri-isobutylene was placed in each reaction flask, using 100 ml. of glacial acetic acid containing 1.5–2.0% acetic anhydride as a solvent. The ozonization was carried out at 10°, the oxygen rate being 0.9–1.0 cu. ft. per hour. Under these conditions fifteen to eighteen hours sufficed for complete oxidation of 0.5 mole. The ozonide obtained from 1.5 or 2.0 moles of olefin was placed (with the acetic acid used as a solvent) in a 2-liter, three-necked flask equipped with a stirrer, a thermometer and an efficient reflux condenser. Stirring was commenced and about 5 ml. of water and 5 g. of zinc dust were added. Considerable heat was evolved and the flask had to be cooled. About 80 ml. of water and 60–70 g. of zinc were added over a two-hour period. The contents of the flask were allowed to warm up gradually to 50–60°, and when most of the zinc had reacted the flask was warmed until gentle refluxing took place. This was continued for at least an hour. Then enough water was added to dissolve most of the zinc acetate sludge and the oil layer was removed and dried over anhydrous magnesium sulfate.

After drying, the oil was fractionated up to 130". The remainder was washed free of acids with a solution of sodium bicarbonate. The water solution containing the sodium salts was saved and evaporated to dryness. The oil remaining was again dried and fractionated. The sodium salts just mentioned were distilled with phosphoric acid. Trimethylacetic acid was the only organic acid isolated, and it had resulted from the secondary oxidation of trimethylacetaldehyde, which was one of the principal scission products obtained from tri-isobutylene ozonide.

Hydrolysis Products.—In Table I are listed the principal fractions obtained from the hydrolysis of tri-isobutylene ozonide.

TABLE I

HYDROLYSIS PRODUCTS OF TRI-ISOBUTYLENE OZONIDE

Fraction	B. p., °C.	Formula	Yield, moles	Average yield
A	60–80	$(CH_3)_3CCHO$ (74°)	0.30–0 44	0.38
B	120–130	$(CH_3)_3CCH_2COCH_3$ (124°)	.20– .50	.40
C	180–190	$[(CH_3)_3CCH_2]_2C{=}O$ (182–185°)	.16– .23	.18
D	158–162 (23 mm.)	$[(CH_3)_3C]_2C(CH_3)COCH_3$	.1– .3	.16

Fraction A, trimethylacetaldehyde, was identified by means of the semicarbazone, m. p. 191". Fraction B was characterized as dimethyl-4,4-pentanone-2. Its semicarbazone melted at 176°.[2] Fraction C could not be obtained in a sufficient degree of purity to give consistent and conclusive analyses, but upon oxidation with dichromate two acids boiling at 164–165 and 177–182" were obtained. These acids were proved to be trimethylacetic and tertiary butylacetic by means of the amides, m. p. 153.5 and 131°, respectively. These facts indicate that this portion should have the structure assigned to it, although no ketonic derivatives could be obtained.

Fraction D also yielded no ketonic derivatives, but by further oxidation (dichromate) a solid acid (neut. eq. 186, b. p. 258–262°, m. p. 69–71°) was obtained. This corresponds to the acid obtained by Butlerow,[1] which he designated as methyldi-*tert.*-butylacetic acid.

In this table the amount of trimethylacetic acid obtained was calculated as trimethylacetaldehyde and it may be seen that the amounts of Fractions A and B are almost identical, indicating that these hydrolysis products are obtained from the same parent hydrocarbon.

In Table II are shown the hydrocarbons which would give rise to the above hydrolysis products of their ozonides.

Table II

Structure of Isomeric Tri-isobutylenes

Hydrocarbon	Hydrolysis products
 $(CH_3)_3CC(C(CH_3)_3)=C(CH_3)_2$ (I)	 $(CH_3)_3CC(CH_3)(C(CH_3)_3)—COCH_3$
 $(CH_3)_3CCH_2C(CH_3)=CHC(CH_3)_3$ (II)	$(CH_3)_3CCH_2COCH_3$ and $(CH_3)_3CCHO$
 $(CH_3)_3CCH_2C(=CH_2)CH_2C(CH_3)_3$ (III)	$[(CH_3)_3CCH_2]_2CO$ and $HCHO \longrightarrow CO_2 + H_2O$

In order to obtain the ketone indicated from hydrocarbon number I it is necessary to assume that the pinacolone rearrangement suggested by Butlerow[1] has taken place during ozonolysis. Otherwise, acetone and hexamethylacetone, $[(CH_3)_3C]_2CO$, would be formed and no such products were obtained from this reaction.

In view of these facts, it is possible to assume that the formation of tri-isobutylene is actually a condensation involving the hydroxyl group of tertiary butyl alcohol and an hydrogen atom of di-isobutylene. Since the latter hydrocarbon exists in two isomeric forms, this mode of formation accounts for two forms of tri-isobutylene as follows

(I) 
$$(CH_3)_3C\underset{\displaystyle C(CH_3)_2}{\overset{}{C}}\boxed{H + HO}C(CH_3)_3 \longrightarrow [(CH_3)_3C]_2C{=}C(CH_3)_2 + H_2O$$

(II) 
$$(CH_3)_3CCH_2C(CH_3){=}\overset{H}{C}\boxed{H + HO}C(CH_3)_3 \longrightarrow (CH_3)_3CCH_2C(CH_3){=}CHC(CH_3)_3 + H_2O$$

Then a shifting of the double bond in the second hydrocarbon would produce a third isomer, *e. g.*

(III) $(CH_3)_3CCH_2C(CH_3){=}CHC(CH_3)_3 \longrightarrow [(CH_3)_3CCH_2]_2C{=}CH_2$

This theory is in accordance with the work of Lermontoff,[3] who synthesized di- and tri-isobutylene by saturating tertiary butyl iodide with isobutylene and heating this solution in a sealed tube with calcium oxide.

However, the above mechanism does not seem adequate to explain the formation of polymers when isobutylene is dissolved in cold concentrated sulfuric acid. The following formulas indicate a mode of formation which

---

[3] Lermontoff. Ann.. 196, 116–122 (1879).

would produce the above olefins without requiring the presence of an alcohol or other derivative.

(IA) 
$(CH_3)_2C{=}CH_2 + (CH_3)_3CC\boxed{H}{=}C(CH_3)_2 \longrightarrow [(CH_3)_3C]_2C{=}C(CH_3)_2$

(IIA) 
$(CH_3)_2C{=}CH_2 + (CH_3)_3CCH_2\underset{CH_3}{C}{=}\overset{\boxed{H}}{C}H \longrightarrow (CH_3)_3CCH{=}\underset{CH_3}{C}CH_2C(CH_3)_3$

(IIIA) Same as III

Conclusions

From the data thus obtained, it appears that the hydrocarbon, known as tri-isobutylene, prepared by the action of sulfuric acid on tertiary butyl alcohol exists in at least three isomeric forms. These olefins are present in an approximate ratio of two moles of pentamethyl-2,2,4,6,6-heptene-3,4 (formula II) and one mole each of trimethyl-2,4,4-*tert.*-butyl-3-pentene-2,3 (formula I) and dimethyl-4,4-neopentyl-2-pentene-1,2 (formula III). It also seems apparent that during hydrolysis of the ozonide the hydrocarbon of formula I undergoes a pinacolone rearrangement instead of breaking down into two simple ketones.

STUDIES IN THE CHLOROPHYLL SERIES. IV. THE DEGRADATION OF CHLOROPHYLL AND ALLOMERIZED CHLOROPHYLL TO SIMPLE CHLORINS

BY J. B. CONANT, J. F HYDE, W. W. MOYER AND E. M. DIETZ

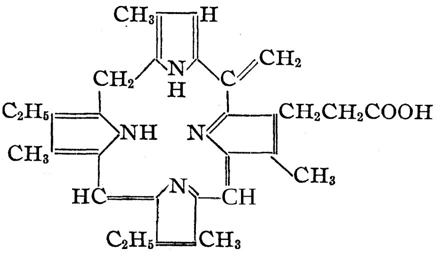
RECEIVED DECEMBER 8, 1930 PUBLISHED JANUARY 12, 1931

The thermal decomposition of chlorin *e* was described in the first paper of this series; the chief product of the reaction is pyrochlorin *e*, a monobasic acid whose spectrum resembles that of the parent compound. We have now studied this relatively simple chlorin in more detail and found that it is very closely related to phylloporphyrin. The ester of pyrochlorin e appears to be isomeric with the ester of phylloporphyrin, although the pyrochlorin *e* itself contains an additional molecule of water (a similar relationship between the hydrated free acid and the ester is found with chlorin e). By catalytic hydrogenation or reduction with hydrogen iodide by Fischer's method[1] and reoxidation, phylloporphyrin is formed in good yields. In the light of Fischer's recent syntheses,[2] phylloporphyrin appears to have one more carbon atom than was formerly supposed. This explains

[1] Fischer and Bäumler, Ann., 474, 65 (1929).

[2] Fischer and Helberger, *ibid.*, 480, 235 (1930).

why this porphyrin ($C_{32}H_{36}O_2N_4$) and pyrochlorin e have the same carbon skeleton although only two carbon atoms were eliminated from chlorin e ($C_{34}H_{38}O_7N_4$) in the pyrolysis. We suggest formula I for pyrochlorin *e;* the transformation to phylloporphyrin would involve the change of a methylene to a methyl group by virtue of a shift of hydrogen. This formulation corresponds to one of the two alternative formulas for phylloporphyrin suggested by Fischer.



I

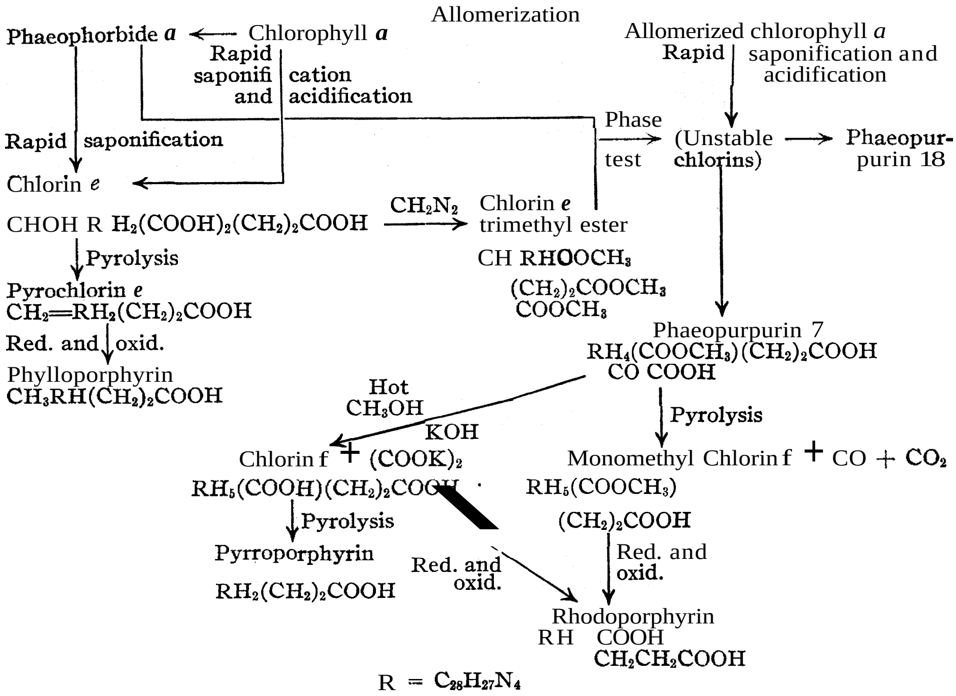
Pyrochlorin e may be considered as a normal degradation product of chlorophyll a since the relationship between chlorin e and the phaeophorbides was shown in the third paper to be closer than was at one time thought. (Both the phaeophorbides and the trimethyl ester of chlorin e give the phase test.)

After passing through the phase test the original structure of the chlorophyll molecule is in some way altered. This is apparent both from the failure of the products to give the phase test and from the fact that rhodoporphyrin or pyrroporphyrin and not phylloporphryin is obtained from them in the reactions which convert chlorins to porphyrins. We have now been able to show that phaeopurpurin 7, a characteristic product of the phase test, is formed by the rapid saponification of allomerized chlorophyll. Thus it is clear that the changes brought about by the phase test and allomerization are essentially the same as Willstatter pointed out. The degradation products of the phaeopurpurins are related to allomerized chlorophyll a, just as pyrochlorin e is related to unallomerized chlorophyll a.

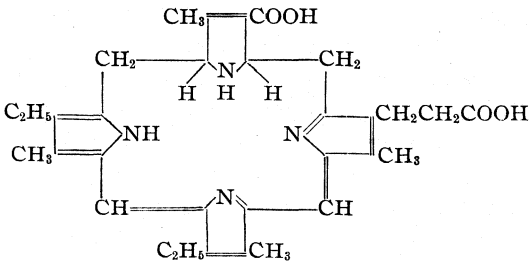
The degradation of both the "normal" and "allomerized series are outlined in the accompanying diagram. The decomposition of the phaeopurpurins, and the reactions of pyrochlorin e are here reported for the first time and the details are given in the experimental portion of this paper. The most satisfactory account of all these changes is indicated by the formulas given in the diagram. The symbol R is taken for $C_{28}H_{27}N_4$: thus, rhodoporphyrin is $RH{}^{COOH}_{CH_2CH_2COOH}$. The analyses of the compounds fit into this scheme as well as could be expected—it is, of course, impossible to be certain of a few hydrogen atoms. (The calculated values given in the experimental portion all correspond to the formulas given in this diagram.)

The following facts seem established by these transformations. (1) Allomerization and the phase test are equivalent and result in the change from a potential phylloporphyrin structure to a potential rhodoporphyrin and pyrroporphyrin structure. (The last part of this statement is implied in Willstatter's diagram if not explicitly expressed.) (2) The $=\underset{|}{C}-OCH_3$ group of methyl phaeophorbide is connected to the β-position of the pyrrole ring which in rhodoporphyrin holds the COOH group. This follows from the formation of rhodoporphyrin from monomethyl chlorin *f*, whose methoxyl group can be traced back to that of methyl phaeophorbide *a*. **(3)** Allomerization (phase test) changes the nature of one carbon atom of the chlorophyll skeleton so that it is easily eliminated together with carbon dioxide. Such elimination occurs in the change from phaeopurpurin 7 to chlorin f and monomethyl chlorin f. On the other hand, the same carbon atom is retained in the pyrolysis of chlorin *e* (unallomerized series).

It seems to us that the most satisfactory explanation of the phase test (allomerization) is to be found in the assumption that it is essentially an oxidation reaction involving the "extra" carbon atom. The transfer of hydrogen may be intra-molecular to a pyrrole ring or intermolecular to reduction products not yet isolated. The first explanation has been incorporated in the formulas given in our diagram.

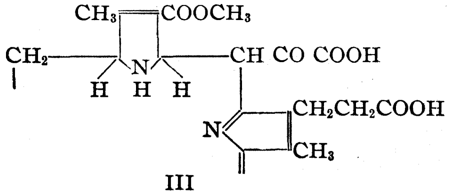


Chlorin f is the simple chlorin of the allomerized series; it differs essentially from pyrochlorin *e*, a simple chlorin of the unallomerized series, in that the extra carbon on the bridge has been eliminated. We suggest the following formula (II) for chlorin f:

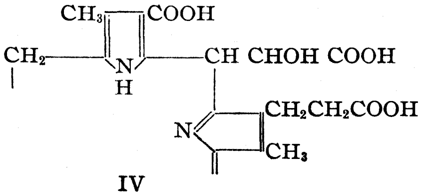


II

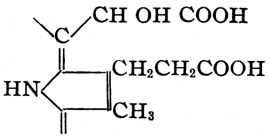
If the foregoing account is correct, the essential group in phaeopurpurin 7 is an a-keto acid on the bridge; this grouping has been suggested by Fischer as occurring in chlorin *e*. We have strong evidence for its presence (as shown in formula III) in phaeopurpurin 7, in that carbon monoxide is evolved in the pyrolysis and potassium oxalate is split off in the alkaline decomposition to chlorin f. For the corresponding compounds in the unallomerized series we might postulate such a grouping as that shown in IV, the change between the two being the internal oxidation and reduction previously referred to.



III



IV



V

This grouping could also take the form V (with or without lactone formation from the β-carboxyl); the presence of the linkage  $\mathrm{C{=}\underset{|}{C}{-}CHOHCOOH}$ would account for the ease with which chlorin e loses carbon dioxide without losing the "extra" carbon atom.

The nomenclature we have adopted warrants a word of explanation. The chlorin obtained from phaeopurpurin 7 by saponification is probably the same compound that Willstatter isolated from hydrolysis of altered chlorophyll; we have therefore retained this investigator's name for it; it is perhaps identical with the chlorin 10 of Treibs and Wiedemann.[3]

A number of interesting by-products were obtained in connection with the transformations outlined in the diagrams. In addition to pyrochlorin e there is formed in the pyrolysis of chlorin e a porphyrin which we designated as "pyrochlorin e porphyrin" in our first paper. After this was published Fischer and Moldenhauer[4] reported the preparation of a compound which they designated as chloroporphyrin e_3, from chlorin *e* by the action of hydrogen iodide. The absorption spectrum arid properties of this compound appeared to be identical with those of our pyrochlorin e porphyrin and this was confirmed by preparing some of Fischer's compound by his method and comparing'the two spectra in a Hartridge revision spectroscope. However, further study of our pyrochlorin e porphyrin convinced us that it was a mixture of phylloporphyrin with another porphyrin. We were able to separate this mixture by a long and tedious fractionation with hydrochloric acid. The chloroporphyrin e_3 was also resolved by the same method. The absorption spectrum of the new porphyrin which was thus separated from the admixed phylloporphyrin was distinctly different from phylloporphyrin and from that reported by us for pyrochlorin e porphyrin or by Fischer for chloroporphyrin e_3. However, on placing solutions of phylloporphyrin and the new porphyrin in two glass cells and passing a beam of light through both the resulting absorption spectrum was identical with that given for both our porphyrin and chloroporphyrin e_3. We propose to designate the porphyrin thus purified and freed of phylloporphyrin as pyrochloroporphyrin. Its analyses indicate that it is isomeric with phylloporphyrin.

In the conversion of the simple chlorins to porphyrins by means of reduction and oxidation, certain chlorins were formed which resembled in spectrum Fischer's synthetic chlorins. Thus, by the hydrogen iodide method we obtained from pyrochlorin *e*, a chlorin very similar to Fischer and Treib's phyllochlorin[3] which these investigators prepared from phylloporphyrin. A small but definite shift in one of the lines in the absorption spectrum and a difference of 15° in the melting point of the esters distinguishes our phyllochlorin from that of Fischer and Treibs. Some of the same phyllochlorin was obtained by catalytic hydrogenation and reoxidation of pyrochlorin *e;* this method was the most advantageous for the conversion to phylloporphyrin. The same phenomenon was met with in the allomerized series. In the conversion of chlorin f to rhodoporphyrin by means of hydrogen iodide, a chlorin was obtained in small amounts whose type of spectrum resembled the "synthetic" chlorins rather more than the parent chlorin or chlorin *e*. If the chlorin spectrum is characteristic of a partially

---

[3] Treibs and Wiedemann, *Ann.*, 471, 146 (1929).

[4] Fischer and Moldenhauer, *ibid.*, 478, 54 (1930).

hydrogenated porphyrin (or its equivalent, see formula I for pyrochlorin *e)*, it is evident that many isomeric chlorins may be expected. From the pyrolysis of phaeopurpurin 7 we have also obtained two porphyrins in small amounts which appear to be new. The analysis of one of these (designated as porphyrin 8 in the experimental portion) indicates that it is isomeric with rhodoporphyrin monomethyl ester. The nature of this isomerism as well as that of pyrochloroporphyrin with phylloporphyrin (see above) remains to be explained.

The preparation of relatively large quantities of phaeopurpurin 7 and its dimethyl ester has been simplified by starting directly with phaeophytin a and b and putting this material through the phase test using as the reagent at room temperature a propyl alcoholic solution of potassium hydroxide. The unstable chlorins were treated with diazomethane, yielding dimethyl phaeopurpurin 7. From this by alkaline hydrolysis phaeopurpurin 7 may be obtained. As noted in the previous paper, it is particularly interesting that one methoxyl group is so much more resistant to alkaline hydrolysis than the other two. It was possible to prepare dimethyl phaeopurpurin 7 in the pure state without first separating the *a* and b series by virtue of the fact that in the b series the products of the phase test are rhodins *i* and k, which Willstatter showed to be relatively stable; they are not transformed by treating with diazomethane. Starting with pure methyl phaeophorbide b we found that there was no substance formed with acid number corresponding to dimethyl phaeopurpurin 7. In this new procedure from phaeophytin *a* and b all the b series is lost, but, in spite of this, because of the great saving in labor, this is very much the best method of preparing the compound.

Experimental

Pyrochlorin e.—The preparation of this compound has been improved by using boiling diphenyl and a shorter time of heating. A typical procedure is as follows: a 100-g. portion of diphenyl was heated to boiling over a free flame and 1 g. of chlorin *e* was then quickly added and the boiling continued for five minutes with vigorous shaking. On adding the chlorin there was a short, but vigorous, evolution of gas. The hot reaction mixture was then poured cautiously into a liter of ether in a two-liter flask. The reddish-brown ether solution thus obtained was extracted repeatedly (about 10 times) with 200-cc. portions of 1% hydrochloric acid until the color was very light, each fraction being washed twice to remove diphenyl. These extracts were retransferred to about 2 liters of ether. The ether solution of the 1% acid extract was re-extracted with 0.5% hydrochloric acid. This retreatment leaves the impurity with the red line at 650 mp in the ether. The "pyrochlorin e porphyrin" was transferred to 2 liters of ether from which it crystallized in prismatic needles as usual on evaporating the solution to 100 cc. In this way from two 1-gram runs 250 mg. of porphyrin was obtained, which represents a 15% yield. The combined mother liquors from the two runs containing the pyrochlorin e were then worked up in the usual way and yielded 0.615 g. of pyrochlorin e, which is a 36% yield.

Anal. Calcd. for $C_{32}H_{38}O_3N_4$ ($C_{32}H_{36}O_2N_4 \cdot H_2O$): C, 73.0; H, 7.22; N, 10.65. Found: *C*, 74.1, 74.3, 74.5; H, 7.0, 7.4, 7.5; N, 10.3, 10.4.

The spectrum in ether has been published (paper I). The spectrum in 8% hydrochloric acid was as follows: 1, 672.7---669.2—628.1---625.0; II, 613.5—592.4; III, 563.4---541.8---525 2; E. A. 442.2. Order of intensity: I, III, II.

Methyl Ester of Pyrochlorin e.—The pyrochlorin e was methylated in ether solution with diazomrthane. The ester crystallizes only after concentrating the ether solution to a very small volume and diluting with ethyl alcohol. It comes out in beautiful, almost perfectly equilateral, triangles of bright luster; it melted sharply at 184". The spectrum was identical line for line in a revision spectroscope with the spectrum of the parent substance.

Spectrum of Pyrochlorin e Ester in Ether.—Concn. 0 2 g./5 liters at 65 mm. depth: I, 677.1—637.1---627.4; II, 614.5---610.3—595.8---594.2; III, 595.5-"-548.2 (hazy); IV, 534.3---532.5---525 5; V, 517 9---516.2480.7; E. A.441.8. Order: I, V, II, IV, III.

In 10% Hydrochloric Acid.—I, 674.8---672.6---626.4; II, 614.2—595 6---590.0; III, 563.9---550---543.5---525.9; E. A. 444.1. Order: I, III, II.

Anal. Calcd. for $C_{33}H_{38}O_2N_4$: C, 75.85; H, 7.28; N, 10.73; OCH_3, 5.94. Found: C, 75.5, 75.7; H, 7 2, 7.8; N, 10.6, 10.7; OCH_3, 5.7, 6.2.

The statement in our previous paper that pyrochlorin e was unstable has not been verified. Carefully purified material, even after long standing, has been found to be unchanged. A solution of pyrochlorin e ester in glacial acetic acid was boiled for twenty-four hours without apparent change. No other product could be found. Decomposition with potassium hydroxide (alcoholic) and pyridine at 220° for five hours yielded phylloporphyrin, identified by mixed melting point of the esters. The copper, zinc and iron salts were made by heating pyrochlorin e ester with the corresponding acetates in glacial acetic acid. The only one of these which could be obtained in nicely crystalline condition was the copper salt.

The copper compound dissolved in ether with a deep blue-green color from which it was not extracted by strong acid and showed the following spectrum: I, 648.7---646.0--609.8---606.9; II, 589.1---576.2; III, 550.5---532.3; IV, 613.8—493.7; E. A. 434.5. Order: I, IV, II, III.

Anal. Calcd. for $C_{33}H_{36}O_2N_4Cu$: C, 67.9; H, 6.16; N, 9.6; OCH_3, 5.3; Cu, 1.09. Found: C, 66.6, 68.3; H, 6.4, 6.7; N, 9.3; OCH_3, 4.7; Cu, 1.01, 1.05.

The iron salt gave a deep green ether solution, from which it was not extracted with concentrated hydrochloric acid. Its ether solution behaved in a peculiar way in that when shaken with dilute ammonia the color became brown and the spectrum was altered considerably. On shaking with acid the original color and spectrum returned. Dilute potassium hydroxide does not appear to effect the same change. The initial spectrum in ether was: I, 671.4—646.1---644.1; II, 619.2---617.1-600.3---596.1; III, 564---545.8 (very faint); IV, 533.1—526.2; V, 513.3---509.0499.6---497.2—487.5 (double max.); E. A. 444.9. Order: I, V, 11, IV, 111.

The spectrum after treatment with ammonia was as follows: I, 690.7---673.4—646.6---644.6; II, 532.4---526.8; III, 513.6---508.4—500.0—49F488.5; E. A. 452. Order: I, 111, 11.

The color of the zinc complex in ether was pure blue. It was readily attacked by 10 or 15% hydrochloric acid, which extracted it with a pure green color. Its spectrum in ether was: I, 672.0---669.3—641.8; II, 634.2---633.3-622.3---620.0; III, 603.6---591.0; IV, 557.8---544.5; V, 534.1—525.1; VI, 517.3---512.9—487.6 (hazy); E. A. 446.6. Order: I, II, VI, III, V, IV.

Catalytic Hydrogenation of Pyrochlorin e.—Pyrochlorin e was reduced in glacial acetic acid in the usual way; 5.5 moles of hydrogen per mole of compound was absorbed when the reaction mixture had become colorless, which required about an hour and a half. On exposure to air without removal of the catalyst the solution became brown and on working up the product a porphyrin was obtained which was identical in spectrum in ether and acid solution with phylloporphyrin with the exception of a weak line at 652–645. In addition to this porphyrin a small amount of a chlorin was obtained which could be extracted with 7.5% hydrochloric acid; its spectrum was similar but not identical with Treibs and Wiedemann's phyllochlorin. This same phyllochlorin was obtained in better yields by the reduction using hydrogen iodide.

Reduction of Pyrochlorin e **with** Hydrogen Iodide.--Since the ester of pyrochlorin *e* was more readily available in a pure condition than the free acid, it was used for preparative purposes; in smaller runs with the free pyrochlorin *e* the results were identical. **A** 250-mg. sample of the pyrochlorin *e* ester was dissolved in 30 cc. of glacial acetic acid and 5 cc. of 45% hydriodic acid added; the color of the solution turned from a deep indigo-blue to a pure green. The flask containing the reaction mixture was then placed on the steam cone and heated for eight to ten minutes with frequent shaking. During this time the green color of the solution became lighter and the solution took on a yellowish-brown shade. The reaction mixture was immediately poured into 500–600 cc. of ether contained in a separatory funnel. On adding about 200 cc. of water and shaking vigorously the material went back in solution, and on standing for about an hour the ether solution became intensely green with a strong red fluorescence. Partially neutralizing the acid with ammonia immediately after transferring to ether seemed to accelerate the change to green. The extraction was then carried out in the usual manner after washing the ether solution several times with water to remove the acetic acid. Extraction with 1% hydrochloric acid removed phylloporphyrin along with a large proportion of another porphyrin with a line near 650. Extractions with 4 and 5% acid removed only small amounts of the green compound, which came out readily with 6 and 7% acid. These latter extracts contained the bulk of the coloring matter present and were colored pale blue. This main fraction, after transferring to ether, was esterified with diazomethane and concentrated for crystallization, a double volume of low-boiling petroleum ether being added. On standing overnight the material crystallized in round clusters of triangular plates with a deep blue luster and having a melting point of 148–150° on the block. In some preparations clusters of long hair-like needles appeared, but three recrystallizations from petroleum ether failed to raise the melting point above 150". The yield in this case was 140 mg. or 56% of the theoretical if the molecular weight of the material is considered to be the same as that of pyrochlorin *e* ester. **A** sample was tested for homogeneity by carefully fractionating and comparing the spectra of various fractions with the mother liquor. In every case the spectra compared were identical. In catalytic hydrogenation this chlorin required **3.3** moles of hydrogen per mole of compound for its conversion to the corresponding leuco-compound. On reoxidation phylloporphyrin was formed, as indicated by the comparison of its spectrum with known phylloporphyrin. There was, however, a weak line near 650 due to some impurity which is usually found in impure phylloporphyrin., In fact, this line appears in the reduction and reoxidation of pure phylloporphyrin.

The spectrum of the new phyllochlorin was as follows, in ether: I, 662.1---660.4—-632.1---620.4—615.1; **II,** 606.6---599.5—594.1---591.6—586.8; **III,** 552.4---549.7—544.3---540.5; IV, 525.3—519.5; V, 512.7---508—479.4; VI, ---455.8---; E. **A.,** 432.4. Order: I, V, **II,** IV, **III,** VI.

In **7%** Hydrochloric Acid.—I, 656.4---653.3—624.6---621.1; **II,** 606.6---588; **III,** 556---546.2; IV, 536---521.8; E. **A.,** 436.0. Order: I, 11, **IV,** 111.

Anal. (monomethyl ester). Calcd. for $C_{33}H_{40}O_2N_4$: C, 75.6; H, 7.6; N, 10.7; OCH_3, 5.9. Found: C, 75.44, 75.42; H, 7.75, 7.54; N, 11.06, 11.03; OCH_3, 6.77, 655.

The fraction of material containing phylloporphyrin from the hydrogen iodide reduction was esterified with diazomethane, after drying its ethereal solution, and refractionated with 0.5% hydrochloric acid. The ester thus obtained crystallized in the way characteristic of phylloporphyrin ester and melted at 230° on the block. A mixture with some known phylloporphyrin ester of melting point 235° melted at 230–233°. Comparison of its spectrum in ether and acid solution with known phylloporphyrin in the revision spectroscope showed the identity of the two spectra throughout.

Pyrochloroporphyrin.—The porphyrin mixture obtained in the pyrolysis of chlorin e as previously described amounts to about 150 mg. per gram of chlorin e. This material from 2 g. of chlorin e was dissolved in about three and one-half liters of ether with the aid of 10% acid. Fractionation of the resulting solution was begun with 0.3% acid. Each fraction of acid was washed twice with 300-cc. portions of ether before retransferring the colored matter to ether. With ten or fifteen extractions approximately one-third of the total material was removed, which appeared to be fairly pure phylloporphyrin as judged by a comparison of the spectrum with known phylloporphyrin. By continuing the extraction and gradually increasing the strength of acid to 0.4%, approximately one-quarter of the remaining coloring matter was removed. Comparison of its spectrum with the first fraction showed it to be a mixture. This second fraction was discarded. The wash ether was now replaced by fresh ether and the extractions continued using 0.5 and 0.6% acid. In this way approximately another third of the colored material was removed without finding any further change in spectrum. The spectrum of this material was easily distinguished from that of phylloporphyrin in the revision spectroscope. The mother liquor, though still quite colored, was discarded. The first and last fractions were then esterified and the resulting ether solutions of the esters subjected to fractionation. It was necessary in this case to use slightly more concentrated acid, since the esters were slightly higher in acid number than the free porphyrin acids. Thus the phylloporphyrin ester was extracted with 0.4 and 0.5% acid, while 0.6 or 0.8% acid was necessary for the convenient extraction of the pyrochloroporphyrin ester. This latter porphyrin solution was likewise washed first with 0.4 and 0.5% acid to remove further possible amounts of phylloporphyrin ester. In each case when about half of the coloring matter had been extracted, the mother liquors were discarded. The ethereal solutions of the extracted porphyrin esters were concentrated to a small volume for crystallization. The phylloporphyrin ester crystallized in the usual red prismatic needles, while the pyrochloroporphyrin ester appeared as long hair-like needles. Approximately 80 mg. of the former and 45 mg. of the latter were obtained. The yield is no criterion of the relative proportions of the two compounds present in the original mixture, since a large amount of the material was discarded. The mixture was judged to consist of approximately equal amounts of the two compounds. The material described in our first paper as "pyrochlorin e porphyrin" was undoubtedly more than 50% pyrochloroporphyrin, since this compound is much less soluble than phylloporphyrin, so that by recrystallization a considerable proportion of phylloporphyrin would be left in the mother liquor. The melting point of the phylloporphyrin ester was 235–236°, that of the pyrochloroporphyrin ester 226–237°. The former compound mixed with phylloporphyrin ester melted at 236–237°, while the latter also mixed with phylloporphyrin melted at 228–230°.

Spectrum of pyrochloroporphyrin ester in ether: I, 641.7—631.8; II, ---606.6--- III, 593.7---581.3—574.7---573.2; IV, 550.9---549.4—534.6---532.6; V, 522.8---521.1—487.8; E. A., 445.2. Order: V, IV, III, I, II.

The line previously recorded at 664–658 was obviously due to an impurity which has been removed in this fractionation. Spectrum in 1% acid: I, 609.0---599.0; II, 585.5---570.5—548.8---545.7; III, 526.2---514.2; E. A., 437.5. Order: 11, I, 111.

Anal. of methyl ester. Calcd. for $C_{33}H_{38}O_2N_4$: C, 75.85; H, 7.28; N, 10.73; OCH_3, 5.94. Found: C, 75.99; H, 7.45; N, 10.6; OCH_3, 6.3, 5.9.

Anal. of free acid. Calcd. for $C_{32}H_{36}O_2N_4$: C, 75.6; H, 7.09; N, 11.0. Found: C, 75.3, 75.0; H, 7.0, 7.2; N, 10.4, 10.2.

The spectrum of the phylloporphyrin ester fraction was identical in every detail with the spectrum of a known sample, compared line for line in the revision spectroscope.

A sample of the material designated as chloroporphyrin e_3 by Fischer and Moldenhauer[4] was prepared in the manner described by them. This sample was subjected to careful acid fractionation in the same way as the "pyrochlorin e porphyrin" mixture. The results were identical. The phylloporphyrin ester after its refractionation amounted to 45 mg. The pyrochloroporphyrin ester amounted to 43 mg. The crystal form in each case was the same as that of the corresponding fractions in the pyrolysis experiment: The spectra of the corresponding fractions in ether and acid were likewise identical in every detail as shown by direct comparison. The phylloporphyrin ester melted at 225–228°, and its mixture with a known sample melted at 230–234°. The melting point of the pyrochloroporphyrin ester was 226–230°, and when mixed with a sample of pyrochloroporphyrin ester prepared as above, gave no depression.

Reduction of Pyrochloroporphyrin.—A sample of pyrochloroporphyrin ester was dissolved in a few cc. of glacial acetic acid. A few drops of 45% hydriodic acid was added and the mixture was then heated on the steam cone for ten minutes. On transferring to ether and working up in the usual way, a major portion of the colored matter was extracted with 0.5% hydrochloric acid. This material was identical in spectrum both in acid and ether by direct comparison with known phylloporphyrin.

The spectrum as measured in ether was as follows: **I,** 633.0—628.5-–615.0 (hazy shadow); **II,** 606.6---601.8; **III,** **592.3---589.8—578.5-–573.1;** IV, 543.3---540.7—531.3---529.3; **V,** 519.6---516.8—486.2; **E.** A. 438.8. Order: V, **111, IV, I, 11.**

Another small sample of material was reduced catalytically to the leuco compound. The reduction may have been carried too far since the reoxidation took place very slowly. On retransferring to ether considerable scum was formed. However, a small amount of material could be extracted with 0.5% acid which checked in spectrum with known phylloporphyrin, though the ether solution was slightly brown and obviously impure.

Preparation of Dimethyl Phaeopurpurin 7 from Crude Phaeophytin.—A solution of 18 g. of crude phaeophytin (*a* and *b*) in 60 cc. of pyridine was added to 4 liters of ether and shaken for ten minutes with 400 cc. of a mixture of 25% potassium hydroxide in n-propyl alcohol. The solution turned deep green upon the addition of the alkali. Three liters of water was added to the saponification mixture and shaken; the alkaline layer was removed and the product transferred to 10 liters of ether by acidification. The ether solution, after washing with water and drying with sodium sulfate for ten minutes, was treated with an excess of diazomethane in ether solution. When a test showed that the product was alkali insoluble, the ether solution was extracted from eight to ten times with 1500-cc. portions of 11% acid. The acid solution used should be cold and all operations should be performed rapidly in order to prevent hydrolysis of the ester. Each acid extract was washed with 1500 cc. of ether in a 4-liter separatory funnel before transferring to ether. The material in the acid extracts was transferred to 8 liters of ether in all. This ether solution was washed with a 0.1 N solution of potassium hydroxide to remove some acidic material resulting from hydrolysis. Upon concentrating the ether solution, the dimethyl phaeopurpurin 7 crystallized in glistening hexagonal plates; the yield was 2–2.5 g.

Preparation of Phaeopurpurin 7.—A solution of 2.6 g. of dimethyl phaeopurpurin 7 in pyridine was added to 3 liters of ether and shaken for five minutes with 300 cc. of 25% n-propyl alcoholic potash. Water was added and the aqueous layer was acidified with shaking in the presence of 6 liters of fresh ether. The phaeopurpurin 7 was then extracted by 8% acid. The acid extracts were washed with ether through an intermediate separatory funnel and then the product was transferred to ether, 8 liters for all the extracts. The yield of phaeopurpurin 7 was 1.66 g.

A second procedure was adopted for preparing phaeopurpurin 7 which saved time but resulted in a slightly less pure product, The phase-test saponification of phaeophytin was carried out as described under the preparation of dimethyl phaeopurpurin 7. After methylation, instead of extracting the ester with 11% acid, the dry 10-liter ether solution (from 18 g. of phaeophytin) was shaken for five minutes with 500 cc. of 25% *n*-propyl alcoholic potash. Water was added and then the product was transferred back to the same ether solution by acidification. The resulting ether solution was then extracted with 8% acid until the color of extracts was a weak green. The acid extracts were washed with an equal volume of ether and transferred to 8 liters of fresh ether. The yield was 1.33 g. of phaeopurpurin 7.

Phaeopurpurin 18 and dimethyl phaeopurpurin 7 were relatively resistant to pyrolysis in diphenyl, as might be expected. Thus for the former it required five and one-half hours at 250° for the loss of 0.6 mole of carbon dioxide and for the latter four hours at the same temperature for 0.7 of a mole. The pyrolysis product was a complex mixture of porphyrins and chlorins which has not yet been separated into sufficient quantities of pure materials to warrant description.

Pyrolysis of Phaeopurpurin 7.—This substance lost one mole of carbon dioxide with comparative ease. A sample of 0.1630 g. was heated in diphenyl at the boiling point for ten minutes, the oil-bath was removed and the system swept with pure nitrogen for twenty minutes longer. The potash absorption bulb gained 11 mg., which corresponds to 96% of one mole of carbon dioxide lost by the sample. A sample of 0.1520 g. of phaeopurpurin 7, heated in diphenyl at 160–170° for forty-five minutes, lost 9 mg. of carbon dioxide, or 84% of one mole. An hour longer of heating at the same temperature did not change the weight of carbon dioxide. In addition to carbon dioxide, carbon monoxide was evolved. This was established by passing the gas through hemoglobin solution and noting the characteristic bands of CO-hemoglobin. The products resulting from the pyrolysis of phaeopurpurin 7 consisted of a mixture of porphyrins and one chlorin. The chlorin, which had an acid number of 11, and which we shall designate as monomethyl chlorin f was easily separated from the porphyrin mixture, since all the porphyrins were readily extracted by 5–9% acid. By laborious and careful fractionation, two porphyrins were isolated from the porphyrin mixture. One porphyrin had an acid number of 8, and the other 6. Besides the porphyrins 6 and 8 there are small amounts of some other porphyrins with lower acid numbers.

For preparative purposes, the pyrolysis was carried out on a larger scale. To a solution of 60 g. of boiling diphenyl was added 500 mg. of phaeopurpurin 7 and the solution heated at the boiling point for five minutes. After cooling, the diphenyl was poured into 500 cc. of ether and dilute alkali was added to extract the pyrolysis product. The alkaline solution was washed twice with fresh ether to remove all but traces of the diphenyl, and the pyrolysis product was then transferred to 2 liters of ether by acidification of the alkaline solution. The ether solution was extracted with 3 and 4% acids and then with 6–9% acids; the 9% extracts were washed with ether to remove traces of the chlorin. The chlorin was then extracted by means of 11–13% acids. The 6–9% acid porphyrin portion was separated by careful acid fractionation. The yields of the porphyrins were small. From 1 g. of phaeopurpurin 7 was obtained 70 mg. of the pyroporphyrin 8 and 30 mg. of the pyroporphyrin 6. The proportions of the two porphyrins and accompanying impurities may have varied with the method of pyrolysis and source of the phaeopurpurin 7, but this could not be checked exactly. Monomethyl chlorin f, which could he easily isolated and purified, was formed in 15–16% yields under all conditions; the yield from 1 g. of phaeopurpurin 7 was 150–165 mg.

Monomethyl Ester of Chlorin f.—This substance crystallizes from ether in eight-sided plates which approach an oval in contour. The acid number is 11, and the hydrochloric acid solution is pure blue. The ether solution is clear green without an olive tinge. The solubility in ether is about the same as that of chlorin e. The ether spectrum varies only slightly from that of chlorin e (1 mg. in 30 cc. ether): I, 684—647.5—637---631; II, 615—603; III, 563—553; IV, 531—524; V, 508—483.5; E. A. 433. Order: I, V, IV, II, 111.

The spectrum in 13% acid: I, 681—594; II, 577---568; III, 534---532—521--420; IV (very faint), 495---487; E. A. 447. Order: I. II, II, IV.

Anal. Calcd. for $C_{33}H_{40}O_4N_4$: C, 71.2; H, 7.2; N, 10.07; OCH_3, 5.6. Found: C, 71.4, 71.6; H, 6.6, 6.8; N, 10 0, 10.08; OCH_3, 6.1, 5.8.

Dimethyl Ester of Chlorin *f*.—This substance, prepared by the action of diazomethane on monomethyl chlorin *f*, or by the action of dimethyl sulfate on the alkaline solution, crystallizes from ether and methyl alcohol in rough aggregates of needles or sharp-pointed plates. The acid number lies between 13 and 14, and the acid solution is blue. The color and spectrum of the ether solution is the same as that of the monomethyl ester. The melting point is 182" (block). The hydrolysis of the ester (phase test conditions) yielded an alkali-soluble chlorin apparently identical with chlorin *f*; methylation with dimethyl sulfate regenerated the dimethyl ester.

Anal. Calcd. for $C_{34}H_{40}O_4N_4$: C, 71.8; H, 7.04; N, 9.86; OCH_3, 10.9. Found: C, 71.54, 72.0; H, 7.05, 6.9; N, 9.66, 9.88; OCH_3, 10.6.

The **Porphyrins** from Pyrolysis of Phaeopurpurin 7.—The porphyrin of acid number 8 is bluish-green in acid solution with a slight red fluorescence. It crystallizes from ether solution in stout diamond-shaped prisms. The spectrum in an ether-pyridine solution (1 mg. in 20 cc. of ether and 10 cc. of pyridine): I, 645---639; II, 595—580—571; III, 562—538; IV, 522—504; E. A., 444. Order: 111.11, IV, I.

The spectrum in 9% acid: I, 621–601; II, 585---574—543; III, 527---516; E. A., 444. Order: II, I, III.

Anal. Calcd. for $C_{33}H_{36}N_4O_4$: C, 71.7; H, 6.5; N, 10.15; OCH_3, 5.6. Found: C, 71.6, 71.8; H, 6.4, 6.5; N, 9.7; OCH_3, 6.3.

The porphyrin 6 crystallizes from ether in pointed plates with oval sides. The solution in acid is purplish-blue. The spectrum in ether solution: I, 675---660, faint shadow; II, 638—632.5; III, 590---576—571; IV, 552—539; V, 515—502---491; E. A , 436. Order: IV, V, III, II, I.

The spectrum in 6% hydrochloric acid: I, 608—600; II, 581---565—550---540; E. A., 435. Order: II, I.

The substance contains one methoxyl group; found, 6.52, 6.71% OCH_3.

Hot Saponification of Phaeopurpurin 7.—To a boiling solution of 30 g. of potassium hydroxide in 90 g. of n-propyl alcohol was added 400 mg. of phaeopurpurin 7 and the solution was refluxed for five minutes. The color of the solution was dark green with a deep red fluorescence. Water and ether were added and the mixture shaken. The aqueous alkaline layer was drawn off and the material transferred to 2 liters of fresh ether by acidification. The resulting ether solution was of a purplish-red color. The saponification product was a mixture of porphyrins and chlorin f. Acids of 4–8% extracted the porphyrins, leaving the ether colored green. The chlorin was extracted by 10–11% acids and transferred to fresh ether. Careful fractionation of the porphyrin extract with 5 and 6% acids removed the porphyrin of lower acid number. The material of higher acid number was in lesser amount and was not isolated. As the porphyrin of acid number 5 became more pure, more and more ether had to be used to keep it from crystallizing from solution. Finally, the pure porphyrin was contained in 4 liters of ether, from which was obtained 30 mg. of substance upon concentrating the ether solution. The yield of chlorin f was 111 mg. The same products were obtained when 35% potassium hydroxide in methyl alcohol was employed at the boiling point for thirty seconds.

Another saponification of phaeopurpurin 7 was carried out with the same quantity of material and procedure as described above. The saponification product, transferred to 3 liters of ether, was then methylated with diazomethane and the esters of the chlorin and porphyrin were fractionated from the ether solution. The porphyrin fraction was removed by 9% acid and the chlorin ester by 13–16% acid. The porphyrin ester corresponding to the insoluble porphyrin 5 was obtained by careful fractionation with 8% acid and washing the acid extracts with ether. Much material was lost as the ester during this acid fractionation—the acidic material was removed by washing the final ether solution with 0.1 *N* alkali. The yield of chlorin *f* ester was 146 mg.; of porphyrin 5 ester, 10 mg.

Potassium oxalate as a product of the reaction was demonstrated in another experiment; 400 mg. (0.6 of a millimole) of dimethyl phaeopurpurin 7 was hydrolyzed by boiling with 100 cc. of 25% methyl alcoholic potassium hydroxide for ten minutes. The reaction mixture was worked up in the usual way, the acidified aqueous layer being repeatedly extracted with ether and finally filtered through charcoal to remove all traces of the complex organic products. The aqueous solution was concentrated, made faintly alkaline with ammonia and calcium chloride added to the hot solution. The precipitate was washed with dilute acetic acid and collected on a microfilter; it weighed 39 mg. On treatment with dilute hydrochloric acid 30 mg. (0.23 millimole) of calcium oxalate dissolved. The calcium oxalate was reprecipitated from the hydrochloric acid solution, filtered off, dissolved in sulfuric acid and titrated with standard permanganate. The total oxalate thus determined was 20 mg. of calcium oxalate (0.16 millimole). Considering the losses encountered in the manipulations, the quantity of oxalate found corresponds to the yield of chlorin f and the accompanying porphyrin (about 40%). In a "control experiment" chlorin e was substituted for phaeopurpurin 7 and the same procedure employed; no calcium oxalate was obtained.

Chlorin *f*.—This substance is very insoluble in ether, from which it crystallizes in microscopic prismatic needles barely visible at a magnification of 60 diameters. The acid number is 10 and the color in acid solution is deep blue. The solution in ether is green without the olive tint characteristic of chlorin e. The spectrum in ether: I, 685—645---631; II, 617—603; III, 561---554; IV, 531—524; V, 510—481; E. A., 436. Order: I, V, IV, II, III. The spectrum in 12% hydrochloric acid: I, 680—629---611—597; II, 577---568; III, 535---521; E. A. 439. Order: I, III, II.

Anal. Calcd. for $C_{32}H_{38}O_4N_4$: C, 70.9; H, 7.05; N, 10.34. Found: C, 71.7, 71.4; H, 6.3, 6.6; N, 10.0, 10.3; OCH_3, 0.

A Porphyrin from the Saponification of Phaeopurpurin 7.—This porphyrin was obtained in very small quantities and is characterized by its insolubility in ether and the solubility in dilute alkali. It dissolves readily in 0.1 N potassium hydroxide with a pink solution. The acid number lies between 5 and 6; the color of the acid solution is light blue with a purplish-red fluorescence. It contains no methoxyl group. It appears to be the dibasic acid corresponding to porphyrin 6 from the pyrolysis experiments. The spectrum in ether solution: I, 637---632; II, 593---578—573; III, 557---553—542---537; IV, 518---511—503---492; E. A., 436. Order: III, IV, II, I. Spectrum in 0.1 N potassium hydroxide: I, 664—650; II, 574---556; III, 549---537; IV, 513—496; E. A., 436. Order: I, IV, III, II. Spectrum in 6% acid: I, 616.5—598; II, 585---573—541; 111,524---511 (very faint); E. A., 440. Order: 11, I, III.

Action of Hydriodic Acid on Dimethyl Ester Chlorin f.—A solution of 20 mg.

of chlorin f dimethyl ester in 30 cc. of glacial acetic acid was heated on a steam cone for ten minutes with 2 cc. of 45% hydriodic acid. The brownish-red reaction mixture was poured into ether and the acetic acid was washed out with water and ammonia. Finally, the ether solution was extracted with dilute alkali, which removed most of the material, and the product was transferred to fresh ether by acidification. Fractionation with 6% acid removed a porphyrin, leaving a green solution. The porphyrin on further purification proved to be identical with rhodoporphyrin in acid number, color and spectrum in acid and ether solution. The green solution was washed with 9% acid and then the chlorin removed with 12% acid. The chlorin had a spectrum somewhat similar to those of the "synthetic chlorins" reported by Fischer: I, 680—638 (two maxima); II, 627.5—621; III, 608—593; IV, 563---545; V, 531---525—510.5; VI, 508—478.5; E. A. 438. Order: I, VI, III, V, II, IV.

Pyrolysis of Chlorin f.—A 0.1029-g. sample of chlorin f was heated in diphenyl at 240–260° for twenty minutes; 1.7 mg. of carbon dioxide was lost. After heating for two and one-half hours longer at the boiling point of diphenyl, the loss of carbon dioxide in all was 4.6 mg. This corresponds to over 50% of one mole of carbon dioxide. The result may not be accurate due to the small weight of sample. The pyrolysis product was a mixture of porphyrins from which was obtained by fractionation with 1.5–2% acid, a considerable amount of pyrroporphyrin. The remainder of the material was of higher acid number. The pyrroporphyrin was identical in acid number, color and spectra in acid and ether solutions with a known sample of pyrroporphyrin. A mixed melting point of the esters showed no depression.

Alkali Decomposition of Monomethyl Chlorin f.—A mixture of 65 mg. of monomethyl chlorin *f*, 6 cc. of 25% methyl alcoholic potassium hydroxide, 3 cc. of pyridine and 50 mg. of magnesium oxide was heated at 150–156° for five hours in a silver-lined autoclave.[5] The decomposition product was shaken with 20% hydrochloric acid and transferred to a liter of ether. The red ether solution, without purification, checked in color and spectrum with an authentic sample of rhodoporphyrin. Fractionation showed the presence of only one substance which were removed by 4–5% acid. The color and spectrum in ether and acid solution were identical with those of rhodoporphyrin. The fractionated material was converted to the methyl ester by the use of diazomethane. The ester crystallized from ether in rectangular plates, characteristic of rhodoporphyrin dimethyl ester. The melting point was 255°, and a mixed melting point with a known sample of dimethyl rhodoporphyrin showed no depression.

Alkali Decomposition of the Porphyrins from the Pyrolysis of Phaeopurpurin 7.—A 20-mg. sample of porphyrin 6 and a 10-mg. sample of porphyrin 8 were heated in separate silver crucibles with proportionate amounts of alkali, pyridine and magnesium oxide according to the procedure of Treibs and Wiedemann, to 150–160° for five hours. The phyllins were decomposed with 20% acid and the products transferred to ether. In each case rhodoporphyrin was the sole product. The material was identicai in color and spectrum in ether and acid solution, and in acid number, with authentic rhodoporphyrin.

Saponification of Allomerized Chlorophyll.—Crude chlorophyll[6] (from spinach) was separated into the *a* and b components by Willstatter's procedure. The pure chlorophyll *a* gave the "phase test" and on rapid saponification yielded chlorin *e* with only a trace of material with higher acid number. Samples of this pure chlorophyll *a* were allomerized by standing in absolute alcohol solution for twenty-four to forty-eight hours; the allomerization was demonstrated by the failure of the resultant material to give the phase color. A solution of 150 mg. of allomerized chlorophyll in alcohol was diluted

---

[6] We are indebted to Dr. H. A. Spoehr for supplying the crude chlorophyll.

with water and ether and the material thus transferred to dry ether in the usual way. The ether solution was evaporated to dryness in a silver container and the residue treated with 15 cc. of boiling alcoholic potassium hydroxide, **(35%)** and the boiling continued for thirty seconds. On diluting with water and acidification with concentrated hydrochloric acid, the color change showed the removal of magnesium. On working up the product in the usual way, including the treatment of the unstable chlorins with diazomethane, dimethyl phaeopurpurin 7 was the main product. It was identified by its color, acid number, spectrum in ether, in 12% hydrochloric acid and, after hydrolysis, in 0.1 *N* alkali (the spectra were compared with a known sample in a revision spectroscope); as a by-product a porphyrin ester with acid number about 8 was obtained. In another experiment allomerized phaeophytin *a* was prepared by treating allomerized chlorophyll *a* with concentrated hydrochloric acid. The rapid hot saponification of the allomerized phaeophytin *a*, followed by the diazomethane treatment in the usual way, yielded dimethylphaeopurpurin 7 and only a trace of higher chlorins; the porphyrin appeared to be absent.

Summary

1. It has been shown that the saponification of allomerized chlorophyll *a* yields phaeopurpurin 7, a characteristic product of the phase test; allomerization and the phase test appear to be equivalent processes.

2. Phaeopurpurin 7 (a monomethyl ester) on pyrolysis loses carbon dioxide and carbon monoxide, forming the monomethyl ester of a simple chlorin which appears to be a hydrogenated rhodoporphyrin. The corresponding dibasic acid is formed by the action of hot alcoholic potassium hydroxide on phaeopurpurin 7, oxalic acid being split off. These facts show that phaeopurpurin 7 is an α-keto acid.

3. Pyrochlorin e is a simple chlorin of the unallomerized series; it still contains the carbon atom which is eliminated as carbon monoxide in the allomerized compound. It appears to be isomeric with phylloporphyrin. All these facts point to an oxidation–reduction process as being involved in the phase test and allomerization.

THE STEREOCHEMISTRY OF N-PHENYLPYRROLES. THE PREPARATION AND RESOLUTION OF N-2-CARBOXYPHENYL-2,5-DIMETHYL-3-CARBOXYPYRROLE. XIII[1]

BY L. H. BOCK[2] AND ROGER ADAMS

RECEIVED DECEMBER 15, 1930 PUBLISHED JANUARY 12, 1931

The search for the presence of stereoisomerism in certain substituted molecules containing rings of an aromatic or semi-aromatic type is a natural development from the study of diphenyl compounds. Such a field, the study of which is being undertaken in this Laboratory, includes compounds in the series of the phenylpyridines, dipyridyls, phenylpyrroles, phenylpyrazoles, etc. The difficulty of synthesis, however, is a severe hindrance to the rapid development of the study of these types. Only recently has the first dicyclic compound other than a diphenyl been found in which this type of isomerism exists. The compound was a phenylquinone.[1a] In all of the researches connected with the various substances just mentioned the attachment of one ring to the other has been attempted always through carbon linkages.

A preliminary study has now been made to determine whether certain properly substituted dicyclic compounds with carbon–nitrogen linkages between the rings might not show similar isomerism. A class of such compounds which has interesting possibilities is the N-phenylpyrroles represented by the general structures (I), (II) and (III). This communication describes a compound which belongs to Type I. It is N-2-carboxyphenyl-2,5-dimethyl-3-carboxypyrrole (IV), prepared by condensing anthranilic acid with 3-carbethoxy-2,5-hexadione (prepared from chloroacetone and acetoacetic ester) and then saponifying. Resolution was effected by means of the brucine salt. The same remarkable difference in solubility between the two diastereoisomericsalts exists as in the salts from previously resolved diphenyl compounds.

[1] For the preceding papers in this series see (a) Shildneck and Adams, THIS JOURNAL, 53, 343 (1931); (b) Stoughton and Adams, *ibid.*, 52, 5263 (1930).

[2] This communication is a portion of a thesis submitted by L. H. Bock in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry at the University of Illinois.

The active forms do not racemize upon boiling for eight hours in ethyl alcohol. They are, however, essentially completely racemized upon boiling for twenty-four hours in 0.1 *N* sodium hydroxide solution.

If the usual explanation of the phenomenon in the diphenyl series is applied here, it may be said that there is restricted rotation between the benzene ring and the pyrrole ring due to the interference of the ortho substituted groups. Whether the same conditions for the appearance of the phenomenon hold as in the diphenyl series is to be determined, However, the possibility must not be overlooked that in this molecule the optical activity may be dependent, not upon the restricted rotation but upon the character of the nitrogen atom or it may be dependent on a combination of the two. Experiments which are now under way and which will be reported soon should indicate with considerable certainty whether this latter explanation is likely, and at that time a detailed discussion of the theoretical possibilities will be given.

Based on the results just described, optical activity may also be expected in properly substituted N-phenyltetrazoles, N-phenylpyrazoles, N-phenylpyrrodiazoles, etc., as well as in the ortho substituted dicyclic compounds with the two nitrogens attached to each other as in N,N-dipyrroles, N,N-dipyrazoles, N,N-ditetrazoles and N,N-dipyrrodiazoles, etc. Representatives of these classes are being prepared.

Experimental

3-Carbethoxy-2,5-hexadione.—This compound was previously prepared by Weltner[3] from monochloroacetone and acetoacetic ester. In a 1-liter, three-necked flask equipped with a mercury-sealed stirrer, reflux condenser and dropping funnel were placed 260 g. of acetoacetic ester and 25 g. of sodium. The mixture was stirred at room temperature until all of the sodium had dissolved. This required about twenty-four hours. Then 250 cc. of dry ether was added and 99 g. of monochloroacetone was slowly added. Stirring was continued for eighteen hours. The reaction mixture was filtered, washed with water and extracted with ether. The product distilled at 95–105° (3 mm.). The yield was 96 g. (48% of the theoretical amount).

N-2-Carboxyphenyl-2,5-dimethyl-3-carboxypyrrole.—A solution of 18.6 g. of 3-carbethoxy-2,5-hexadione and 13.7 g. of anthranilic acid in 100 cc. of absolute ethyl alcohol was refluxed for one hour. The reaction mixture was then refluxed for fifteen minutes with alcoholic sodium hydroxide, filtered, cooled and acidified with dilute hydrochloric acid. Eight grams of crude product precipitated. It was purified by crystallization from one liter of ethyl acetate containing a little alcohol; m. p. 224.5–225.5°. It is soluble in alcohol, ether and acetic acid but only slightly soluble in ethyl acetate and chloroform.

Anal. Calcd. neut. equiv.: 129.6. Found: 128.6. Calcd. for $C_{14}H_{13}O_4N$: C, 04.84; H, 5.0. Found: C, 65.33; H, 5.1.

Resolution of **N-2-Carboxyphenyl-2,5-dimethyl-3-carboxypyrrole.**—A solution of 15.5 g. of brucine in 400 cc. of dry ethyl acetate was added hot to a suspension of 10 g. of N-2-carboxyphenyl-2,5-dimethyl-3-carboxypyrrole in 400 cc. of hot ethyl acetate. A

clear solution resulted from which the brucine salt precipitated when the side of the beaker was rubbed with a stirring rod. The mixture was cooled and filtered, yielding *12.8* g. of salt which gave $[\alpha]_D$ *—37".* On concentrating the filtrate, *10* g. of salt of $[\alpha]_D$ +12° was obtained. The first fraction was recrystallized from *200* cc. of absolute alcohol to constant rotation. The more soluble fraction was recrystallized from ethyl acetate.

I-Salt.—0.1137 g. made up to *15* cc. with chloroform at 20° gave α_D —0.68°; *l = 2;* $[\alpha]^{20}_D$ —44.9°; m. p. 231–232° (dec.).

Anal. Calcd. for $C_{37}H_{39}O_8N_3$ (monobrucine salt): C, *67.96;* H, *6.0.* Found: C, *67.74;* H, *6.1.*

d-**Salt.**—0.1551 g. made up to *15* cc. with chloroform at 20° gave α_D *\$0.28";* *l = 2;* $[\alpha]^{20}_D$ +13.5°; m. p. 175–180° (dec.).

Anal. Calcd. for $C_{37}H_{39}O_8N_3$: C, *67.96;* H, *6.0.* Found: C, *67.71;* H, *6.1.*

d- and l-N-**2-Carboxyphenyl-2,5-dimethyl-3-carboxypyrroles.**—The salts were decomposed by shaking in a separatory funnel with dilute hydrochloric acid and ether. The acid went into the ether layer and was obtained by evaporating to dryness. The acids were crystallized from ethyl acetate to constant rotation.

I-Acid.—0.1349 g. made up to *15* cc. with absolute alcohol at 20° gave α_D *—0.49';* *l = 2;* $[\alpha]^{20}_D$ –27.2°; m. p. 203–204°.

d-Acid. *—0.1753* g. made up to 15 cc. with absolute alcohol at 20° gave α_D + *0.63;* *l = 2;* $[\alpha]^{20}_D$ + 27.0°; m. p. *202–204".*

Racemization Experiments.—About *0.3* g. of *l*-compound in *50* cc. of absolute alcohol was boiled for eight hours. No change in initial rotation took place. In boiling glacial acetic acid, the rotation dropped to nearly zero in one hour but there was obviously decomposition occurring which probably accounted for this. Only a gram could be recovered from the heated solution.

A solution of 0.2107 g. of I-acid in *25* cc. of *0.1 N* sodium hydroxide gave an initial rotation of α_D —0.39"*([or]* $^{20}_{D}$ *—23.1).* After eighteen hours' standing at room temperature, no change occurred. Upon boiling for twenty-four hours, the rotations were as follows: *1* hr., a_D *—0.39";* *4* hrs., *or,* *—0.31°;* *8* hrs., α_D —0.26°; *24* hrs., α_D —0.03°. Upon acidification racemic acid was obtained, m. p. *224–225".*

Summary

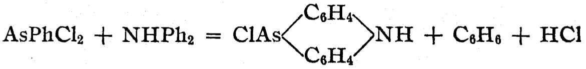
The preparation and resolution of N-2-carboxyphenyl-2,5-dimethyl-3-carboxypyrrole has been described.

URBANA, ILLINOIS

NOTES

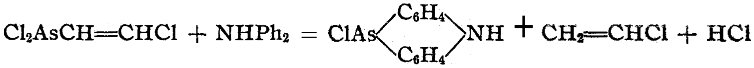
The Reaction between Dichloro-arsines and Secondary Aromatic Amines.—Lewis and Stiegler [THIS JOURNAL, 52,4164 (1930)] appear to have overlooked work already published on this subject.

Burton and Gibson [J. *Chem. Soc.,* 464 (1926)] having shown that the reaction between phenyldichloro-arsine and diphenylamine did not yield 10-phenyl-5,10-dihydrophenarsazine but 10-chloro-5,10-dihydrophenarsazine according to the equation



$$AsPhCl_2 + NHPh_2 = ClAs\left<\begin{matrix}C_6H_4\\C_6H_4\end{matrix}\right>NH + C_6H_6 + HCl$$

were led to compare the analogous reaction using β-chlorovinyldichloroarsine as described by Lewis and Stiegler [This Journal, **47**, 2546 (1925)]. They found (*loc. cit.*, p. 466) that not only is 10-chloro-5,10-dihydrophenarsazine and not "6-chlorovinylphenarsazine" formed by the action of β-chlorovinyldichloro-arsine on diphenylamine, but, by proving the production of vinyl chloride in the reaction, showed that the course of the latter may be expressed



$$Cl_2AsCH{=}CHCl + NHPh_2 = ClAs\begin{matrix}C_6H_4\\ \\C_6H_4\end{matrix}NH + CH_2{=}CHCl + HCl$$

Burton and Gibson also proved that the reaction between phenyldichloroarsine and other substituted diphenylamines and of β-chlorovinyldichloroarsine and phenyl-a-naphthylamine proceeds analogously. These results have since then been fully verified by Seide and Gorski [*Ber.*, 62, 2186 (1929)]. Scherlin and Epstein [*Ber.*, **61**, 1823 (1928)] have also shown that the reaction between β-chloro-ethyldichloro-arsine and diphenylamine yields 10-chloro-5,10-dihydrophenarsizine, the reaction being quite similar.

Phenylmagnesium Fluoride.—The relative reactivities of RX compounds with magnesium in ether is in the order RI > RBr > RCl > RF. Actually, only one RMgF compound (n-amylmagnesium fluoride) has been prepared, and this synthesis was effected by unusually extensive refluxing with a large quantity of iodine.

In connection with studies concerned with improved catalysts for the formation of organomagnesium halides, it was observed that none of the highly active catalysts induced a reaction between fluorobenzene and magnesium in ether. There has been described recently a satisfactory method for the preparation of phenylmagnesium chloride in the absence of a solvent, and this method is distinctly superior to the very slow formation of this compound when ether is used with varying quantities of iodine and with the magnesium–copper alloy.[1] In this study involving no solvent and a sealed tube it was shown that when fluorobenzene was heated with magnesium at 300° for about 200 hours, a small quantity of diphenyl formed. The formation of diphenyl is almost certain evidence for the intermediate formation of phenylmagnesium fluoride,[2] and the statement was made that this Grignard reagent would probably be prepared by heating at a lower (as yet undetermined) temperature for a longer time.

---

[1] Gilman and St. John, *Rec. trau. chim.*, 49, 717–723 (1930).

[2] Gilman and Brown, This Journal, 52, 5045 (1930).

It now appears, in strict accordance with our knowledge of the very deliberate rate of reaction of chlorobenzene and magnesium in ether,[1] that even the most refractory RX compound will probably react with magnesium in ether if sufficient time be permitted for such a reaction. This finds support in some studies made in sealed, small test-tubes wherein it has been shown that fluorobenzene undergoes reaction with the activated magnesium-copper alloy in ether after being allowed to stand at room temperatures for eighteen months, and that phenylmagnesium fluoride is formed. Individual tubes opened at intervals of one month showed no positive color test at the end of six months. Reaction, therefore, had set in some time between six and eighteen months. Quite probably a compound like *p*-difluorobenzene will form *p*-fluorophenylmagnesium fluoride more readily, because *p*-dichlorobenzene reacts more readily than chlorobenzene.

It is altogether reasonable to expect that a distinctly shorter time will be required for the formation of phenylmagnesium fluoride when the proper temperature range in sealed-tube experiments is determined or when superior catalysts are discovered. At present, however, if one desires a pure RMgX compound from a highly inert RX compound, it is merely necessary to enclose the reactants in a container to exclude the atmosphere and moisture and wait for the reaction to run its course. The compensations for such devastating delays are that the RMgX compound will almost certainly be of a high order of purity and will be formed in a high yield because side reactions are drastically reduced with the use of relatively inert RX compounds. The difficulties in most cases are more apparent than real because of the ready accessibility of the related RBr and RI compounds. In our case we needed phenylmagnesium fluoride in studies on the relative reactivities of some organometallic compounds.

A New Compound of Benzaldehyde and Anthrahydroquinone.—During an investigation on the autoxidgtion of anthrahydroquinone in benzaldehyde solution,[1] it was found that such a solution (oxygen being excluded), when containing a trace of hydrochloric acid, gave on standing in the dark at room temperature for twelve to seventy-two hours a new compound in good yield. The presence of benzoic acid appeared to favor larger yields. No reaction occurred: (1) in the absence of hydrochloric acid; (2) with anthrone substituted for anthrahydroquinone; or (3) between anthrahydroquinone and either benzoic acid or benzoin in acetone solutions.

---

[1] Backstrom and Beatty, to be published.

Since free anthrahydroquinone is awkward to handle on account of its oxidizability, a more convenient. preparation of the compound is as follows. Take 250 cc. of commercial benzaldehyde, 10 g. of anthraquinone, 10 g. of benzoic acid, 1 cc. of hydrochloric acid and 20 cc. of ethyl alcohol (to favor the photo-reduction of the anthraquinone):[2] seal the container to exclude oxygen and expose the mixture to sunlight or other illumination until the anthraquinone has dissolved. Steam distil the solution to remove aldehyde, etc., then treat the remaining tar with enough alcohol and ether to dissolve the resinous matter, leaving a dry, crystalline residue, Dissolve this in hot alcohol and add two volumes of filtered sodium hydrosulfite solution (100 g. of hydrosulfite and 100 g. of sodium hydroxide per liter of water) and two volumes of water: the anthraquinone remains in solution, and the compound may be filtered off and recrystallized from alcohol or acetone. The yield is only about 10% of the anthraquinone taken.

The compound is slightly soluble in ether, acetone and 95% alcohol (0.6 g. per 100 cc. at the boiling point), and readily soluble in hydrocarbons; the solutions are not fluorescent. It dissolves in concentrated sulfuric acid with a red color turning brown. Acetone and alcohol solutions give identical crystals—large, colorless, hexagonal tablets—melting at 211–212° (corr.) with decomposition and sublimation of anthraquinone.

Aqueous alkali is without effect on the compound; alcoholic alkali causes a very slow hydrolysis; with alcoholic hydrochloric acid the action is faster (20 mg. per hour per 25 cc.). The products of hydrolysis are benzaldehyde, qualitatively detected by its odor, and anthrahydroquinone, distinguished by its characteristic fluorescence which disappears on shaking with air.

Note on the Interaction of Tertiary Butyl Chloride and Naphthalene.—Wegscheider[1] had studied the reaction between isobutyl chloride and naphthalene in the presence of anhydrous aluminum chloride and had obtained isobutylnaphthalene boiling at 280°. The so-called isobutylnaphthalene was probably a-tertiary butylnaphthalene, b. p. 278–287°, which was later prepared from a-naphthylmagnesium bromide and *tert.*-butyl bromide by Späth.[2]

Besides the liquid butylnaphthalene, Wegscheider had also obtained a small amount of two solid substances, one crystallizing in fine, white needles of m. p. 80° and the other forming white leaflets or prisms of m. p. 146–147°. Wegscheider thought that probably the lower-melting compound was α,β-dinaphthyl and the substance of m. p. 146–147° was α,α-dinaphthyl (m. p. 154°), being somewhat impure and therefore of depressed melting point.

The writer tried to prepare *tert.*-butylnaphthalene from one mole of *tert.*-butyl chloride and one mole of naphthalene using a small amount (about 1% of the combined weight) of aluminum chloride as catalyst and finally heating the mixture just above its melting point until no hydrogen chloride came off. A liquid mono-*tert.*-butylnaphthalene of b. p. 280° never was formed; on distilling the reaction product, about half a mole of naphthalene was recovered and a fraction boiling over 300° was obtained. On changing the proportions of the starting materials to two moles of *tert.*-butyl chloride and one mole of naphthalene, practically all of the naphthalene was converted into two isomeric di-*tert.*-butylnaphthalenes which could be separated by fractional crystallization from methanol or ethanol. The one as the main product is quite soluble in these alcohols and forms fine, white needles of a salol-like odor. The substance melts at 82–83' and boils at 319'.

Anal. Subs., 0.1200, 0.1285: CO_2, 0.3960, 0.4230; H_2O, 0.1075, 0.1139. Calcd. for $C_{18}H_{24}$: C, 89.93; H, 10.07. Found: C, 90.03, 89.91; H, 10.03, 9.92.

The other di-*tert.*-butylnaphthalene, melting at 145–146° and boiling at 320°, crystallizes in white prisms and is not easily soluble in alcohol.

Anal. Subs., 0.1271, 0.1205: CO_2, 0.4185, 0.3963; H_2O, 0.1147, 0.1086. Calcd. for $C_{18}H_{24}$: C, 89.93; H, 10.07. Found: C, 89.93, 89.72; H, 10.10, 10.09.

---

[1] Wegscheider, *Monatsh.*, 5, 238 (1884).

[2] Späth, *ibid.*, 34, 2013 (1913).

An attempt was made to establish the position of the *tert.*-butyl groups in the naphthalene ring by means of boiling the di-*tert.*-butylnaphthalenes with dilute nitric acid, but no oxidation to the naphthalene-dicarbonic acids took place.

Very probably Wegscheider had already obtained these two isomeric di-*tert.*-butylnaphthalenes but his belief that his compounds of m. p. 80° and 146–147° were *α,β*-dinaphthyl and *α,α*-dinaphthyl was erroneous.

COMMUNICATIONS TO THE EDITOR

PHOTOCHEMICAL REACTIONS OF GASEOUS METHYL IODIDE

Sir:

In a recent communication to Nature, Iredale[1] has discussed the action of light upon gaseous methyl iodide. From a study of the short wave limit of the absorption spectrum, he calculates the energy of the C–H bond to be 65 Cal. and suggests, with Herzberg and Scheibe,[2] that the initial process is the dissociation of methyl idodide into CH_3 and I, since the absorption is continuous. Studies of the photochemical decomposition and oxidation of gaseous methyl iodide in progress in this Laboratory for some time past lend additional support to the idea that CH_3 and I are the initial products. The reaction behaves as though the process were actually that of the oxidation of free methyl groups. Formaldehyde, paraformaldehyde and methylal seem to be the products, while the iodine originally present in the methyl iodide can in all cases be recovered as free iodine.

A possible mechanism for the process is

$$\begin{aligned} CH_3I &\longrightarrow CH_3 + I \\ CH_3 + O_2 &\longrightarrow CH_2O + OH \\ CH_3I + OH &\longrightarrow CH_3OH + I \\ 2CH_3OH + CH_2O &\longrightarrow (CH_3O)_2CH_2 + H_2O \end{aligned}$$

Kinetic measurements are being made to determine the actual mechanism.

THE THERMAL CHLORINATION OF METHANE BY A FLOW METHOD

Sir:

We have recently been investigating the thermal (non-catalytic) chlorination of methane by a flow method. The following conclusions as to the kinetics of the reaction may be of interest.

The reaction takes place readily in pyrex glass reaction tubes above about 200° at 1 atm. total pressure. The rate is unaffected if the reaction tube is packed with broken glass, or if the internal surface of the tube is coated with potassium chloride. The reaction is, therefore, homogeneous. The effects of changes in concentration of reactants indicate that it is also bimolecular.

At the lower temperatures (225–300°) the reaction is inhibited by oxygen. Thus at 225° and five minutes' heating, 30% of the chlorine reacts when the reaction mixture consists of 60% methane and 40% chlorine at 1 atm. With 5% of oxygen present there is no measurable reaction. At 300° the suppression by oxygen is still considerable, but at 375°, at which temperature the rate of the unsuppressed reaction is very high, 5% of oxygen has no measurable effect. This effect of oxygen points to a chain mechanism. This is borne out by a discrepancy between the observed reaction rate at any temperature and that calculated by the collision theory of bimolecular gas reactions. About 1000 more molecules react than the theory predicts. A recent study of the photochemical chlorination of methane by Coehn and Cordes [Z. *physik.* Chem., Abt B, 9, 1 (1930)] has demonstrated that a chain mechanism applies here also, chains being some 10^4 molecules in length at the maximum.

This work is being extended and will be later reported in full.

glass wool, removed copper from solution, Elissafoff concluded that the copper was adsorbed at the interface and that the increased concentration of copper was responsible for the increase of rate. This conclusion was justified by close parallelism between the increased rate of reaction when the copper concentration was increased tenfold, and the increased amount of copper removed from a solution of similarly increased copper concentration.

At the time my attention was called to this article, I conducted a few brief tests with results incompatible with those of Elissafoff. The experiments could not be amplified for lack of time, and therefore it seems best to indicate them briefly now. Hydrogen peroxide solutions were decomposed in quartz vessels by freshly prepared copper sulfate solutions containing one millimole per liter of copper sulfate. It was found that the velocity constant was nearly first order and not easily reproduced in the presumably neutral solutions employed. It is felt that the data from one series of experiments may be compared among themselves, however. It was also found that the addition of glass wool to a solution containing hydrogen peroxide and copper sulfate did increase the rate of decomposition hut to a less extent than Elissafoff observed. The reaction velocities for the promoted reaction increased appreciably with time, which points to a dependence of rate upon an adsorbed catalyst. However, it was found that a filtered extract of the glass wool increased the rate quite as much as the solid material. Also it was found that increasing the amount of glass wool ten-fold increased the rate of reaction very little. From these observations it was concluded that the glass wool no doubt removed copper from solution as Elissafoff says, but not as copper sulfate. The copper probably formed a basic salt upon the surface of the glass wool, and then solid copper peroxide, a reaction which is favored by the alkali from the glass. The reaction in the absence of glass wool can be and probably is homogeneous; thus it seems probable that the mechanism of the reaction is different under "promotion" conditions than otherwise, and that this reaction is not an example of the effect of adsorption upon catalytic reaction rates.

THE OXIDATION OF CARBON MONOXIDE BY DISSOCIATED WATER VAPOR

Sir:

In a recent publication Harteck and Kopsch[1] have shown that atomic oxygen, from a discharge tube, has very little effect on carbon monoxide;

---

[1] Harteck and Kopsch, *Z. Elektrochem.*, **36,** 714 (1930).

only 5% reacted. At the suggestion of Professor Hugh S. Taylor we have carried out experiments on the action of dissociated water vapor on carbon monoxide. It seems entirely probable that in the water vapor discharge tube[2] we have a source of hydroxyl, also the reaction[3] $OH + CO = CO_2 + H$ is 24,000 cal. exothermic. That we do get oxidation is shown by the results given in Table I.

TABLE I

RESULTS OF EXPERIMENTS

Water through tube, mole	CO, mole	CO converted to CO_2, %
0.039	0.005	21.60
.059	.005	26.30

We have also passed a constant quantity of oxygen through the tube and then varied the water vapor concentration. It is to be pointed out that the exit of the tube did not become very warm, which means that the water vapor was not decreased to such an extent that recombination of the atomic oxygen took place on the walls. Also, there was no back diffusion to the discharge tube in any of the experiments. The results are given in Table II.

TABLE II

EXPERIMENTAL DATA

Water through tube, mole	Oxygen, mole	CO, mole	CO converted to CO_2, %
0.003	0.028	0.005	5.90
.012	.028	.005	24.30
.059	.028	.005	37.10

Since Copeland[4] has found that water vapor is essential for the production of atomic oxygen, we can attribute the oxidation in Harteck and Kopsch's experiment to the presence of a small quantity of water.

Further details will be published shortly.

NEW BOOKS

Handbuch der anorganischen Chemie. (Handbook of Inorganic Chemistry.) By Dr. R. ABEGG, Dr. FR. AUERBACH and Dr. I. KOPPEL. Die Elemente der achten Gruppe des periodischen Systems. Eisen und seine Verbindungen. (The Elements of the Eighth Group of the Periodic System. Iron and its Compounds.) Second part, B, Lieferung 1. S. Hirzel Königstrasse 2, Leipzig, Germany 1930. xvi + 462 pp. 139 figs. 17 × 24 cm. Price, unbound, M. 45.

In a preface to this instalment Dr. Koppel, the sole surviving editor of this Treatise, states that it had been the intention to issue the volume on Iron as a complete whole, but that delays in its preparation had made it desirable to issue it in two parts, A and B. A is to deal with the iron atom, iron metal, alloys, the compounds of iron with the metalloids other than the halogens, its passivity, corrosion, technology and analysis. B is to deal with the compounds of iron.

The present volume (B 1) constituting the first part of B, discusses the compounds of di- and trivalent iron other than the complex cyanides, the compounds of hexavalent iron, the carbonyls and nitrosyls of iron and a number of substances which according to the opinion of various investigators are derived from mono-, tetra- and pentavalent iron.

This volume maintains the valuable features characteristic of the earlier volumes of this Treatise, namely, a connected, clear and critical presentation of the subject matter from a broad theoretical standpoint.

ARTHUR B. LAMB

Elementary Practical Physical Chemistry. BY FRANK SHERWOOD TAYLOR, M.A., B.Sc., Chemistry Master at Gresham's School, Holt. Oxford University Press, American Branch, New York, 1928. xi + 130 pp. 51 figs. 12.5 × 18.5 cm. Price, $1.25.

The scope of the book is indicated in the preface, in which the author says: "This book has been written for the use of the advanced classes of schools and the first-year classes of the universities. It assumes that no apparatus is available other than that found in every school laboratory, and also that the student's time is strictly limited."

The contents of the book may be summarized as follows: Part I includes the usual procedures for the determination of molecular weights, osmotic pressures and dissociation. Part II deals with ionization (the author calls it "the ionic hypothesis"), particularly with such subjects as electrolysis, solubility products, indicators, complex ions, and the e. m. f. series. In Part III, besides the usual experiments on reaction velocities, several exercises are included dealing with the effects of temperature, concentration, light and catalysis on the speed of reactions. Part IV includes three simple experiments on the distribution of a solute between two solvents. Part V deals with heterogeneous equilibria, in which certain applications of the phase rule are introduced. Part VI is an introductory treatment of colloids, consisting of easy preparation methods.

Many of the experiments are qualitative rather than quantitative, and in all cases the theroetical basis of the experiment is briefly outlined. Many teachers might find the book useful as a source of lecture table and extra laboratory experiments.

J. H. REEDY

Volumetric Glassware. By VERNEY STOTT, B.A., F.Inst.P., Senior Assistant, National Physical Laboratory; Formerly Scholar of Peterhouse, Cambridge, England. H. F. and G. Witherby, 326 High Holborn, W. C., London, England, 1928. 232 pp. 40 figs. 14 X 22 cm. Price, 20 s. net.

The units of volume, their origin and history, are discussed in Chapter I. Tables are given showing the corrections to be added to apparent weight of water at observed temperature to give volume in ml. at standard temperature. The details of construction of measuring flasks and graduated cylinders, a device for determining the internal diameter of the necks of flasks at the graduation mark, general instructions for graduating and testing, are ably discussed. The tolerances and specifications of the National Physical Laboratory are stated in detail and a comparison is made with the tolerances and specifications of the United States Bureau of Standards. The author points out that satisfactory graduations for burets and graduated cylinders require that every numbered graduated line (every tenth line) extend completely around the cylinder or buret and the remainder at least half-way around. The effect of drainage based on delivery time of pipets and burets has been carefully studied and precautions outlined so that best results may be obtained.

The machines used for placing the graduation marks on volumetric apparatus are described, especial attention being given to those used for placing the graduations on burets and graduated cylinders in conformity with the specifications of the National Physical Laboratory and the U. S. Bureau of Standards.

A series of Calibration Tables useful in calibrating and testing volumetric apparatus completes the volume.

The book gives an excellent treatise on volumetric glassware and the information contained would be very useful to manufacturers, users and those engaged in calibrating and testing such apparatus.

E. L. PEPPER

An Introduction to Organic Chemistry. By ERIC JOHN HOLMYARD, M.A., M.Sc., D.Litt., F.I.C., Head of the Science Department, Clifton College. Longmans, Green and Co., 55 Fifth Avenue, New York, 1930. xi + 282 pages. Illustrated. 12.5 × 19 cm. Price, $1.75.

This excellent elementary textbook is based upon the author's "Outlines of Organic Chemistry" and "is intended for complete beginners—boys and girls who have just passed the School Certificate examination and are now about to enter upon the wider field of study that lies invitingly before them." It contains clear directions for many experiments and interesting discussions of the simpler portions of organic chemistry theory, but it does not cover as wide a field as is usually covered by the most elementary courses which are given in this country. It makes no mention, for example, of the Grignard reaction, of tautomerism or of the relation between color and chemical constitution.

We cannot refrain from quoting the first paragraph of Chapter One. "Those about to begin the study of organic chemistry stand at the threshold of a new world, a world of entrancing beauty and surpassing interest. With sufficient resemblance to inorganic chemistry to render its features not completely unfamiliar, it nevertheless has characteristics of its own that excite the admiration of the simple tourist, captivate the permanent settler and stimulate the explorer to penetrate its utmost recesses. There cannot be many, and there should not be any, dull moments in the study of organic chemistry. And for the novice there is the reassuring fact that organic theory is easy, logical and almost invariably obeyed, the rare exceptions serving mainly to impart a slightly piquant effect to the whole, like a *retroussé* nose upon a profile otherwise severely Grecian."

Following shortly after this is a section entitled "A Day's Experience," in which the many contacts of a London business man with the products and materials of organic chemistry are enumerated. After he has reached his office, "feeling a little stuffy in the nose, he uses his ***artificial silk*** handkerchief (made of cellulose dyed with an organic dye), upon which he has taken the precaution to sprinkle a few drops of ***eucalyptus oil,***" etc. And in the evening he "finally arrives home to a savoury organic dinner, washed down with organic beer and followed by an organic cigar." The book has a distinctly British and a distinctly pleasing atmosphere.

Holmyard's book is too elementary for the short courses in organic chemistry which are offered at American colleges. But we are not acquainted with a better book for the uses of the exceptionally bright high-school student who wishes for an acquaintance with organic chemistry beyond the scope of the regular high-school inorganic chemistry course.

TENNEY L. DAVIS

Gesammelte Abhandlungen zur Kenntnis der Kohle. (Collected Contributions to the Knowledge of Coal.) Vol. 9. By Professor Dr. FRANZ FISCHER, Director of the Kaiser-Wilhelm-Institut für Kohlenforschung. Verlag von Gebrüder Borntraeger, W 35 Schöneberger Ufer 12a, Berlin, Germany, 1930. viii + 759 pp. Illustrated. 16.5 X 25.5 cm. Price, bound, M. 70.

This volume is a collection of papers describing work done at the Kaiser Wilhelm Institute for Research on Coal chiefly during the years 1928 and 1929. The papers are for the most part reprints of papers already published elsewhere, principally in *Brennstoff-Chemie.* There are included, however, some sixteen papers not previously published, as well as an Appendix containing a history of the Institute, a description of the new Lecture Hall erected in 1929 and an account of its dedicatory exercises.

The researches described here are in part continuations of the earlier researches of the Institute relative to the origin and constitution of coal and the coal-formers, and extend them, for instance, on the biological side. Other researches are concerned with the chemical and technological problems of fuels, particularly the production of coke. Finally, there are many researches dealing with the purification of gases, catalysis and the thermal and electrical treatment of gases, all of which point to the increasing importance of synthetic fuel.

The articles are arranged under the following heads:

I. Bacteriological Researches
II. Lignin, Humic Acid and Related Fields
III. Origin and Constitution of Coal
IV. Montanic Acid
V. Chemical and Technological Researches on Coal
VI. Researches on Gases. (a) Gas purification. (b) Benzine synthesis. *(c)* Catalytic, thermal and electrical treatment of gases
VII. Carbides
VIII. Miscellaneous Articles and other Publications. Appendix: History of the Institute.

The unpublished articles are particularly concerned with the bacteriological study of coal and with the synthesis of benzine.

This volume is at once a most convenient collection of related articles and a striking demonstration of the success of the Kaiser Wilhelm Institute under the leadership of Dr. Franz Fischer.

ARTHUR B. LAMB

Die **Globuline.** (The Globulins.) By Dr. MONA SPIEGEL-ADOLP, Assistant at the Institute of Medical Colloid Chemistry of the University of Vienna. Vol. IV, "Handbuch der Kolloidwissenschaft." Verlag von Theodor Steinkopff, Residenzstrasse **32,** Dresden-Blasewitz, Germany, **1930.** xv + **452** pp. **68** figs. **15.5** X **23.5 cm**. Price, unbound, RM. **33;** bound, RM. **35.**

The distinctive chemical properties of the globulins, and their very widespread occurrence in living tissues, mark them out as among the most important of proteins. With acids and bases they are as reactive as the albumins, while their great change in solubility with changing salt concentration sets them apart from other proteins. The study of this property offers a wide and important field of physico-chemical investigation, and will undoubtedly throw light on the biological function of the globulins.

Dr. Mona Spiegel-Adolf's book is the first comprehensive monograph devoted specifically to this class of proteins. It opens with a long chapter on the occurrence of globulins in nature, the methods used in separating them from other substances, and their chemical composition and structure. Two chapters follow on the reactions of globulins with acids and bases, and the associated physico-chemical phenomena, which are treated in great detail. All those chapters deal with aspects of protein behavior in which the globulins do not fundamentally differ from the albumins, while Chapter IV deals with the distinctive behavior of globulins in neutral salts. Chapter V discusses their interaction with colloids and salts of heavy metals; and the final chapter treats of the globulins in biology and medicine, especially in their relation to immunity.

The author has gathered together a great amount of material from the most diverse sources, and has presented it very fully, with a wealth of tables and diagrams. The presentation of the work discussed is so full and so impartial that this monograph should be of great value as a work of reference.

The discussion is devoted almost entirely to the serum globulins and cdestin; the globulins of other plant and animal tissues are scarcely more than mentioned. In our present state of ignorance concerning these substances, this is probably inevitable; but this gap indicates clearly the need for further study in this important field. Even the serum globulins remain very ill-characterized, as compared with such proteins as egg albumin or hemoglobin. Dr. Spiegel-Adolf's presentation of what has already been done makes clear the need for further exact studies in many directions: both in the preparation of pure globulin solutions, and in the analytical and physico-chemical study of their properties.

The most characteristic property of globulins, their solution and precipitation by neutral salts, might well have been treated more fully. The work of Osborne and Harris on the solubility of edestin, for instance, remains a model of investigation in this field, and deserves presentation at greater length. Moreover, the original valence rule applied by Mellanby to the solvent action of neutral salts on serum globulin is clearly a special form of the ionic strength principle later formulated by G. N. Lewis, and theoretically elucidated by Debye and Huckel. The theories of Debye and Hückel have indeed already been successfully applied to some protein systems. They deserve some discussion in such a book as this, for they promise to throw light on aspects of protein behavior which have hitherto remained perplexing and obscure.

[Contribution from the Missouri School of Mines and Metallurgy]

THE SOLUBILITIES OF ALKALI CHLORIDES AND SULFATES IN ANHYDROUS ALCOHOLS

By E. R. Kikn and H. L. Dunlap

Received June 2, 1930 Published February 9, 1931

A search of the literature for information on the solubilities of inorganic salts in various anhydrous alcohols will show that comparatively little work has been recorded. Most of the data have been obtained for salts in aqueous alcohols[1] and practically all these data concern only methyl and ethyl alcohols. The solubilities of salts in these alcohols show a wide variation with different investigators. These discrepancies in results may be attributed to varying amounts of water in the alcohols, or the methods for determination may have permitted moisture to reach the solutions.

Most of the data are for one temperature only. No reference was found on the solubilities of sodium and potassium chlorides and sulfates in the lower alcohols over a wider range of temperature. Thus it was thought that such a study might show some relationship between the solubility of a salt in the various alcohols and their increasing molecular weight.

Preparation and Purification of Materials.—The salts used were Baker's c. p. salts. These salts were further purified by two recrystallizations from distilled water. After the final recrystallization, the salts were washed, pulverized and dried in an electric oven at a temperature of 150° until they gave no further loss in weight. They were then transferred to tightly fitting ground-glass stoppered bottles and kept until needed.

The alcohols were first carefully fractionated[2] using the fraction that boiled within 0.5° of the correct boiling point as accepted in the "International Critical Tables." After this fractionation, the alcohols were placed over freshly calcined lime and allowed to stand with frequent shaking, for several days, depending upon the alcohol. Methyl and ethyl alcohols were allowed to stand for a longer time. Then, after refluxing for twelve hours, the alcohols were decanted from the lime and again fractionated, the fraction boiling nearest the accepted boiling point being

---

[1] (a) Landolt-Bornstein, "Physikalish-Chemische Tabellen," pp. 730–737; (b) C. A. Lobry de Bruyn, *Z. physik. Chem.*, 10, 783 (1892).

[2] Brunel, Crenshaw and Tobin, This Journal, 43, 561–577 (1921).

collected. This fraction was then further dehydrated by the use of aluminum amalgam.

The aluminum amalgam was prepared by refluxing mercury with sandpapered aluminum chips for twelve hours. About 200 g. of this amalgam was used per liter of alcohol.

After standing over the amalgam for several days, the alcohols were carefully decanted to avoid the possibility of the formation of aluminum alcoholates[3] and again fractionated, retaining that fraction which checked the accepted boiling point within 0.2°, pressure and stem corrections being made. To test this method for dehydrating the alcohols, solubility tests on ethyl alcohol were made using potassium chloride as the solute. After its first dehydration with aluminum amalgam, a solubility determination was made and then the alcohol was again treated with aluminum amalgam and a solubility determination repeated at the same temperature. These two determinations checked very closely. In the final fractionation, the alcohols were distilled into double capped ground-glass stoppered bottles. At all times during distillations they were protected from moist air by means of calcium chloride tubes.

Apparatus.—The thermostat was similar to that developed by Goodhue and Dunlap.[4] The thermostat was electrically heated and the temperature controlled to a tenth of a degree. The method of agitation was the same as that used in the above reference.

The method for obtaining samples was similar to that devised by Weber and Dunlap,[5] but a few modifications were made to adapt it to this work It was found more practical to use a 500-cc. Kjeldahl flask provided with a well-rolled cork stopper which had been extracted previously with alcohol. A strip of thin rubber, provided with two small holes for the condenser and the sampling tube, was fastened over the cork and top of the flask to prevent moisture from coming in contact with the cork. The lower end of the sampling tube was fitted with a shortened Soxhlet thimble for filtering out the suspended salts. By forcing dry air into the flask through the driers at the top of the condenser, a sample of any amount could be taken. To prevent the thimble from removing some of the dissolved salt by adsorption, the solution was first forced back and forth through the thimble while the outlet was protected by a drying tube. The thimble was raised out of the solution during the agitation.

Procedure.—The alcohols were carefully transferred to the flasks and an excess of dry pulverized salt was added. The condenser with the filtering apparatus was attached and placed in the thermostat, with the flask submerged. The time of agitation for saturation was determined by

[5] Weber and Dunlap, *Ind. Eng. Chem.*, 19, 481 (1927).

experimentation. It was found that an hour and a half was sufficient in most cases, but more time was always allowed. After equilibrium had been reached, 25 cc. was removed; after one hour and a half, a check sample was also removed. These were collected in tightly fitting ground-glass stoppered bottles, cooled to room temperature in a desiccator and weighed.

With the chlorides, the contents of the weighing bottles were transferred to casseroles, diluted with water to about 50 cc. and then titrated with standard silver nitrate solution, using potassium chromate as an indicator. This method was checked by running blank determinations with C. P. sodium chloride having present 25 cc. of the alcohol. The two butyl alcohols, however, are immiscible with water so they were first evaporated to dryness, taken up in water, and then titrated as above.

The solutions containing the sulfates were transferred to weighed casseroles and carefully evaporated to dryness, and then reweighed. Checks were made on all determinations and only those which gave reasonably close checks were averaged for the final data. The average deviation of these check determinations was about 0.5% in the methanol, 2% in the ethanol and propanol, and 4% in the isopropanol, butanol and isobutanol solutions. These data calculated to moles of solute per mole of solvent are recorded in Table I.

Summary

Anhydrous potassium sulfate was found to be insoluble in all the alcohols used, and sodium sulfate is soluble in only three of the alcohols. The solubility of sodium sulfate in methyl alcohol increases with a rise in temperature. In ethyl and isopropyl alcohols, the solubility of sodium sulfate reaches a maximum and then decreases. The solubilities of the sulfates in alcohols follow the general trend of their solubilities in water, that is, the sodium being more soluble than the potassium sulfate.

The chlorides of both sodium and potassium in methyl alcohol show a slight decrease in solubility with temperature. In ethyl, n-propyl and isopropyl alcohols both salts pass through a maximum solubility and then decrease, the potassium decreasing more rapidly than the sodium chloride. In the butyl alcohols there is a slight increase in solubility with rise of temperature for both salts.

The solubility of all the salts decreases as the molecular weight of the alcohol increases.

THE COMPRESSIBILITY ISOTHERMS OF METHANE AT PRESSURES TO 1000 ATMOSPHERES AND AT TEMPERATURES FROM –70 TO 200°

BY HAMLINE M. KVALNES AND V. L. GADDY

RECEIVED JUNE 6, 1930 PUBLISHED FEBRUARY 9, 1931

The formation of methane as a side reaction in high pressure syntheses involving hydrogen and carbon monoxide and its use as a reactant have emphasized the need of compressibility data for the gas over a wide pressure and temperature range. Previously existing data on the compressibility of methane are for the temperature range 0 to 200° at pressures to 300 atmospheres. Amagat[1] determined the compressibility of methane for temperatures between 14.7 and 100.1° at pressures from 40 to 300 atmospheres. The absolute volumes are not given but only PV relative to the volume of a certain manometric tube. Burrell and Robertson[2] measured an isotherm at 15° to a pressure of forty atmospheres. Keyes, Smith and Joubert[3] determined five isotherms for the temperatures 0, 50, 100, 150 and 200° at pressures to about 300 atmospheres. Later Keyes and Burks[4] improved the apparatus used by Keyes, Smith and Joubert, and redetermined the data for the same temperatures and approxi-

mately the same pressure range. In the present work the data are extended to cover the temperature range −70 to 200° at pressures to 1000 atmospheres.

Method, Apparatus and Calibrations.—The method and apparatus used in the present experiments are, for the most part, the same as those already fully described in papers from this Laboratory dealing with the compressibility of carbon monoxide, hydrogen, nitrogen and mixtures of the latter two.[5] The only modification made in the equipment consisted in simplifying the former purification train to contain only two low temperature traps, one packed in ice and the other in solid carbon dioxide.

The 20-cc. bronze pipet used at the lower pressures was calibrated with hydrogen before and after the zero degree work on methane. All other pipet calibrations were made with methane at 0°.

All temperatures were controlled by hand in a manner similar to that formerly described[6] for control of temperatures below 0°. The thermocouple was the same as that used in the aforementioned work and has since then been compared with another copper–constantan thermocouple calibrated by the Bureau of Standards at temperatures of −25.92, −50.42 and —70.50'. The latter calibration was made against a platinum resistance thermometer, "standardized in the manner provided in the definition of the International Temperature Scale." It was considered accurate to about one microvolt, which is equivalent to about 0.03° in the temperature range —25 to −70°. The comparison indicated that the low temperatures were —24.99 ± 0.03°, —49.93 ± 0.03° and —69.90 ± 0.03°, for the listed temperatures of —25, —50 and −70°.

Calculations.—To determine the compressibility factor at a given pressure and temperature by the method employed in this work, it is necessary to measure the quantity of gas contained in a pipet of known volume at the given pressure and temperature. To do this the gas is allowed to expand into a larger volume where it is measured at 25° and at a pressure ranging from 480 to 1000 mm., according to the quantity of gas obtained. It is desired, however, to know the volume of gas at 760 mm. and 0°. The temperature change is calculated by using the temperature coefficient of expansion α for the gas. For gases such as hydrogen and nitrogen it is sufficiently accurate to correct the gas to 760 mm. by the ideal gas law. Methane, however, differs significantly from the ideal gas even at atmospheric pressure. The value for PV at 760 mm. and 0° is given in the "I. C. T."[6] as 0.9976. P V was assumed equal to 1 at zero pressure and the value for any other pressure was taken

from a straight line through the two points. Using the above correction for change of compressibility with pressure, samples measured at the two extremes of the pressure range checked to within 0.05%.

Gas.—The 500 cubic feet of methane gas required for this investigation were made available to the Fixed Nitrogen Research Laboratory through the courtesy of the du Pont Ammonia Corporation. It was prepared from a mixture of hydrogen and methane by condensation at the temperature of liquid air and subsequent fractional distillation to remove traces of dissolved hydrogen. The previous history of the gas precluded the presence of nitrogen. Ordinary methods of analysis failed to show any other impurities. Other tests[7] indicated a purity of 99.88 ± 0.02%.

Experimental Results

The experimental results are given in Table I. Each PV value with the exception of those given for zero and one atmosphere pressure is the average of two or more separate determinations. At all temperatures determinations were made at pressure intervals sufficiently small accurately to define the shape of the isotherms. At the lowest temperatures this necessitated obtaining a few data at pressure intervals of five atmospheres.

The PV value at zero pressure and 0° was taken as the reciprocal of the aforementioned "I. C. T." value of 0.9976, which agreed to better than 0.1% with the value obtained by extrapolation of the PV–P curve through the points at 1, 30 and 40 atmospheres. The remaining values at zero pressure were calculated, using the ideal gas temperature factor, while those at one atmosphere were taken from a curve drawn through the zero, 20, 30 and 40 atmosphere points.

Figure 1 is a plot of the isotherms obtained by dividing each PV value by the value at zero pressure for that temperature. The curves thus all have the same origin, that is, $PV = 1$, at zero pressure. They are drawn through every experimentally determined point, and in all cases give smooth curves.

Discussion

The data obtained by Keyes and Burks[4] on the compressibility of methane have been incorporated in Table I. Their results are given in specific volumes so that it was necessary to calculate the corresponding PV values and plot them for the pressures given in order to obtain the values of the table at the even pressures. No extrapolations beyond the range of pressures examined by Keyes and Burks were made. The error in plotting was less than 0.05%.

The range of temperature and pressure in this work duplicates the

---

[7] Dr. Rossini of the Bureau of Standards used some of this gas in an investigation to be published in the *Bureau of Standards Journal of Research.* He found by analysis 0.12% of CO, and combustion ratios of carbon to hydrogen checked this value.

[a] Keyes and Burks, THIS JOURNAL, **49,** 1403 (1927).

pressure range of Keyes and Burks[4] at 0 and 50°, while at the three higher temperatures they duplicate only the extremes of the pressure ranges. Throughout the entire pressure range for 0 and 50°, the present results are higher than those of Keyes and Burks by 0.05 to 0.20%. At 100, 150 and 200" agreement of the two sets of data appears satisfactory except at 60 atmospheres at 150° and at 200 and 250 atmospheres at 200°. Here the maximum deviation, which occurs at 250 atmospheres at 200°, amounts to 0.24%.

The order of taking the data presented in Table I was very irregular. In the course of a day determinations would often be made at three or four different temperatures over a comparatively small pressure range. This manner of collecting the data minimized the chance that any one isotherm might contain a constant error peculiar to itself. The regularity of the data, as a whole, attests the accuracy of the method.

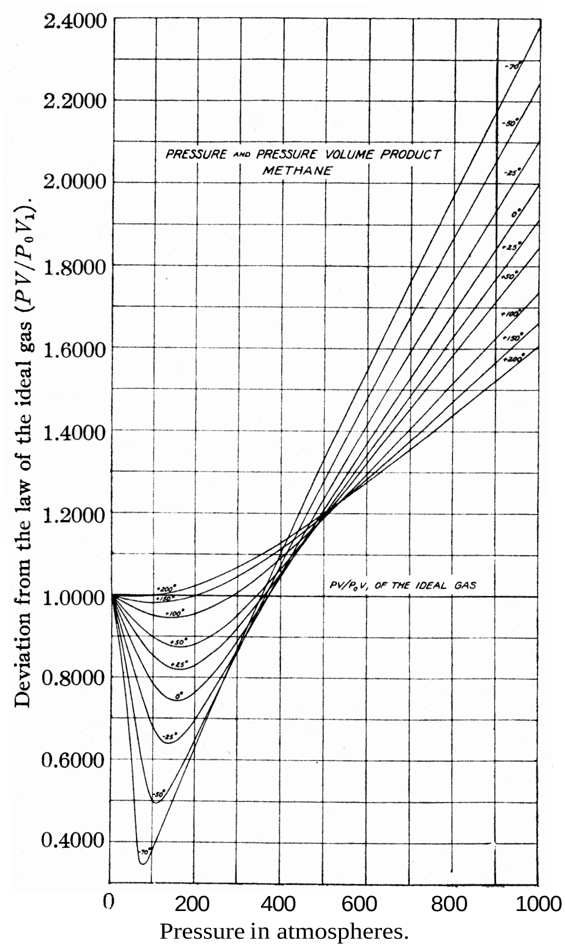

Fig. 1.

Two lines of evidence indicate that adsorption did not occur on the walls of the pipet to any appreciable extent. First, when gas was allowed to expand from the pipet at high pressure, there was no increase in the quantity of gas obtained after the outlet valve was completely opened. Second, two pipets having wall surfaces in the ratio 1:4 and volumes in the ratio 1:16 gave results agreeing to 0.05% or better at 70 atmospheres and −50" and at 80 atmospheres and −25°.

Below 100° the isotherms show great curvature at all pressures. Above 370 atmospheres this is in such a direction that the slope of the isotherm decreases with increase in pressure. The 100° isotherm is straight through the 500–1000 atmosphere range, while through this same range the slopes of the 150 and 200" isotherms increase with increase in pressure.

The "unique point' found in nitrogen[6] at 380 atmospheres and with carbon monoxide[6] at 375 atmospheres is duplicated in methane at 533 atmospheres for the 100 to 200° range. This indicates that through a certain temperature range every gas may exhibit this phenomenon. Below the "unique" temperature range the P V isotherms will deviate with decreasing temperature toward the isotherm of the gas and liquid at the critical temperature and above this range will deviate toward the isotherm of the ideal gas, becoming identical with it at infinite temperature. Hydrogen at −70° is already above the range, nitrogen is within it from 100 to −70°, while carbon monoxide is within it for the temperature interval −70 to 200°.

The authors wish to express their appreciation for the advice and encouragement received from Dr. E. P. Bartlett during the progress of this work. The range of experimental data was made possible through the cooperation of the staff of the Fixed Nitrogen Research Laboratory.

Summary

The compressibility isotherms of methane have been determined to 1000 atmospheres at nine temperatures through the range −70 to 200°. In the range of pressure and temperature duplicated, the results are in agreement with those of Keyes and Burks. With the exception of the pressure interval 500–1000 atmospheres at 100° the compressibility isotherms have considerable curvature.

COBALTIC SULFATE AS AN OXIDIZING AGENT[1]

BY SHERLOCK SWANN, JR., AND THEODORE S. XANTHAKOS

RECEIVED JUNE 23, 1930 PUBLISHED FEBRUARY 9, 1931

Since the oxidation potential of cobaltic sulfate is the highest of any of the easily regenerated oxidizing agents which might be used as oxygen carriers in the electrolytic oxidation of organic compounds, a study of its behavior as an oxidizing agent seemed desirable.

By the use of organic compounds of varied susceptibilities to oxidation, such a study should give an indication of the feasibility of cobaltic sulfate as an oxygen carrier and should also indicate the type of oxidation for which cobaltic sulfate is best adapted. The work was undertaken with these ideas in mind.

The only reference found in a literature search where cobaltic sulfate was used as an oxidizing agent was in a paper by Conant and Aston[2] in which they showed that isobutyric aldehyde was oxidized to acetone and other products.

Experimental

At the beginning of the investigation a method for the preparation of cobaltic sulfate was sought. That which suggested itself immediately was the electrolytic method described by Erich Müller,[3] which consisted in the oxidation of cobaltous sulfate in 8 N sulfuric acid at a platinum anode. The yields obtained were not entirely satisfactory under these conditions. A study was therefore undertaken to determine the optimum conditions for the preparation in the hope of improving the yield and shortening the time required.

The apparatus consisted of a large porous cup of 800 cc. capacity as the anode compartment which was placed in an 1000-cc. beaker. A platinum sheet of 80 sq. cm. area was used as the anode while a sheet of copper of about 300 sq. cm. area on the anode side which surrounded the porous cup served as the cathode.

The anolyte consisted of 500 cc. of a saturated solution of cobaltous sulfate in sulfuric acid. The catholyte was of the same composition. In all cases a current of 5 amperes was employed. The anode current density was therefore about 0.06 ampere per sq. cm. The temperature was controlled either by a cooling coil or an ice-bath

Experiments were carried out at various temperatures and with different concentrations of sulfuric acid The results are given in the tables.

The free acid concentration was determined electrometrically. The cobaltic sulfate prepared was always in suspension in the anode liquor, which was so viscous that a sample could not be taken by means of a

[3] Erich Muller, "Elektrochemisches Praktikum," 4th ed., p. 210.

pipet. A quantitative analysis was therefore not possible. It was estimated by weight after filtration by suction through asbestos. The product was not dried further.

TABLE I

EFFECT OF TEMPERATURE

Free acid normality	Temp., °C.	Duration of oxidation in hours	$Co_2(SO_4)_3$ per 100 cc. of soln., g.
8	25	5.5	0
8	23	5.5	Very little
8	18	5.5	Very little
8	10	3.5	15
EFFECT OF FREE ACID CONCENTRATION			
8.3	10	2.75	33.2
9.55	10	3.5	47.7
10.7	10	2.5	40
11.9	10	3.67	21

This method of determining cobaltic sulfate is not accurate on account of the large amount of mother liquor retained by the crystals. The results should be comparable, however, because each determination was made in the same way.

In order to determine the effect of current density, some experiments were carried out in a much smaller cell. The method of analysis was different in this set of experiments. At the end of each run the anolyte was poured into a standard solution of $N/10$ sodium oxalate. The excess oxalate was titrated electrometrically with $N/10$ potassium permanganate. The results of these experiments are shown in the following table.

TABLE II

EFFECT OF CURRENT DENSITY ON YIELD

Amp.	Current density in amp. per sq. cm.	Duration of oxidation in hours	Yield of $Co_2(SO_4)_3$, g.
0.7	0.0088	2.75	2.48
1.0	.043	2.75	4.00
0.7	.047	2.75	3.15
1.0	.073	2.75	3.75
1.0	.180	2.75	4.40
0.7	.350	2.75	2.97

The temperature in these experiments varied between 10–13". It was noticed that the crystals of cobaltic sulfate became smaller with increase of current density until at 0.18 amp. per sq. cm. the solution could be drawn up into a pipet very readily. The optimum current density is roughly between 0.01 and 0.2 amp. per sq. cm.

Finally the current and material yields of cobaltic sulfate were determined. Since small crystals were obtained at a current density of 0.18 amp. per sq. cm., the current density used in this set of experiments was almost the same, 0.17 amp. per sq. cm. The current efficiency was determined as the oxidation progressed by an analysis of a 1-cc. sample of anode suspension drawn out by means of the pipet. The cobaltic sulfate was determined electrometrically as in the last set of experiments. The cobaltic sulfate was present in the form of fine crystals which were distributed uniformly throughout the anode liquor. The results are shown in Table III.

TABLE III

EFFECT OF DURATION OF OXIDATION ON CURRENT EFFICIENCY AND YIELD

Duration of oxidation	Amp.	Current efficiency, %	Material yield in % by wt.	$Co_2(SO_4)_3$, normality of anode suspension
1 hr. 40 min.	1	84.3	...	0.225
2 hrs. 52 min.	1	74.5	...	.415
3 hrs. 52 min.	1	63.8	(93.33)	.560
5 hrs.	1	..	...	.564

Temp., 6°. Normality of H_2SO_4, 10. Normality of $CoSO_4$, 1.2. Volume of anode solution, 100 cc. Theoretical amount of electricity, 2 faradays.

The anode liquor was always kept free from soluble organic materials since they either retarded the rate of oxidation of the cobaltous salt or prevented its oxidation.

From the results of the experiments carried out it may be shown that satisfactory conditions for the preparation of cobaltic sulfate in the apparatus described are as follows.

The solution must not be allowed to rise in temperature above 10°. The normality of free sulfuric acid should be 10. The current density may vary roughly between 0.01–0.2 amp. per sq cm.[2] Higher current densities cause the product to form in smaller crystals than in the case of lower current densities. Not more than a five-ampere current should be employed for 500 cc. of anolyte; otherwise the temperature cannot be controlled. The cobaltic sulfate precipitates out in the form of greenish-blue crystals on account of its insolubility in the strong sulfuric acid. The maximum yield will be obtained at the end of four hours.

Oxidations with Cobaltic Sulfate.—In order to estimate the strength of cobaltic sulfate as an oxidizing agent, it was tried with the following organic compounds of varied susceptibilities toward oxidation: amylene, benzene, ethyl alcohol and acetic acid.

It was thought that cobaltic sulfate might be used to best advantage as an analytical reagent to oxidize certain organic compounds to carbon dioxide quantitatively rather than as an oxidizing agent in preparations because too large quantities were necessary on account of its high molecular weight. With this idea in mind the following compounds were studied: acetone, glycerin, ethylene glycol, and formic, tartaric, citric and malic acids.

Apparatus and Procedure

For the oxidations to test the oxidizing power of cobaltic sulfate a shaking machine was set up, holding an Erlenmeyer flask of 500-cc. capacity which could be surrounded by an ice–salt bath.

The organic compound to be oxidized was placed in the flask with the cobaltic sulfate suspension just as formed in the anode compartment of the cell. A rubber stopper was inserted containing a rubber tube leading to a gas-collecting bottle filled with water. The flask was surrounded by an ice–salt bath and was then shaken for two to three hours. At the end of that time it was found that oxidation had taken place and the green suspension had turned to a pink solution. The gas was analyzed for carbon dioxide and the solution steam distilled after the removal of insoluble material.

The steam distillate was neutralized with standard sodium hydroxide, evaporated to dryness and the salt weighed. The salt was dissolved in water and less than the theoretical quantity of sulfuric acid was added to liberate any organic acid. Sufficient water was used to obtain a solution of 1 to 2% of free organic acid. This was distilled away from the sodium sulfate and a Duclaux[4] test run.

The procedure for the complete oxidations was not the same. In this case the apparatus and procedure of Franz and Lutze[5] was followed.

The organic compound to be oxidized was placed in a three-necked flask equipped with a stirrer. In one neck was placed a glass tube leading to the bottom of the flask and drawn out to a capillary. This was connected by rubber tubing to a soda lime tower. The tubing could be closed by a screw clamp. The soda lime tower was connected to the air line. The other neck of the flask was connected to a train consisting of a wash bottle containing water, a large calcium chloride tower, an anhydrone tower and an ascarite tube in the order named.

A weighed amount of the organic compound was placed in the flask with the cobaltic sulfate suspension. Liquids were washed in with a little water and the connection to the air line shut off. The stirrer was started and the oxidation was allowed to proceed for about an hour. The air line was then opened and a slow stream of air was allowed to bubble through the liquid in the flask for half an hour while the flask was heated by a water-bath. The ascarite tube was weighed and the percentage of carbon dioxide calculated.

In the preparations of cobaltic sulfate for these runs it was found that the yields were practically identical if the conditions were always the same. Therefore, no determination of the amount of cobaltic sulfate in the suspension was made. It was assumed that the same quantity was present in every run. The results of the investigation are given in Table IV.

TABLE IV

RESULTS AND CONCLUSIONS

	CO_2, %	Aldehydes	Acids	Moles of compound	Moles of $Co_2(SO_4)_3$
Amylene (mixture)	0	Trace	Formic and others	0.422	0 14
Benzene	0	Phenolic	Compounds	5	14
Acetic acid	0 2	.....	....	75	.14
Ethyl alcohol	4 08	Considerable	Considerable acetic	0164	14
Acetone	13	None	Considerable acetic	0149	14
Glycerine	0	None	Considerable formic	0274	14
Ethylene glycol	96 05			0099	14
Formic acid	99.96			0205	14
Tartaric acid	101.22	..	....	00099	11
Citric acid	99.87	..	....	000745	14
Malic acid	100.3	..	....	001368	14
Malic acid	73.2			002543	14

The amount of product from the oxidation of benzene was insufficient for purposes of identification. Phenolic compounds were shown to be present by their odor.

---

[4] Kamm, "Qualitative Organic Analysis," 1923, p. 139

[5] Franz and Lutze, Rer., **57B,** 768 (1924).

The results of the oxidation of amylene, benzene, ethyl alcohol and acetic acid show that cobaltic sulfate behaves as a strong oxidizing agent and should be an excellent oxygen carrier for anodic oxidations in cases where no interference with its formation occurs.

It may seem strange that while formic acid is completely oxidized when no other compounds are present, it remains unoxidized in the presence of amylene and glycerin. This may be explained by the fact that formic acid might be more difficult to oxidize than the other two compounds in strong acid. Hatcher and West[6] found formic acid in the oxidation of malonic acid by acid perrnanganate. They showed that the rate of oxidation of formic acid was inversely proportional to the PH of the solution. The Duclaux test was carried out with great care and it is not believed that the information from it is misleading.

The results of the experiments on complete oxidation indicate that cobaltic sulfate may be used in the same manner as persulfates for types of compounds which are easily oxidized to carbon dioxide.

In all cases where cobaltic sulfate is used as an oxidizing agent most of it decomposes to yield free oxygen. Rapid decomposition sets in even at low temperatures. The organic compound seems to catalyze this decomposition. Consequently for complete oxidations it is necessary to use very large quantities of cobaltic sulfate. It is used, therefore, to best advantage as an analytical reagent and not for the purpose of oxidizing large quantities of material.

Summary

1. **A** study of the electrolytic preparation of cobaltic sulfate has been carried out.

2. The behavior of cobaltic sulfate as an oxidizing agent for organic compounds has been studied. It has been shown that cobaltic sulfate is a strong oxidizing agent. It may be used as an analytical reagent for oxidizing certain compounds quantitatively to carbon dioxide.

THE PHOTOCHEMICAL DISSOCIATION OF TRIATOMIC MOLECULES. II. POTASSIUM CYANIDE

BY DONALD STATLER VILLARS

RECEIVED JUNE 24, 1930 PUBLISHED FEBRUARY 9, 1931

In a previous article[1] the dissociation energetics of hydrogen cyanide were investigated and it was found that if this molecule were of an atomic binding, as are the corresponding hydrogen halides, one should not expect it to have a continuous absorption spectrum in an energy region less than 6.2 volts ($\lambda > 1990$ Å.). This was verified experimentally. The next molecule chosen for investigation was potassium cyanide. This should be more amenable to experimentation, if one may infer an analogy between the corresponding cyanides and halides.

The Heat of Dissociation of Normal Potassium Cyanide.—The *atomic* heat of formation (Q_A) of potassium cyanide (the heat of formation from the gaseous atoms) may almost be estimated from data in the "International Critical Tables."

$$\begin{aligned} \text{KCN (c)} + Q + L_{S_K} + L_{S_C} + {}^1/_2 D_{N_2} &= \text{K} + \text{C} + \text{N} \qquad (1)\\ \mathbf{1.2} + 0.9 + \mathbf{6.4} + 4.8 &= \mathbf{13.3}\text{ v} = Q_{A-\text{KCN(c)}} \end{aligned}$$

From this value must be subtracted the heat of sublimation, L_S, to get the atomic heat of formation of gaseous potassium cyanide. This is not known but an estimate may be obtained by a method to be described below.

$$Q_{A-\text{KCN(g)}} = \mathbf{13.3}\text{ v.} - L_S = E_1 \qquad (2)$$

When we consider the four possible dissociation combinations as in the previous work, we find we have the heat of formation of CN but not that of either KN or KC. However, we shall assume that the stability of such unsatisfied (as to valence) molecules is quite small, especially as their band spectra are not known, and, if this is so, such modes of dissociation should occur relatively infrequently when compared with the process

$$\text{KCN (g)} + E_2 \longrightarrow \text{K} + \text{CN} \qquad (3)$$

The energy, E_2, then is

$$\begin{aligned} E_2 &= \mathbf{13.3} - L_S - \mathbf{7.3}\text{ v.}\\ &= 6.0 - L_S \qquad (4) \end{aligned}$$

Experimental

The apparatus was of the same type as that used in the investigation of hydrogen cyanide, with the exception of a small Gaertner quartz spectrograph which was used instead of an E_1 Hilger. Although the dispersion of this instrument is much less (the whole spectrum of visible and ultraviolet is spread over a distance of about 105 mm.), nevertheless, this proves to be an advantage as the light strength of the instrument is so much the

greater. The hydrogen arc (initial pressure of hydrogen 1.45 mm.) was run at about 0.55 ampere and 3500 volts and exposures of five and ten minutes were made. The potassium cyanide (Baker's 96–98% pure; SO_2, 0.05%; Cl, 0.25; org. matter, trace) was placed in the quartz tube adjacent to the constriction leading to the quartz absorption cell and after evacuating and outgassing the latter the cyanide was heated to distil it over into the cell. It melted quite readily and the liquid boiled (pressure 10^{-4} mm.), at the same time turning black. The distillation did not take place very readily, but several drops of the melt were pushed bodily across the constriction. The cell was sealed off and the isolated product had a clear transparent appearance with a reddish tint. No liquid-air trap was used during the evacuation process. The potassium compound was quite ruinous to the cell at high temperatures (1050°) as it caused such a rapid devitrification of the quartz that it fell to pieces shortly after cooling to room temperature.

A possible objection which might be made to the present work is that the spectra observed do not come from potassium cyanide, but from potassium hydroxide which might have been left behind as an hydrolysis product after the evacuation. Before the cyanide was sealed off, it had absorbed an appreciable amount of water during the glass blowing. This objection is overthrown by two considerations. First, an analysis of the residue showed that, within titration errors, there was no potassium hydroxide present. Second, it has been shown in a subsequent research, which will be reported later, that potassium hydroxide has to be heated to a much higher temperature before it will reach a vapor pressure great enough to absorb.

Results

Figure 1 gives the microphotometer record of the hydrogen source transmitted by the cell at room temperature (no absorption). The banded structure is due to the impurities in the lamp, the latter being only newly broken in. Figure *2* gives the record of the absorption at about 830° and Fig. 3 that at 875°. It is seen that, at this latter temperature, there are two regions of absorption. A visual study of the original plate indicated that the long wave length limits of these two regions are 2175 and 2900 Å., which correspond, respectively, to 5.7 and 4.3 volts, the difference being 1.4 v.

Since the difference of 1.4 v. is, within the errors of measurement, equal to the excitation energy of CN (1.8 **v.)** or K (1.6 v.), it is indicated that the photochemical dissociation process requiring least energy is the one resulting in normal products. This conclusion is not yet inescapable for the following reasons. If the longest wave length limit of continuous absorption should be at an energy corresponding to dissociation into a normal and an excited product, the next continuous absorption region should correspond to dissociation into a product in the next higher excited state. These energies would be in the following steps: K' (1.6), CN' (1.8), K" (2.71, CN" (3.21, K' + CN' (3.4), etc. Granting that in the roughness of the measurement the two expected regions spaced by 0.2 v.

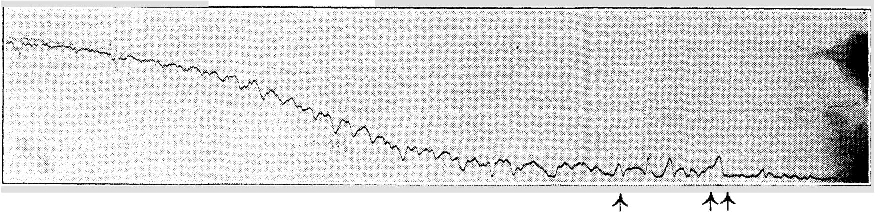

Fig. 1.—Plate M8, H_2 lamp, five minutes, cell at room temperature.

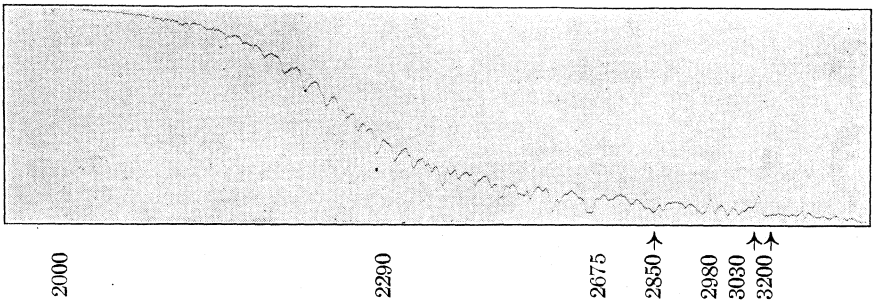

Fig. 2.—Plate M8 KCN, 790–870°.

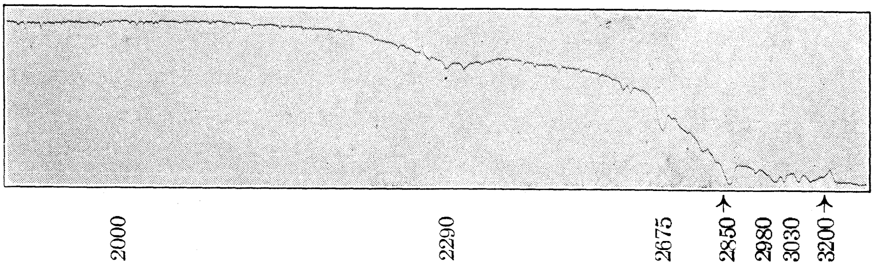

Fig. 3.—Plate M8 KCN above 875".

(K' and CN') are indistinguishable and that the one 1 v. farther on (K") has too low an intensity, the next one (CN") is at the experimentally observed distance from the first two (1.5 v.). One could decide for or against this possibility if he knew the heat of sublimation of potassium cyanide. For, if the first photochemical act were a dissociation into two *normal* products the energy, E_2, should exactly equal the energy corresponding to the convergence limit of continuous absorption (4.3 v.).

If the act were a dissociation into a normal and an excited product, the longest wave length limit should correspond to $E_2 + 1.6$ v. (or $+ 1.8$).

Although there are no measurements given of the heat of sublimation of potassium cyanide, an estimate may be obtained by making use of the third law. We know that, in order to absorb light, the vapor pressure must reach a value of the order of magnitude of 1–10 mm. Absorption not setting in until a temperature of 870° was reached, we shall assume the vapor pressure at this temperature to be 1 mm. Now if we can know the entropy of crystalline and gaseous potassium cyanide at that temperature we can calculate from the free energy of sublimation the heat of sublimation by the equation

$$AF = AH - TAS = -RT\ln K = -RT\ln p\text{ vapor} \qquad (5)$$

$$\log p_{\text{atm.}} = -\Delta H/4.575T + \Delta S/4.575 \qquad (6)$$

Latimer[2] has shown that the entropy of diatomic solids may be well represented by the sum of "atomic" entropies

$$S^\circ_{298\text{ solid}} = (3/2)R\ln A - 0.94 \qquad (7)$$

If we treat potassium cyanide as a diatomic molecule, counting 26 as the atomic weight of CN, we get

$$S^\circ_{298\text{ KCN (c)}} = 18.73\text{ E. U.}$$

Latimer's equation for the entropy of a diatomic gas

$$S^\circ_{298\text{ gas}} = R\ln(w^{3/2}A_1^{1/2}A_2^{1/2}) + 30.22 \qquad (8)$$

gives

$$S_{298\text{ KCN (g)}} = 49.58$$

and

$$\Delta S_{298} = 30.85$$

Correcting for temperature, we have

$$\begin{aligned}\Delta S_{1143} &= 30.85 + 3R\ln T/298 - (5/2)R\ln T/298 \\ &= 29.51 \qquad (9)\end{aligned}$$

Substituting these values in Equation 6 above and using for the pressure 0.00132 atm. we get AH = 48.75 kg. cal. = 2.1 v. = L_S. Therefore, $E_2 = 5.9 - 2.1 = 3.8$ v., which agrees very well with the observed long wave length limit of continuous absorption of (4.3 v.). It should be emphasized here, before passing on, that our estimate of the entropies of solid and gaseous potassium cyanide is extremely crude and for that reason the calculated value of E_2 is subject to considerable error.

From the above we see that, on the one hand, if the first photochemical act were dissociation into a normal and an excited product, the heat of dissociation into normal products would be approximately $4.3 - 1.6 = 2.7$ v., which corresponds to a heat of sublimation of $L_S = 6.0 - 2.7 = 3.3$ v. (= 74 kg. cal.). This requires, if our A S is correct, a vapor pressure of 10^{-5} mm., which is not enough for absorption. On the other hand, if the first act is a dissociation into normal products and we go to the

---

[2] Latimer, THIS JOURNAL, **43,** 818 (1921).

extreme of taking the observed value of 4.3 v. for E_2 (a value which does not necessarily follow as the convergence limit of the absorption series was not actually observed), this gives a heat of sublimation of L_S = 6.0 − 4.3 = 1.7 v. (= 37 kg. cal.), which corresponds to a vapor pressure of 170 mm., much nearer the correct order of magnitude to account for light absorption in a cell only some 77 mm. in length.

Validity of the **Franck–Kuhn**[3] Criterion of Atomic and Ionic Binding.—It has been pointed out recently by Sommermeyer[4] that the test proposed by Franck and Kuhn[3] as a distinction between an ionic and an atomic binding is not definitive and is rigorous only when an atomic binding is indicated. This is because of the discovery by Herzberg[5] and Heitler[6] of a *second class* of atomic molecules, the *normal* state of which dissociates on vibration into a normal and an excited product. Thus, the thermal dissociation of normal CN (convergence limit at 9.5 v.) is supposed by Mulliken[7] to result in a normal ^3P carbon atom and an excited ^2D nitrogen atom. CN excited 1.8 v., however, dissociates into two normal atoms (convergence limit 8.6 v. above normal state of molecule). The potential energy curves of the *first class* of atomic molecules are represented in Fig. 4, while those of the new *second class* are represented by Fig. 5. Rigorously, when the longest wave length convergence limit is at an energy equal to the heat of dissociation into *normal* products, it means that the molecular state which dissociates into atoms on vibration (atomic binding) is an excited state of the molecule. Our data show that this obtains in potassium cyanide vapor, but are not sufficient to define whether it is a second-class molecule of atomic binding or a molecule of ionic binding. We may be reasonably certain, however, that it is an ionic molecule, first because the only second-class atomic molecules known are those having unsatisfied

free valences, and second because the crystal structure[S] of potassium cyanide is the same as that of rock salt and presumably of an ionic nature. In general, the potential energy curves of ionic molecules cross in the same way as do those of second class atomic molecules (Fig. 5). This must be so if the data on electron affinities of the halogens are correct, for they are usually less (~ 3.5–4.5 v.) than the ionization potential of the metal (5.12, Na; 7.5, Ag; 4.3, K; etc.). This is not a necessary condition for validity of the principle that the first photochemical dissociation act (the one requiring least energy) of an ionic molecule will result in normal products. It makes no difference whether the ionic binding curve crosses the atomic binding one or not. Although at the end of the curve for NaCl (Fig. 5) the dissociated state, $Na^+ + Cl^-$, is higher than the one, Na + Cl, still we cannot expect to find an extra continuous absorption region corresponding to dissociation into the former products, because it belongs to the same potential energy curve as the initial (absorption) state and such large changes in vibrational quantum number with no change in electronic quantum number not only are not known, but they violate the Franck–Condon principle.

The change with temperature in the relative stability of the ionic and atomic forms of silver iodide postulated by Franck and Kuhn[3] is due, we should like to suggest, not to a variation in shape of the curves for different temperatures (they must necessarily be independent of temperature) but to the variation of the free energy of the reaction

$$\text{Ionic} \rightleftharpoons \text{Atomic} \tag{10}$$

From Equation 5 may be obtained[9]

$$\Delta F = D_0 - T A S' \tag{11}$$

where D_0 is the heat of reaction (absorbed heat) at the absolute zero and[10]

$$S'_{\text{rot.}} = R \ln 8r^2 IkT/h^2 \tag{12}$$

$$S'_{\text{vibr.}} = -R \ln (1 - e^{-\epsilon/kT}) \tag{13}$$

Thus

$$AS' = R \ln I_A (1 - e^{-\epsilon_I/kT})/I_I(1 - e^{-\epsilon_A/kT}) \tag{14}$$

$$\longrightarrow R \ln I_A \epsilon_I/I_I\epsilon_A \text{ for } \epsilon << kT$$

$$\longrightarrow R \ln I \qquad \text{ for } \epsilon >> kT$$

Since the moment of inertia in the atomic bound molecule is presumably larger and the vibrational quantum smaller, AS' is positive and therefore A F will vary from a positive quantity at O°K. (= D_0) to a negative quantity at very high temperatures. This corresponds to the behavior postulated by Franck and Kuhn of the ionic and atomic forms of silver iodide. If this suggestion is valid, it seems that it should be possible, by going to still higher temperatures, to find one above which the atomic form of sodium chloride is in greater abundance than the ionic form.

Summary

Potassium cyanide vapor at 875° absorbs light in two regions, the long wave length boundaries of which are approximately 2175 (5.7 v.) and 2900 Å. (4.3 v.). The latter absorption region is interpreted, according to Franck, Kuhn and Rollefson, as representing dissociation of the ionic molecule into a normal potassium atom and a normal CN radical and agrees within 0.5 v. with the calorimetric data, supplemented by an estimate of the heat of sublimation (48.8 k. cal.). The former absorption act takes place at an energy 1.4 v. greater and represents dissociation into a normal and an excited dissociation product (K excitation 1.6; CN, 1.8 v.). The change with temperature in stability of the two molecular forms postulated by Franck and Kuhn is explained in the light of the free energy.

THE MEASUREMENT OF THE CONDUCTANCE OF ELECTROLYTES.[1] III. THE DESIGN OF CELLS

BY GRINNELL JONES AND GILES M. BOLLINGER

RECEIVED SEPTEMBER 22, 1930 PUBLISHED FEBRUARY 9, 1931

Historical Introduction

In 1923 H. C. Parker[2] published two papers which challenge a fundamental postulate of the Kohlrausch method for the measurement of the conductance of electrolytes, by the observation that "cell constants" are apparently not really constant but vary with the resistance being measured. If a solution of specific conductance, κ, is placed in a cell, A, whose length is l and whose cross section is a, then the fundamental premise of the Kohlrausch method is that the resistance, R_A, is given by the equation

$$R_A = \left(\frac{l}{a}\right)_A \frac{1}{\kappa} \qquad (1)$$

$(l/a)_A$ is designated as the "cell constant"[3] and has been assumed to have a fixed value for any given cell at a given temperature, and this assumption is vital for the Kohlrausch method.

If we have two different cells, A and B, and fill them with the same solution and designate the corresponding resistances and cell constants by

---

[1] The first two papers in this series are: Grinnell Jones and R. C. Josephs, THIS JOURNAL, 50, 1049 (1928); Grinnell Jones and Giles M. Bollinger, ibid., 51,2407 (1929).

[2] H. C. Parker, ibid., 45, 1366, 2017 (1923).

[3] If the cross section is not uniform the cell constant is $\int_0^l \frac{dl}{a}$.

suffixes, we may eliminate the specific conductance of the solution used giving

$$\frac{R_A}{R_B} = \frac{(l/a)_A}{(l/a)_B} \tag{2}$$

Therefore, if Equation 1 is valid, the ratio of the resistances of any pair of cells when filled with the same solution should be the same as the ratio of the cell constants, and should be independent of the composition and concentration of the solution used and hence of the resistance being measured. This ratio should also be independent of the frequency and the voltage used in the measurements.

Parker compared the resistances of two cells, sealed together so as to facilitate filling them with a common solution, and found that the ratio of the resistances, instead of being constant, varied in a complicated but systematic manner with the specific conductance of the solution chosen for the comparison. Parker has recorded data and drawn curves for seven cases. In these curves the ratios of the resistances are plotted as ordinates and the resistances of the cell having the lower cell constant as abscissas. The lines depicting the resistance ratio, instead of being horizontal and straight, have a varied shape. All show a steep negative slope at low resistances. Three of his curves show both a maximum and a minimum, two a minimum but no maximum, and two show a gentle negative slope at high resistances but no maximum or minimum. The phenomena are evidently very complicated. He has not determined the influence of variations in frequency on the cell resistance ratios. Although the variations are apparently exaggerated in his figures because the zero on the ordinate scale is not shown, the variations are substantial. In one case recorded by Parker the deviation amounts to 0.33%. If, as seems probable, the errors in the two cells are in the same direction, this figure is the difference in the errors, and the actual error in using Equation 1 may be greater by a considerable and unknown amount. All measurements were made with solutions of potassium chloride.

Parker regards polarization as the cause of the steep negative slope of these curves at low resistances. He is doubtless correct in this interpretation although he makes no attempt to show that the shape of his curves is in conformity with the known facts about polarization. In view of the earlier literature on polarization this interpretation lacks novelty.

On the other hand, Parker appears to have been the first to observe the more gentle and usually positive slope of these curves at resistances above the range in which polarization predominates. At any rate he was the first observer with the courage to record his data, and we shall therefore call this anomaly the Parker Effect to distinguish it from polarization. This positive slope at moderate resistances is ascribed by Parker to adsorption of electrolyte at the electrodes, although the arguments in favor of this suggestion are extremely weak. He is unable to account for the peculiarities of his various cases by the aid of this hypothesis. He offers no explanation of the appearance of a maximum and a negative slope at very high resistances and gives it little consideration because it does not appear in all of his cases.

Randall and Scott[4] have confirmed the existence of the Parker Effect. They used a single pair of cells only, not sealed together, and a single frequency (1000 cycles), but used four electrolytes, potassium chloride, barium nitrate, sodium sulfate and sulfuric acid. For potassium chloride their results are similar to those of Parker. The steep negative slope at low resistances, which Parker ascribed to polarization, is absent for the other three electrolytes. The Parker Effect, represented by a positive slope of the resistance ratio curves, was obtained with barium nitrate as well as with potassium chloride. They concluded from their experiments that the Parker Effect is absent in the case of sodium sulfate and sulfuric acid and regarded this alleged difference in behavior of these electrolytes as supporting the hypothesis advanced by Parker that adsorption is the cause of the phenomena since it is characteristic of adsorption to vary greatly in different cases. It should be noted, however, that when the cells were filled with sulfuric acid and with sodium sulfate, measurements at high resistances were omitted. Whereas with potassium chloride the highest resistance measured in the longer cell was about 64,000 ohms, when using sulfuric acid the upper limit was only 5100 ohms, and, therefore, these experiments do not prove that the curves might not have been similar if comparable resistances had been used. In the case of sodium sulfate the upper limit was about 31,000 ohms, a little less than half that used with potassium chloride. The result with this most dilute solution does show a rise of about 0 10%; nevertheless this rise is ignored by Randall and Scott in drawing their curves and in the interpretation of their data. Randall and Scott offer no reason for ignoring the evidence of their data on the highest resistance they measured or for not extending the measurements on sodium sulfate and on sulfuric acid to as high resistances as were used with the other salts. The only suggestion for a remedy of the Parker Effect that they offer is that sodium sulfate would be a better substance than potassium chloride for standard solutions for the determination of cell constants. But this suggestion, even if it were based on unquestionable premises, would not give a means of obtaining accurate conductance data if adsorption of the salt being measured can cause an error.

Some recent experiments by F. A. Smith[5] are of interest as an extreme example of the Parker Effect. His cell contained three electrodes consisting of coaxial cylinders open at the ends, two of which were concentric and

---

[4] M. Randall and G. N. Scott, THIS JOURNAL, 49,636 (1927).

[5] F. A. Smith, *ibid.*, 49, 2167 (1927).

close together and the third at some distance from the others, presenting its edge to an edge of the others. By using the two electrodes positioned close together, a cell of low cell constant was available, and by using one of the close electrodes and the distant electrode a second cell having a cell constant about two hundred times greater was available. Smith's data afford comparison between two cells of widely different cell constant, covering a great range in concentration and extending to very high resistances under conditions that insure identity of composition of the solution in the two cells. Smith reports a change in the apparent cell constant ratio between the most concentrated solution and the most dilute amounting to more than 50%. This is an extreme case of the Parker Effect. Smith reports such data on three cases, ammonium chloride dissolved in liquid ammonia, ammonium nitrate dissolved in liquid ammonia, and potassium chloride in water. The data on these three cases, when plotted as resistance ratio against resistance in one cell, all fall on the same curve. This creates a presumption that the cause of the effect is purely electrical, rather than due to adsorption. If the effect is to be explained as due to adsorption it will have to be maintained that the adsorption in these three cases and the variation thereof with the concentration cause an identical effect on the conductance, which is hardly plausible. Smith used a single frequency of 1000 cycles only. His cells were closely shielded and without proper grounding of the bridge, which probably contributed to the very large errors, so that errors of this magnitude are not to be regarded as common or unavoidable.

O. Redlich[6] has devised a radically different method of measuring conductance in an effort to avoid errors due to electrode processes (polarization, adsorption, etc.). His apparatus may be regarded as a double alternating current potentiometer instead of a Wheatstone–Kohlrausch bridge. His cell contained three platinized platinum electrodes of the usual type which served as current electrodes, and near each a small platinum potential electrode through which no current flows when the measurements were being made. With a given solution in the cell he made measurements by the Kohlrausch method between three pairs of large electrodes and also by his new method between three pairs of small electrodes. The solution was replaced by another of different specific conductance and the measurements repeated. In this way several cell resistance ratios were compared using two radically different methods of measurement. He varied the specific conductance of the solution used by about ninetyfold and when using the large electrodes and the Kohlrausch method found no variation in cell constant ratio greater than 0.03%. Just what difference in cell design or bridge design or manipulation as compared to Parker's is responsible for the comparatively small Parker Effect in his experiments is

[6] *O.* Redlich, *Z. physik.* Chem , 136,331 (1928).

not discussed by Redlich and is not immediately obvious. So long as the resistances being measured did not exceed 2300 ohms the results by the new method agreed with those of the older method within about 0.03%. At higher resistances discrepancies up to 0.1% occurred.

Recently Shedlovsky[7] has designed, built and tested a new form of cell intended to eliminate any effects at the electrodes which would disturb conductance measurements, especially polarization and adsorption. In Shedlovsky's cell the two end electrodes, which carry the current and are subject to electrode effects, were in different adjacent arms of the bridge and hence electrode disturbances tended to compensate each other. The midpoint of the bridge was inside the cell itself and consisted of a loop of fine smooth platinum wire. Since the loop composing the midpoint was nearer to one of the end electrodes than to the other, the difference of the resistance of the portions in the two arms had to be balanced by a resistance box in the same arm as the short portion of the cell. Shedlovsky provided three different midpoint loops at different positions which could be used in turn. He made measurements at three different frequencies, 1000, 2000 and 3000 cycles. He filled his cell with four different solutions (0.005 *N* KCl, 0.001 N HCl, 0.002 N HCl, 0.004 N HCl) and on each filling measured each electrode combination at each of his three frequencies. By subtracting the readings obtained by the use of the three different loops he attempted to eliminate the electrode effects entirely. Although the individual readings show deviations from the mean up to a maximum of 0.08%, the results indicate that the differences obtained as described above are probably reliable to within 0.01%. It should be pointed out, however, that the specific conductance of the solutions used in these tests only covered a fourfold range, so that the test was not as severe as if a wider range had been used. This range is inconveniently small for the practical use of the cell. The necessity of taking multiple readings and subtracting the results is a disadvantage in the routine use of the cell; nevertheless Shedlovsky's cell is evidently a distinct step in advance in eliminating polarization and other electrode effects. It would be interesting to have

---

[7] T. Shedlovsky, THIS JOURNAL, 52, 1806 (1930). During the course of our experimental study of the problem we learned that Dr. Theodore Shedlovsky of the Rockefeller Institute for Medical Research in New York was engaged in a study of the same problem. We have kept in touch with each other's work by occasional visits and frank discussion and correspondence while attacking the problem along different lines Dr. Shedlovsky's paper has been published after the completion of our experimental work but before the completion of our manuscript. We wish to compliment Dr Shedlovsky on his literary skill in writing his paper so as to embody only ideas already in the literature and his own new ideas with a complete exclusion of ideas based on our work which we had disclosed to him in advance of publication. Since Dr. Shedlovsky's paper has now been published it is not necessary for us to attempt the same difficult task, but we cordially acknowledge Dr. Shedlovsky's priority on all points covered in his recent paper on cell design.

data obtained with the Shedlovsky cell on concentrated solutions in which polarization is a more serious difficulty.

It is evident that the Parker Effect, unobserved or at least unreported until 1923, throws suspicion on the data on the conductance of electrolytes obtained by the Kohlrausch method. The work cited above appears to show that the concept of a fixed and definite cell constant is invalid. Although there is no certain criterion for estimating the magnitude of the error, since the method of intercomparison of cells shows only the differences in the errors in two cells and not the absolute error in either, it is evident that errors up to at least 0.3% are likely to be present with cells of the type commonly used in spite of precautions which eliminate errors due to polarization. In one case with a cell of unusual design an error of 50% was reported. Moreover, there is no adequate theory to account for the error or errors. The hypothesis that adsorption is responsible fails to account for the known facts and has not suggested to anyone a practical remedy.

The general consistency of the data in the literature makes it seem improbable that errors of as much as 0.3% are commonly present in the results of the more careful and experienced investigators. This may indicate that some faulty detail of design may have aggravated the error in the cases cited above. But an adequate understanding of the nature and causes of the Parker Effect is urgently needed to permit an estimate of the reliability of the great mass of data now available, and, more important still, to guide the design of cells which may be relied on to have a fixed and definite cell constant.

The Determination of Phase Displacement in Conductance Cells.—All of the earlier experimenters on the Parker Effect, except Shedlovsky, have been content to use a single frequency, but our experience in the study of the errors in the bridge made it probable that the study of the influence of variations in frequency would be a great aid in understanding the nature of the phenomena. Accordingly, at least two frequencies were used in each case except in some of the preliminary trials.

Although nearly all experimenters on conductance since the time of Kohlrausch have used a capacitance in parallel with the resistance box to obtain a sharp balance, very few have recorded these capacitance readings, C_P, or made any attempt to interpret them. This is doubtless due to the fact that there was so much reactance in their circuits outside the cells (such as inductance in a helically wound slide wire, capacitance and inductance in the resistance boxes and in the bridge, and capacitance introduced by shields) that the capacitance required to obtain a balance did not depend solely or even largely on the reactance in the cell itself and, therefore, it was not to be expected that the parallel capacitance required could be correlated with the design of the cell, the frequency, specific conductance, or chemical nature of the solutions used. Some of the investigators of polarization in cells, beginning with Wien, have obtained significant information from the study of the reactance in their cells, but none of the experimenters on the Parker Effect has published the capacitance required to obtain a balance. Our bridge was designed to avoid inductance and capacitance as much as possible and it was therefore hoped that the capacitance required in parallel with the resistance box would depend primarily on the reactance in the cell and give a clue to the nature of the error responsible for the Parker Effect. We, therefore, recorded the capacitance required to obtain a balance in each of the readings, by the use of a calibrated condenser in parallel with the resistance box. The precision of these capacitance readings was much less than the precision of the resistance readings because the capacitance in most cases was very low (commonly under 100 micromicrofarads at resistances over 1000 ohms, where the Parker Effect becomes serious, and in some cases it was even below 5 micromicrofarads) and because the bridge was not designed as a capacitance bridge; nevertheless, the results did prove to be helpful in the interpretation of the data.

Since the phase displacements in the ratio arms of the bridge have been made as nearly equal as possible, we can regard the phase displacement, θ, in the arm of the bridge containing the resistance box and parallel condenser as equal to the phase displacement in the cell itself.[8] This can be computed from the well-known formula for a parallel combination of resistance and capacitance

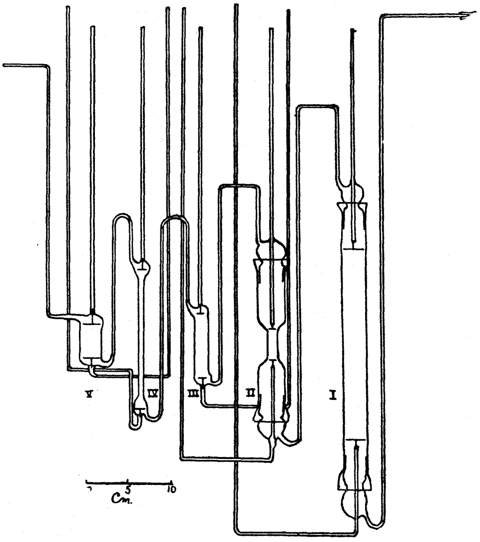

Fig. 1.—Pipet type cells, I–V.

$$\tan \theta = C_P \omega R \tag{3}$$

where f is frequency in cycles per second and $\omega = 2\pi f$.

Five cells differing greatly in design were selected or especially built and sealed together by their filling tubes, as had been done by Parker, to facilitate filling them with a common solution. These cells are shown somewhat diagrammatically in Fig. 1. Cells I, II, III had approximately the same cell constants but differed greatly in dimensions. The electrodes in cells I and II were made interchangeable by means of ground joints

---

[8] Grinnell Jones and R. C. Josephs, THIS JOURNAL, 50, 1070 (1928).

These joints were very carefully ground and made perfectly tight by means of a trace of pure, soft paraffin around the outer edge. The upper joints were protected from the oil by a layer of mercury and the lower joints by the air trapped under the rim. Cells IV and V differed greatly in dimensions and cell constants from the others. The dimensions of these cells are shown in Table I.

TABLE I

If adsorption plays a significant part in the Parker Effect, it would be expected that lightly platinized electrodes should give less Parker Effect than heavily platinized electrodes. We, therefore, determined to make a series of measurements to test the Parker Effect with light platinization, and then give the cells a heavy platinization and repeat the measurements. But in order to have a fixed standard of reference, cell III was given a heavy platinization in advance and remained unaltered during both series. The other four cells were treated with aqua regia to remove an old platinization and were then given a light platinization using a solution of platinum chloride and hydrochloric acid (with no lead acetate) as shown in Table I. At this stage the platinization was so slight as to be barely perceptible to the eye as a slight tarnish or dimming of the bright electrode. The first series of measurements on cell resistance ratios was then carried out. For this purpose a potassium chloride solution of suitable concentration was prepared in a large "Non-Sol" bottle and thence forced into the five cells in series by compressed air. The cells were filled and emptied repeatedly to ensure thorough rinsing. In order to avoid changes in concentration of the solution by evaporation, the air used was first bubbled through some of the same solution before it entered the stock bottles. The cells were then placed in the thermostat and, after waiting for at least one-half hour for temperature equilibrium, the resistance of each cell was measured with 1090 cycles and with 2280 cycles. The capacitance required across the box in the other arm of the bridge to secure a balance was also determined from the reading of the condensers and recorded for each measurement. The solution was then replaced by a more concentrated solution and the measurements repeated. Twelve different solutions covering the range 0.0005 to 1.0 N were used. The cells, except No. III, were then given a much heavier platinization on top of the light platinization, as is shown in Table I. The electrodes at this stage did not have the deep sooty black color which can be obtained by using platinizing solutions containing a trace of lead acetate but were black with a slightly grayish or metallic appearance. Then the second series of measurements on cell resistance ratios was carried out.

The solutions used in the second series were approximately of the same concentration but not identical with the solutions used in the first series. The ratio of the specific conductance of these solutions can be computed from the data on cell III because in this case the cell itself was unchanged, but no direct comparison can be made between the first and second series without making due allowance for the difference in specific conductance, and for the fact that the cell constants may have been slightly changed by the additional platinization.

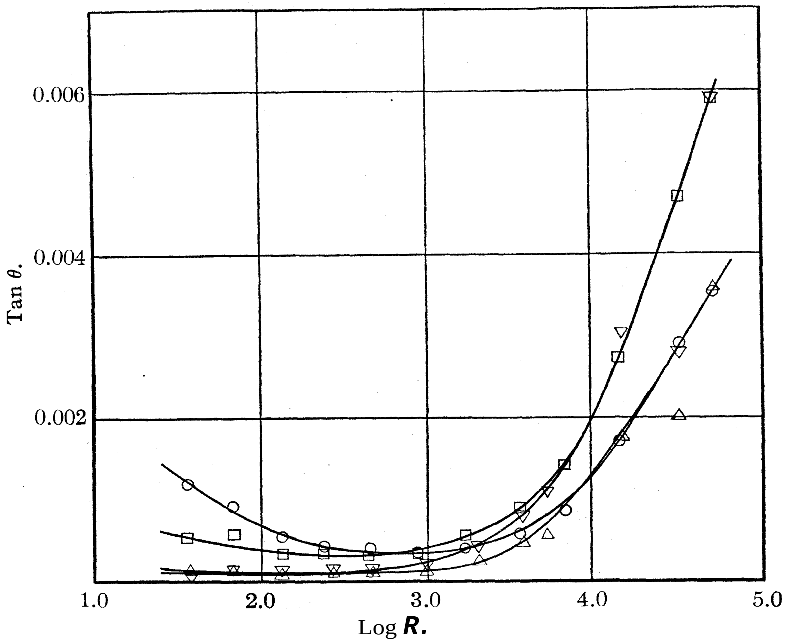

Fig. 2.—Cell I: ○, 1090 L; 0,2280 L; △, 1090 H; ▽, 2280 H.

The primary data of these cell comparisons are shown in Tables II to VI, inclusive, in which the successive columns have the significance: (1) the number of the solution of potassium chloride used; (2) the approximate concentration; **(3)** the resistance in ohms when measured with 1090 cycles, R'; (4) the capacitance in micromicrofarads required in parallel with the resistance box in the other arm of the bridge to give a balance, C_P, when using 1090 cycles; (5) the tangent of the phase angle, $\tan \theta = C_P\omega R$, when using 1090 cycles; (6) the resistance with 2280 cycles, R''; (7) the parallel capacitance at 2280 cycles; (8) the tangent of the phase angle at 2280 cycles; (9) the change in resistance caused by changing the frequency from 1090 to 2280 cycles, $-(R''-R')$, with sign reversed for convenience; (10) the percentage change in resistance with reversed sign, $-100(R'' - R')R'$.

The Significance of Phase Displacement in Cells.—Figures 2 to 6 give plots of tan θ against log R for each of the five cells at two frequencies and with two degrees of platinization. The log R is plotted as abscissa instead of R merely to avoid confusion due to crowding of the points at the lower resistances. In the legend under Figs. 2–10 the numbers 1090 and 2280 designate the frequency used, L signifies light platinization, and H heavy platinization.

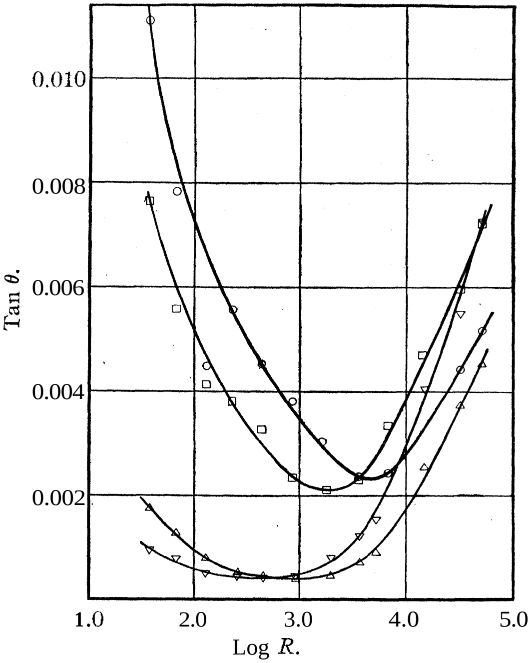

Fig. 3.—Cell II.

In these curves the outstanding feature is that the phase displacement goes through a minimum which indicates that there are two phenomena superimposed on each other. At low resistances the phase angle is undoubtedly one aspect of polarization. These data and curves make it evident that there is another and distinct disturbing effect which causes a phase displacement and which increases rapidly with the resistance being measured. This disturbance apparently also causes an error in the resistance which is responsible for the Parker Effect. Our task is, therefore, to analyze the data for the purpose of elucidating the nature of this disturbing effect and to ascertain the sign of the error in the resistance caused thereby and the factors controlling its magnitude and, if possible, to find a means of eliminating this error. From a study of these data and curves the following general conclusions may be drawn.

(1) The measured resistance with 2280 cycles, R", is always less than with 1090 cycles, R', when all other conditions remain unchanged. Tables II–VI give 109 instances of this without a single exception and this conclusion is in accord with much other experience in this Laboratory.

$R')/R'$, goes through a minimum at intermediate values of the resistance. (This is not shown by Cell IV, for which data at very low resistances are not available.)

(4) For any given cell and frequency the phase displacement, $\theta = \tan^{-1}C_P\omega R$, goes through a minimum at intermediate values of the resistance being measured. This minimum is shown in nineteen cases in the tables. In the case of Cell IV at 2280 cycles when heavily platinized the minimum was not observed but it would probably be found below the lowest resistance measured.

(5) Increasing the frequency or increasing the platinization causes the minimum in the phase angle to occur at a lower resistance.

At low resistances, where polarization has the predominating influence, the following characteristics appear.

(6) For any given cell and frequency the parallel capacitance always has its greatest value at the lowest resistance measured, and decreases rapidly from this high value with increasing resistance.

(7) The parallel capacitance is much less at 2280 cycles than at 1090.

(8) For any given cell and frequency the phase angle is reduced by increasing the resistance being measured.

(9) The phase angle is reduced by increasing the frequency.

(10) The effect of increasing the platinization is to reduce greatly the parallel capacitance, the phase angle, and the change in resistance caused by a change in frequency. This drop in parallel capacitance is doubtless due to an increase in the series capacitance since the two are related by the equation

$$C_s = \frac{1}{C_P\omega^2 R^2} \qquad (4)$$

(11) A comparison of the curves for the different cells indicates that polarization and the related effects are reduced by increasing the area of the electrodes and increasing the distance between them.

At high resistances, where polarization becomes relatively insignificant and the disturbance responsible for the Parker Effect predominates, the phenomena are very different.

(12) The parallel capacitance becomes nearly independent of the resistance and of the frequency.

(13) The phase angle is increased by increasing the resistance or by increasing the frequency.

(14) The parallel capacitance and phase angle are not influenced by the degree of platinization.

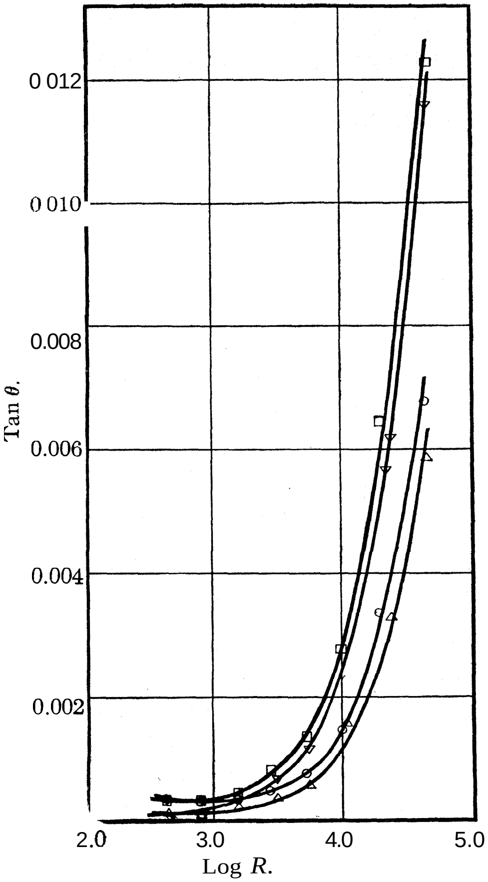

Fig. 5.—Cell IV: O, 1090 L; □, 2280 L; A, 1090 H; V, 2280 H.

The Cell Resistance Ratios—Polarization and Parker Effect.—From these data on five cells we can obtain ten intercomparisons similar to Parker's, each at two frequencies and with two degrees of platinization. All of the possible forty curves have been drawn but since they are not all mathematically independent, we have selected illustrative examples of the different types for reproduction in Figs. 7 to 10. The cell resistance ratios from which these curves are drawn are not printed, in order to save space, because they can be readily computed by anyone interested from the data in Tables II to VI.

The curves obtained are of varied types.[9] The curve depicting the ratio V/III shows a steep fall with increasing resistance at low resistance (especially when unplatinized) and a steep rise at high resistances, giving a sharp minimum. I/III, on the other hand, has a negative slope throughout—gentle at low resistances but steep at high resistances. II/III is like I/III in showing a negative slope throughout, but is much steeper at low resistances than at high resistances. Attention is called to the fact that in drawing curve II/III it was necessary to use a vertical scale only about $^1/_{20}$ of that used in the other cases. In the case of V/IV [not printed] when lightly platinized both frequencies give curves with a sharp minimum similar to V/III; when heavily platinized and using 1090 cycles there is a minimum although a flat one, but with 2280 cycles the minimum disappears entirely, giving a positive slope throughout.

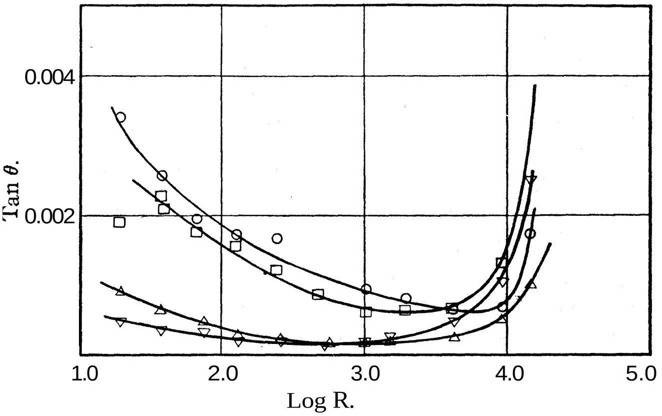

Fig. 6.—Cell V: O, 1090 L; □, 2280 L; A, 1090 H; V, 2280 H.

This variation in the shape of curves in different cases is clearly due to the fact that there are errors in both cells and the location of the points above or below the true cell constant ratio depends on the sign of the error and on which of the two cells has the greater fractional error. With only resistance ratio curves as a guide it would be extremely difficult to decide as to which of the two cells has the predominating influence and as to the sign of the error. Indeed, as will be shown, Parker himself reached

---

[9] In comparing these curves with those of Parker it should be noted that we have plotted log R as abscissa instead of R, to avoid undue crowding of points at low resistances. It should also be noted that Parker always puts the cell of lowest cell constant in the numerator, whereas we have found it desirable in all cases in which cell III was used to put this cell in the denominator to facilitate comparison of the different curves.

an erroneous conclusion on these questions at resistances high enough so that polarization ceases to be the controlling influence; but by using our tan θ curves as an indication of the quality of the cells, together with a consideration of the influence of the frequency and of the degree of platinization, we hoped to be able to unravel the nature of the disturbances and to determine the sign and perhaps the magnitude of the errors.

These data confirm Parker's results in showing that the ratio of the resistances of two cells when filled with a common solution is not independent of the concentration of the solution used. An extreme example is given by a comparison of cells V and II when both were lightly platinized. When using 1090 cycles and with both cells filled with a normal potassium chloride solution, the ratio of the resistances was 0.28497, whereas when both were filled with a 0.0005 N solution the ratio was 0.28851, a difference of 1.25%.

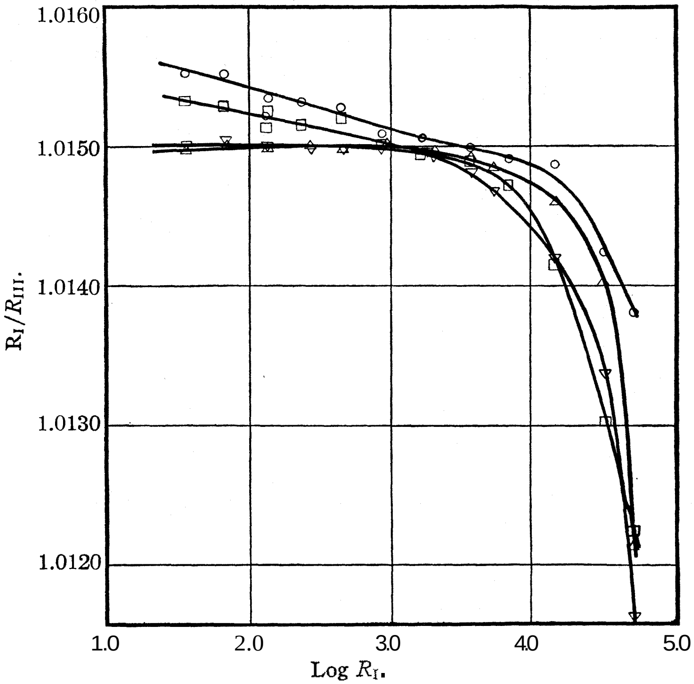

Fig. 7.—Cell resistance ratios, I/III: O, 1090 L; □, 2280 L; A, 1090 H; ▽, 2280 H.

Although our various curves differ among themselves greatly in slope and curvature, none of them shows both a maximum and a minimum, as do some of Parker's. His curves indicate clearly that in some of his experiments there were at least three disturbances present, but ours show indications of only two causes of error. It seems probable that this simplification of the problem has been accomplished by the improvements in our bridge as compared to that used by Parker. These improvements have been described in the first and second papers of this series. Of the two disturbances which remain, the one which predominates at low resistances is clearly polarization and the other is presumably responsible for the Parker Effect.

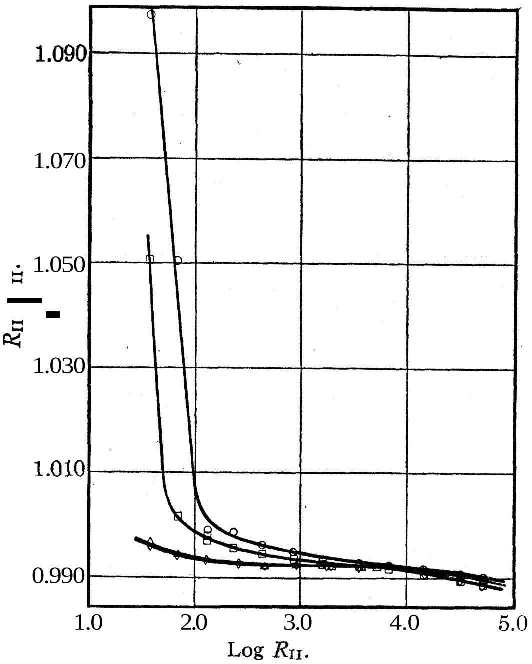

Fig. 8.—Cell resistance ratios, II/III: ○, 1090 L; □, 2280 L; A, 1090 H; V, 2280 H.

Polarization has long been known and has been the subject of many investigations. One of the effects of polarization is to cause a capacitance in series with the resistance of the cell, as is clearly shown by the phase displacement. If this were a pure capacitance and followed the harmonic laws characteristic of geometric capacitance, it could be compensated without causing an error in the resistance measurements. But it has been demonstrated by Wien,[10] Miller,[11] and others that one aspect of polarization is an added polarization resistance in series with the true electrolytic resistance of the solution in the cell. The error in the measured resistance of a cell due to polarization is always positive. The polarization resistance is independent of the distance between the electrodes and therefore the percentage error caused by polarization resistance can be decreased by using cells of high cell constant. Of two cells which are alike except in the distance between the electrodes, the shorter cell will have the relatively greater polarization error when both are filled with the same solution. Polarization can also be minimized, as was suggested long ago by Kohlrausch, by platinization of the electrodes, by the use of high frequencies and by the use of large electrodes. The behavior of our cells at the lower resistances as shown in the tables and curves and

[10] M. Wien, *Wied. Ann.*, 58, 37 (1896).

[11] C. Miller, Phys. Rev., [2] 22, 622 (1923).

summarized above (see pp. 424–425, paragraphs numbered 6–11) is clearly consistent with this interpretation. Increasing the platinization or increasing the frequency at low resistances always causes a decrease in the phase angle and tends to make the cell resistance ratios more nearly constant. From the consideration of the dimensions of our cells we should expect that the influence of polarization would be the greatest in cell II and decrease in the order V, III, I, IV. It will be apparent from these curves, data and discussion that in order to minimize errors due to polarization it is desirable to use a high frequency and to use a cell of high cell constant so that the resistance being measured will be high; but both of the expedients aggravate the disturbance responsible for the Parker Effect and, therefore, do not furnish a satisfactory solution of the problem unless and until the cause of the Parker Effect can be ascertained and a remedy for it invented.

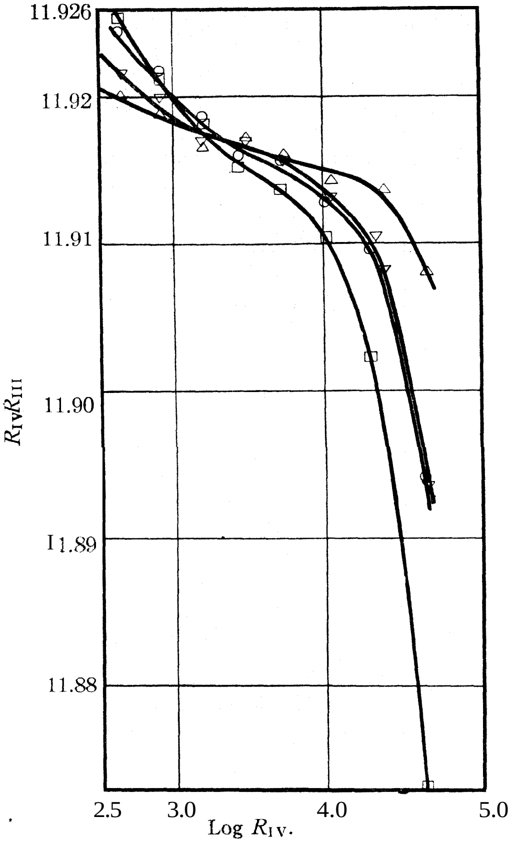

Fig. 9.—Cell resistance ratios, IV/III: ○, 1090 L; □, 2280 L; A, 1090 H; ▽, 2280 H.

The disturbance which predominates at the higher resistances and is presumably responsible for the Parker Effect is clearly different from polarization. It is independent of the degree of platinization and is aggravated rather than cured by an increase of frequency. The hypothesis that adsorption is responsible, as suggested by Parker[12] and supported by Randall and Scott,[13] is discredited by the fact that the effect was not increased by a tenfold increase in the amount of spongy platinum present. This disturbance is like polarization in causing the current to lead the voltage but it differs in that the phase displacement increases rapidly with increased resistance being measured, whereas the

---

[12] H. C. Parker, THIS JOURNAL, 45, 1378 (1923); 45, 2021 (1923).

[13] M. Randall and G. N. Scott, ibid., 49, 642 (1927).

phase displacement due to polarization decreases with the resistance, as is shown by the occurrence of a minimum in the phase displacement and the rapid rise at the higher resistances. It also differs from polarization in that the phase displacement corresponds to a parallel capacitance which is independent of the frequency and the resistance. This suggests that we are dealing with a real parallel capacitance instead of a series capacitance.

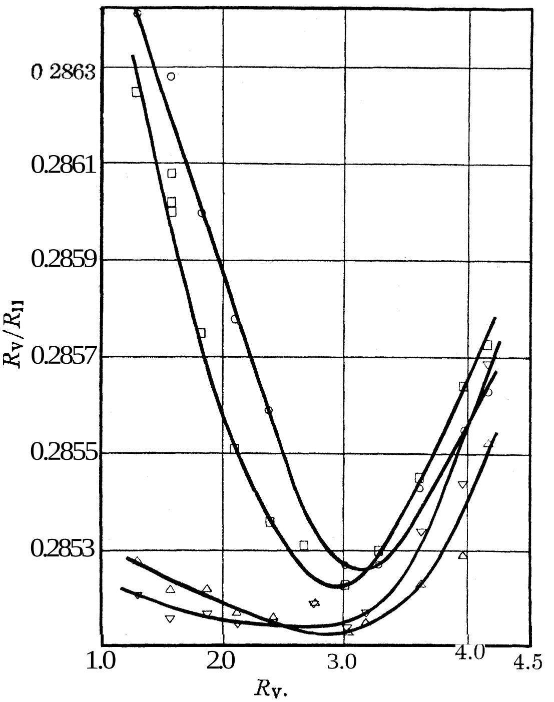

Fig. 10.—Cell resistance ratios, V/III: O, 1090 L; □, 2280 L; A, 1090 H; ▽, 2280 H.

We now come to the question of the sign of the error in the resistance which is responsible for the Parker Effect. Parker accounted for the positive slope in his resistance ratio curves in the following manner. ‘‘It is evident from the direction of the effect in the more dilute solutions that if the correction which should be applied to the resistances to give a constant ratio, is *relatively* greater for the shorter cell, then the correction is negative." . . "The facts gathered thus far indicate that the effect is in the cell itself and that the correction is negative, that is, that the resistances, R, should be corrected by an amount ΔR, which should be subtracted from the apparent resistance.’’[14] But our cells show both positive and negative slopes in the resistance ratio curves at the higher resistances. The rapid increase in the phase displacement at the higher resistances and the increased slope of the resistance ratio curves at the high resistances are clearly related. Both the phase displacement and the slope of the resistance ratio curves are increased by increasing the frequency, thus clearly showing that the disturbance responsible for the Parker Effect is increased by increasing the frequency. But since increasing the frequency always decreases the apparent resistance at high resistance as well as at low resistances, it follows that the error in the resistance due to the Parker Effect must always be negative and increase in magnitude with the frequency and

[14] H. C. Parker, THIS JOURNAL, 45, 1375 (1923).

the resistance being measured. Hence, contrary to Parker's conclusion, the correction must be positive. The fact that the error is always negative suggests a shunt path for the current which is electrically in parallel with the solution between the electrodes. A shunt is much more effective across a high resistance than across a low resistance, which is the case for the disturbance responsible for the Parker Effect. The clear indication of a parallel capacitance given by a study of the data suggests that the shunt is not a pure resistance but contains the equivalent of a condenser, The influence of a shunted condenser would increase with the frequency, which accords with our experience. But if the impedance in the shunt were due solely to capacitative reactance, it could be fully compensated by a condenser shunted across the resistance box without causing an error in the resistance, which is not the case. We must, therefore, infer that the shunt contains resistance as well as reactance. And now a renewed inspection of the pipet cells with the vision thus sharpened reveals the shunt clearly; it consists of the resistance in the filling tube, and the capacitance through the glass walls of the cell and the thermostat oil between the solution in the filling tube and the mercury in the contact tube of opposite polarity; together with distributed capacitance between the electrolyte in the cell proper and the filling tubes and contact tubes, as shown diagrammatically in Fig. 11. Having once seen the shunt we wonder why no one ever saw it before, and are chagrined that our eyes had been blind so long.

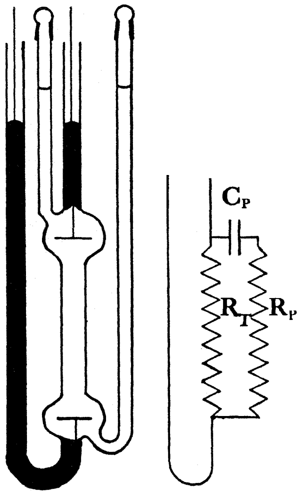

Fig. 11 —Capacitance bypaths in pipet cell.

Since according to this hypothesis the disturbance causing the Parker Effect is not primarily an electrode effect, it would be expected that the degree of platinization will have little if any influence, which is in accord with our experience.

The earlier investigators who came the nearest to the solution of this problem appear to be Morgan and Lammert.[15] They measured the resistance of a series of solutions covering a wide range of resistance at two different frequencies in several cells with unplatinized electrodes. They have observed points (1), (2). and (3) listed above (pp. 420–423). They say: "Throughout the work the capacities were measured and found to be

---

[15] J. L. R. Morgan and O. M. Lammert, THIS JOURNAL, 45, 1693–1697 (1923). This paper was published only one month after the first paper of Parker [*ibid.*, 45, 1366 (1923)] and therefore Morgan and Lammert must have written their manuscript before they had an opportunity to read Parker's paper.

greater at 500 cycles than at 1000 cycles, but as the difference in the resistance at the two cycles [sic] increased, the difference in the capacities decreased. Inasmuch as the condensers were of the type used to balance out capacity in the cell and were not standardized, the actual values are qualitative and are not given." They evidently anticipated our point (7) above without publishing the proof; but they did not interpret the capacitance readings either in terms of phase displacement in the cells or as an indication of a capacitative shunt which could cause an error in the resistance which is a function of the frequency, nor did they distinguish between errors in resistance due to polarization and errors due to capacitative shunt or offer any interpretation of or cure for the Parker Effect.

Mathematical Analysis of Errors Due to Shunt.—In the pipet cells as usually designed the electrodes are placed horizontally one above the other and the electrical contact to the electrodes is made by means of wires dipping into the glass tubes which are commonly filled with mercury to the level of the liquid in the thermostat. These contact tubes and the filling tubes through which the electrolyte is added to the cell are commonly brought out of the thermostat vertically and in close proximity to each other, thus creating capacitance between them as indicated diagrammatically by C_P in Fig. 11. This arrangement provides an additional path for the current through the resistance of the electrolyte in the filling tube, R_P, and the capacitance between the filling tubes and the contact tubes, C_P. If the thermostat is filled with water instead of oil the resistance in the thermostat liquid will be part of the shunt resistance, but since it is known that the use of water introduces errors, this case will not be considered further here. In an oil-filled thermostat the glass parts of the cell with the intervening oil may be regarded as a pure capacitance, and all of the shunt resistance is in the filling tubes and contact tubes. This shunt across the cell obviously tends to make the apparent resistance of the cell less than the true resistance of the electrolyte between the electrodes. The capacitance in the shunt is of course distributed along the resistance and therefore a precise analysis of the problem in the case of any given cell would require a precise knowledge of the geometrical form, the dielectric constant, and power factor of the glass used and of the thermostat liquid; and, even with all of these data at hand, would be a mathematical problem of great complexity.[16] For the sake of analyzing the effects of this shunt we can assume that a shunt composed of a resistance, R_P, and a capacitance, C_P, in series across the electrodes is electrically equivalent to the distributed capacitance and resistance actually present, and that dielectric

---

[16] *See* Shedlovsky, THIS JOURNAL, 52, 1793 (1930), for an interesting attempt to solve a similar problem for a simpler case in which the capacitance is assumed to be uniformly distributed along the resistance.

losses in glass and oil are negligible in comparison with the losses in the filling tube The reactance of the shunt is

$$X_P = \frac{1}{\omega C_P} = \frac{1}{2\pi f C_P} \tag{5}$$

and the impedance of the shunt is

$$Z_P = R_P + jX_P \tag{6}$$

Let R_T be the true resistance of the cell;[17] R be the measured resistance of the combination of cell and shunt at the frequency of f; X, the measured reactance of the combination at frequency f; $Z = R + jX$, the impedance of the combination at frequency f. Then by the law of parallel branches

$$\frac{1}{Z} = \frac{1}{R_T} + \frac{1}{R_P + jX_P} = \frac{R_T + R_P + jX_P}{R_T(R_P + jX_P)} \tag{7}$$

$$Z = \frac{R_T(R_P + jX_P)}{R_T + R_P + jX_P} = \frac{R_T(R_P + jX_P)}{(R_T + R_P + jX_P)} \times \frac{R_T + R_P - jX_P}{R_T + R_P - jX_P} \tag{8}$$

$$Z = \frac{R_T^2 R_P + R_T R_P^2 + R_T X_P^2}{(R_T + R_P)^2 + X_P^2} + \frac{jX_P R_T^2}{(R_T + R_P)^2 + X_P^2} \tag{9}$$

Therefore $$R = R_T \frac{(R_T R_P + R_P^2 + X_P^2)}{(R_T + R_P)^2 + X_P^2} = R_T \left(1 - \frac{R_T R_P + R_T^2}{(R_T + R_P)^2 + X_P^2}\right) \tag{10}$$

and $$X = X_P \frac{R_T^2}{(R_T + R_P)^2 + X_P^2} \tag{11}$$

Let ΔR designate the error due to the shunt, then

$$R = R_T + AR \tag{12}$$

and hence the error

$$\Delta R = -\frac{R_T(R_T R_P + R_T^2)}{(R_T + R_P)^2 + X_P^2} \tag{13}$$

or the fractional error

$$\frac{AR}{R_T} = -\frac{R_T R_P + R_T^2}{(R_T + R_P)^2 + X_P^2} \tag{14}$$

Since none of the terms in this equation can ever have a negative real value, the error is always negative. But

$$X_P = \frac{1}{\omega C_P} \tag{5}$$

$$\frac{\Delta R}{R_T} = -\frac{(R_T R_P + R_T^2)\omega^2 C_P^2}{(R_T + R_P)^2 \omega^2 C_P^2 + 1} \tag{15}$$

When working under such conditions that polarization is negligible, unless the cell is of poor design, C_P will be about 20 $\mu\mu$f. or less. If C_P has this

---

[17] It will be noted that in this mathematical analysis of the effect of the shunt, the cell proper (the electrodes and the electrolyte between them) is treated as a pure resistance. This is strictly true only if the reactance of the cell $X_C = 0$, that is, if the reactance due to polarization is negligible. An inspection of Curves 2–6 indicates clearly that for well-platinized electrodes the phase angle and hence the reactance falls rapidly with increasing resistance and would become negligible above 1000 ohms if the Parker Effect were not present.

value, 2×10^{-11} farads, and the measurement is made with 5000 cycles ($\omega = 31{,}400$; $\omega^2 = 10^9$) or less, and if the total resistance of $R_T + R_P$ does not exceed 100,000 ohms, the value of $(R_T + R_P)^2\omega^2C_P^2$ will not be greater than $10^{10} \times 10^9 \times 4 \times 10^{-22} = 4 \times 10^{-3}$. Under these circumstances if we ignore this term in the denominator of Equation 16, the error in $\Delta R/R$ will not be greater than 0.4%. With a frequency of 1000 (which is that most commonly used) and $C_P = 20$ $\mu\mu$f. and $R_T + R_P = 100{,}000$, the error in $\Delta R/R$ due to using the simpler form cannot exceed 0.02%. Therefore, at audio frequencies, except in the case of cells of abnormally bad design, $(R_T + R_P)^2\omega^2C_P^2$ will be small in comparison with 1 and therefore it will be approximately true that

$$\Delta R/R_T = -(R_TR_P + R_T^2)\omega^2C_P^2 \tag{16}$$

A further simplification is possible for the case of measurements made with an equal arm bridge which has been designed so that the capacitances between the arms are small and properly balanced by the earthing device, which is the case in our bridge, and if the conditions are such that polarization is negligible. In such a case the condenser shunted across the resistance box when adjusted so as to give a phase angle equal to that of the cell will have a capacitance, C_R, very nearly equal to the capacitance in the shunt across the cell, and the fractional error due to this capacitance[18] on the resistance box will be $-R_R^2\omega^2C_R^2$ which will be substantially equal to the $-R_T^2\omega^2C_P^2$ and thus will compensate for one term in the equation for the error in the cell, leaving as the net fractional error due to capacitance and resistance in the shunt across the cell approximately

$$\Delta R/R_T = -R_TR_P\omega^2C_P^2 \tag{17}$$

The actual error is therefore approximately

$$\Delta R = -R_PR_T^2\omega^2C_P^2 = -R_P \tan^2\theta \tag{18}$$

Combining Equations 18 and 12 gives

$$R = R_T - R_PR_T^2\omega^2C_P^2 = R_T - R_P \tan^2\theta \tag{19}$$

Experimental Verification of the Shunt Theory.—For any given cell filled with a given solution, R_T and R_P are constants, and ω can be held constant during a series of measurements. If now we vary C_P it may be predicted from Equation 19 that an increase in C_P will result in a decrease in the measured resistance, R, which will be proportional to the square of the total capacitance in the shunt. In order to make this test the capacitance in the shunt was artificially increased by connecting one lead wire from a variable air condenser to the mercury in one of the contact tubes, and connecting the other lead wire to a small piece of platinum foil dipping into the filling tube of opposite polarity. The total capacitance in the shunt due to the cell itself and to the condenser was then measured as usual by the capacitance required in parallel with the resistance in the

---

[18] See Grinnell Jones and R. C. Josephs, THIS JOURNAL, 50, 1076 (1928).

other arm of the bridge. Resistance measurements were made with 500 and 2280 cycles at various settings from 0 to 25 $\mu\mu$f. of the variable air condenser which was in parallel with the cell.

The actual data are omitted for the sake of abbreviation and because the actual values are dependent on the particular cell and solution used. The variation of the apparent resistance with the capacitance, which alone is important for our present purposes, is shown in Fig. 12, in which we have plotted the measured resistance as ordinate against the square of the capacitance as abscissa. It will be observed that the experimental points at each frequency are on a straight line within the limit of error of the data. The intercept of each of these lines on the resistance axis should be the true resistance. It will be observed that the intercepts of the lines for the two frequencies are the same.

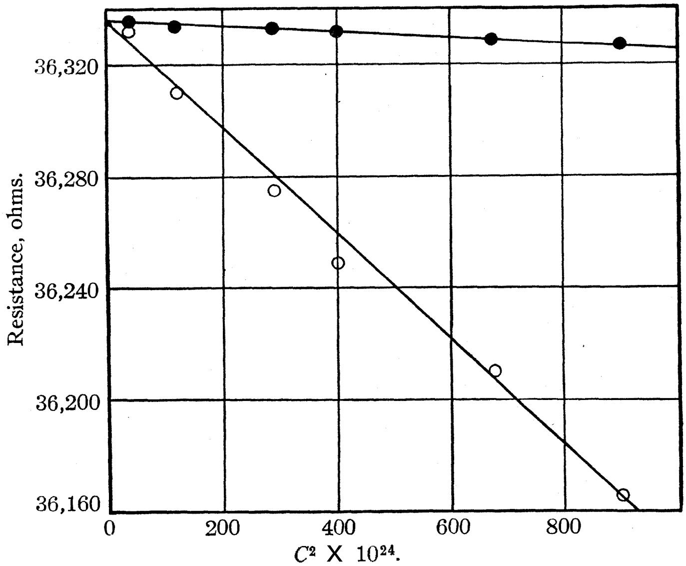

Fig. 12.—For upper curve $f = 500$; for lower curve $f = 2280$.

We next made a series of measurements in which the frequency was varied while the other factors were kept constant. In order to magnify the capacitance effect, 25 $\mu\mu$f. was added across the cell in the manner just described and the resistance determined at ten different frequencies within the range from 500 to 2280 cycles. In addition, the resistance was determined at several lower values of the capacitance at three frequencies. The actual results are omitted for the reasons explained above but they are shown in Fig. **13,** in which the measured resistance is plotted against the square of the frequency. As will be seen, the results at each frequency are on a straight line and these lines all have a common intercept on the axis of zero frequency which should be the true resistance. The value for the true resistance thus obtained is the same as that shown in the previous plot.

A special experiment was carried out to determine whether or not a significant change in capacitance and in resistance could be produced merely by a change in the relative position of the filling tube and the cell without any change in the electrodes or in the cell proper. A cell of the pipet type similar in shape to that shown in Fig. 11 was filled with potassium chloride solution and its resistance determined at several frequencies. The capacitance was 6 micromicrofarads. The filling tube was then extended and bent so as to conform with the shape of the cell and fitted closely to the cell. The effect was an increase in parallel capacitance to 14 micromicrofarads and a great increase in the variability of the resistance readings with change in frequency as shown in Table VII.

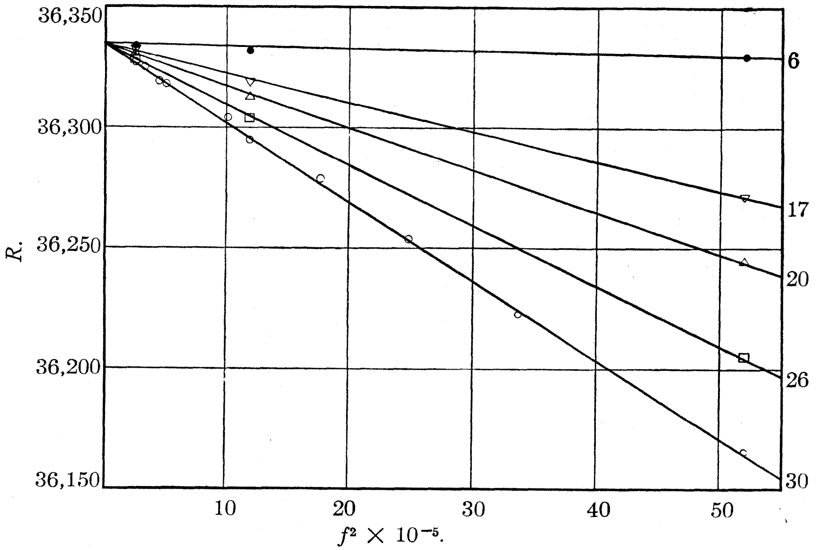

Fig. 13.—The values of C_P for these curves are given on the right-hand margin.

TABLE VII

CHANGE IN RESISTANCE CAUSED BY ALTERATIONS IN FILLING TUBE

Frequency. cycles	(Frequency)^2	Original filling tube $C_P = 6\mu\mu f$. Resistance ohms	New filling tube $C_P = 14\mu\mu f$. Resistance ohms
500	2.50×10^5	36,308	36,306
710	5.05		36,303
1090	11.9	36,306	36,295
1575	24.8		36,285
2280	52.0	36,304	36,258

The resistance readings when plotted against the square of the frequency give a straight line similar to that shown in Fig. **13.** This experiment definitely proves that altering the relative position of filling tubes and cell influences the parallel capacitance and that the resistance changes caused thereby vary with the frequency in accordance with our theoretical equation.

We next consider the effect of varying R_P while keeping the other factors constant. For this purpose we must use Equation 15 instead of the simplified form (17) because we wish to consider the influence of values of R_P greater than the upper limit assumed in deriving the simplified form. By differentiating Equation 15 with respect to R_P and holding all other factors constant and placing $\partial(\Delta R/R_T)/\partial R_P = 0$, it is possible to show that $\Delta R/R_T$ rises with increasing R_P to a maximum when $R_P = 1/C_P\omega$ and then falls again. The value of R_P which produces the maximum error is very large. Thus, for example, if $C_P = 10^{-11}$ farads, and $f = 2280$, $R_P = 1/(2 \times 3.14 \times 2280 \times 10^{-11}) = 7{,}000{,}000$ ohms. R_P will be far below this value in pipet cells of the usual design and the partial derivative indicated above will be positive. It will, therefore, be advantageous to design the cell so as to keep R_P low, provided this can be accomplished without increasing C_P.

In order to vary R_P while keeping all other factors constant, we devised a suitable expedient. A pipet type of cell was filled with a solution giving a resistance of about 50,000 ohms with both filling tubes filled as usual. Measurements were made at 500, 1090 and 2280 cycles and the true resistance ascertained by the method indicated in Fig. 13, and thus the error at 2280 cycles due to the shunt was estimated to be 0.02%. Then one of the filling tubes was emptied, leaving the inner wall wet with the solution, thus enormously increasing the resistance in the shunt without altering anything else. The error at 2280 cycles, estimated in the same manner, was now 0.10%. The inner wall of the filling tube was then dried by inserting a capillary tube and applying suction so that a stream of air passed down through the filling tube until it appeared to be dry. The error at 2280 cycles as determined in the same manner was now reduced to 0.025%. Apparently in this case the resistance in the filling tube was in excess of that which gave the maximum error. Although, owing to a lack of knowledge of the value of the resistance in the filling tube, the evidence of these experiments in support of our equation is not of the same quantitative nature as was obtained by varying the frequency and the capacitance, these experiments do support in a qualitative manner the predictions of our mathematical analysis.

Parker reported a difference in his cell constant ratios when the tube connecting his two cells was filled with the solution and when the solution in the tube was interrupted by an air bubble but could offer no explanation of this fact or reconcile it with his hypothesis that the error was due to adsorption. Our experiment just cited indicates that the reason for the influence of the bubble in the connecting tube was that the resistance in the shunt was changed thereby.

An interesting and important corollary of the analysis of the influence of the magnitude of the resistance in the shunt is that capacitance between the two lead wires and the mercury in the contact tubes in the pipet form of cell can do no harm provided an oil thermostat is used, because it is in effect a pure capacitance and can be compensated by a pure capacitance across the box without error in the resistance. In this case the resistance in the mercury and in the copper wires is negligible and the resistance in the oil enormously greater than the value $R_P = 1/C_P\omega$ which gives the maximum error. On the other hand, if water is used as the thermostat liquid, this water forms a part of a shunt between the contact tubes and may have a resistance which will cause a substantial error.

Parker Effect Due to Capacitative Shunt.—The expression for the error due to a capacitative shunt also accounts for the Parker Effect. If we use subscripts A and B to designate two different cells, in which the subscript A refers to the cell of lower cell constant, then the ratio of the measured resistance will be

$$\frac{R_A}{R_B} = \frac{R_{TA} + \Delta R_A}{R_{TB} + \Delta R_B} \tag{20}$$

Since AR is very small in comparison with R_T this can be developed into a power series and the higher terms neglected, giving

$$\frac{R_A}{R_B} = \frac{R_{TA}}{R_{TB}}\left(1 + \frac{\Delta R_A}{R_{BA}} - \frac{\Delta R_B}{R_B} + \dots\right) \tag{21}$$

Then by Equation 17

$$\frac{R_A}{R_B} = \frac{R_{TA}}{R_{TB}}\,[1 - (R_PR_T\omega^2C_P^2)_A + (R_PR_T\omega^2C_P^2)_B + \dots] \tag{22}$$

For any given cell, R_P will be proportional to R_T, since both are proportional to the specific resistance of the solution used, so that we may write $R_P = kR_T$, where the value of k will depend on the dimensions of the cell and of the filling tube and

$$R_T = (l/a)\ (1/\kappa)$$

and hence

$$\frac{R_A}{R_B} = \frac{R_{TA}}{R_{TB}}\left[1 - \left\{\left(\frac{kl^2}{a^2}\,C_P^2\right)_A - \left(\frac{kl^2}{a^2}\,C_P^2\right)_B\right\}\frac{\omega^2}{(\kappa)^2}\right] \tag{23}$$

It is thus evident that the variation of the resistance ratios R_A/R_B with increase in the specific resistance (or decrease in κ) will be positive if $(kl^2/a^2C_P^2)_B > (kl^2/a^2C_P^2)_A$ and negative in the converse case.

Our data, depicted in part in Curves 7 to 10, give examples of both positive and negative slope of the resistance ratio curves, and we have been able to correlate at least qualitatively the slope of these curves with the dimensions of the cells, which determine k, l/a and C_P, but the detail of this correlation must be omitted to save space. It may also be predicted from this equation that the slope of the resistance ratio curves (in the region where polarization is avoided), regardless of its sign will increase in magnitude with an increase in frequency and with an increase in the specific resistance of the solution used, which is fully in accord with our experience, and for a given pair of cells the slope can never change in sign with variation in frequency or variation in the specific conductance of the solution used, which is in accord with our experience.

Since sealing the cells together, as was done by Parker and in our experiments described above, would probably increase the capacitance,[19] it is to be expected that the error would be increased thereby, and it therefore seemed worth while to determine whether or not the effect is present in disconnected cells of the pipet type.

We therefore made another series of cell comparisons similar to those recorded above, using four separate disconnected cells of the pipet type, all heavily platinized, using 500, 1090 and 2280 cycles. The results are not published in detail, because they are similar in all respects to those given in Curves 7 to 10, except that the slopes are more gentle. The maximum variation in the resistance ratios observed in these experiments was only 0.05%, but the deviations are systematic and show in milder form the characteristics already observed with the connected cells.

This demonstration that Parker's expedient of sealing his two cells together to facilitate filling them with a common solution aggravates the error is important because it increases the reliance which may be placed on the great mass of data in the literature which were usually obtained with single cells.

Cell Design to Avoid Errors Due to Polarization and Shunt.—The theory of errors due to capacitative shunt has not only given a complete explanation of the nature and cause of the Parker Effect but has guided us in the design[20] of cells in which the error is eliminated. From the equation for the error due to a capacitative shunt, $\Delta R = -R_P R_T^2 \omega^2 C_P^2 = -R_P \tan^2 \theta$, it is evident that it will be well to beep each of the factors in this equation as low as other considerations permit.

It would of course be possible to design a cell without filling tubes as an integral permanent part of the cell but the filling tubes serve a useful purpose in facilitating the filling of the cells without contamination or evaporation of the solutions and should not be sacrificed except as a last resort. The resistance in the filling tubes might be reduced by making them of large diameter, but this tends to increase the capacitance, which

---

[19] There is a certain analogy between capacitance shunt errors in cells which are sealed together and the effect of appended coils in a resistance box. See Grinnell Jones and R. C. Josephs, THIS JOURNAL, 50, 1084 (1928).

[20] See E. W. Washburn [THIS JOURNAL, 38, 2431 (1916)] for a mathematical analysis of cell design including a discussion of several considerations not taken up in detail in this paper.

offsets the gain. The filling tube should, however, be kept full of solution to avoid the high resistance of the surface film wetting the inner wall. The resistance in the filling tube will of course be proportional to the specific resistance of the solution being measured, and therefore this factor helps to set an upper limit to the resistance which can be measured accurately in any given cell.

It should be pointed out that although dipping electrode cells as commonly designed have no filling tube at all, nevertheless they do have a capacitative shunt. As usually designed, the electrodes are supported by two vertical contact tubes which are commonly close together. These electrodes should be immersed to a considerable depth in order that the lines of flow of the current may not be cut off by the surface of the solution and thus make the effective cell constant too greatly dependent on the depth of immersion of the electrodes. This creates a shunt across the path between the electrodes, through the glass walls of the contact tubes acting as a condenser and the resistance of the solution between these tubes. The impedance of this shunt will be a function of the frequency and errors due to capacitative shunt may therefore be expected with dipping cells, in spite of the fact that they have no filling tubes, especially when used with dilute solutions.

For any given solution the working value of the resistance will depend on the cell constant of the cell used, and can therefore be controlled within wide limits provided a sufficient number and variety of cells are available. But there is a limit below which it is not safe to go with R_T because of errors due to polarization. The limit will of course depend on the precision desired, on the frequency used, and on the dimensions and platinization of the electrodes. As the result of our experience we have set the lower limit of the resistance to be measured at about 1000 ohms when using well-platinized cells (see Figs. 2–6). But unless the upper limit can be many times the lower limit, a very great number of cells of closely graded cell constants will be needed to cover the whole range of specific conductance from that of very good conductivity water, 1×10^{-7}, up to about 0.5 for the best conducting aqueous solutions at room temperatures. Washburn[21] recommends that the upper limit be placed at 10,000 ohms, which with a lower limit of 1000 ohms would require seven cells to cover the entire range. To cover this range with four cells will require that the upper limit be placed at nearly 50,000 ohms, which is the upper limit which we have thought it desirable to strive for. It is, therefore, apparent that there are serious practical difficulties in any attempt to solve the problem by restricting the measurements to low values of the resistance to be measured.

An attempt to solve the problem by lowering the frequency would be

---

[21] E. W. Washburn, THIS JOURNAL, **38**, 2450 (1916).

defeated by the fact that errors due to polarization increase rapidly with decrease in the frequency. Lowering the frequency tends to raise the safe lower limit of the resistance which can be measured without the appearance of an error due to polarization, which would defeat any attempt to make a substantial reduction in the shunt error by any considerable reduction of the frequency below 1000 cycles. Moreover, in the practical routine of conductance measurements it is possible with a suitable oscillator to change the frequency instantly by a mere turn of a dial and repeat the measurement at another frequency in a moment. If the measured resistance proves to be substantially independent of the frequency it shows that many of the possible errors, including polarization, shunt errors, and errors due to capacitance and inductance in the bridge and resistance boxes which have been discussed in the first paper of this series, have been eliminated. On the other hand, if there is a significant variation in the apparent resistance with variation in frequency it proves that some error is present and gives a clue as to the magnitude and nature of the error. Therefore, if it is possible to do so there will be a great advantage in avoiding the error due to a shunt by some other means than lowering the frequency, and judging of the success or failure of the attempt by noting the effect of variations in frequency.

The capacitance in the shunt can be reduced to a very small value by designing the cell so as to avoid close proximity of the filling tubes and the portions of the cell of opposite polarity. Each of the filling tubes should be placed at a safe distance from the other filling tubes and from the contact tube at the other end of the cell. This is most conveniently done by making the cells of the form shown in Fig. 14. Our experience indicates that a separation of 15 cm. between parts of the cell of opposite polarity is adequate. Shields placed close to any part of the cell should be avoided.

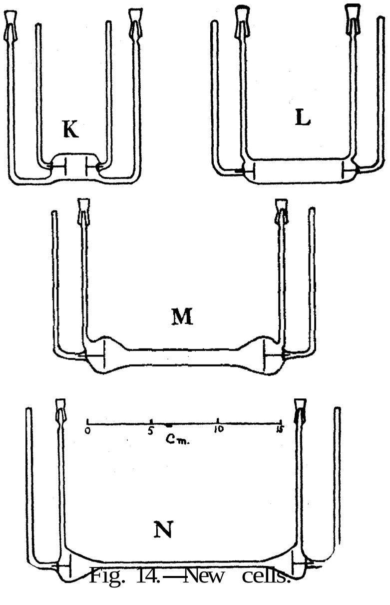

Fig. 14.—New cells.

New Cells—Description and Tests.—Four cells of the new form, designated K, L, M, N, which are depicted in Fig. 14 and whose dimensions are shown in Table VIII, were constructed and thoroughly tested.

These new cells were at first given a light platinization and then tested. The results of these tests will be omitted, because no new conclusions could be drawn from them. The cells when lightly platinized showed the

The cells were filled with common solutions of potassium chloride and the resistance and capacitance of each measured as before, except that the readings were taken not only with 1090 and 2280 cycles, but also with 500, 3000, and 4000 cycles as well. The results are recorded in Tables IX to XII. A consideration of the values of tan θ at high resistances indicates that cell K, in which the electrodes are 1.5 cm. apart, is superior to cells II and IV, about the same as cells I and V, and inferior to cell III. In cell K the electrodes are comparatively close together, but the disadvantage of this close proximity is partly avoided by the design which places the filling tubes outside the contact tubes (see Fig. 14). The separation of electrodes and filling tubes is apparently inadequate in this cell. In this cell the capacitance which makes trouble is probably that between the portion of the cell between the electrodes and the filling tubes and contact tubes.

We infer that in cells having electrodes as close together as this it would have been better to extend the filling and contact tubes in the direction of the axis of the cell for several centimeters before bending them upward.

Cell L, in which the electrodes are 6 cm. apart, shows a definite improvement over all of our older cells in having a lower phase angle at high resistances than any of the older cells. Nevertheless, cell L does have a measurable parallel capacitance at high resistances and therefore a slight although reduced error due to capacitative shunt.

However, in cells M and N, in which the separation of the electrodes is 11.5 and 16.5 cm., respectively, the parallel capacitance is so low that it is no longer measurable with our bridge, since it is of the same order of magnitude as the unavoidable capacitance in bridge, boxes, lead wires and in the condensers at their zero setting. Readings of less than 5 micromicrofarads have little significance in our apparatus. But these capacitance readings, in spite of their lack of precision, do prove that cells M and N have a lower phase angle at high resistances than any of the other cells and therefore by

virtue of Equation 17 the error due to capacitance shunt has been greatly reduced and probably made negligible.

A surer test of the quality of the new cells is the variation in the apparent resistance with variation in frequency, because this is not dependent on the capacitance measurements of low precision. It will be recalled that with the old cells the variation of resistance with frequency increased rapidly with the resistance being measured and at about 50,000 ohms a change in the frequency from 1090 to 2280 cycles caused the following decreases in resistance: cell I, 133.5 ohms; II, 96 ohms; III, 37 ohms; IV, 58.4 ohms. These figures may be compared with the corresponding values for the new cells: cell K, 9.9 ohms; cell L, 4.3 ohms; cell M, 0.3 ohm: cell N, **3** ohms. When the frequencies increased to 4000, cell K shows a further drop of 4 ohms, cell L of 6 ohms and cells M and N are unchanged.

It is apparent that the effect of variation in frequency has been greatly reduced in the new cells and the effect which remains is not proportional to the square of the frequency, which has been demonstrated to be characteristic of errors due to a capacitative shunt. The slight remaining frequency effect must therefore be ascribed to some other cause, probably polarization.

Attention is called especially to cell M, which shows an apparent variation between 1090 and 4000 cycles of only **0.3** ohm which is less than

0.001%. An error of this magnitude might be caused by a change in temperature of less than 0.0005°. The change of 1.2 ohms in cell M between 500 and 1090 cycles is probably due to some polarization at the lower frequency. It may therefore be regarded as established that there is no real change in the conductance of electrolytes with a change in frequency up to 4000 cycles. The slight frequency effect remaining in the other new cells and the much greater frequency effect reported by other experimenters is due to errors caused by polarization or faulty design of bridge or cells.

Debye and Falkenhagen[22] have made a theoretical study of the effect of variation in frequency on the conductance of dilute solutions based on the Debye–Hückel interionic attraction theory of electrolytes. One of the most important theoretical deductions of Debye and Hückel is that the electric forces between the ions tend to maintain a space lattice structure and oppose the motion of an ion under the influence of an outside electric field and thus cause a decrease in conductance which is proportional to the square root of the concentration. Debye and Falkenhagen conclude that at extremely high frequencies the influence of the interionic forces in retarding the motion of an ion in an electric field tends to disappear, so that the conductance increases with increasing frequency. Thus, for example, with 0.001 N potassium chloride solution and a wave length of 14.9 meters, corresponding to a frequency of 20 million cycles per second, the retardation by the interionic attraction is reduced to one-half of its value at zero frequency.[23] Falkenhagen and Williams[24] have reviewed the paper referred to and interpreted it by the computation of numerical values for numerous specific cases as a function of the mobility and valence of the ions, the concentration, temperature, nature of solvent, and the frequency. It is apparent from this analysis that the theory predicts no measurable change of conductance with variations in frequency within the audio range. Neither of these papers contains any experimental verification of the theoretical deductions.

Sack,[25] in a brief preliminary notice, claims to have demonstrated the variation of resistance with variation of frequency at frequencies from 6 million to 20 million cycles but the effect is not much, if any, greater than the experimental errors in the method.

A third test of the quality of the cells is the constancy of the cell resistance ratios. These ratios are not given here since they may be computed readily by anyone interested, from the data in Tables IX to XII; they are shown in Fig. 15. These ratios are much more nearly constant than those

given by any of the older cells. Considering only the values at resistances above 1000 ohms in order to avoid the effects of polarization, it will be seen that the Parker Effect has been substantially eliminated with the new cells. The ratio of L to M and of M to N remains within 0.01% of the mean except at the lower resistances, where the tan 8–log R curves show that polarization plays a part. The elimination of the Parker Effect by the avoidance of capacitative shunt in the design of the cells furnishes additional evidence as to the validity and usefulness of our new theory that the Parker Effect is due to the shunt. This test agrees with the first two tests in showing that cell K is not quite so good as the others.

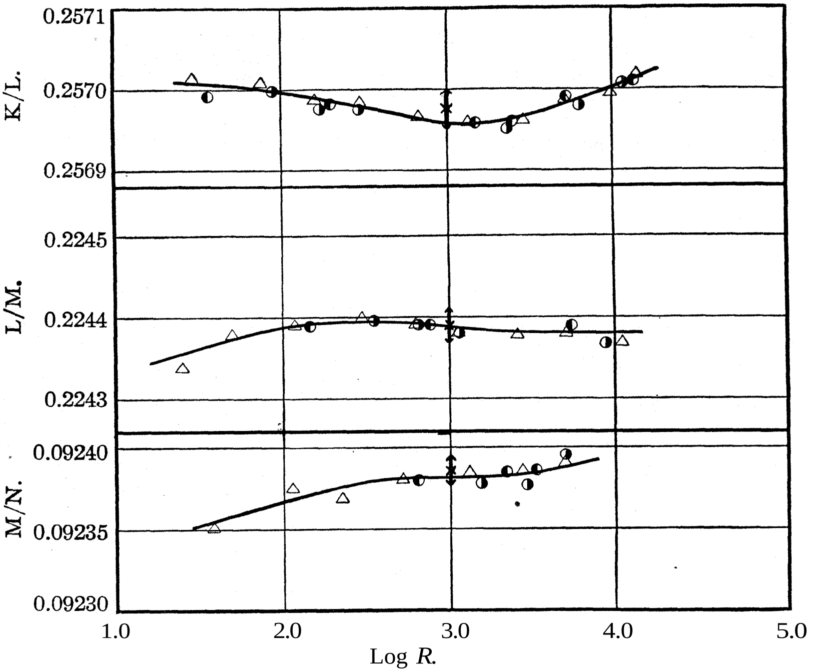

Fig. 15.—A, KCl; ◐, Na_2SO_4; ◑, $Ba(NO_3)_2$.

Effect of Change of Electrolyte.—It now remains to compare the behavior of other electrolytes with that of potassium chloride. For this purpose we have selected barium nitrate and sodium sulfate because Randall and Scott have reported experiments with these salts which they interpret as showing a specific effect of the salt used. We, therefore, made a series of cell comparisons using these two salts, similar to those reported above with potassium chloride, although less extensive. The results are shown in Tables XIII to XVI.

We have plotted the tan θ–log R curves (although they are not reproduced here) and find that the points fall on the same curves as the data

obtained with potassium chloride. The cell resistance ratios for all three salts also were found to be alike within 0.01%, as is shown in Fig. 15. With none of the three salts is there any variation in resistance with variation in frequency from 1090 to 3000 cycles per second greater than 0.01%. We conclude, therefore, that the hypothesis, first suggested by Parker and later supported by Randall and Scott, that adsorption is responsible for the Parker Effect is without a sound theoretical or experimental basis and is unnecessary to account for the known facts. Of course, this does not preclude the possibility that a real adsorption effect may be demonstrated in the future with some other electrolyte or in extremely narrow tubes.

On the other hand, our hypothesis that the Parker Effect is due to a shunt

across the electrodes containing resistance and capacitance is in accord with all of the known facts. It has led to an equation for the error due to the shunt which has been confirmed quantitatively as to the influence of frequency and capacitance on the error and has guided the design of a new type of cell in which capacitance between parts of the cell of opposite polarity is made negligible, with the result that the new cells have a very low phase angle and show no Parker Effect and no variation of resistance with frequency.

Acknowledgment.—Grateful acknowledgment is made for an appropriation from the Bache Fund of the National Academy of Sciences and from the Milton Fund of Harvard University for the expenses of this work.

Summary

1. The observation of Parker that the ratio of the resistances of two conductance cells when filled with a common solution and measured with an alternating current bridge is not independent of the specific conductance of the solution used, has been confirmed experimentally with cells of the type commonly used. The curves obtained are, however, of simpler form than those obtained by Parker and this simplification of the problem is ascribed to the use of a superior bridge, thus avoiding some causes of error present in Parker's work.

2. By using an unshielded bridge carefully designed to avoid inductance and capacitance, the phase angle between the current and the voltage in conductance cells has been measured and made significant in the study of errors in conductance measurements and in the design of cells. The phase angle in the cells depends on the frequency used, the resistance being measured, the degree of platinization, and the dimensions of the cell.

3. The conclusion of earlier investigators that the error due to polarization is positive in sign and can be minimized and made practically insignificant by a combined use of proper platinization, large electrodes, high frequency, and high resistance, is confirmed.

4. It is demonstrated for the first time that with cells of the type commonly used there is a capacitative shunt between parts of the cell of opposite polarity, which has the effect of making the measured resistance lower than the true resistances of the electrolyte between the electrodes.

5. By the use of alternating current theory the error due to the capacitative shunt is shown to be approximately AR $= -R_P R_T^2 \omega^2 C_P^2 = -R_P \tan^2 \theta$. The validity of this equation has been demonstrated by special experiments. The error due to capacitative shunts differs from that due to polarization in sign and in being increased by an increase in the frequency used and in the resistance being measured. The error due to capacitative shunt varies as the square of the capacitance in the shunt and as the first power of the resistance in the shunt whereas neither of these influences the error due to polarization. On the other hand, the degree of platinization, which has a great influence on the polarization, is without influence on the error due to capacitative shunt.

6. The equation for the error due to capacitative shunt has guided the design of new cells in which close proximity of parts of the cell of opposite polarity is avoided.

7. It has been demonstrated by measurements of phase angle and by intercomparisons of cells that the new cells are greatly superior to the forms commonly used. The new cells can be used at frequencies and resistances so high as to make errors due to polarization negligible without introducing errors due to capacitative shunt so that results which seem to be reliable within 0.01% may be obtained with them.

8. Although earlier experimenters have reported a variation in the conductance of electrolytes with change in frequency, it has been demonstrated experimentally that no change greater than a few thousandths of one per cent. occurs between the limits of 1090 and 4000 cycles per second when errors due to polarization and capacitative shunt are avoided.

9. The most convenient test of the quality of cells is the observation of the variation in apparent resistance with variation in frequency.

10. It has been shown experimentally that the ratio of the resistances of a pair of cells when filled with a common solution is independent of the electrolyte used for three different electrolytes, This does not confirm observations of earlier experimenters and removes the only experimental support for the hypothesis of Parker that adsorption is responsible for the Parker Effect.

THE VAPOR PRESSURE OF PYRIDINE[1]

BY P. A. VAN DER MEULEN AND RUSSELL F. MANN

RECEIVED OCTOBER 18, 1930 PUBLISHED FEBRUARY 9, 1931

In the course of a study of certain complex compounds containing pyridine, a search made of the literature revealed that the vapor pressure curve of this substance below the normal boiling point has been only partially determined. Kahlbaum[2] determined the vapor pressure at six temperatures below 51°. Zawidzki[3] reports a single value at 80°; the "International Critical Tables"[4] give the boiling point as 115.3°, but the vapor pressure as 760 mm. at 115.50°.[5,6] The present study was undertaken to fill the gaps between these data.

Experimental Work

Pyridine C. P. brand of Baker was purified as recommended by Arndt and Nachtwey.[7] This involves preparation of the pyridine perchlorate, purification of the perchlorate by crystallization, and liberation of the pyridine. The product was dried over solid potassium hydroxide, and was distilled with a fractionating column. The first and last quarters were rejected. The middle fraction, passing over between 115.1 and 115.3° was collected. This was redistilled as required.

The apparatus used was similar to that employed by Mortimer and Mur-

phy[8] in their modification of the static isoteniscope method of Smith and Menzies.[9] The apparatus was checked against the values for the vapor pressure of water given by Holborn and Henning.[10]

The isoteniscope was attached to the apparatus by means of a slip joint provided with a mercury seal, making possible the removal of this portion of the apparatus for the purpose of cleaning and filling. For temperatures above 25° a four-liter beaker surrounded by an asbestos sheath provided with peep holes was used as a constant temperature bath. A white mineral oil served as the bath liquid. Below 25° a wide-mouthed Dewar flask of clear glass was employed as a thermostat. The liquid was chilled ether. It was found necessary to use two high-speed propeller-type stirrers to maintain a uniform temperature throughout the bath. All thermometers used in this work were standardized by means of a Reichsanstalt standard thermometer. The manometer was of the ordinary open-end type, 7 mm. wide, securely mounted on a brick wall, and shielded from the heat of the bath. All manometer readings were made with a cathetometer, as were also readings of the levels in the U-arm of the isoteniscope. Manometer and barometer readings were reduced to mm. of mercury at 0°. A brass scale correction for the barometer was necessary.

Manipulation.—For each set of determinations the detachable isoteniscope arm was thoroughly cleaned, and pyridine was redistilled directly into this portion of the apparatus. The isoteniscope was then immersed in a bath of solid carbon dioxide and ether to chill the pyridine, and the apparatus was pumped out with a Hy-vac oil pump. Pumping was continued for one-half hour. A portion of the sample was then allowed to distil over into the U-tube. As an open-end manometer was used throughout the experiment, readings were not made below $-15°$, since at lower temperatures the pressure was less than 1 mm.

Determinations were continued up to and slightly above the normal boiling point of pyridine, a complete series of determinations being made at one time. Several samples of pyridine were used for the pressure determinations and a sufficient number of checks were made to insure the accuracy of the results.

Experimental Data.—In order to secure a suitable empirical equation we followed the lead of Antoine,[11] Cox,[12] and Davis,[13] and adopted the empirical equation

$$\text{Log } p = A - \frac{B}{t + 205}$$

---

The best values for A and B were then calculated by the method of least squares from our fifty vapor pressure determinations between −15 and +116° The resulting equation is

$$\text{Log } p = 6.8827 - \frac{1281.3}{t + 205}$$

where p is expressed in mm. of mercury and t is temperature in degrees centigrade.

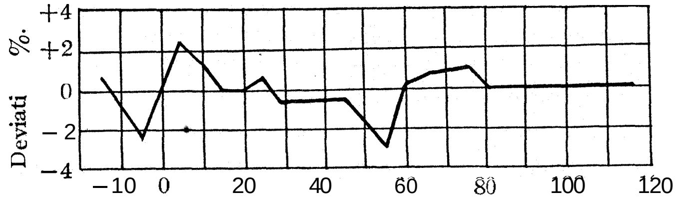

Fig. 1.

The deviations of our experimental results from this equation have been plotted in Fig. 1. The maximum deviation is 3.1%. Vapor pressures at round temperatures calculated from this equation are given in Table I.

TABLE I

VAPOR PRESSURE OF PYRIDINE AT ROUND TEMPERATURES

Temperature, °C.	Calculated pressure, mm.	Temperature, °C.	Calculated pressure, mm.
−20.0	0.91	60.0	111.6
−10.0	2.05	70.0	167.3
0.0	4.29	80.0	243.8
$10.0	8.38	90.0	346.3
+20.0	15.4	100.0	481
30.0	27.0	110.0	.653
40.0	45.0	115.2	760
50.0	72.1	120.0	872

Summary

Pyridine has been purified by crystallization of the perchlorate, followed by redistillation. The vapor pressure of this purified pyridine has been determined by the isoteniscope method. The relation between temperature and vapor pressure between −20 and +120° is best represented by the empirical equation

$$\text{Log } p = 6.8827 - \frac{1281.3}{t + 205}$$

THE QUINHYDRONE ELECTRODE. I.

BY J. LIVINGSTON R. MORGAN, OLIVE M. LAMMERT AND MARGARET A. CAMPBELL

RECEIVED OCTOBER 27, 1930 PUBLISHED FEBRUARY 9, 1931

Introduction

Ever since its discovery by Haber and Russ[1] and its early development by Granger and Nelson[2] and by Biilmann,[3] the quinhydrone electrode has been a favorite substitute for the hydrogen electrode in the determination of the hydrogen-ion concentration of solutions. This early work indicated that, for moderate precision at least, the electrode is quickly and easily prepared, develops its potential almost instantaneously, does not require a gas bubbling through the solution continuously and can be used, therefore, for work on body fluids containing dissolved carbon dioxide, and is not affected by atmospheric pressure; moreover, it can be used in solutions in which the reducing effect of hydrogen, or of hydrogen and platinum black, prohibits the use of the usual hydrogen electrode. In view of the ease with which the electrode can be prepared, the fact that the electrodes deteriorate in a comparatively short time constitutes only a minor objection. The real limitation of the electrode lies in the fact that even for work of moderate precision the electrode cannot be used in alkaline solutions above a PH of 8.5, particularly in the presence of oxygen.

Preliminary to some work on polarization which demanded a standard electrode of constant potential in acid solution, we undertook a study of the quinhydrous electrode, since it could be connected to the electromotive chain without the introduction of liquid junction potentials. Up to the time that this investigation was initiated, little work had been done from the point of view of the reproducibility of the electrode with a precision greater than 0.0001 volt; the interest of previous investigators lay primarily in the theory of the reaction producing the electrode, in the values of its potential compared to the well-known standard electrodes, in its salt error, and in the design of new forms of electrode for particular applications.

Since that time, however, the work of Biilmann and Jensen[4] has appeared. These investigators studied the reproducibility of the electrode and its value compared to the hydrogen electrode, their measurements being reported to 0.00001 volt. However, inasmuch as our method of attack differed from theirs, and inasmuch as their work was limited to a study

with comparatively few electrodes and did not cover many of the controversial points, it seemed wise to continue the research.

We confined the first part of our work to the reproducibility of the electrode since its actual value was of no immediate interest to us. With the hope of reproducing conditions in different laboratories we selected for the base of our electrodes a variety of metals: gold, platinum, platinum--iridium alloy, platinum–rhodium alloy, old platinum which was roughened by repeated platinization and deplatinization, having been used for years as hydrogen electrodes, and new platinum purchased at different times from different companies, platinum and gold wires of different cross sections and lengths and foils of different areas. All in all we used 194 electrodes cut into different sizes from **37** different pieces of metal with the result that we had groups of four to six electrodes, the electrodes within a group being as nearly identical as we were able to make them. A total of 3299 cells were prepared by combining these electrodes in pairs and on these cells more than 8000 measurements of the potential differences were made under varying conditions. Obviously a summary of such a large number of determinations is difficult but is attempted in view of the very general usefulness of the electrode, because of the precision with which the electrode may be prepared, and in view of the fact that there are so few data given in the literature to substantiate the preferences of different investigators as to the metal to be used as a base and as to the method of preparation of the electrode and solution.

In this paper we shall report the results of our work on the method of preparation of the metal electrode, on the method of cleaning and drying the electrodes, on the method of preparation of the quinhydrone solution, and on a comparison of the reproducibility possible with electrodes of different sizes and compositions for measurements made in the presence of air. In other papers to follow we shall present results on the reproducibility possible when the air is replaced by nitrogen, on a comparison of the potentials developed in quinhydrone solutions by electrodes of different sizes arid compositions, both in air and in nitrogen, on the behavior of the electrode prepared in solutions other than in 0.1 N hydrochloric acid, and on the electromotive force of the quinhydrone compared with other well-known half-cells. Much of the material for these papers is at hand; however, in view of the fact that some time must elapse before the data and compilations can be completed, it seems wise to make this preliminary report for the benefit of any who wish to use the electrode under the conditions described in this paper.

Preparation **and** Purification of Materials.—Several lots of quinhydrone, purchased from Eastman Kodak Co., and melting at 169–170° were used. The water and ethyl alcohol used were redistilled; the air for drying the electrodes **was** compressed by a water pump and conducted through dilute sulfuric acid, distilled water, soda lime and calcium chloride; the cleaning mixture was prepared from *c.* P. chemicals.

Apparatus

The electromotive force measurements, made in the usual manner with a Leeds and Northrup, Type K, potentiometer and a Type R, No. 2500 e, galvanometer, are believed to be precise to 0.000001 volt, since the usual precautions as to shielding,[5] temperature control and thermoelectric effects have been taken,

Electrode Vessel.—A 600-cc. pyrex beaker fitted with a wood and cork stopper was used as electrode vessel. In each stopper was inserted seven lengths of glass tubing which extended about 5 cm. below the stopper and about 2.5 cm. above. Six of these tubes carried the electrodes and prevented them from touching one another in the solution; the seventh carried the motor-driven stirrer.

Electrodes.—Wires and foils were sealed, with the aid of sealing-in glass, into a piece of glass tubing. Connections with the potentiometer wires were made in some cases with mercury, in other cases, when longer wires were used, directly with a wire connector. Each electrode tube was supplied with a cork stopper fitting the glass tube in the cover of the electrode vessel. A more detailed description of the electrodes is as follows.

Small Wires.—0, Nos. 1–6; Pt, 7–12; Ir, 7–12; Rh, 7–12; Au, 7–12. (Approximately 0.38 mm. in diameter and 1.5 cm. in length.) ***Series O,*** six electrodes cut from same piece of new C. P. platinum. ***Series Pt,*** six from same piece of new C. P. platinum different from O. ***Series Ir,*** six from same piece new platinum–iridium, 10% alloy. ***Series Rh,*** six from same piece new platinum–rhodium, 10% alloy. ***Series Au,*** six from same piece new 24K gold.

Large Wires.—A, Nos. 1–6; B, 1–6; Pt, 1–6; Ir, 1–6; Rh, 1–6; Au, 1–6; St, 1–6. (Approximately 1 mm. diameter, 2 cm. length.) ***Series A,*** six pieces of old platinum of unknown composition which had been around the laboratory for years and which, just previous to this work, had been used for hydrogen electrodes. ***Series B,*** six electrodes of old platinum but cut from same piece of wire. History similar to A. ***Series Pt,*** new C. P. platinum, six from same piece. ***Series Ir,*** six from new piece platinum–iridium, 10% alloy. ***Series Rh,*** six from new piece platinum–rhodium, 10% alloy. ***Series Au*** and ***Series St,*** six electrodes in each series from each of two new pieces of 24K gold.

Special Wires (Am Pt, Nos. 1–6 and L & N, Nos. 1–4) ***Series Am Pt*** (0.60 mm. × 2 cm.) six electrodes cut from the same piece of new C. P. platinum wire bought of the American Platinum Co., and recommended by Cullen.[6]

Series L & N.—Four gold electrodes bought from Leeds and Northrup and described by Parker and Greer.[7]

Aside from the short wire electrodes described, sets of electrodes, usually of six each, were made from the same pieces of metal but cut into 15-cm. lengths and the middle portion of the wire covered with glass tubing. The same length of electrode was exposed to the solution and a similar length exposed at the other end of the tubing which carried the wire connector. These electrodes are described as "long."

Foils.—D-F and I-N (old); P and G (new). ***Series D-F*** (approximately 1 X 2 cm.) and ***Series I-N*** (approximately 2 × 2 cm.) six pieces of each size whose age, history and compositions are unknown; had been used as hydrogen electrodes. ***Series P:*** Twenty platinum foil electrodes cut from the same piece of new C. P. platinum foil: 4 foils each size: P_{11-1}-P_{11-4} (1 X 1 cm.); P_{12-1}-P_{12-4} (1 X 2 cm.); P_{13-1}-P_{13-4} (1 X 3 cm.); P_{22-1}-P_{22-4} (2 X 2 cm.); P_{23-1}-P_{23-4} (2 X 3 cm.). ***Series G:*** Twenty gold foil electrodes cut from the same piece of new 24K gold foil: 4 foils each size: G_{11-1}-G_{11-4}

(1 × I cm.); G_{12-1}-G_{12-4} (1 × 2 cm.); G_{13-1}-G_{13-4} (1 X 3 cm.); G_{22-1}-G_{22-4} (2 × 2 cm.); G_{23-1}-G_{23-4} (2 X 3 cm.).

While the short platinum wires and long platinum and gold wires were sealed directly into the glass tube, the gold with the aid of a wax, the platinum foils and short wire gold electrodes and foils were sealed to platinum wire which was then sealed into the glass. For the gold–platinum joint borax was used as a flux. The two pieces of wire, very clean, were dipped into the flux and then placed end to end on a piece of charcoal. Fusion was brought about by playing a small flame from an air gas torch along the platinum until the platinum was red hot and then applying the torch to the gold. In sealing the metal into the glass the sealing-in glass was applied to the platinum wire just above the joining of the two metals and the seal made to cover this joint. In this way no platinum–gold couple touched the solution and no mercury the gold.

Procedure and Results

The method of procedure which we adopted to determine the reproducibility of the potential of the quinhydrone electrode involved, in the first place, the preparation of series of either four or six electrodes as nearly identical as possible. These electrodes were then immersed in 0.1 N hydrochloric acid containing the quinhydrone and their potential differences compared, pair by pair, under a number of varying conditions.

The Method of Preparation of the Metal Electrode.—Early in our work it became evident that by far the greatest source of error involved in the preparation of reproducible quinhydrone electrodes lay in the preparation of the metal electrode to be immersed in the quinhydrone solution. The greatest care was necessary in sealing the electrode into the glass tubing. The smallest cracks or imperfections in the seal gave rise to large variations in the voltages of the electrodes and although at times these imperfections were invisible to the eye even through a magnifying glass, inevitably sooner or later the mercury just above the seals in these troublesome electrodes became so discolored that it was obviously being attacked by the solution.

This point is well illustrated by the behavior of a cell made up of electrodes B_3 and B_4. The first day the difference in potential between the two electrodes was 0.00054 volt and became 0.00050 volt at the end of four hours. The next day, the electrodes having been cleaned and dried again, the same cell gave a difference of potential of 0.07417 volt which became 0.04695 volt at the end of one and one-half hours. Finally on a third day and after another cleaning process this combination gave a potential of 0.05577 volt which finally dropped to 0.03607 volt. When electrode B_3 was measured against one of a pair of electrodes which had been giving a low potential difference its value was still very high (0.02957 volt); B_4 on the other hand gave about the same low potential as the reference electrode. B_3, exhibiting both a crack and acid attacked mercury on being examined, was remade and when next measured against B_4 gave a potential of 0.00000 volt.

Up to this point nearly all of the cells, made up of supposedly identical electrodes, had given potential differences which varied from 0.00000 volt to about 0.000030 volt. As the latter value seemed, in view of the reproducibility reported by earlier workers, too high and could not be lowered by repeated cleansing of the electrodes, all of the electrodes then in existence were remade. During this process it became obvious that the seal, which was made in the usual manner with sealing-in glass between the platinum and soft glass used, must be heated for some time in the flame and must be carefully annealed. To test the perfection of the seal the electrodes were suspended in water which was then heated to the boiling point. The electrodes were not removed until the water had cooled, when the defective ones were either cracked or the tubes filled with water. Electrodes tested in this way gave readily reproducible potentials over long periods of time even when heated for some time in very hot cleaning mixture. Of the electrodes prepared in this way and combined over a period of three years in pairs to give 3300 cells, only 29 electrodes have had to be remade because they gave potentials which were exceedingly large or did not give constant potentials in a reasonable length of time. The results just quoted apply only to those electrodes which either were not dried or were dried by some method at room temperature. When. however, the electrodes were heated directly in the flame the mortality was much greater. These points will be discussed presently.

Our observation, namely, that these imperfections and cracks in the seals were the cause of considerable variation in potential, is not new. Biilmann and Jensen,[8] Biilmann,[9] and Cullen[6] have all found difficulty with electrodes in which fissures were formed, as they were quite likely to be formed with their method of drying the electrode. However, as they give no results which indicate the magnitude of errors produced in this way, we report our results in some detail to emphasize the recommendation, originally Biilmann's,[10] that several metal electrodes be immersed in the solution for a preliminary intercomparison whenever the quinhydrone electrode is used.

Because of this difficulty with electrodes made with short wires a number of investigators prefer electrodes made with longer pieces of platinum or of gold or with pieces of a base metal welded to the noble metal. While in an investigation involving the measurement of as large a number of potentials as ours, mercury as a connecting medium proved infinitely more convenient than wire connectors, nevertheless, in an attempt to determine whether the variations in potential which, though small, still remained could be obviated by dispensing with mercury, we made a number of elec-

[10] Biilmann, *Trans. Faraday Soc.*, *19,* 819 (1924).

trodes with the longer wires, but with the same surface area exposed to the solution. A rather thorough examination was made of this point with a large number of small and large platinum, gold, platinum–iridium and platinum–rhodium wires, 102 long electrodes having been made and compared with the same number of short electrodes. No difference in reproducibility was found between the two types of electrodes.

The Method of Cleaning and Drying the Electrode.—A variety of methods for cleaning and drying the electrodes were tried in the first part of this work with the idea of finding some method which would give low and consistently reproducible results. We wished to replace Biilmann's[11] original method, which was to wash the electrodes with distilled water and to heat them to a red heat in an alcohol flame, by a method which would avoid the heating and consequent difficulty with cracks. In the first place we attempted to dry the electrodes with filter paper but the initial potential differences were as high as 0.00054 and 0.00071 volt and the time necessary for the electrodes to come to a constant potential difference was great. We also tried a number of cleaning mixtures besides the usual chromic acid–sulfuric acid cleaning mixture. In one case the electrodes were boiled for five minutes in 6 N potassium hydroxide, in 6 N sulfuric acid, in 6 N nitric acid and then in distilled water, the electrodes being rinsed in hot distilled water between solutions. In another case the electrodes were cleaned in a 33% alcoholic sodium hydroxide solution and then soaked in distilled water for some time. In both cases the equilibrium potential differences were very much higher than when the chromic acid cleaning mixture made of the C. P. chemicals was used. For instance one pair of electrodes gave an equilibrium potential difference of 0.00016 volt with both the $KOH–H_2SO_4–HNO_3$ and alcoholic sodium hydroxide treatment and a potential difference of 0.00002 volt with the chromic acid mixture.

Our method as finally adopted for the work reported in this paper was to submerge the electrodes in cold cleaning mixture, which was then heated to about 125° and allowed to cool to room temperature. The electrodes were usually left in the mixture overnight as a matter of convenience, although the time of treatment with the cleaning mixture seemed to be of no importance. In the morning the electrodes were rinsed with a stream of tap water, then soaked for aboat five or ten minutes in distilled and conductivity water and finally rinsed with ethyl alcohol. They were then inserted in the cork holders already described and dried in a current of purified air. About twenty minutes sufficed to dry them thoroughly. This method was very satisfactory, being convenient, not too time consuming and without the disastrous effects upon the electrodes characteristic of the heating method. The results obtained by this method are given later for a number of series of electrodes in Table I.

---

[11] Biilmann, *Ann. chim.*, [9] **15**, *109* (1921).

In that table are included results obtained when the electrodes were connected in pairs during the entire process of cleaning, drying, and between measurements, as well as results obtained when the electrodes were not short circuited in this way. We made a rather extended study of this point, since it is well known that in the preparation of silver, copper or zinc electrodes two similar electrodes reach the same potential much more readily if they are short circuited in the solutions of their salts for some time prior to use. Furthermore, in the preparation of some electrodes for the measurement of the conductance of non-aqueous solutions two of us[12] learned that much more satisfactory results could be obtained if the electrodes were short circuited during the pre-treatment and drying, and in some unpublished work done in these laboratories[13] it was found that no equilibrium potential of any kind could be obtained when unplatinized platinum was used as a base for hydrogen electrodes unless the electrodes were short circuited.

In the case of the quinhydrone electrode, however, our work indicates that there is no difference in the results obtained when the electrodes are shorted or unshorted. Furthermore, in a series of six electrodes which had been shorted in pairs, potential differences of about the same magnitude were observed between two electrodes which were treated in this way as pairs, as between one electrode of one shorted pair and another electrode from another shorted pair. What we were not able to indicate in the table, however, was that with the shorted electrodes the potential differences decreased regularly until an equilibrium value was reached, when they became constant, whereas with the unshorted electrodes the potential differences sometimes, though not always, decreased to a minimum and then changed sign. This was particularly noticeable with the small wires. Because of this slightly greater irregularity in the potential differences of the unshorted electrodes, we shorted ours throughout most of our determinations.

It is interesting to note that when the electrodes are prepared and cleaned in this way they seem to take up fairly well defined potential differences which appear to be characteristic of the metal comprising the electrodes. For instance, in Series A, electrodes Nos. 1 and 2 could always be counted on to give an equilibrium potential of something less than 0.000010 volt, while electrodes Nos. 3 and 4 gave equilibrium potentials between 0.000010 and 0.000020 volt and Nos. 5 and 6 a value of about 0.000010 volt. These characteristic values reappeared time and time again throughout several years whenever these electrodes were coupled, although the electrodes were remade during that time, in some cases a number of times, and cleaned and used many times.

[12] Morgan and Lammert, THIS JOURNAL, 45, 1692 (1923).

[13] Travers, "Thesis," Vassar College, 1928.

To see whether this method of cleaning and drying gave results of the same order of magnitude as those obtained when the electrodes were heated, we heated a number of electrodes, selecting electrodes whose characteristic behavior was well known to us because of a large number of results available. Of the seventy-eight electrodes heated, nine cracked and gave the abnormally large results characteristic of cracked electrodes. Furthermore there was very little gain in precision when the electrodes were heated. The average potential, the range of differences and the deviations are practically the same. With the gold electrodes, however, the results were more satisfactory although the tendency of the gold electrodes to crack was greater. However, whereas the air-dried electrodes are likely to give higher initial readings, which then drop to a constant potential difference if the electrodes are short circuited, the flame heated electrodes are likely to give lower initial readings which then rise to higher values in the course of an hour. All in all there seems to be little advantage in the method of heating the electrodes over the method of air drying them and considerable disadvantage due to the readiness with which they crack.

A few determinations on the reproducibility were obtained when the electrode was not dried but was rinsed with some of the acid solution used. Our experience with conductance cells led us to believe that there would be no difficulty in obtaining at least as satisfactory a reproducibility as could be obtained with the dried electrodes but our results indicate that while the gold wires are if anything more readily reproducible with this method, the platinum electrodes are not, the averages, ranges and deviations all being higher when the electrodes are only rinsed. We varied the treatment somewhat, rinsing the electrodes one time with 0.1 *N* hydrochloric acid immediately after distilled water, another time with alcohol before the 0.1 N hydrochloric acid and still another time with alcohol and 0.1 N hydrochloric acid which was saturated with quinhydrone, but observed no striking difference in the results by different methods. Moreover, inasmuch as the quinhydrone electrode has many applications in solutions which are likely to be limited in amount, the results with the dried electrodes are the more valuable and interesting.

The Preparation of the Quinhydrone Solution.—The influence of the method of preparation of the quinhydrone and subsequent purity on the potentials of quinhydrone electrodes have been the subject of a number of investigations, reference to which is omitted in the interests of brevity. These investigations indicate very generally that the purity of the quinhydrone is of little importance in its effect upon the potential in so far as traces of iron and similar foreign substances are concerned but that methods of preparation and of drying involving raised temperatures or any other procedure which in any way alters the equimolecular proportion of quinone and hydroquinone are to be avoided. Inasmuch as the Eastman product had been compared with other preparations by a number of investigators and inasmuch as we were interested only in the reproducibility of the electrode we used the quinhydrone furnished by the Eastman Kodak Company without further purification. Moreover, we found no difference in the potentials obtained with different lots of quinhydrone, all of which came from the same company.

The concentration of quinhydrone to be used in solution has also been the subject of investigation, the work done indicating that in accordance with the theory of the electrode the concentration of quinhydrone exerts very little influence on the potentials obtained if the concentration is not too low. Biilmann and Jensen[8] have made perhaps the most conclusive study of this point and find that the potentials of cells made up 0.00320 *M* or more concentrated in quinhydrone agree very well with the potentials of cells prepared by saturating the solutions with quinhydrone. However, since the solutions are so readily saturated with quinhydrone we used the saturated solutions throughout the investigation. At the end of each experiment some of the excess quinhydrone remained undissolved. No difference in result was obtained when the quantity of quinhydrone was increased or decreased nor when the solution was heated slightly above 25°. However, whenever the solutions were heated to a temperature above 50°, the potential differences were larger and the solution became dark colored in a much shorter time. For this reason we did not heat the solutions before immersing the electrodes.

We made a number of determinations to discover whether there was any difference in the potential differences obtained when the solutions were stirred and when they were not stirred. We found that the average potential difference, range and deviations are of about the same magnitude, but that in the case of measurements in the unstirred solutions the potential differences varied about a mean value rather than approached an equilibrium value. Therefore, to obviate one source of variation, we stirred our solutions throughout most of our work and recommend that this be done whenever feasible, although it is recognized that to do this would frequently complicate the technique in a given application and would be impossible in others.

The Size and Composition of the Metal Electrode.—Our results on the effect of size and composition of the metal electrode on the reproducibility of the quinhydrone half-cells are summarized in Tables I and II. The voltages given are the average of a number of values taken after the electrodes had been immersed in the solution for at least an hour. The values which are averaged for the short-circuited electrodes represent the potential differences between pairs of electrodes which had been connected during cleaning and between one electrode of the series taken as a reference and the other members of the series, one by one. Our reason for taking the averages of values after sixty minutes is that in our experience any electrodes which, under the conditions of our experiments, will come to equilibrium eventually have done so by that time, which is to say successive readings agreed with one another to within at least 0.000005 volt. To report only the equilibrium values, however, is to exclude many of the results obtained with the small wires and to do this gives an impression that the results with the small wires are better than they are in reality. These results are typical of a larger number of results obtained in the early part of this work before all of the refinements of technique had been developed. In a few cases, however, several results, which were so entirely inconsistent with the rest of the series that they appeared as accidental errors, were discarded, but when this was done the number discarded is indicated in the last column of the table and the original range indicated in parentheses beneath the other value.

From these results it is obvious that the size of the metal electrode has a very definite effect upon the reproducibility possible with the quinhydrone

TABLE II

SUMMARY OF RESULTS SHOWING THE PERCENTAGE VARIATION IN POTENTIAL DIFFERENCES OBTAINED WHEN METALS OF DIFFERENT COMPOSITIONS AND DIMENSIONS ARE USED IN THE PREPARATION OF THE QUINHYDRONE ELECTRODE. SOLUTIONS STIRRED

electrode in 0.1 hydrochloric acid. Both the average potential differences and the range of differences are greater as the size of the electrodes decreases; the larger electrodes reach a constant equilibrium value more readily than the smaller electrodes. Moreover, with the smaller wires, and particularly with the smallest gold wires, the range on the bridge wire over which there is no deflection on the galvanometer becomes greater and the results more erratic. Frequently no equilibrium value is obtained.

This would seem to indicate that when cells are made of such **very** small wires the capacity of the cell is so low that, even with the potentiometer method, enough current is drawn from the cell, while determining the null point, to destroy the equilibrium and hence make the voltage vary. It is probably variations such as these, coupled with additional variations due to concentration polarization, which made it impossible for Biilmann and Lund[14] to use their capillary electrode for more than one or two readings; the question naturally arises where such small electrodes are employed, as to what may be the accuracy of these initial readings. It is possible that a more fortunate form of the microelectrode would be of a type suggested by Boëz[15] in which a sheet of platinum in contact with quinhydrone and two or three drops of the liquid to be examined is held between two cover glasses, since in this type a larger surface of metal could be used.

Table I also gives data on the effect of the composition of the metal on the reproducibility of the quinhydrone electrode,

Upon no point in connection with the quinhydrone electrode has there been such lack of agreement among different investigators as upon the composition of the metal to be used. One group of investigators prefers gold or gold plate, Corran and Lewis[16] suggested that platinum may act as a catalyst for the oxidation of quinol; another group prefers platinum; and still another group reports equally successful reproducibility of potential for either gold or platinum.

Biilmann[g] states that platinum which has been dulled by use should be avoided and that only new bright platinum should be employed, that platinum is preferable to gold for experiments of minute accuracy, since concentrations of quinhydrone sufficient to give exact potentials with bare platinum are not sufficient with gold but that there are some systems in which platinum may not be used.

Any comparison of our results with those of earlier investigators is extremely difficult, since in the first place, while a number of investigators state a preference, they do not always give data to substantiate their preferences, with the result that we do not know even the order of the precision which they are describing. In the second place, the size of the metal is frequently not stated and size is a factor which we find of greater importance than the composition of the electrode. It is quite probable that the entire issue is confused by the fact that some investigators are drawing conclusions as to the precision of the quinhydrone electrode in certain complex systems when they are using electrodes which are too small to give precise results in any systems.

However, in so far as measurements in 0.1 N hydrochloric acid are typical, our results indicate that if an electrode larger than one square centi-

[16] Corran and Lewis, Biochem. J., 18, 1358 (1924).

meter is used, different pieces of the same sample of metal give potential differences, when used as quinhydrone electrodes, which are reproducible with great precision. Table II indicates that it is extremely probable that two pieces of foil larger than one square centimeter of any composition will give potential differences, when cleaned in cleaning mixture, rinsed in water and dried in air, and measured in a solution containing dissolved air under a pressure of one atmosphere, which agree with one another to within something less than 0.00001 volt. This is true whether the metal is the purest gold or platinum obtainable and quite new or whether it is platinum whose exact composition is unknown and which is so old, dulled, roughened and battered (Series D-F and I-N) that it can scarcely be recognized. It is true that we had a few more inexplicably and quite suddenly high results with the gold foils than with the others; on the other hand, the large-surface gold electrodes (L. & N. Nos. 1–4) which we purchased from Leeds and Northrup at two different times gave us some of the best results we had. Quite contrary to Biilmann's experience we found the old platinum foils as good as if not preferable to the new.

As the size of the metal surface diminished, however, we found certain differences in reproducibility among the different metals. The old platinum gave lower averages, ranges and deviations and incidentally reproduced these same results very consistently time after time. The iridium and rhodium alloyed platinum (Series Ir Nos. 1–6, 7–12 and Rh Nos. 1–6, 7–12) gave results which indicated that the reproducibility of different pieces of these metals was of the same order as that of pure platinum (Pt Nos. 1–6, 7–12) purchased at the same time except for the larger rhodium alloyed wires, which gave results lower than either the iridium alloy or pure platinum. Furthermore, all of these electrodes improved in reproducibility as they were used. The old platinum wires (Series A Nos. 1–6 and B Nos. 1–6) gave lower averages, etc., than any of the newer metals except the rhodium alloy. The C. P. platinum from the American Platinum Company recommended by Cullen (Am. Pt Nos. 1–6) gave results intermediate between the results obtained with two samples of platinum from other companies (Pt Nos. 7–12, O Nos. 1–6) which were also smaller in diameter. These electrodes also improved with use. The largest gold wires (St Nos. 1–6), like the foils, gave results as reproducible as the other metals, but the next size of wires (Au Nos. 1–6) and particularly the smallest wires (Au Nos. 7–12) gave much larger values. In fact, *so* troublesome were the very small wires that time and time again we examined the electrodes for cracks, only to find no evidence of any faulty construction whatsoever.

In conclusion, then, we recommend that, from the point of view of the reproducibility of different pieces of the same sample of metal when used for the quinhydrone electrode in 0.1 *N* hydrochloric acid in the presence of air, pieces of platinum foil, preferably old and roughened, of at least one square centimeter surface be sealed into soft glass tubing in the usual manner with sealing-in glass and carefully annealed; further, that electrodes so made be tested for leaks, by boiling in hot water, and cleaned, after the tubes are filled with mercury, by immersion in cold chromic acid cleaning mixture prepared from C. P. chemicals, which is then heated to about 125° and slowly cooled, the electrodes being short-circuited in pairs. The electrodes then should be carefully rinsed in distilled water and in alcohol and dried for about twenty minutes in a current of purified air, after which they should be immersed in the solution whose hydrogen-ion concentration is to be measured, to which has been added quinhydrone in excess of the solubility (0.4–0.6 g. per 100 cc. of 0.1 *N* hydrochloric acid). Several electrodes should be immersed for a preliminary intercomparison to eliminate the possibility of a cracked electrode being used. More consistent results are obtained if the solution can be stirred. Gold foils may be substituted for platinum foils but they are more troublesome to work with, since the metal is softer, give erratic results if accidentally contaminated with mercury, and must be welded to platinum wires to be sealed into glass.

Electrodes prepared in this way give results of great precision with ease and a reproducibility which in our experience is far more satisfactory than that possible with any of the other standard electrodes.

We are indebted to the Special Research Fund of Columhia University for a grant for this work, without which it could not have been completed.

Summary

A study has been made of the reproducibility of the quinhydrone electrode in 0.1 *N* hydrochloric acid under varying conditions and with a large number of electrodes of different sizes, ages and compositions, from which study the following conclusions may be drawn.

1. The quinhydrone electrode can be reproduced with ease and with great precision, two electrodes made from the same piece of foil consistently giving potential differences agreeing with one another to less than 0.000010 volt.

2. The greatest source of error in the quinhydrone half-cell lies in the preparation of the metal electrode, differences of almost 0.1 volt having been observed when the glass of one of the electrodes was cracked. For this reason a method of making, testing and cleansing the electrodes, which reduces the breakage to a minimum, is suggested.

3. The results which are obtained when the electrodes are heated in an alcohol flame before use do not justify the method in view of the large number of electrodes which crack.

4. Electrodes made of longer pieces of wire which can be connected directly to the potentiometer wires without the use of mercury as a con-

necting medium do not give any better results than electrodes made of short wires.

5. The size of the metal exposed to the solution determines the precision with which electrodes properly prepared may be reproduced. Very small, short wires give erratic results, larger, short wires give consistent results but larger deviations than foils or longer lengths of wire, but two foils with dimensions greater than one square centimeter give differences of potential, when measured against one another, of less than 0.000010 volt.

6. The cumposition and age of the metal comprising the electrode is of little importance if the electrode is large enough. However, in 0.1 *N* hydrochloric acid when the electrodes were much smaller than one square centimeter, old roughened platinum seemed to give better results than either new platinum, platinum alloyed with iridium or gold, but the platinum and platinum alloys gave better results than the gold.

Two pieces of metal, cleaned and dried by the method suggested give very nearly the same potential differences whenever they are measured against one another, which fact enables an investigator to select, from a group of electrodes, a few electrodes whose potential differences will invariably be reproduced with great precision.

Work on the effect of nitrogen and on the reproducibility and accuracy of the electrode under other conditions is in progress.

REDUCTION POTENTIAL OF QUADRIVALENT TO TRIVALENT IRIDIUM IN HYDROCHLORIC ACID SOLUTION

BY SHO-CHOW WOO

RECEIVED NOVEMBER 10, 1930 PUBLISHED FEBRUARY 9, 1931

Introduction

It is well known that the most stable compounds of iridium in hydrochloric acid solution are the ions of hexachloriridic and hexachloriridous acids, H_2IrCl_6 and H_3IrCl_6, in which the iridium is present in the quadrivalent and the trivalent states, respectively. Earlier investigations of these compounds were restricted to the determination of their formulas, and until very recently no studies had been made to determine their physico-chemical properties. Since this research was undertaken, however, Ogawa[1] has published measurements of the electromotive force of cells in which the sodium salts of the chloriridic and chloriridous acids were used. He observed steady changes in the electromotive force, and

---

[1] E. Ogawa, *J. Chem. Soc. Japan*, **50**, 123 (1929).

attributed this to the hydrolysis of the salts in the absence of any added acid. In view of the inconstancy of his results it seems desirable to present the determinations that have been made in this Laboratory of the reduction potential for the combination quadrivalent–trivalent iridium in hydrochloric acid solution.

The value of this potential was derived from measurements of the electromotive force of the cell

$$\mathrm{Ir},\ \left\{\begin{matrix}\mathrm{IrCl_6^{=}}\ (c_1\ f.)\\ \mathrm{IrCl_6^{\equiv}}\ (c_2\ f.)\end{matrix}\right. + \mathrm{HCl}\ (1\ f.)\Big\}.\ \mathrm{HCl}\ (1\ f.),\ \mathrm{H_2}\ (p\ \mathrm{atm.}),\ \mathrm{Pt}$$

The methods of. preparation of the iridium solutions and the analytical procedures employed will be described in a later article.

This research was suggested by Professor A. A. Noyes, and to him and to Professor Don M. Yost the author is indebted for many helpful suggestions.

Procedure for the Electromotive Force Measurements.—The type of electrode vessel used was that commonly employed in this Laboratory.[2] The hydrogen was prepared by electrolyzing a solution of sodium hydroxide between nickel electrodes, and it was freed from oxygen by passing it over a glowing tungsten spiral. Before entering the cell, the gas passed through a hydrochloric acid solution of the same concentration as that in the cell.

In order to reduce the liquid potential to a very low value, the concentration of the hydrochloric acid in the iridium solutions was made the same as that used in the hydrogen half-cell, and the total concentration of iridium was made small.

The concentration of the hydrochloric acid in the iridium stock solutions was determined by titrating them with sodium hydroxide, using phenolphthalein as an indicator, after the quadrivalent compound had been reduced to the trivalent state with pure silver. The desired acid concentration for the cell solutions was attained by diluting the stock solutions with the proper amount of hydrochloric acid of known strength. The two half-cells were separated by an ungreased stopcock which was moistened with the acid but was kept closed.

It was found that gold and platinum (to a much less extent) were attacked by the chloriridic acid, but that iridium was not so attacked as was shown by the constancy of the potentials and concentrations. This fact resulted in the use of an iridium-plated glass tube as the electrode in the iridium half-cell. When nitrogen was bubbled through the iridium solution for the purpose of stirring it, the potential did not attain a constant value but usually decreased steadily. With a mechanical stirrer, however, the final electromotive force was reached in a few hours and then remained constant over long periods. The nitrogen may have

---

[2] Schuhmann, THIS JOURNAL, 46, 52 (1924).

contained some oxidizable impurity, for the concentration of the quadrivalent iridium was found to be always less (even 30–40% less) at the end of an experiment than at the beginning. No concentration changes were observed when the mechanical stirrer was used.

Results of **the** Electromotive Force Measurements.-—In Table I is given a summary of the observed values of the electromotive force. The total acid concentration was always 0.998 *f.* (hereafter regarded as 1.0 f.). The "corrected electromotive forces given in the last column are the values of the electromotive force calculated by the usual logarithmic formula for the case that the pressure of hydrogen is one atmosphere and the concentrations of the two forms of iridium are equal. The given electromotive forces, expressed in volts, are those of the cell in the direction in which it was written above.

TABLE 1

RESULTS OF THE ELECTROMOTIVE FORCE MEASUREMENTS

Cell	Temp., °C.	Formal concentration $IrCl_6^-$	Formal concentration $IrCl_6^=$	Pressure of hydrogen	Electromotive force Observed	Electromotive force Corrected
1	25	0.004864	0.005163	719.5	−1.02403	−1.0263
2	25	.004838	.005189	720.2	−1.02365	−1.0261
3	25	,002477	,007631	719 7	−0.99689	−1.0265
4	25	.001976	.008148	720.1	− .98910	−1.0262
5	25	.001976	,008148	719.7	− .98953	−1.0267
					Mean	−1.0264
6	25			721.6	−1.02355	−1.0264
	20			719.8	−1.02840	−1.0313
7	25			721.7	−1.02243	−1.0264
	20			720.7	−1.02735	−1.0313

Discussion of the **Results**

The constancy of the corrected electromotive forces in Cells 1–5 shows that the ratio of the activity coefficients of the chloriridate ion and chloriridite ion does not change appreciably with change in their relative concentrations within the limits here involved. This behavior was to be expected since the difference in the ionic strengths of the solutions is small. Mention should be made, however, of the fact that less satisfactory corrected values were obtained with cells in which a large excess of the chloriridate was present. No explanation of this fact could be found. The difference, however, did not exceed 10 millivolts.

The mean value of the electromotive force at 25° is −1.0264 volts for the cell

$$\text{M, } IrCl_6^= \ (cf.) + IrCl_6^- \ (cf.) + HCl \ (1.0 f.), HCl \ (1.0 f.), H_2 \ (1 \text{ atm.})$$

By taking the mean activity coefficient of the ions in 1.0 f. HCl to be 0.823 as given by Lewis and Randall[3] and assuming that the H^+ and Cl^-

---

[3] Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., Inc., New York, **1923,** p. 336.

ions have in this acid equal activities, this electromotive force may be referred to the molal hydrogen electrode, in which case it becomes —1.021 volts. This is the value for the hypothetical cell

$$\text{M}, \text{IrCl}_6^{\equiv}(c\text{ f.}) + \text{IrCl}_6^{=}(c\text{f.}) + \text{HCl}\ (1.0\text{ f.})\ \text{H}^+\ (1\ m.), \text{H}_2\ (1\text{ atm.})$$

Under the usual conventions[4] this value is also the molal electrode potential for the electronic reaction

$$\text{IrCl}_6^{\equiv}\ (c\,f.) = \text{IrCl}_6^{=}\ (c\text{f.}) + \text{E}^-\ (1\text{f.})\ \text{in } 1.0\,f.\ \text{HCl at } 25°$$

In all these cases c is understood to have a value between 0.002 and 0.008 molal.

This potential corresponds to a greater reducing power than the value (—1.369 volts) for the chlorine electrode. It shows that chloriridous acid is oxidized to cltloridic acid by chlorine at atmospheric pressure so completely that the unoxidized portion is entirely inappreciable.

The corresponding value of the free energy decrease attending the reaction

$$\text{IrCl}_6^{\equiv}\ (c\text{f. in } 1.0\text{ f. HCl}) + \text{H}^+\ (1\text{ m.}) = \text{IrCl}_6^{=}\ (c\text{f. in } 1.0\ f.\ \text{HCl}) + {}^1/_2\,\text{H}_2\ (1\text{ atm.})$$

or attending the above formulated electronic reaction (under the convention that the free energy change H^+ at 1 m. $+ \text{E}^- = {}^1/_2\text{H}_2$ at 1 atm. is zero), is **—23,540** cal. at 25°.

From the measurements of the electromotive force of cells 6 and 7 at 25 and at 20° the value +0.00098 volt/degree is obtained for the temperature coefficient $d\text{E}/d\text{T}$; and from this the corresponding value of the heat content increase ΔH attending this last reaction is found to be **+30,400** cal.

Summary

There have been here presented measurements which show that half-cells consisting of metallic iridium in contact with a 1.0 formal hydrochloric acid solution of equimolal quantities of chloriridic and chloriridous acids (H_2IrCl_6 and H_3IrCl_6) at a concentration (c) between 0.002 and 0.008 formal, when measured against a half-cell consisting of a platinum electrode in contact with hydrogen gas at one atmosphere and with 1.0 formal hydrochloric acid solution, have an electromotive force of **—1.0264** volts at 25°, and of **—1.0313** volts at 20°. Referred to the molal hydrogen electrode (H^+ with activity 1.0 molal), the value of the reduction potential at 25° is computed to be —1.022 volts for the reaction

$$\text{IrCl}_6^{\equiv}(c\ f.\ \text{in } 1.0\text{ f. HCl}) = \text{IrCl}_6^{=}\ (c\text{f. in } 1.0\text{ f. HCl}) + \text{E}^-\ (1\text{f.})$$

The corresponding value of the free energy decrease is **—23,540** calories. From the temperature coefficient of the electromotive force, the heat content decrease for this electronic reaction is found to be **—30,400** cal.

SOLUBILITY OF THALLOUS IODATE IN ETHYL ALCOHOL–WATER MIXTURES

BY VICTOR K. LA MER AND FREDERICK H. GOLDMAN

RECEIVED NOVEMBER 14, 1930 PUBLISHED FEBRUARY 9, 1931

In two important papers Scatchard[1,2] has shown that the simple electrostatic formula first given by Born for the electrical work of transferring charged spheres of average radius r from a medium of dielectric D_1 to one of dielectric D_2, namely,

$$\log_{10} \frac{S_1}{S_2} = \frac{0.4343}{2r} \frac{\epsilon^2}{kT} \left(\frac{1}{D_2} - \frac{1}{D_1}\right)$$

accounts for the solubility data on sodium chloride and potassium chloride in ethyl alcohol–water mixtures over the entire composition range by using such plausible values as $r = 1.31$ and 1.35 Å. He was careful to remark, however, that this simplified theory works better than one has any right to expect.

In connection with our solubility studies[3] on thallous iodate in aqueous salt solutions, we have tested whether this formula would also apply to thallous iodate—alcohol–water mixtures. This salt has the obvious advantage that its solubility is so small that the correction for interionic attraction is negligible in the absence of added salts. The Debye–Hückel limiting law is adequate[4] to correct for this effect if desired. The ease with which iodates may be determined enables determinations of the solubility to be made with sufficient precision when considerable alcohol is present.

Experimental

The preparation of the salt and method of analysis have been described in detail previously.[3] The ethyl alcohol was redistilled from caustic potash and silver nitrate and the solvents made up by weight. Density measurements were made in each case as a check on the accuracy of this procedure.

Discussion

The data are tabulated in Table I, the solubility being expressed in micro (10^{-6}) moles per liter. Column 6 shows that log $S_{H_2O}/S_{\text{alcohol}}$, when divided by the mole fraction, drifts steadily downward by 22%. On the other hand, Column 7 shows that log $S_{H_2O}/S_{\text{alc.}}$ is an almost linear function (to within 7%) of the weight percentage of alcohol over the same concentration range. In Column 8 we give $(-\log f_0)$, the correction for interionic attraction in each solvent employed in calculating Column 9. The linear relation in respect to weight percentage is unaltered.

94.71	Solubility too small to be detected.							

It is unfortunate that Nernst's[6] measurements on the dielectric constants of alcohol–water mixtures do not extend below about 46 weight per cent., so that we might compare the solubility changes with the concentration dependence of $1/D$ without resorting to interpolation over the interval 0 to 46% alcohol. If Equation 1 is to hold, $1/D$ must be more nearly proportional to the weight concentration than to the mole fraction in this range of concentration. This question should be investigated with more modern experimental methods.

If we substitute in Equation 1 for D_1 and D_2, the values 78.8 (H_2O) and 49.6 (46.91% alcohol) and for S_1 and S_2 the solubility of thallous iodate in moles per liter, we compute $r = 0.78$ Å. The volume molar scale has been used in this connection by most investigators but it implies that if there were no electrical effects, the molar solubility would be constant in all solvents. There is no adequate justification for such an ideal law. If we assume Raoult's law to be the ideal, which law demands that the components in the liquid state mix in all proportions without change of volume or of heat content, then the solubility in terms of mole fraction should be identical in the absence of electrical or other effects.

Although volume no longer appears explicitly in this ideal law, the choice of molecular weights for the components used in calculating the mole fraction implies it through the Avogadro hypothesis. Assuming the molecular weights of alcohol and water to be 46 and 18.02, respectively, we get $N_1 = 33.26\cdot10^{-6}$ and N_2 = 2.29.10–t Substituting these values for S_1 and S_2 we find $r = 0.90$ Å. as the average radii of the Tl^+ and IO_3^- ions, on the assumption that the non-ideality arises solely from the net charges on the ions and that our assumptions of the molecular weights of water and alcohol are correct for their mixtures.

Either value of r, namely, 0.78 or 0.90 Å., is a trifle smaller than one might expect for the average radii from other methods of measurement. On the other hand, it actually proves to be as large as the parameter "*a*,"

---

[5] Nernst, *Z. physik. Chem.*, 14,622 (1894).

representing the distance of closest approach of the ions computed with the aid of the general solution of the Debye–Hückel interaction theory.[6] If the ions are spherical and no forces of deformation intrude, "*a*" should equal 2r.

Table II gives the results of computations based upon the solubility data in dilute salt solutions. In the case of uni-univalent solvent salts the calculations can be made with fewer mathematical complications than is the case with higher valence solvent salts.

Column 4 gives the value of "a" computed from the first or Debye approximation on the customary assumption that all individual "*a*" values in the ternary mixture: water, $TlIO_3$, and 1,-1 solvent salt, are equal. By the use of a graphical plot representing the fictitious values of "a_{1st}" which correspond to the same $-\log f$ value computed for a given "$a_{general}$" and a definite value of the Debye κ or $\sqrt{\mu}$, we can readily translate any value of "a_{1st}" into its "$a_{general}$" value. These values are given in Column **5**. No sensible error is introduced in the case of symmetrical valence types in water by considering the fifth approximation equal to the general solution if $a/Z^2 < 0.8$ Å.[7] The "a" values in the nitrate solvents are almost equal to $2r$, but the "a_g" values in the chloride solvents, although no longer absurdly negative as is the case for the "a_{1st}," are still somewhat small. In other words, the neglected higher terms in the Debye theory account for the nitrate data on a purely theoretical basis involving only one parameter but are not quite sufficient to account for the chloride data. Undoubtedly other forces leading to deformation of the ions or complex chloride ion formation occur and must be taken into account for a precise representation of the data. Similar behavior has been noted for lead iodate in 0.1 N chloride solvents.[8] We should point out, however, that a com-

[7] The data for this conversion valid for infinite dilution have been given by La Mer, *Trans. Am. Electrochem. Soc.*, 51, 507 (1927), page 547. The conversion values for finite concentrations will be published later.

[8] La Mer and Goldman, THIS JOURNAL, 52,2791 (1930).

putation for "a" values constitutes a very critical test of the Debye–Hückel theory. The fact that the highly simplified picture employed by Debye and Hückel represents the facts for Pb^+ and Tl^+, which are known to form complexes with chloride ions at higher concentrations, as closely as it does is more remarkable than are the comparatively insignificant deviations just mentioned.

Summary

The solubility of thallous iodate has been measured in ethyl alcohol–water mixtures ranging from zero to 47% ethyl alcohol. The values of the average radii calculated using Born's formula for the electrostatic work of transfer are compared with the values of the parameter "a" computed from the interaction theory for the solubility in salt solutions as extended by Gronwall, La Mer and Sandved.

THE HEAT CAPACITIES AT LOW TEMPERATURES OF MANGANESE SULFIDE, FERROUS SULFIDE AND CALCIUM SULFIDE[1]

BY C. TRAVIS ANDERSON[2]

RECEIVED NOVEMBER 17, 1930 PUBLISHED FEBRUARY 9, 1931

Pursuing its general program of study of the thermodynamic properties of metals, oxides and sulfides which are important in metallurgical processes, the Pacific Experiment Station of the U. S. Bureau of Mines has determined the heat capacities of the sulfides of manganese, iron and calcium. The thermodynamic properties of these sulfides have both theoretical interest and practical importance. The heat capacities of the oxides corresponding to these sulfides have been determined, which enables an interesting comparison to be made.[3] Knowledge of the entropies of these sulfides was especially desired for use in connection with studies of the desulfurization of iron.

The method, apparatus and accuracy have been described in previous publications,[4] but it may be noted that between the sets of experiments

with the different samples the thermocouple was again compared with a standard, and the standard cell checked from time to time with others having Bureau of Standards certificates.

Materials

After considerable preliminary testing of various methods of preparation of pure sulfides, the method of Schöne[5] was modified to give excellent results. Schöne passed carbon dioxide saturated with carbon disulfide vapor over heated carbonates of various metals (especially calcium), obtaining nearly quantitative yields of sulfides. It has been found that the sulfates of metals having very stable oxides are preferable to carbonates, and that control of temperature of heating, and partial vapor pressure of carbon disulfide are essential. When completeness of conversion is desired, it was also found better to prepare a number of small samples than to attempt a single large preparation. The reason for these precautions will be obvious from a consideration of the mechanism of the conversion, which probably involves the reversible formation of carbonyl sulfide from carbon dioxide and carbon disulfide.

The sample of manganese sulfide was prepared from a C. P. grade of manganese sulfate. Small portions of the sulfate were placed in a silica tube which fitted conveniently in a tube furnace. Carbon dioxide was bubbled through gas washing bottles containing carbon disulfide at 25°. The tube furnace was heated to 750°. The resulting manganese sulfide had the theoretical composition of MnS to within the limits of analytical error, in this case about 0.1%. Its density was found to be 3.93 at 21.9°. A 166.3-g. sample was studied.

The ferrous sulfide was prepared from a mixture of iron oxides which were made from strips of pure ingot iron by heating them in air for several days at about 900°. The oxide material so obtained was crushed to −14 mesh and the metallic iron separated mechanically. The iron oxides were placed in the silica tube in the combustion furnace and carbon dioxide saturated with carbon disulfide at 25° was passed over the oxide at about 850°. The resulting sulfide was definitely crystalline and had the theoretical composition of FeS to within the limits of analytical error (0.2%). It had a density of 4.65 at 23.9". The calorimeter was filled with a 270.4-g. sample.

Calcium sulfide proved to be the most difficult of the materials to prepare. Finely divided calcium sulfate was used and was placed in the silica tube which had been used for the preparation of the two other sulfides. The furnace in this case was heated to about 700° and the carbon dioxide was saturated with carbon disulfide at 27°. It was necessary to re-treat the material several times before the sulfate was completely converted to the sulfide. The resulting sulfide had the theoretical composition of CaS to within the limits of analytical error, in this case about 0.1%. The sulfide was necessarily very finely divided, since coarse material could not be completely converted. The sample was compressed into pellets at pressures of several tons per square inch, so that the calorimeter could be filled with an adequate weight of material. The pellets were broken and the calorimeter finally filled with a sample of 77.1 g. Without compressing, the contents would have been less than 10 g. The density was ***2.56*** at 23.6°.

Screen tests using Tyler screens were made on these materials and are shown in

The **Specific Heats**

No previous low temperature measurements have been made on any of these sulfides. The results obtained in this Laboratory on the heat capacities of manganese sulfide, ferrous sulfide and calcium sulfide, expressed in gram calories (15°) per gram formula weight, are shown graphically in Fig. 1. The experimental determinations of heat capacities for ferrous sulfide and calcium sulfide are given in Tables II and III. The values for manganese sulfide, except those between 100° and 170°K. are given in Table IV. The values for the heat capacities for manganese sulfide between 100 and 170°K. with the temperature rise (AT) of the determination are given in Table V and are shown graphically in Fig. 2. Except

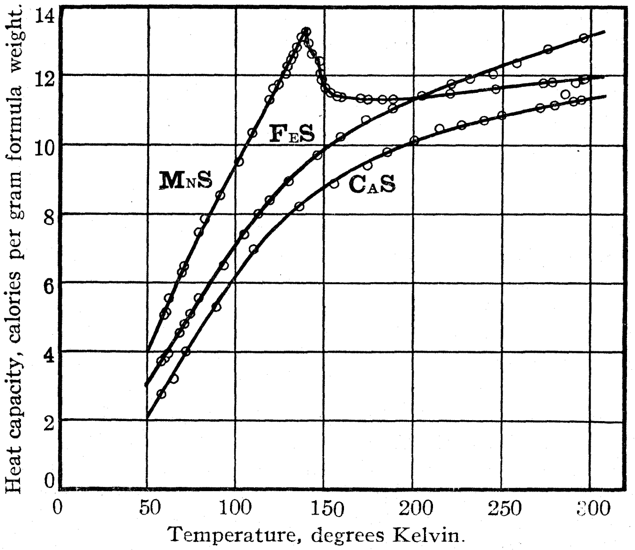

Fig. 1.—The heat capacity of manganese sulfide, ferrous sulfide and calcium sulfide in calories per gram formula weight.

for this range, the temperature rise of the determinations varied from about 3 to 6°. In changing joules to calories the factor $1/4.184$[6] was used. The calculations were made on the basis of Mn = 54.93, Fe = 55.84, Ca = 40.07, and S = 32.06.

another anomaly. The particular sample of ferrous oxide which had been used analyzed only 83% ferrous oxide, the remaining material being a solution of iron and magnetite in the ferrous oxide.

The sample of manganous oxide was apparently a pure sample. These results would indicate that the corresponding sulfides should show anomalies at a higher temperature than their corresponding oxides. This was observed in the case of the manganese sulfide, but the ferrous sulfide curve was normal in the region where the hump was suspected. This would indicate that the hump observed in the ferrous oxide might be attributed to the solution of the magnetite and iron present in the ferrous oxide. However, the trend of the heat capacity curve for ferrous sulfide at room temperature seems to indicate that a transition is starting to take place, as in the case of the ferrous oxide. The heat capacity of the ferrous sulfide above room temperature will be measured in the near future in this Laboratory. Figure 2 shows the heat capacity curve for manganese sulfide in the vicinity of the hump, between 100 and 170°K. Just previously to Run 35 an attempt was made to supercool the manganese sulfide from room temperature to below 60°K. There was no indication of supercooling, since the points fell on the same smooth curve, independently of the history of the substance. The hump was perfectly reproducible, in fact so much so that no measurements were made on the heat of apparent transition. After reaching a maximum the downward part of the curve flattened to about 147°K., at which point it dropped off suddenly from about 12.5 to 12.0 cal. per gram formula weight. This particular anomaly seems to be more nearly a discontinuity, but was also perfectly reproducible. It was thought that this second anomaly might possibly be ascribed to the temperature scale, but after going over that portion of the scale no discrepancy could be found, indicating that this anomaly actually exists, and since the specific heat here drops almost vertically with the temperature, the correspondence with an actual discontinuity is more marked than at the maximum point. The heat capacity curve on either side of the humps possesses very different slopes, but this does not necessarily indicate a change in crystal structure, because the factors causing the anomaly are obviously active over *a* considerable temperature range and may well be affecting the normal course of the curve over a wide temperature interval. **A** study of the magnetic changes in this region would be of great interest.

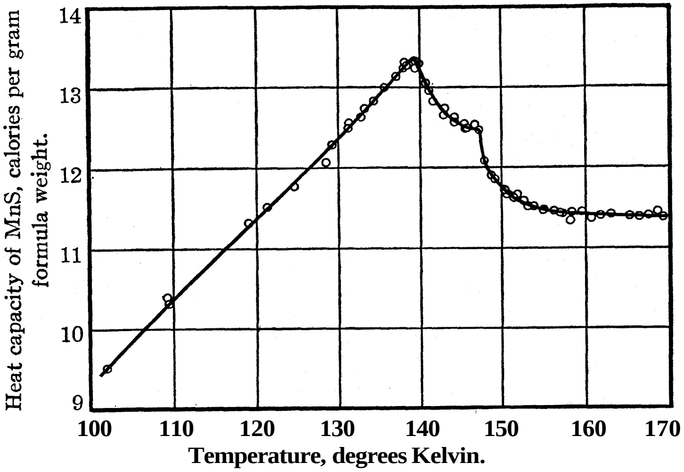

Fig. 2.—The heat capacity of manganese sulfide in calories per gram formula weight.

The experimental data on manganese sulfide do not in themselves give explanation for the double cusped nature of the hump observed. However, it is an obvious hypothesis to suppose that the curve as observed may represent the sum of two simple curves, each of which has a separate hump at temperatures near those of the cusps. This point of view has led Professor E. D. Eastman of the University of California to suggest that there may be some sort of analogy between the factors causing doublet spectral lines and those responsible for the "doublet" hump here observed.

Calculation of Entropies

The entropies were calculated graphically by plotting the heat capacity against the logarithm of the temperature. The heat capacity curves were extrapolated to the absolute zero by means of combinations of Debye and Einstein functions. The Debye functions used had the following parameters (8): for MnS, 205; FeS, 205; and CaS, 284. In Table VI are given the results of the entropy calculations.

TABLE VI

ENTROPY DATA

	MnS	FeS	CaS
Extrap. (0–56.2) °K.	2.14	1.43	1.32
Graph. (56.2–298.1) °K.	16.58	14.68	12.21
S°_{298}	18.7 ± 0.3	16.1 ± 0.3	13.5 ± 0.3

The following combinations of Debye and Einstein functions were found to fit the specific heat curves per formula weights of the three sulfides.

$$C_{\mathrm{MnS}} = D\,\frac{(205)}{T} + E\,\frac{(263)}{T}$$

$$C_{\mathrm{FeS}} = D\,\frac{(205)}{T} + E\,\frac{(370)}{T}$$

$$C_{\mathrm{CaS}} = D\,\frac{(284)}{T} + E\,\frac{(369)}{T}$$

The MnS combination fits the experimental curve up to 50°K., the FeS combination to 75° and that for the CaS to 133°.

Related Thermal Data

The heat of formation of manganese sulfide has been determined by Wologdine and Penkiewitsch[7] by direct combination of manganese and sulfur. They give $\Delta H^\circ_{298} = -62{,}900$ cal. Using this value in combination with the entropies of manganese and rhombic sulfur, as given by Lewis and Randall,[8] and the entropy of manganese sulfide given above, the free energy of manganese sulfide was calculated as —64,000 cal.

Parravano and P. de Cesaris[9] measured the heat of formation of ferrous sulfide by the combination of iron and rhombic sulfur and give $\Delta H^\circ_{298} = -23{,}070$ cal. Using their value and Lewis and Randall's values for the

[9] Parravano and P. de Cesaris, *Gazz. chim. ital.*, *47, 144* (1917).

entropies of iron and rhombic sulfur and the measured entropy of ferrous sulfide, the value —23,600 cal. was calculated as the free energy of ferrous sulfide.

Sabatier[10] determined the heat of formation of calcium sulfide by direct union of calcium and rhombic sulfur. He gives the value of $\Delta H^\circ_{298} = -111{,}200$ cal. Using this value and the values of the entropies of calcium and rhombic sulfur as given by Lewis and Randall, and the entropy obtained for calcium sulfide, the free energy of calcium sulfide was calculated as −109,800 cal.

Summary

The heat capacities of manganese sulfide, ferrous sulfide and calcium sulfide from about 60 to 300°K. have been determined, and their corresponding entropies and free energies calculated.

The following table contains the summarized results.

	S°_{298}	ΔF°_{298}	ΔH°_{298}
MnS	18.7	–64,000	–62,900
FeS	16.1	–23,600	–23.070
CaS	13.5	−109,800	–111,200

THE DECOMPOSITION OF REFRACTORY SILICATES BY FUSED AMMONIUM FLUORIDE AND ITS APPLICATION TO THE DETERMINATION OF SILICA IN GLASS SANDS

BY A. C. SHEAD[1] AND G. FREDERICK SMITH

RECEIVED NOVEMBER 17, 1930 PUBLISHED FEBRUARY 9, 1931

For years the opening of silicates, preparatory to the analysis of the alkali metals, has been a serious problem. The method of J. Lawrence Smith, though satisfactory as to accuracy, is laborious in technique, consequently the hydrofluoric–sulfuric acid process often has been proposed to supplant it but has been unqualifiedly rejected by Hillebrand[2] as unsuitable because of the difficulty of removing fluorides. Lundell[3] proposes to substitute perchloric acid for sulfuric to obviate this difficulty, especially with reference to soda-lime glasses. While working along the same lines, but using crystallized ammonium fluoride, the writers noticed that fusion took place and it occurred to them that possibly a molten reagent might be more ef-

---

fective than the aqueous solutions commonly employed. Such proved to be the case, as will be shown later.

On looking up the literature, it was found that Berzelius[4] noted the fusibility of ammonium fluoride, and that it had been employed by Jannasch[5] to decompose andalusite, but in such a way as to obscure and nullify the peculiar advantages of the reagent. For instance, the flux was formed in the reaction crucible from the aqueous reagents, ammonia and hydrofluoric acid, with the latter in large excess, necessitating the removal of at least 20.0 ml. of water, and leaving in doubt whether the mineral had been decomposed by the excess of hydrofluoric acid used or by the subsequent fusion. Jannasch apparently realized the value of the molten fluoride but his interest was intrigued by his boric oxide flux—this fact and, possibly, a faulty translation, referring to his work, seem to have left this phase of the problem unnoticed ever since.

H. Rose[6] had previously proposed the following scheme, which had apparently been unfamiliar to Jannasch. To a mixture of ammonium fluoride and water in the form of a semi-fluid mass in a platinum crucible is added the finely ground sample of quartz or silicate. The mixture is then evaporated to dryness and ignited. It was stated (contrary to our experience with the dry reagent) that the process has to be repeated three to four times in the case of quartz but is more effective in the case of silicates. Rose's method is undesirable because of the time required in each treatment and the necessary repetition of the operation for complete reaction and because of loss from spattering due to the addition of water to the reaction mixture. Rose did not apply the method quantitatively.

Qualitative tests on finely powdered minerals—among them quartz, orthoclase feldspar, beryl, iron tourmaline—have shown that silica is rapidly eliminated in presence of molten ammonium fluorides. These results encouraged the writers to undertake a quantitative study on the extent of the decomposition. The quartz of glass sand was selected because of its simplicity of composition, its comparative resistance, among the silicon compounds, to attack by hydrofluoric acid, the availability of excellent analyzed samples, and the usefulness of a quick and accurate method of analysis for the commercial product. The samples analyzed were Bureau of Standards glass sand sample No. 81 and one that had been carefully analyzed, using the sodium carbonate fusion method, by one of the writers.?

Method of Analysis.—A weighed sample, previously dried at 110°, was thoroughly mixed with five grams of C. P. crystalline ammonium fluoride

in a tared *25.0* ml. platinum crucible, provided with a well-fitting lid which is kept in place during the subsequent decomposition. The crucible was placed in a hole through a heavy asbestos board of such a size that about a third of the surface of the crucible is exposed to the flame of an adjustable burner of the Tirrill type, and fixed at such a height that the bottom of the empty crucible will be maintained at a dull red heat. The fusion and expulsion of the excess reagent should require about ten minutes. Experience shows that about a gram of quartz of one hundred mesh or finer will be volatilized within this time but that a very small amount of silica will generally remain, necessitating the repetition of the process. The smallest residue of unattacked mineral is easily seen as it tends to segregate itself. The amount left will be large, even in the case of precipitated silica, unless the flux be thoroughly mixed with the sample, in the first place. The fusion is remarkably quiet and the small amount of residue spattering upon the lid can generally be easily removed by the following technique. The lid is heavily coated with ammonium salt upon which some of the residue may be projected. Toward the end of the fume evolution this coat is heated with the burner held in the hand and the flame impinging on the lid; this causes the detachment of the deposit, which falls into the crucible carrying the residue with it.

Before the crucible is allowed to come to redness, after the excess fluoride has been volatilized, it is advisable to add a drop or two of concentrated sulfuric acid, or a few fragments of ammonium bisulfate to prevent the escape of traces of iron or aluminum, as halide. Perchloric acid cannot be used, as ignition forms these halides.

TABLE I

TYPICAL RESULTS

Okla. 171	(By sodium carbonate fusion, etc.)			99.63

[a] Analysis of B. of S. sample No. 81: Fe_2O_3, 0.073; Al_2O_3, 0.265; TiO_2, 0.095; ZrO_2, 0.031; CaO, 0.029; MgO, 0.016; loss on ignition, 0.23. This gives a total of 0.74% impurities in the form finally weighed in these experiments. The indicated silica content is therefore 99.26%.

The time required for the expulsion of silica and excess reagents need not exceed twenty minutes, for both evaporations.

The residue is preponderantly oxides of iron, aluminum and titanium, with but negligible amounts of alkali and alkali earth oxides, and the loss can safely be attributed to silica in this particular case,

The data in Table I are typical of the results obtained.

Discussion

As ammonia fumes are given off copiously on heating ammonium fluoride, and a more fusible compound seems to be formed, it is suggested that the following reaction takes place

$$(NH_4)_2F_2 \textbf{ plus heat } \text{gives } NH_4F_2 \textbf{ plus } NH_3$$

Experiments with the technical grades of the bifluoride lead to the conclusion that previously fused pieces of this flux would probably afford prompter fusion, greater fluidity, a more acid nature and an even quieter melt than the normal salt.

Summary

Molten ammonium fluoride rapidly decomposes powdered quartz and silicates. This reaction has been proved to be quantitative, in the case of glass sand, and shows the possibility of opening silicates preliminary to determining other constituents therein, particularly the alkali metals.

OXYGEN FILMS ON TUNGSTEN. I. A STUDY OF STABILITY BY MEANS OF ELECTRON EMISSION IN PRESENCE OF CESIUM VAPOR

BY I. LANGMUIR AND D. S. VILLARS

RECEIVED NOVEMBER 26, 1930 PUBLISHED FEBRUARY 9, 1931

In this paper we wish to describe a powerful method of studying the properties and detecting the presence of adsorbed films of oxygen on a tungsten surface. This method, not in general use, seems to us to be capable of much wider application than we are making of it here, and for that reason we wish to call it to the attention of chemists. We shall, at the same time, present evidence obtained by it to show that adsorbed oxygen films are held on a tungsten surface by enormous binding forces,[1] very much greater even than those corresponding to the heat of dissociation of the oxygen molecule.

The experimental work on which this paper is based was done by Dr.

K. H. Kingdon; a part has already been published elsewhere.[2] In that article it was shown that minute traces of cesium vapor have a remarkable effect on the electron emission from a tungsten surface. Some of the most important data are summarized quantitatively in Fig. 1, which is Langmuir and Kingdon's Fig. 1. Consider, for example, the curve labeled 20°. This shows that the electron emission in the presence of cesium vapor saturated at 20° (0.001 barye) at low filament temperatures (the right side of the diagram, subsequently to be referred to as Region I) varies with increasing temperature according to the Richardson equation

$$i = AT^2\epsilon^{-b/T} \qquad (1)$$

up to about 640°K.,[3] but is many billionfold greater than that from pure tungsten. Thus at 590° ($10^3/T = 1.7$) the emission is $10^{-6.2}$ amp. cm.$^{-2}$, whereas that from pure tungsten would be the unmeasurable quantity 10^{-31}, if Dushman's[4] values of $A = 60.2$ and $b = 52,600$ are taken.

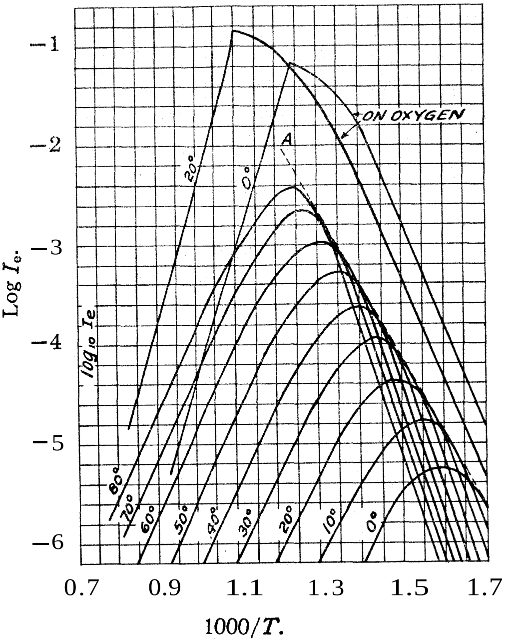

Fig. 1.—Electron emission from tungsten filaments in cesium vapor at various pressures (amps. cm.$^{-2}$)

On increasing the temperature from 640 ($10^3/T = 1.56$) to 715° ($10^3/T = 1.4$), the emission is found to pass through a maximum (Region II) and decrease with further increase in temperature (Region III). This drop in emission is due to an evaporation of the cesium from the surface. Finally, when all the cesium has evaporated off, the points on the curve bend upward again (with decreasing $1/T$) and the emission follows Equation 1.

The most remarkable phenomenon, however, was the effect of oxygen on these composite surfaces. Ordinarily, a layer of oxygen decreases the

[3] All temperatures, unless otherwise stated, will be given in absolute degrees, K. For the method of measuring temperature, the reader is referred to the article of Jones **and** Langmuir, Gen. Elec. *Rev., 30,* 310–319, 354–361, 408–412 (1927).

[4] S. Dushman, H. N. Rowe, J. Ewald and C. A. Kidner, *Phys. Rev.,* 25, 338 (1925).

emission from a pure tungsten surface. Thus, from Kingdon's data,[5] $A = 5 \times 10^{11}$ and b = 107,000, we calculate that the emission from an oxygen-coated surface should be 10^{-33} at 910° ($10^3/T = 1.1$) as compared with $10^{-17.4}$ from pure tungsten. If, now, cesium vapor is admitted to the oxygen-coated filament, the emission at all temperatures is increased so that at 910° it is $10^{-0.9}$, according to the curve in Fig. 1, marked "On Oxygen 20°." The general shape of the curve is the same as before, but now it obeys the Richardson equation up to much higher temperatures. The oxygen increases the stability of the cesium film, holding it much more firmly than tungsten does.

In all of these regions there is a balance between the rates of evaporation and of condensation of cesium on the surface, so that we may assume

$$\underset{\textbf{Rate of evaporation}}{k\Theta\epsilon^{-H_\Theta/RT}} = \underset{\textbf{Condensation}}{\alpha p\ (1 - €3)} \qquad (2)$$

Here 8 is the fraction of surface covered by the cesium atoms, H_Θ is the heat of evaporation, and p the vapor pressure of cesium. The transition Region II thus occurs close to the temperature at which the equilibrium value of 8 begins to be less than unity by a perceptible amount. Region I is that in which (1 – 8) is very small or 8 practically equal to unity. That this is true is also indicated by the fact that increasing the cesium vapor pressure affects the emission only slightly; in fact, decreases it instead of increasing it. Region III gives us the course of evaporation with the temperature.

Oxygen present on the surface produces two effects. One is a slight alteration of the work function, φ, through the cesium layer. The average work necessary to remove an electron from a surface is approximately a linear function of the fraction of the surface covered.

$$\varphi = \varphi_W + \Theta_{Cs}\,(\varphi_{W-Cs} - \varphi_W) \qquad (3)$$

where φ_W is the work function from a pure tungsten surface, φ_{W-Cs} is the corresponding work function from a tungsten surface covered with a complete layer of cesium, and Θ_{Cs} is the fraction of the surface covered with cesium. Evidence supporting this hypothesis has been discussed elsewhere.@ From Equations 1 and 3 it follows that log i is a linear function of Θ in view of the relation connecting b of equation 1 with φ

$$b = \varphi e/k = 11600\ \varphi \qquad (4)$$

if φ is given in volts. Although the work function from a Cs–O–W layer need not be exactly the same as that from Cs–W, this distinction is not very important, as may be seen from a study of Region I of the Cs–O–W and Cs–W curves (Fig. 1). The difference in log i, which, by Equation 1, depends principally upon the work function, is only 0.7 (at 590°), a small fac-

[6] I. Langmuir, *ibid.*, 22,357–98 (1922).

tor indeed when compared with the enormous differences we shall make use of later.

The other effect of the presence of an oxygen film is to hold cesium atoms which would otherwise evaporate under the same conditions of temperature and pressure. This effect comes to light in Region III where we no longer have the surface completely covered with cesium. Every oxygen molecule which strikes a bare tungsten surface is held so strongly that it cannot be dislodged at the low temperatures which are sufficient to evaporate cesium. These adsorbed atoms are, moreover, capable of holding cesium atoms much more tightly than the bare tungsten surface. A relatively high temperature is required therefore to bring about the evaporation of these cesium atoms to produce any given value of θ_{Cs}. It is this effect which allows us to go to much higher temperatures on the Cs–W curve of $\theta_{Cs} = 1$, without evaporating off all the cesium layer. This is the reason that oxygen can increase the emission 10^6 fold.

On first thought it is natural to assume that the curves labeled "On Oxygen" in Fig. 1 correspond to $\theta_O = 1$, where θ_O is the fraction of surface covered with oxygen. On the other hand, when we consider that, in the checkerboard arrangement of the surface, one oxygen adatom[7] may hold more than one cesium atom, perhaps as many as three to seven, our first hypothesis does not seem likely.

We may think of the total fraction of the surface covered by cesium, θ_{Cs}, to be made up of two parts, one of which is the fraction, θ'_{Cs}, which would naturally be present in equilibrium at that temperature if no oxygen were there, and the other of which is the additional fraction, θ''_{Cs}, held by the oxygen present.

$$\theta_{Cs} = \theta'_{Cs} + \theta''_{Cs} \tag{5}$$

It is then to be expected that the additional fraction held, θ''_{Cs}, should be directly proportional to the amount of oxygen present, up to a certain limit. For example, if the number of cesium atoms held by an oxygen atom were n, we would have

$$\theta''_{Cs} = n\theta_O \tag{6}$$

up to the point where $\theta_{Cs} = n\theta_O + \theta'_{Cs} = 1$. Beyond this value, the emission should be nearly constant, although θ_O might continue to increase to values all the way up to unity. For this reason we might expect the work function in Region III (where cesium is more or less evaporated off) to vary linearly with θ_O from 0 to about 0.33 (if $n = 3$), and be little affected by subsequent addition of oxygen to the surface. Notwithstanding this uncertainty in our knowledge of θ_O, we can probably be certain of one thing. Electron emissions of definite value below the maximum (at a

---

[7] Becker, "The Life History of Adsorbed Atoms and Ions," *Trans. Am. Electrochem. Soc.*, *55*, *153–175* (1929), has suggested using the term "adatom" for an adsorbed atom.

fixed comparison temperature and cesium pressure) will correspond to a definite θ_O, no matter what evaporation procedure we have chosen to bring about this state.

Method of Procedure.—In this way, we have been able to develop a method of studying oxygen films on tungsten. First, a well-aged tungsten filament is flashed in vacuum for two seconds, at a temperature of 2700°, to clean its surface completely. It is then allowed to cool to room temperature, and cesium vapor at a pressure of 0.0024 barye (saturation pressure at 28°) is admitted.[8] This instantly (within about one second)[9] forms a complete layer on the tungsten surface and increases the electron emission from values too small to measure to those easily measured in the temperature range 550–900° (see Fig. 1). To produce the film of oxygen which we propose to study, we raise the temperature of the filament to around 2000°, thus evaporating off all the cesium, surround the bulb with liquid air to lower the cesium vapor pressure to an infinitesimal amount, and admit oxygen, at 0.1 mm. pressure, covering the surface with a complete layer of the latter. The filament is then allowed to cool to room temperature, any residual oxygen is pumped out and cesium vapor is again admitted by simply removing the liquid air from the bulb. On now heating the fila-

---

[8] This may be readily done in one of two ways. If a high frequency induction outfit is available, a nickel capsule containing a mixture of cesium dichromate and silicon may be placed in a side arm of the tube (pyrex). The whole may be baked out at as high a temperature as desirable, after which the cesium is liberated by bringing the nickel to a red glow by means of the high frequency coil. If the latter is not available, a second method is to use a mixture of metallic calcium and cesium chloride. The tube (lime or hard glass) may not be baked out at temperatures above 350° as the calcium would begin to react. When ready to drive over the cesium, the temperature is increased by heating with a Bunsen flame. This method has disadvantages over the first one in that the baking temperature may not be as high, and that the reagents, being hygroscopic, are apt to become contaminated while being handled.

[9] We calculate that a fraction of cesium on the surface of $\theta_{Cs} = 10^{-5}$ may be readily detected by using a galvanometer ballistically and determining the positive ion emission while flashing the filament to 1500°. (All atoms on the filament pass off instantaneously as positive ions during the flashing if submitted to sufficient accelerating potential, say, 45 v.). An ordinary galvanometer has a sensitivity such that 10^{-9} coulombs will give a kick of 1 cm. This is equivalent to 6.3×10^9 positive ions. A surface completely covered with cesium contains 4 X 10^{14} atoms cm.^{-2}. Thus, the fraction readily detected is $\theta_{Cs} = 6.3$ X $10^9/4$ X $10^{14} = 1.57$ X 10^{-5}. If n cesium atoms were held by each oxygen atom present, one could readily detect $\theta_O = 1.57$ X $10^{-5}/n$. This suggests that an extremely powerful method of studying surfaces of low 8 is to choose a cesium pressure low enough for the constant positive ion current to be small, and a filament temperature such that $\theta'_{Cs} = 0$. By making the filament positive with a sufficient voltage, all cesium atoms striking the surface will be instantaneously changed to cesium ions and flow to the cathode. This current should be balanced out of the galvanometer. If there were a small trace of oxygen on the filament, θ''_{Cs} would have a definite value, which could be determined by flashing the filament. The ballistic kick then will tell one how great is θ''_{Cs} and the relative value (although not absolute) of θ_O.

ment to temperatures from 600 to 1200°, with positive voltage on the anode, no measurable electron emission is detected. To get the typical electron emission from the adsorbed cesium film, it is first necessary to "activate" the oxygen film. The maximum activation is produced by flashing the filament for a few seconds at temperatures from 1600 to 1800°, the exact temperature and time being of little importance.

After activation, the filament, in the presence of cesium vapor at 20°, gives at 650° an emission which is roughly only five times as great as before the oxygen film was produced. The activated oxygen film, however, allows us to raise the filament temperature to 850° or even 900° before losing enough of the adsorbed cesium to cause a decrease in emission. Under these conditions, the currents are 10^5 or 10^6 times greater than in the absence of the oxygen film.

We propose to use this increase as a measure of the amount of adsorbed oxygen and in this way study the rate of evaporation of these oxygen films.

In the absence of cesium vapor, the effect of oxygen is to decrease greatly the electron emission from tungsten. This change in emission can also be used to detect and study oxygen films, and has been used in the work to be described in the second paper of this series. The method has, however, the disadvantage that even at 1700° the emission from an ordinary filament is less than 10^{-8} ampere and at temperatures as high as this the films may evaporate somewhat even during the measurements. With cesium vapor, not only can much smaller amounts of oxygen be detected, but the tests for the oxygen are made at such low temperatures that no evaporation occurs.

This qualitative test becomes quantitative as soon as we know the law by which θ''_{Cs} depends on θ_{O} (Eq. 6). Until then we may reproduce at will particular values of θ_{O} without having more than approximate knowledge of their absolute magnitude.

In our studies of the evaporation of the films, the oxygen-covered filament was heated at a definite "evaporation temperature" for successive time intervals. After each heating to the evaporation temperature, the filament was cooled and the condition of its surface was then determined by measuring its electron emission[10] at a series of "test temperatures" ranging from 802 to 1092°

Similar data were obtained at other temperatures. By comparing the rapidity of the deactivation at various evaporation temperatures, as revealed by the changes in emission at any given test temperature, we can obtain the relative temperature coefficients of the rates of evaporation.

It was shown by Langmuir[11] that the rate of evaporation m is related to

---

[10] This method is similar to that used by Langmuir in his study of thoriated tungsten filaments, *Phys. Rev.*, 22, 357–398 (1923).

[11] I. Langmuir, *ibid.*, 2, 329 (1913).

the vapor pressure, p, of a substance by the equation

$$m = (1 - r)\,(M/2\pi RT)^{1/2}p \tag{7}$$

where M is the atomic or molecular weight and r is the reflection coefficient of incident atoms. In the present case, from evidence that will be discussed in later papers of this series, we believe that r is small and has no appreciable temperature coefficient. Thus the temperature coefficient of the rate of evaporation is approximately the same as that of the vapor pressure (neglecting the factor $T^{1/2}$). In this way by the Clapeyron equation we may determine the heat of evaporation of adsorbed oxygen from the temperature coefficient of the rate of evaporation.

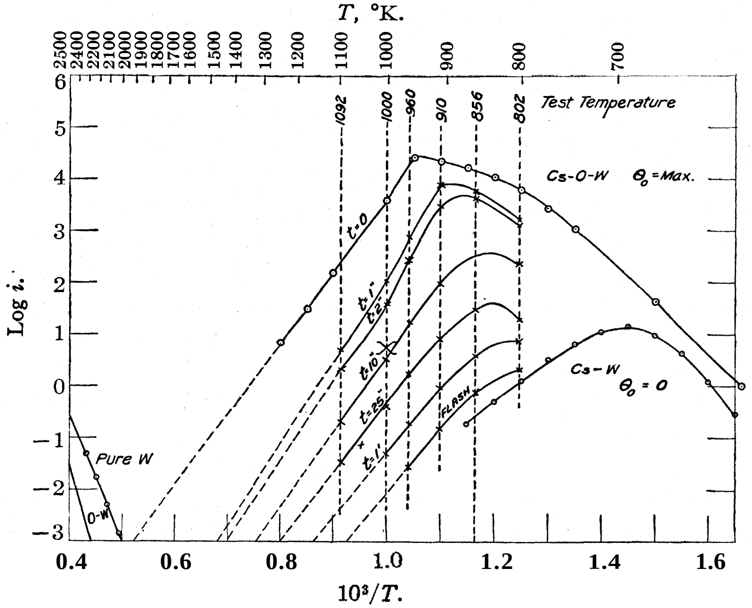

Fig. 2.—Electron emission from Cs–O–W surfaces of varying oxygen and cesium content. Total emission from 50-mm. 4-mil wire (0.01016 cm. diam.) in microamperes. O, Values from other data2 calculated to wire of area used (0.1598 sq. cm.). X, Experimental values. Cesium vapor pressure, 0.00246 baryes (28 °C.). *t* is time of oxygen evaporation at 2070 °K.

Experimental Data.—The experimental data on the electron emission from Cs–O–W surfaces of varying θ_O for one characteristic evaporation temperature are given in Fig. 2. Each of these curves corresponds to a definite time of evaporation of oxygen at 2070°. A similar set of curves was obtained for two lower evaporation temperatures, 1978 and 1856". As these curves have the same appearance as those in Fig. 2, we shall not reproduce them here. To get the temperature coefficient of the rate of evaporation, and from it the heat of evaporation, one might pick the point X in Region III, half-way between the top and bottom curve, and compare the evaporation time which gives a surface of that electron emission at that particular test temperature, with the evaporation time at the next evaporation temperature (1978°) which gives the same electron emission at the same test temperature. From what has been said above, it is reasonable that the surface is the same in both cases. As may be seen from Fig. 2, this arbitrary half-way curve was not among those determined experimentally. The time which would give this curve may be determined by any method of interpolation. That method which gives a straight line is, however, always the most convenient. From the logarithmic[12] form of Equation 2.

$$-\frac{\mathrm{d}\ln\Theta}{\mathrm{d}t} = k\epsilon^{-H_\Theta/RT} = k' \qquad (8)$$

we see that if H_Θ is constant, a plot of log A, where $A \equiv \log i - \log i_0$ and i_0 is the emission from the cesiated surface of $\Theta_0 = 0$, against evaporation time, t, should give us this straight line, in view of the relation between A and Θ (Equations 1, 3 and 4).

$$\frac{\mathrm{d}\ln\Delta}{\mathrm{d}t} = \frac{\mathrm{d}\ln\Theta}{\mathrm{d}t} \qquad (9)$$

The "half life"[13] may then be determined from the curve by inspection. Plotting log $t_{1/2}$ against $1/T$ would now give us a curve the slope of which is a measure of the heat of evaporation. Figure 3, in which is plotted log Δ against t for four different test temperatures, shows that these curves are essentially straight, at least in the Θ region studied in these experiments. The velocity constant k' is then related to the time of half evaporation by the equation

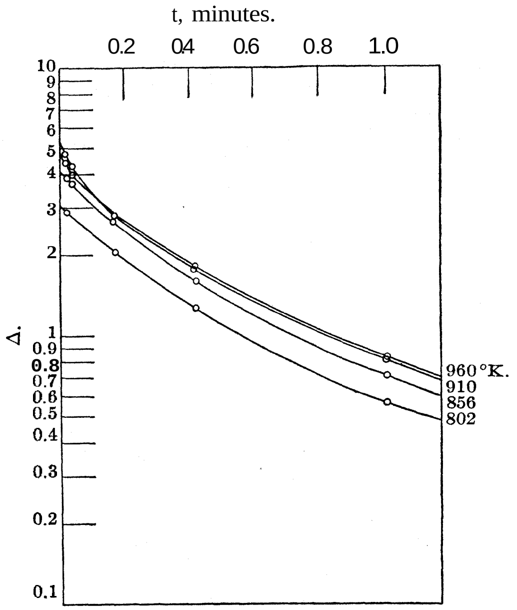

Fig. 3.—Course of evaporation with time at 2070°K., as measured at test-temperatures indicated. $\Delta \equiv \log i - i_0$ and is proportional to the covering fraction, Θ_0.

$$t_{1/2} = (\ln 2)/k' \qquad (10)$$

---

[12] In this and following papers we **shall** follow the customary notation in which log designates the common logarithm and ln the natural logarithm.

[13] This "half life," in view of the consideration involved in Equation 6, does not necessarily mean the time it takes for Θ_0 to reach 0.5. It is the evaporation time it takes to obtain surface conditions such that, at the particular test temperature used. the sum $\Theta'_{Cs} + \Theta''_{Cs} = 0.5$.

A closer inspection of Fig. 3, however, reveals the fact that the half times obtained at different test temperatures are slightly different. In this example they are 0.27, 0.23, 0.32 and 0.33 minutes at the test temperatures 960, 910, 856 and 802°, respectively. It is obvious that some method of averaging must be resorted to if we are to get the best value of the temperature coefficient of evaporation. In doing this we have not limited ourselves to determining the half time, but have compared the times it takes for the surface to reach other stages of evaporation as well. Table I gives these evaporation times in minutes for different evaporation temperatures, test temperatures and A (proportional to Θ). We might next proceed to plot log t against $1/T$ for each separate set of times to reach the same stage of evaporation and find the average slope of all of these straight lines, but it is much simpler to reduce all times to values relative to that at the evaporation temperature 1978° as unity, average them, and plot the single set of three points. We have chosen the latter procedure.

TABLE I

EVAPORATION TIMES

Test temp , 802°K. ($A_,$ = 0.15)

	Evaporation temp., °K.				
Δ	1856 Minutes	1078 Minutes	2070 Minutes	t_{1856}/t_{1978}	t_{2070}/t_{1978}
0.8	81.8	6.90	0.714	11.85	0.1034
9	66.9	5.42	.632	12.34	.1166

1.3	76.4	4.61	0.636	16.57	0.1379
1.5	53.8	3.52	533	15.28	.1514
2.0	32.2	2.07	352	15.56	.1701
2.4	19.9	1.47	.245	13.54	.1667
Test temp., 960° ($A_,$ = 0.225)					
1.3	72.2	5.08	0.653	14.22	0.1286
1.5	50.7	3.53	.447	14.36	.1266
1.9	33.7	2.28	.384	14.78	.1684
2.3	19.9	1.63	.273	12.21	.1675
				Mean 13.77	0.1458

A = log i_O − log i, where i = electron emission from Cs–O–W surface of $\Theta_O = x$, and i_O = emission from Cs–W surface of $\Theta_O = 0$. $A_,$ = amperes at which filament a was run during emission readings. t_{1856}/t_{1978} = evaporation time relative to that at temperature 1978°.

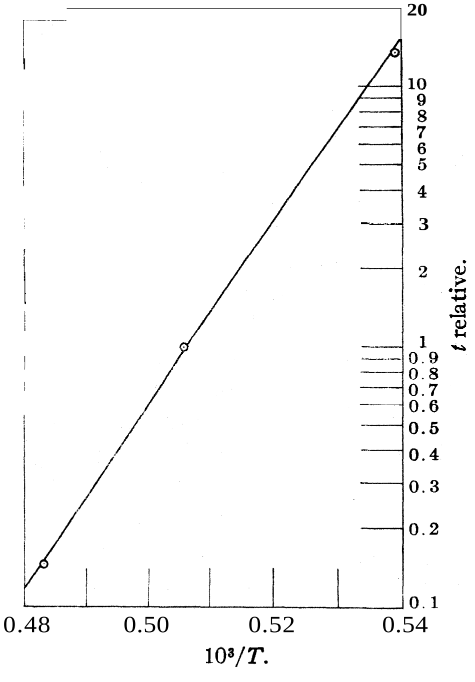
TABLE II

TEMPERATURE COEFFICIENT OF EVAPORATION

T, °K.	$t_{1/2}$, min.	t_{relative}	$10^4/T$
1856	27	13.77	5.39
1978	2	1.00	5.06
2070	0.3	0.146,	4.83

Thus Columns 5 and 6 of Table I give the relative times for each determination. These are averaged and given in Table II.

The heat of evaporation corresponding to the slope of the log $t_{\text{av.}}$ *versus* $1/T$ plot (Fig. 4) is 162 kg. cal. This is the heat per gram molecule of the substance dissociated. If the oxygen comes off in the form of atoms, as we have reason to believe, it is the heat per gram atom of oxygen. This is some 2.5 times the heat of dissociation of oxygen[14] (per gram atom). It is no wonder, therefore, that a bare tungsten surface has such a power of taking up oxygen. The practically constant slope of the curves in Fig. 3 indicates that we are taking our measurements in a region where H_Θ is independent of Θ. We conclude therefore that 162 kg. cal. is most probably the heat of evaporation from a surface almost bare ($\Theta_O \sim 0.15$). In a later paper we shall present data from a Θ region between 0.35 and 0.7 which show that H is less than 162 kg. cal., and decreases with increasing Θ.



Slope equivalent to H = 162 kg. cal.

Fig. 4.—Relative evaporation time.

Concluding Remarks.—In the foregoing pages we have presented a method of studying the rate of loss of adsorbed oxygen from tungsten. Since this consists primarily in detecting the amount of oxygen on the surface, it may be used equally well for studying

---

[14] Taking the heat of dissociation of oxygen per gram molecule to be 131 kg. cal., Rodebush and Troxel, THIS JOURNAL, 52, 3467 (1930); Copeland, *Phys.* Rev., **36,** 1221–1231 (1930).

the accumulation of oxygen. As an illustration in this connection, we refer to the difficulty of Rodebush[15] and his co-workers in finding a suitable method of detecting beams of oxygen molecules or atoms. We suggest that these could be readily identified by an adaptation of the above procedure. A beam of molecules impinging on a hot (1600°) clean (by preliminary flashing to 2700°) tungsten filament will deposit with almost one hundred per cent. efficiency until the surface has received its maximum sensitivity. The deposition of oxygen molecules on a cold surface does not affect the emission in the presence of cesium vapor. It is almost certain (it has not been tried) that a beam of oxygen atoms impinging on a cold surface will modify its subsequent emission in cesium vapor to the same extent as a molecular beam hitting a hot surface. If this is true, we have a method of distinguishing between atomic and molecular oxygen.

If a layer of $\Theta_O = 0.33$ ($n = 3$ in Equation 6) gives the maximum emission ($10^6 \times$ the Cs–W emission), then a layer of $\Theta_O = 0.33 \times (\log 2)/(\log 10^6) = 0.017$ will cause a doubling of the emission, which certainly can be readily detected. A beam of the density ordinarily used in molecular ray experiments will deposit a complete layer in about one second.[16] It therefore would take only 0.017 second to deposit out of such a ray enough oxygen to be readily detected. These rays usually originate from enclosures in which the pressure is 0.1 mm. It may be seen that with such a sensitivity much lower pressures may be used, with the consequence that the beam can be better resolved. Hitherto, the most hopeful method of detecting oxygen beams seems to have been that of Knauer and Stern,[17] who have a small box with an entrance consisting of a slit which may be moved back and forth across the beam. By measuring the pressure change in the box, the distribution of intensity in the beam may be determined. Up to now this is the only practical method invented to detect beams of inert gases, but this need no longer apply to the case of oxygen. The use of a movable tungsten wire in detecting beams is not only a much more simple method, but is also practical, as has been demonstrated by Taylor,[18] who detected cesium beams by the positive ion current from a wire mounted on a contrivance capable of moving it across the beam.

We wish to acknowledge our indebtedness to Dr. K. H. Kingdon for the experimental data which we have used and to Mr. Saunders MacLane, who gave valuable assistance in analyzing these data.

[16] Pressures as low as 10^{-7} baryes would bring about the deposition of a layer of $\Theta = 1$ in about five hours. On account of this extreme sensitivity, all stray oxygen would have to be removed from the apparatus. This would be readily done, we believe, by the cesium vapor present under the conditions of the experiment.

Summary

A method is presented of studying the rate of loss of oxygen from an adsorbed film on tungsten, as well as of detecting its presence in a gas. This consists in observing its effect on the electron emission of a tungsten filament, sensitized by the presence of minute traces of cesium vapor (10^{-6} mm.). Under properly chosen conditions a monatomic oxygen film makes its presence known by increasing the emission a millionfold.

Using this method, the heat of evaporation of oxygen from the adsorbed layer was found to be 162 kg. cal. (7.0 v.) per gram atom.

THE ADSORPTION OF GAS MIXTURES BY SILICA

BY E. C. MARKHAM AND ARTHUR F. BENTON

RECEIVED NOVEMBER 28, 1930 PUBLISHED FEBRUARY 9, 1931

Introduction

Studies of the adsorption of gases by catalytically active solids, particularly in the last decade, have contributed greatly to a qualitative understanding of the kinetics and mechanism of contact catalysis. Frequently, however, more than one of the reactants or products are simultaneously adsorbed, and in such cases it is obviously necessary to have information concerning the adsorption of one gas in the presence of a second. Such data should also be useful in connection with the practical problem of separating the components of a mixture of gases or vapors. In addition, the behavior of mixtures may be expected to furnish a deeper insight into the nature of adsorption.

Comparatively little is known about the adsorption of the individual constituents of gas mixtures. Richardson and Woodhouse[1] studied the adsorption of carbon dioxide–nitrous oxide mixtures on charcoal. With their static method, however, the composition of the gas phase and of the adsorbed layer can be estimated only approximately. Klosky and Woo,[2] employing the flow method, have studied the adsorption of sulfur dioxide–butane and sulfur dioxide–methyl chloride mixtures on titania gel. Their results indicate that the presence of a second gas decreases the amount of the first gas adsorbed. Other recent studies on the adsorption of gaseous mixtures are those of Putnoky and Szelényi[3] on ethanol–ether–air mixtures with various silica gels, and of Frolich and White[4] on mixtures of methane and hydrogen at elevated pressures in contact with charcoal.

From the standpoint of contact catalysis it would be more interesting to study the adsorption of mixtures by catalytically active adsorbents than by such materials as charcoal and titania gel. Griffin[5] has shown that the presence of a small amount of carbon monoxide, less than 0.05 cc., upon a sample of catalytically active copper, increases the amount of hydrogen adsorbed at low pressures but decreases the amount adsorbed at higher pressures. This is an indication of the complexity of adsorption of gas mixtures by active catalysts.

As a preliminary investigation to the study of mixture adsorption by active catalysts it seemed advisable to investigate first the behavior of a solid which normally shows adsorptions of the "secondary," or non-selective, type. Silica was chosen as a suitable material, since previous work[6] has shown that its behavior with a number of gases is of the type in question.

Carbon monoxide, carbon dioxide and oxygen were selected because silica does not induce interaction between any of these at the temperatures used, yet it adsorbs convenient amounts of each, a small amount of oxygen, a large amount of carbon dioxide and an intermediate amount of carbon monoxide.

Experimental Procedure

The apparatus used in this investigation is illustrated in Fig. 1. The entire apparatus up to G and H, including the gas generators and purifying lines, was constructed of pyrex glass, all joints being fused. The pyrex-to-soft glass seals (G, H) were effected by surrounding the ends of the tubing by glass cups which were filled with deKhotinsky cement. The adsorbent was contained in bulb B, which could be maintained at either 0 or 100° by an ice- or steam-bath. The pressure in bulb B was determined by the mercury manometer M. A Topler pump, T, was connected as indicated to bulb B and to the calibrated gas buret A, the latter being connected to the buret of a modified Orsat gas analysis apparatus (not shown).

The individual gases from the generators and purifying lines (not shown in Fig. 1), entering at C, D, E, could be passed directly over the adsorbent in B, or into any of the three mixture reservoirs, only one of which is shown in the figure (1, 2). From these reservoirs the mixtures passed over calcium chloride and phosphorus pentoxide, respectively, in X and Y, and thence through bulb B, or to buret A for analysis. Freshly boiled water was used as the confining liquid in the reservoirs, except for mixtures containing carbon dioxide, for which a concentrated solution of magnesium sulfate was preferable on account of the diminished solubility of carbon dioxide.

The mixtures were passed over the adsorbent in bulb B for about two hours, the pressure in the bulb being maintained at exactly 760 mm. by regulation of the head of concentrated sulfuric acid in N. The failure of the manometer M to denote any change of pressure within the bulb after standing for an hour or more after it was closed off by stopcocks indicated that equilibrium had been reached. As a further check on the establishment of equilibrium, mixtures were passed over the adsorbent in one case for fifteen minutes and in a second case for two hours, the same adsorption being obtained

[6] Benton, *ibid.*, 45, 887 (1923).

in each instance. After equilibrium was reached the gas was removed from the bulb by means of the Topler pump and forced into the gas buret A, where its volume was determined. From this buret it was passed into the gas analysis apparatus.

The isotherms of the individual gases were determined by streaming the pure gas over the adsorbent until equilibrium was reached. Successive small amounts of gas were pumped out of the bulb by means of the Topler pump and the volumes read in the buret. After each removal of gas the pressure in the bulb was determined by means of the mercury manometer after it had become constant, thus indicating that equilibrium had been reached.

All adsorptions were repeated and the results duplicated to within an average of about 0.05 cc., with the exception of mixtures containing carbon dioxide. In such mixtures the solution of carbon dioxide in the confining liquid in the reservoir caused a progressive change which made it impossible to carry out duplicate runs with mixtures of identical composition. All gas analyses were run in duplicate and checked to within one-tenth of one per cent., and in most cases to within a few hundredths of one per cent.

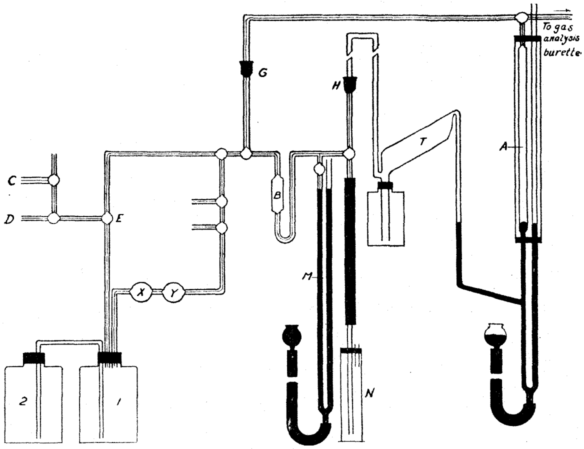

Fig. 1.—Apparatus.

The free space in the bulb was determined by measuring the amount of helium necessary to fill it at a pressure of 760 mm. and at temperatures of 0 and 100°. It is assumed that helium was not adsorbed by the silica.

The adsorptions of the separate gases are calculated by taking the difference between the volumes of the gas in question and of helium required to fill the bulb containing the adsorbent at a given temperature and pressure. In the case of mixtures the amount of each component adsorbed is obtained as follows. From the total volume of gas pumped out of the bulb, and its analysis, the total volume of each component present (that is, gas adsorbed plus gas in free space) is known. The amount of each component in the free space is obtained from the analysis of the mixture which is passed over the adsorbent, together with the volume of the free space as determined with helium. By subtraction of the amount of each gas in the free space from the total amount of that gas present, the quantity adsorbed may be calculated. All pressures have been expressed in mm. of mercury at 0°, and volumes in cc. at 0°, 760 mm.

Oxygen was prepared by electrolysis of a solution of sodium hydroxide between nickel electrodes. Carbon monoxide was generated by dropping concentrated sulfuric acid on hot 85% formic acid solution. Carbon dioxide was obtained by dropping sulfuric acid into a concentrated solution of chemically pure sodium bicarbonate. To each generator were attached the usual devices for removing spray and for purifying and drying the gases.

The adsorbent was prepared by prolonged washing of C. P. precipitated silicic acid and subsequent heating to 250° for a period of several days. The sample of adsorbent weighed 19.6 g.

Experimental Results

Isotherms for Individual Gases.—The isotherms of oxygen and of carbon monoxide have been determined at 0 and at 100°. Since inconveniently large amounts of carbon dioxide are adsorbed at 0° the isotherm for this gas has been determined only at 100°. The experimental data are recorded in Tables I and II. Pressures are expressed in mm. of mercury at 0°, and volumes are in cc. at 0° and 760 mm. The calculated values recorded in these tables will be discussed in a later section.

All the measurements with carbon monoxide and oxygen, both singly and in mixtures of the two, were completed before any carbon dioxide was used. All the values so obtained were found to be accurately reproducible, regardless of the order of the experiments. On first employing carbon dioxide, however, the adsorptive capacity of the silica for this gas underwent a gradual increase of about 6 cc. during nine successive runs, after which it remained constant for three additional runs. It was then found that the adsorptive capacity for oxygen had been slightly increased, while it had remained unchanged for carbon monoxide. From this point on, the new values were accurately reproducible. Because of the above effects it is necessary in comparing adsorptions in mixtures with those of the separate gases, to use the data headed "100° (before CO_2)" in Table I for comparison with oxygen–carbon monoxide mixtures, and those headed "100° (after CO_2)" for comparison with oxygen–carbon dioxide mixtures.

It is not known whether or not the increase in adsorptive capacity produced by repeated treatments with carbon dioxide is due to a displacement of water from the silica.

Adsorption of Mixtures.—The adsorption of each gas in mixtures of carbon monoxide and oxygen has been determined at 0 and at 100°. The adsorption of each gas in mixtures of carbon dioxide and carbon monoxide and in mixtures of carbon dioxide and oxygen has been determined only at 100°.

The results obtained are recorded in Tables III to VI. The pressures of each gas in the various mixtures are given in the first and second columns. The values recorded in the third and sixth columns are the volumes which would be adsorbed at the pressures given if the second gas were not present, as determined by interpolation from the isotherms for the individual gases.

The volumes actually adsorbed in the mixtures are given in the fourth and seventh columns headed "observed." The fifth and eighth columns headed "calculated" will be discussed in a later section.

Discussion

Adsorption of Single Gases.—Langmuir,[7] assuming adsorption in a unimolecular layer on a plane surface, has derived an equation of the general form

$$V = V^\circ \frac{ap}{1 + ap} \tag{1}$$

where V is the volume of gas adsorbed at pressure p, a is a constant at a given temperature, and V° is the saturation value, or the amount of gas adsorbed when the surface is entirely covered. This equation may be written in the form

$$1/V = (1/aV^\circ)(1/p) + (1/V^\circ)$$

If this equation holds, a plot of $1/V$ against $1/p$ should yield a straight line whose slope and intercept should permit a calculation of a and V°.

In Figs. 2 and 3 are shown the plots of $1/V$ against $1/p$ for the various gases at the two temperatures. It is evident that Equation 1 is satisfactory. The values of V° and a thus obtained are given in Table VII.

The values calculated from Equation 1, with the constants of Table VII, are given in Tables I and II under the columns headed "calculated."

Although Equation 1 agrees with the experimental data within the estimated limits of error at almost every point, it must nevertheless be

---

[7] Langmuir, THIS JOURNAL, 40, 1361 (1918).

TABLE VII

CONSTANTS IN ADSORPTION EQUATION

Gas and temperature	$V°$, cc.	a, mm.$^{-1}$
O_2 at 0°	397.0	0.000100
CO at 0°	322.6	.000235
O_2 at 100°, before CO_2	171.3	.000040
O_2 at 100°, after CO_2	153.9	.0000466
CO at 100°	60.2	.000183
CO_2 at 100°	426.4	.000311

regarded as purely empirical, since V_0, the saturation value, is widely different not only for different gases but for the same gas at different temperatures. Owing to the fact that in these experiments ap is small compared to unity, that is, that the volume adsorbed is so nearly proportional to the pressure, only the product aV^0 can be estimated accurately,

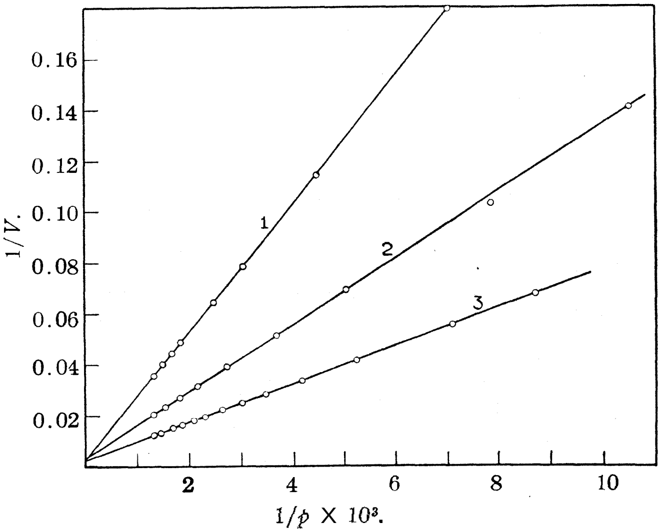

Fig. 2.—Variation of $1/V$ with $1/p$ for the adsorption of oxygen at 0° (Curve 1), carbon monoxide at 0° (Curve 2), carbon dioxide at 100° (Curve 3).

while a and $V°$ are each subject to considerable uncertainty. The errors in the values of V^0 thus introduced are enormously less than the differences shown in Table VII. It is obvious, however, that the equation could be more adequately tested by extending the measurements to higher pressures.

Adsorption in Binary Mixtures.—If it is assumed that the surface of the adsorbent is uniform and capable of adsorbing only a single layer of gas, and, furthermore, that there is no interaction between the adsorbed gases, an equation can be derived which relates the amount of one gas adsorbed to its pressure and to the pressure of the second gas.

Let σ_1 and σ_2 represent the fractions of the surface covered by Gases 1 **and 2,** respectively. The rate of condensation of Gas 1, μ_1, is equal to $k_1p_1\ (1-\sigma_1-\sigma_2)$, where $(1-\sigma_1-\sigma_2)$ is the fraction of the surface free from gas, p_1 is the pressure of Gas 1, and k_1 is a constant at a given temperature. The rate of evaporation, ν_1, can be expressed by the equation $\nu_1 = k_1'\sigma_1$.

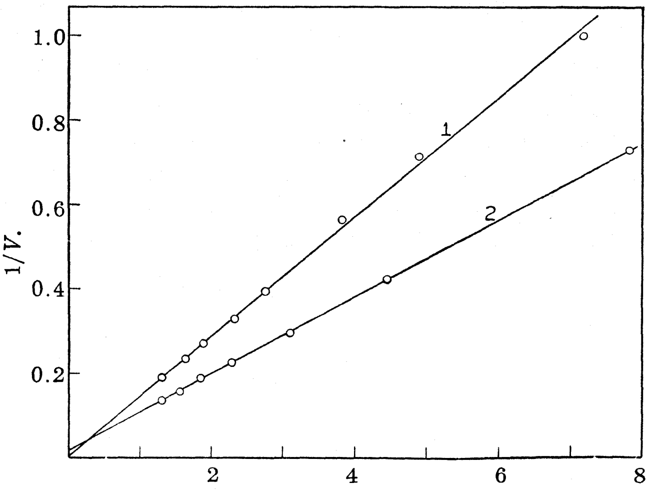

Fig. 3.—Variation of $1/V$ with $1/p$ for the adsorption of oxygen at 100° (Curve 1), and of carbon monoxide at 100° (Curve 2).

Similarly for Gas 2, $\mu_2 = k_2p_2\ (1-\sigma_1-\sigma_2)$ and $\nu_2 = k_2'\sigma_2$. At equilibrium, where the rates of condensation and evaporation are equal

$$k_1p_1\ (1 - \sigma_1 - \sigma_2) = k_1'\sigma_1$$

Substitution of a for k_1/k_1' and simplification gives

$$\sigma_1 = \frac{ap_1\ (1 - \sigma_2)}{1 + ap_1} \tag{2}$$

Similarly for Gas 2

$$\sigma_2 = \frac{bp_2\ (1 - \sigma_1)}{1 + bp_2} \tag{3}$$

Substitution in (2) of the value of σ_2 from **(3)** gives

$$\sigma_1 = \frac{ap_1}{1 + ap_1 + bp_2} \tag{4}$$

and for σ_2

$$\sigma_2 = \frac{bp_2}{1 + ap_1 + bp_2} \tag{5}$$

The fraction of the surface, a, covered by a gas may be expressed by the equation, a = V/V^0, where V and V^0 have the same significance as before. Making the substitutions for σ_1 and σ_2 in Equations 4 and 5, we arrive at the final equations

$$V_1 = \frac{aV_1^\circ p_1}{1 + ap_1 + bp_2} \tag{6}$$

$$V_2 = \frac{bV_2^\circ p_2}{1 + ap_1 + bp_2} \tag{7}$$

Equations 6 and 7 involving constants previously determined from the isotherms ior the separate gases indicate that the presence of a second gas should diminish the amount of the first gas adsorbed, particularly at high pressures of the second gas. From these equations and the constants recorded in Table VXI, the adsorbed volumes have been calculated and recorded in the fifth and eighth columns of Tables III, IV, V, VI.

The values recorded in Table III show that in mixtures of carbon monoxide and oxygen at 0° the adsorption of each gas at given pressure is materially diminished by the presence of the other gas. The amount of oxygen adsorbed, however, is more than the amount calculated from Equations 6 and 7, while the reverse is, in general, the case for carbon monoxide. Table IV shows essentially similar relations for these gases at 100°.

In mixtures of carbon dioxide with oxygen or with carbon monoxide, the adsorption of the dioxide is many times greater than that of the second component. Tables V and VI show that at the higher pressures of carbon dioxide the adsorbed volumes of either oxygen or carbon monoxide are not only greater than the calculated volumes but even exceed the amounts which would be adsorbed in absence of the carbon dioxide. At the lower pressures of the dioxide the adsorbed volumes of oxygen and carbon monoxide are less than the isotherm volumes but greater than the calculated. It is seen that the corresponding comparison is, in general, true with respect to the amount of carbon dioxide adsorbed in these mixtures.

Equations 6 and 7 require that the ratio of the adsorbed volumes should be proportional to the ratio of the pressures of the two gases. Division of (7) by (6) gives the expression

$$\frac{V_2}{V_1} = \frac{bV_2^\circ p_2}{aV_1^\circ p_1}$$

or, since in these experiments $p_2 = 760 - p_1$

$$\frac{V_2}{V_1} = \frac{760bV_2^\circ}{aV_1^\circ p_1} - \frac{bV_2^\circ}{aV_1^\circ} \tag{8}$$

Thus, if V_2/V_1 is plotted against $1/p_1$, the experimental points should lie on a straight line whose slope is $760\ bV_2^\circ/aV_1^\circ$. When plotted in this manner the observed adsorptions in mixtures of carbon monoxide and oxygen at 0 and at 100° agree fairly well with Equation 8. In the case of mixtures containing carbon dioxide, however, the plotted points lie on a distinct curve, which approaches the theoretical straight line at the lower pressures of the dioxide.

The applicability of Equation 7 (or 6) may be tested without employing the constants obtained from the isotherms of the separate gases, by putting it in the form

$$\frac{1}{V_2} = \frac{1 + 760a}{bV_2^\circ p_2} + \frac{b - a}{bV_2^\circ}$$

By plotting $1/V$ against $1/p$ for each gas in each mixture, it was found that the points yield satisfactory straight lines for both components of the carbon monoxide–oxygen mixtures, and for carbon dioxide in mixtures containing this gas. The points for either oxygen or carbon monoxide in mixtures with the dioxide yield distinct curves.

Conclusions

The results of this study show that the assumptions underlying Equations 6 and 7 are fairly satisfactory for mixtures of carbon monoxide and oxygen, but prove inadequate when applied to mixtures containing carbon dioxide. It is apparent that the failure of the equations in the latter case cannot be attributed entirely to the assumptions of unimolecular adsorption and uniformity of surface, since these assumptions are also necessary in deriving Equation 1 for the individual gases, and this equation has been shown to give satisfactory results over the range in question.

It is concluded, therefore, that the failure of Equations 6 and 7 in the case of mixtures containing carbon dioxide is to be attributed mainly to interaction between the adsorbed molecules in the sense that the rate of evaporation of a given molecule may be decreased by the presence in an adjacent space of a molecule of a second gas. Elaboration of this idea may be postponed until further data have been accumulated.

Summary

1. The adsorption of each gas in binary mixtures of carbon monoxide and oxygen has been measured at one atmosphere and temperatures of 0 and 100°, and in mixtures of carbon dioxide with carbon monoxide and with oxygen at 100°. The isotherms of the separate gases have been determined at the same temperatures.

2. The results have been interpreted on the basis of a simple extension of Langmuir's theory of adsorption to the case of gas mixtures. The equations so derived permit the adsorption of each gas in the mixture to be calculated for any given partial pressures without the employment of constants other than those obtainable from the isotherms of the separate gases. The equations indicate that each gas in the mixture should be adsorbed to a smaller extent than if it were present alone at the same partial pressure.

3. With mixtures of carbon monoxide and oxygen there is rough agreement between the calculated and observed adsorptions. On the other

hand, in mixtures containing carbon dioxide the observed values are not only greater than the calculated, but in many cases even exceed the adsorptions found in the absence of the second gas. Pending the accumulation of further data, it is suggested that this anomaly may be due to some kind of mutual interaction between the two kinds of adsorbed molecules.

NUCLEAR SPIN AND THE THIRD LAW OF THERMODYNAMICS. THE ENTROPY OF IODINE

BY W. F. GIAUQUE

RECEIVED NOVEMBER 29, 1930 PUBLISHED FEBRUARY 9, 1931

Much interest is attached to the problem of determining the manner in which nuclear spin is concerned in the application of the third law of thermodynamics. The somewhat complicated but well-established situation which exists in hydrogen has recently been discussed.[1] In this case nuclear spin results in ortho and para forms which establish equilibrium with each other so slowly that it is impractical to use heat capacity measurements to obtain the entropy. However, it was suggested that hydrogen might be the only substance in which nuclear spin would appreciably affect the calorimetric properties at temperatures above a few degrees absolute. If this proves to be true, it will be convenient to ignore the effect of nuclear spin on the absolute entropy except for hydrogen. This would be possible since, as first pointed out by Gibson and Heitler,[2] for certain gas reactions, the limiting contribution which nuclear spin makes to the entropy cancels in obtaining the entropy change which occurs during a reaction.

The diatomic elements offer a suitable opportunity for obtaining information concerning the above problem and of these the ones consisting primarily of one isotope present the most favorable cases. Diatomic gas molecules which consist of two isotopes of the same element do not have the division of such molecules into ortho and para states. This is the situation most open to suspicion in connection with the possibility of anomalous calorimetric effects. For example, in chlorine the 35–37 molecules would be expected to establish their limiting spin entropy below the lowest attained temperature. The 35–35 and 37–37 molecules are of the type in which we are more interested. Since these latter two would behave differently if the nuclear spins of the two isotopes are different, we believe it best to confine the initial investigation to simpler substances. Of these nitrogen is at present under experimental investigation and existing data on iodine are sufficient for our purpose. In this paper we shall consider the case of iodine.

The nuclear spin of iodine is undetermined but it is known to be large. This is determined from the fact that alternation of intensity in the lines of its band spectrum has not been observed.[3] This is the limiting case approached when the nuclear spin is large. Elements with spins of a few units give an easily observed intensity alternation. However, it can be shown that the limiting nuclear spin entropy has been essentially established at a temperature of 10°K. and presumably much lower even though we are unaware of its exact value.

The available data consist of heat capacity measurements of several observers on solid iodine extending to below 10°K., various vapor pressure determinations and measurements of the band spectrum of diatomic iodine gas.

The Heat Capacity and Entropy of Iodine.—Of the numerous low temperature determinations of the heat capacity of iodine,[4] only the series due to Lange can be given any weight as an accurate piece of work. Lange covered only the range from 9 to 52°K. but fortunately even at 52°K. the heat capacity is rapidly approaching the equipartition value. In extending the curve to room temperature a decision had to be made between data with extreme deviations of as much as 6%. In making this decision the value of $C_p - C_v$, which is known from the following thermodynamic relationship, was of considerable importance.[5]

$$C_p - C_v = \frac{\alpha^2 VT}{\beta}$$

where α and β are the coefficients of expansion and compressibility, respectively. Lewis and Gibson[6] have given the above difference as 0.9 calories/degree per gram atom of iodine at 298.1°K. A repetition of their calculation, using the data given in the "International Critical Tables," raises this somewhat. The value adopted was 1.0 calorie/degree per gram atom at room temperature. When this amount was considered it became evident that the only reasonable C_v curve which could be extended to 298.1°K. passed quite well through the results of Nernst, Koref and Lindemann.[4a]

On calculating the entropy from the above curve a value was obtained which agreed so closely with that given in the "International Critical Tables" by Rodebush and Rodebush[7] that the "International Critical Tables" value was adopted except with regard to the estimate of accuracy.

[7] Rodebush and Rodebush, "International Critical Tables," Vol. V, p. 88.

We believe that the value of $S_{298.1^\circ\mathrm{K.}} = 27.9$ calorie/degree per mole of solid iodine (I_2) is reliable to 0.1 unit. This value, as will be shown, is not the absolute entropy of iodine, but is, as we shall now assume, the absolute entropy less the unknown amount of the limiting nuclear spin entropy.

The entropy of gaseous iodine may be obtained from the band spectrum for this substance. A summary of the spectroscopic data with references has been given by Birge.[8]

$$S^\circ = \frac{3}{2} R \ln M + \frac{5}{2} R \ln T - R \ln P + \frac{5}{2} R - 7.267 + R \ln Q + RT \frac{\mathrm{d} \ln Q}{\mathrm{d}T}{}^{9}$$

where $Q = \Sigma p e^{-\epsilon/kT}$, p is the *a priori* probability and ϵ the energy of the state concerned. The other symbols in the above expression have their usual significance. In evaluating Q the vibrational energies were obtained from the expression

$$\epsilon_v \text{ (in cm.}^{-1}) = 214.26\,(v + \tfrac{1}{2}) - 0.592\,(v + \tfrac{1}{2})^2$$

where $v = 0, 1, 2, 3$, etc. This formula yields the same values as the older type given in "Molecular Spectra in Gases,"[8] but has been converted to the later nomenclature which recognizes the existence of one-half unit of zero point vibration.

In considering the rotation the approximation $Q_r = 4a^2 1kT/h^2$ was sufficiently accurate for our present purpose since the rotational deformation of the iodine molecule is not great. This value of Q_r takes into consideration the fact that the symmetry of the iodine molecule reduces the number of states, and thus Q_r, by a factor of two.

$$I = 742.6 \times 10^{-40} \text{ g. cm.}^2 = \text{the moment of inertia}$$

$$Q = Q_v Q_r = \frac{4\pi^2 IKT}{h^2} \sum_{v=0}^{v} e^{-hc\epsilon_v/kT}$$

The values used for all natural constants are those given in the "International Critical Tables." The rotational approximation leads to

$$RT \frac{\mathrm{d} \ln Q_r}{\mathrm{d}T} = R = 1.9869 \text{ calories/degree per mole}$$

$$RT \frac{\mathrm{d} \ln Q}{\mathrm{d}T} = R\left[T \frac{\mathrm{d} \ln Q_r}{\mathrm{d}T} + T \frac{\mathrm{d} \ln Q_v}{\mathrm{d}T}\right]$$

$$= R\left[1 + \frac{hc}{kT} \frac{\Sigma \epsilon_v e^{-hc\epsilon_v/kT}}{\Sigma e^{-hc\epsilon_v/kT}}\right]$$

From the above we find

$$\begin{aligned} S^\circ_{298.1} &= S_{\mathrm{Translation}} + S_{\mathrm{Rotation}} + S_{\mathrm{Vibration}} \\ &= 42.50 + 17.75 + 2.04 \\ &= 62.29 \text{ calories/degree per mole} \end{aligned}$$

The value 62.29 E. U. is the absolute entropy of iodine *less* the amount due to nuclear spin.

[9] Giauque, THIS JOURNAL, 52,4808 (1930).

The AS for the vaporization of iodine could be calculated from the above data and compared with that found from the vapor pressure data. However, a more severe test of the individual experimental data will be **made.**

The Heat of Vaporization of Iodine

$$F^\circ = H^\circ - TS^\circ$$
$$= E_0^\circ + RT^2 \frac{\mathrm{d}\ in\ Q_v}{\mathrm{d}T} + \frac{7}{2}RT - TS^o$$

where E_0° is the energy content of perfect molecular iodine gas at the absolute zero. From the data given above

$$F^\circ_{298\cdot1} = E_0^\circ + 342 + 3.5 \times 1.9869 \times 298.1 - 298.1 \times 62.29$$
$$= E_0^\circ - 16{,}154 \text{ calories for } I_2 \text{ gas}$$
$$H^\circ_{298} = E_0^\circ + 2415 \text{ calories}$$

From Rodebush and Rodebush[7]

$$F^\circ_{298\cdot1} = E_0^\circ - 5137 \text{ calories for } I_2 \text{ solid}$$
$$H^\circ_{298\cdot1} = E_0^\circ + 3178 \text{ calories}$$

Therefore $\Delta F^\circ_{298\cdot1} = \Delta E_0^\circ - 11{,}017$. With sufficient accuracy the value of $C_{p(g)} - C_{p(s)}$ may be taken as $9.0 - 13.0 = -4.0$ calories/degree per mole between 0 and 100°. Then for the above range $\Delta H_T = \Delta E_0^\circ + 429 - 4.0\ T$

$$\frac{\mathrm{d}(\Delta F/T)}{\mathrm{d}T} = -\frac{\Delta H}{T^2}$$

Evaluating the integration constant from the value of $\Delta F_{298\cdot1}$

$$AF^o = \Delta E_0^\circ + 429 + 4.0\ T \ln T - 61.186\ T$$
$$= -RT \ln P$$

where P is the vapor pressure of iodine in atmospheres. From this equation each measurement of vapor pressure gives a value of ΔE_0°.

The value of ΔE_0° should remain constant if our assumption that the nuclear spin entropy has reached its limiting value below 10°K. is correct.

The results from the data of Baxter, Hickey and Holmes[10] and of Baxter and Grose[11] are given in Table I.

In Table II the earlier and somewhat less accurate data of Ramsay and Young[12] are considered for completeness but are given no weight.

Before proceeding with the main object of this paper, we will pause to obtain a very reliable equation for representing the vapor pressure of solid iodine. Taking $\Delta E_0^\circ = 15{,}640$, we find

$$-RT \ln P \text{ (atm.)} = 16{,}069 + 4.0\ T \ln T - 61.186\ T, \text{ or}$$
$$\log P \text{ (atm.)} = -\frac{3512.3}{T} - 2.013 \log T + 13.374$$

359.1	21.25	15644	386.9	87.0	15689

An accurate value of $\Delta H_{298.1}$ for the sublimation of iodine may be calculated from

$$\Delta H_T = 15{,}640 + 429 - 4.0\,T$$
$$\Delta H_{298.1} = 14{,}877 \text{ calories per mole}$$

This value is more reliable than the value of ΔE_0°, since any error in the 429 calorie term which appears in the equation does not affect the constancy of the ΔE_0° calculated. However, since the value of ΔE_0° would be shifted by an exactly compensating amount, a reliable value of ΔH is assured. It may be well to add that there is no reason for questioning the reliability of ΔE_0°.

The excellent constancy of ΔE_0° in Table I is a substantial proof of the assumption on which the calculation was based. If, for example, the effect of nuclear spin appeared in the heat capacity measurements above 10°K. to an extent which caused an effect of one entropy unit, a linear trend of about 100 calories would have been evident in ΔE_0°. Thus the data on iodine confirm the idea that the $\int_0^T C_p \mathrm{d} \ln T$ with the usual extrapolation below a few degrees absolute will usually ignore the effect due to nuclear spin. As mentioned above, this is not even approximately true in the case of hydrogen, but this substance is unusual in many ways; for example, unlike all other substances it condenses at temperatures far below those at which the limiting high temperature spin distribution is approached. Since Bonhoeffer and Harteck[13] have shown that the perturbing effects of increased pressure are effective in restoring equilibrium in the case of hydrogen at room temperature, it would be expected that the intimate contact associated with condensation would be even more effective. However, in hydrogen, condensation does not occur until such low temperatures have been reached that the rate has been decreased sufficiently to permit the establishment of a false equilibrium.

In iodine the results indicate that the ortho molecules, which have the rotational quantum numbers $j = 1, 3, 5 \ldots$, do not carry the rotational multiplicity of the lowest ortho state, namely, $p = 2j + 1 = 2 \times 1 + 1 = 3$, into the solid as is the case with hydrogen. However, the results indicate that both para and ortho iodine carry their respective spin multiplicities into the solid state.

We have had many interesting discussions of the above results with Professor Linus Pauling, who has recently[14] given a quantum mechanical discussion of the conditions under which molecules may possess rotational quantum levels in the solid state. Pauling has expressed the difference between the hydrogen and iodine cases as follows: the rotational quanta of the hydrogen molecule involve energies and forces which are large compared to the similar quantities concerned in crystalline hydrogen; thus crystallization is unable to prevent rotational motion. In the case of iodine with its relatively very small rotational quanta and relatively large crystal forces, rotation within the solid becomes impossible.

To illustrate the way in which the third law should be used, we will consider the reaction

$$\begin{aligned} H_2(g) + I_2(s) &= 2HI(g) \\ S_{298\cdot 1},\ HI(g) &= 49.8 \text{ E. U.} \quad S_{298\cdot 1},\ I_2(s) = 27.9 \text{ E. U} \\ S_{298\cdot 1},\ H_2(g) &= 31.23 \text{ E. U.} \\ \Delta S_{298\cdot 1} &= 2 \times 49.8 - 31.23 - 27.9 = 40.5 \end{aligned}$$

In no case is the given entropy value the absolute entropy. In the case of hydrogen the value[8] 31.23 was obtained by reducing the known absolute

---

[13] Bonhoeffer and Harteck, *Z. physik. Chem.*, [B] 4, 113 (1929).

[14] Pauling, *Phys. Rev.*, 36, 430 (1930).

entropy by the amount due to the nuclear spin effect. In the case of hydrogen iodide[15] the effect of nuclear spin has not been observed either in the band spectrum or in the low temperature heat capacity measurements and is thus eliminated. For solid iodine we have seen above that the heat capacity with the usual extrapolation at very low temperatures has eliminated the effect of the nuclear spin which it is known to possess. Thus by a simple artifice the cancellation of nuclear spin entropy effect has been accomplished and the correct entropy change during reaction has been obtained.

Were it possible to measure the heat capacity sufficiently close to the absolute zero of temperature, the correct absolute entropy would be obtained but this is not practicable. Thus it appears necessary to make the very plausible assumption that the usual methods of obtaining entropy, while not absolute, for the reasons given above, will lead to correct entropy changes in reactions, except in the case of hydrogen, where the adjusted value given above may be used.

Further investigations are necessary and are being undertaken to find if substances other than hydrogen deviate from the proposed rule.

Summary

The heat capacity, vapor pressure and spectroscopic data on iodine have been used to obtain accurate values for the heat of sublimation and entropy of iodine.

The heat of sublimation of iodine was found to be 15,640 calories per mole at the absolute zero and 14,877 calories per mole at 298.1°K.

With the assistance of the spectroscopic data a reliable equation for the vapor pressure of solid iodine has been obtained.

$$\text{Log}_{10} P \text{ (atm.)} = -\frac{3512.3}{T} - 2.013 \log_{10} T + 13.374$$

$$S_{298.1},\ I_2(s) = 27.9 \pm 0.1 \text{ calories/degree per mole}$$

$$S_{298.1},\ I_2(g) = 62.29 \text{ calories/degree per mole}$$

These quantities are not the absolute entropies of iodine but are less than the absolute entropies by the amount of entropy due to nuclear spin This amount is at present unknown.

The values given can be used in combination with other such values to obtain entropy changes accompanying chemical reactions.

It has been determined that the limiting high temperature entropy effect due to nuclear spin in iodine persists to temperatures below 10°K. This is important since if, as expected, this characteristic proves to be general except for the known exception of hydrogen, it will greatly simplify the complications introduced by nuclear spin in connection with the application of the third law of thermodynamics,

---

[15] Giauque and Wiebe, THIS JOURNAL, 51, 1441 (1929).

Although odd and even rotation species exist in diatomic iodine gas, the data show that molecular rotation of the type existing in solid hydrogen does not occur in solid iodine. However, the results indicate that both para and ortho iodine carry their respective spin multiplicities into the solid state.

PHOTOCHEMICAL STUDIES.
XII. THE PHOTOCHEMICAL REACTION BETWEEN NITRIC OXIDE AND MERCURY VAPOR

BY W. ALBERT NOYES, JR.

RECEIVED NOVEMBER 29, 1930 PUBLISHED FEBRUARY 9, 1931

The field of investigation initiated by the fundamental researches of Cario[1] and of Cario and Franck,[2] in which the spectra of thallium and of silver and the dissociation of hydrogen were produced through the agency of excited mercury atoms, has proved to be of great theoretical interest. These phenomena, ascribed to inelastic collisions of the second kind, have been shown to be quite universal and have been demonstrated for a large variety of reactions by many different workers. It is not necessary at this point to give a detailed list of such reactions.[3]

The exact mechanism of such photosensitized reactions is of some interest. The various experimental facts and theoretical ideas concerning the action of excited mercury on hydrogen and water vapor have been summarized and discussed recently by Beutler and Rabinowitsch.[4] The production of ozone from oxygen, first studied by Dickinson and Sherrill,[5] has been investigated from different angles by other investigators.[6] Various mechanisms have been proposed to account for this reaction[7] and among others one which depends, essentially, on the fact that oxygen is paramagnetic. It was with the object of throwing further light upon the mechanisms of some types of photosensitization that the present investigation, involving also the action of excited mercury on a paramagnetic gas, nitric oxide, was undertaken.

I. Experimental

The nitric oxide used in these experiments was prepared by the method of Winkler,[8] introducing some of the modifications suggested by Johnston and Giauque.[9] This method is based upon the reaction: $2NO_2^- + 4H^+ + 2I^- = 2NO + I_2 + 2H_2O$. The flask C (Fig 1) was partially filled with a solution made by dissolving *75* g. of potassium nitrite and **38** g. of potassium iodide in **225** cc. of distilled water. The flask **A** contained a 50% (by weight) solution of sulfuric acid. The column D was filled with glass beads and contained concentrated sulfuric acid (about 93%). The column ***G*** also contained glass beads and was filled with a 50% solution of potassium hydroxide. The flask T served merely as a protective trap in case of accident. *J* contained anhydrous calcium chloride for removing most of the moisture and K contained phosphorus pentoxide.

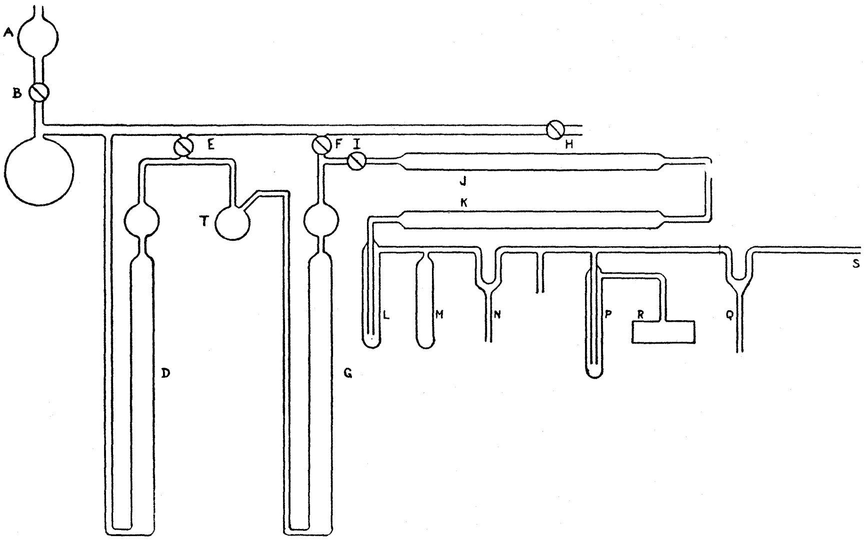

Fig. 1.

The stopcock I was closed and the mercury in cut-offs N and Q was lowered. The entire apparatus as far as I was then evacuated with continual flaming to as low **a** pressure as could be obtained with a mercury diffusion pump. The stopcocks E and F were then opened and the gas preparation apparatus was evacuated through H by means of an oil pump. This evacuation was carried on until a low pressure was attained, limited largely by the vapor pressure of water over the solution in C. In this way practically all of the air in the gas phase and a large fraction of the air dissolved in the various solutions was eliminated. Stopcocks E, F and H were closed and a few drops of the sulfuric acid solution allowed to enter C through the stopcock B. The gas evolved bubbled through the 75-cm. column of sulfuric acid in D and then through the concentrated potassium hydroxide in G. Stopcocks E, F and H were opened and the gas pumped out. This process was repeated at least twice before gas was admitted to the main apparatus. Finally stopcocks E, F and H were closed and I opened. Nitric oxide was allowed to flow through the calcium chloride and phosphorus pentoxide tubes

---

[8] Winkler, *Ber.*, 34, **1408 (1901).**

[9] Johnston and Giauque, THIS JOURNAL, **51,3194** (1929).

for several minutes and then the mercury in the cut-off N was raised and liquid air was placed around the trap L. When sufficient nitric oxide had collected in L the stopcock I was closed. The amount of nitric oxide prepared was never large, usually only sufficient to exert about five centimeters pressure when the liquid air was removed from L. The liquid air was now removed from L and placed around M and the nitric oxide sublimed over. The last fraction was allowed to escape by lowering the mercury in N with the vacuum pumps attached to S in operation. This process of purification by sublimation was repeated at least three times before using any nitric oxide for an experiment.

The nitric oxide as it leaves C would contain as impurities some hydriodic acid, traces of nitrogen and iodine and unknown amounts of other oxides of nitrogen (with perhaps a small amount of free oxygen). The hydriodic acid is probably partially removed by the sulfuric acid. Passage of the gas through the concentrated potassium hydroxide should remove most of the iodine, the remaining traces of hydriodic acid and nitrogen dioxide. The only nitrogen oxide not accounted for would be N_2O, although this would probably not be formed in any appreciable quantity. It is quite soluble in water but probably would not be completely removed. The repeated distillations with liquid air would tend to eliminate practically all of the highly volatile impurities such as nitrogen and oxygen completely. The others, namely, hydriodic acid and the various foreign oxides of nitrogen, would have exceedingly low vapor pressures at the temperature of liquid air. They would probably not be removed completely by the distillation process.

The vapor pressure[9] of nitric oxide at the temperature of boiling oxygen (90.13° K.)[10] is about 3.2 mm. and at the temperature of boiling nitrogen it is about 0.1 mm.[11] In most of the experiments described in the present paper, the pressure of nitric oxide used was not greater than 0.15 mm., so that the gas could be admitted to the reaction vessel from a trap immersed in liquid air. In these experiments the only possible volatile impurities were nitrogen and oxygen. These were swept away as far as possible by submitting the solid at liquid-air temperatures to a high vacuum, as well as by the process of sublimation already described. When pressures of several millimeters of nitric oxide were necessary, the liquid air was removed from the trap L and the gas coming off allowed to bubble through about one centimeter of mercury in the cut-off N. This would tend to remove those oxides of nitrogen which react readily with mercury and would also make it possible to use only the first portion of gas coming off from the solid. Since nitric oxide is much more volatile than any of the impurities (other than nitrogen and oxygen), this method should ensure a high purity of the gas used.

The pressures were all measured by means of a McLeod gage.

The reaction vessel was of fused quartz, *25* mm. in diameter and 48 mm. in length. It was sealed to the vacuum line by a graded quartz to pyrex seal. No stopcocks or other sources of organic impurities were present in the line between the two cut-offs N and Q. The admission of gas to the line while L was immersed in liquid air should ensure absence of organic vapors as impurities. In certain of the later experiments a reaction vessel made of Corex glass was used. This glass may be sealed directly to pyrex.

The quartz mercury arc lamp and the reaction vessel were both immersed in a water-bath. The distance from the lamp to the window of the reaction vessel was negligible. The current through the lamp was supplied by a motor generator. The variations between runs is to be ascribed undoubtedly to variations in voltage of the line supplying the lamp.

---

[10] Giauque and Johnston, THIS JOURNAL, 51, 2313 (1929).

[11] Calculated from the formula given by Giauque and Johnston,[9] although their data did not extend to such low temperatures.

II. Results

The first object of the experiments was to determine the effect of pressure of nitric oxide on the rate of the reaction. In the reaction of excited mercury with oxygen,[5,6] a film of mercuric oxide was produced on the side of the reaction vessel toward the source of radiation. In the present experiments no such film was noticed.

It seems evident that the gas remaining in the reaction vessel after the completion of the reaction is nitrogen. This is rendered reasonable by the fact that the final pressure attained after very long exposure is always, very close to one-half the initial pressure. That conditions are actually not quite as simple as this is indicated by the variation in pressure, both with and without illumination, after the pressure had attained approximately one-half the initial value. With continuous illumination the pressure would decrease to a value less than one-half the initial pressure, but on standing there would be a gradual pressure increase. It seemed impossible, however, to repeat this process indefinitely, for sooner or later the pressure decrease during illumination would cease and the pressure would gradually increase with or without illumination. Every precaution was taken to be sure that this increase was not due to a leak in the apparatus.

The reaction seems to lead to the production of nitrogen dioxide. The action of this gas on liquid mercury has been studied previously.[12] It is not exceedingly rapid at low pressures. The final reaction is supposed to be represented by the equation[13] $4Hg + 2NO_2 = 4HgO + N_2$, but the initial step is almost certainly the formation of a mercuric or mercurous salt, perhaps a nitrite, which may then evolve nitrogen more slowly.

TABLE I

RESULTS OF A TYPICAL RUN

Reaction vessel, quartz. Current, 5.8 amp. Temp., 25°

Time, min.	Pressure, mm.	Pressure (calcd.), mm.
0	0.0339	(0.0339)
55	.0307	.0299
213	.0229	.0224
303	.0206	.0208
968	.0171	.0171

Table I shows the results obtained during a typical run. The values in the third column are calculated by means of the equation

$$(2.303/t) \log_{10} (p_0 - {}^1/_2\, p_0)/(p - {}^1/_2\, p_0) = 4.91 \cdot 10^{-3} \qquad (1)$$

Many other runs were made and in all cases the reaction rate followed the equation

$$-dp/dt = k_1 (p - {}^1/_2\, p_0) \qquad (2)$$

within the experimental error, p_0 being the initial pressure and p the pressure at the time t. Table II shows a typical run with Corex glass.

TABLE II

TYPICAL RUN WITH COREX GLASS

Reaction vessel, Corex. Current, 6.3 amp. Temp., 25°. $k_1 = 1.45 \cdot 10^{-4}$

Time, min.	Pressure, mm.	Pressure (calcd.), mm.
0	0.1285	0.1285
175	.1260	.1270
950	.1199	.1203
1660	.1148	.1148

In order to determine the possible effect of pressure on the values of the constant, k_1, a series of runs was made at varying pressures with other conditions identical as nearly as possible. Nitric oxide from the same preparation was used and the runs followed each other as closely as possible Table III shows the results obtained.

TABLE III

EXPERIMENTAL DATA

Time interval, min.	Initial pressure, mm.	Final pressure, mm.	Current, amp.	k_1
31	0.1178	0.1128	6.2	$2.9 \cdot 10^{-3}$
30	.0340	.0330	6.1	2.0
30	.00353	.00338	6.0	3.1

Similar series were made on two other occasions with results which showed no systematic variation of k_1 with pressure.

In order to ascertain whether the reaction was really due to the action of excited mercury, or whether it should not be ascribed either to some foreign gas acting as sensitizer or to direct photochemical decomposition of the nitric oxide, the trap P was, during several runs, immersed either in liquid ammonia (−33°) or in liquid air. Constants obtained under these conditions were uniformly much lower, in some cases being actually zero. The fact that the zero value was not always obtained is undoubtedly due to the insufficient time allowed for the complete removal of mercury vapor. In one case in which liquid air had no apparent effect, close examination showed mercury droplets to be present in the reaction vessel. These had undoubtedly been placed there in the process of flaming the line before the run. Table IV shows a summary of the constants obtained under various conditions.

One run was made at considerably higher pressures of nitric oxide. The initial pressure was 24.13 mm., the time three hours and the final pressure 23.37 mm., giving a value for k_1 of $3.7 \cdot 10^{-4}$. This indicates, as would be expected, that k_1 decreases with pressure. An experiment was made with the same nitric oxide after evacuating the line to a lower pressure. In this

TABLE IV

SUMMARY OF REACTION RATE CONSTANTS

Experimental conditions	k_1 (min.$^{-1}$)
Quartz vessel	$4.7\cdot10^{-3}$
Quartz vessel, *liq.* NH_3 *on P*	0.8
Quartz vessel, liq. *air on P*	.4
Cores vessel	$2.1\cdot10^{-4}$
Corex vessel, liq. *air* on *P*	0.35

way the presence of inhibiting impurities due to the preparation at higher pressures (see Sec. I) would be detected. A value of $4\cdot10^{-3}$ for k_1 was obtained, indicating that the rate was the same as for other lots of nitric oxide.

An attempt was made to determine the percentage transmission of the Corex glass for a wave length of 2536 Å. An average of four determinations gave 0.038 as the ratio of this radiation transmitted by Corex to that transmitted by quartz. That is, an exposure of about five seconds with quartz gave about the same darkening of the plate as an exposure of one hundred and thirty seconds with Corex. The experimental arrangement used in the study of the fluorescence of this line was used. This value should be considered as approximate. An attempt to make the measurement with a rotating sector gave even less reliable results due to the feeble transmission.

The experiments with Corex were carried out with a slightly higher average current through the mercury arc lamp than those with the quartz vessel. The ratio of rates (Corex/Quartz) as given in Table IV is 0.045, which should be considered as too high rather than too low. The square root of 0.038 is 0.19 and the square is 0.0014. Both of these values are considerably removed from 0.045, so that we feel safe in stating that the rate is proportional to the intensity of the resonance radiation.

Studies were also made of the quenching of the fluorescence of mercury vapor by nitric oxide. The apparatus shown schematically in Fig. 2 was used. A is a mercury arc lamp of the vertical type with the lower part immersed in water kept at room temperature. B is a quartz lens and C is the fluorescence tube, approximately 80 cm. in length and tapered and bent over at the end to reduce back reflection in the manner described by Hughes and Thomas.[14] The slit of the spectrograph is shown at D. The various parts of the apparatus were placed in such a manner that radiation was not directly reflected into the spectrograph.

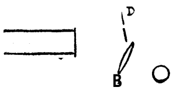

Fig. 2.

With short exposures (up to about one minute) the 2536 Å. line of mercury alone was shown on the photographic plate. With exposures of several minutes a few other lines could be detected, but especially those at 3132, 3654, 4046, 4358 and 5461 Å. These lines are denoted as ($3^3D_1 \longrightarrow 2^3P_2$), ($3^3D_2 \longrightarrow 2^3P_2$), ($2^3S_1 \longrightarrow 2P_0$), ($2^3S_1 \longrightarrow 2^3P_1$) and ($2^3S_1 \longrightarrow 2^3P_2$),

[14] Hughes *and Thomas,* Phys. *Rev., 30,*466 (1927).

respectively, all of which have initial energy levels which may be produced from the excited state (2^3P_1) by the absorption of lines emitted by the mercury arc. It seems safe to say that very little, if any, reflected radiation need be considered in interpreting these experiments. We assume, therefore, that the intensity of the 2536 Å. as indicated by the spectrograph is proportional to the intensity of the fluorescence.

In determining the extent to which nitric oxide quenches the fluorescence of mercury vapor, exposures were made of five seconds' duration at intervals of one centimeter on the photographic plate with mercury vapor in the fluorescence tube in a high vacuum. Nitric oxide was then admitted and exposures of 5, 10, 15, etc., seconds were made in such a way that they alternated on the photographic plate with those without nitric oxide. Visual comparison was used to ascertain equality of intensity. The average of three plates showed that thirty-three seconds with nitric oxide at a pressure of 6.1 mm. gave the same blackening of the plate as five seconds without. With 2.0 mm. of nitric oxide the ratio was 18/5. Hydrogen was used as a comparison. The hydrogen was not specially purified except by passage through a liquid-air trap. With 6.0 mm. of hydrogen the ratio found was 100/5.

III. Theoretical

The present work was undertaken because nitric oxide is a paramagnetic gas. All, or nearly all, of the homogeneous gas reactions which have been proved definitely to be of the third order, involve nitric oxide.[15] This may indicate that the paramagnetic character of these molecules renders reactions involving triple collisions more probable than for ordinary gases. Hinshelwood[15] has summarized arguments against the existence of N_2O_2 as a definite intermediate.

The line spectrum of mercury has been quite satisfactorily analyzed.[16] The normal state is designated as $^1S_0$, with no resultant electron spin to be ascribed to the kernel and the two valence electrons (s electrons) with their spins antiparallel, giving a resultant of zero. This state, then, should be essentially nonmagnetic. The resonance line (2536 Å.) involves in absorption a $^1S_0 \longrightarrow {}^3P_1$ transition. In the triplet state produced when mercury vapor absorbs this radiation, the electron spins are parallel instead of antiparallel and the atom as a whole now possesses a net electronic orbital angular momentum. This should mean that excited mercury is paramagnetic. Further details concerning the mercury spectrum need not be given here.

The spectrum of nitric oxide has received a great deal of attention. The

[16] See, for example, Grotrian, "Graphische Darstellung der Spektren von Atomen und Ionen mit ein, zwei und drei Valenzelektronen," Julius Springer, Berlin, 1928, Vol. II, p. 78.

nitric oxide molecule contains an odd number of electrons and the normal state is a $^2\Pi_{1/2,\,3/2}$ state. For reasons which need not be given here[17] the $^2\Pi_{1/2}$ state will be nearly non-magnetic for small values of the resultant quantum number J, while the $^2\Pi_{3/2}$ state will be paramagnetic. The works of Sponer,[18] Sponer and Hopfield,[19] Jenkins, Barton and Mulliken,[20] Guillery[21] and Schmid[22] have shown that the β, γ and δ bands in all probability have as the same final state the normal $^2\Pi$ state. The upper states seem to be best described as $^2\Sigma$, $^2\Pi$ and $^2\Sigma$ states, respectively.[23] In addition to the normal doublets, NO shows X-type doubling.[24]

The various electron energy levels for NO are given as follows:[23]

X level	($^2\Pi$)	0 volt
A	($^2\Sigma$)	5.45 volts
B	($^2\Pi$)	5.60 volts
C	($^2\Sigma$)	6.45 volts
D	($^2\Sigma$)	6.58 volts

The β, γ and δ band systems (X-B, X-A, X-C, resp.), extend from about 2250 Å. toward shorter wave lengths. Since all of these bands have the normal $^2\Pi$ state as the final state in emission, they should also be observed in absorption. In the experiments described in the present paper, the absorption should be exceedingly feeble, both on account of the low pressures used and because of the fact that a cooled mercury arc lamp gives practically no continuous emission in this region. In view of the results obtained at higher pressures and the fact that the elimination of mercury vapor by liquid air practically stops the reaction, direct absorption of radiation by nitric oxide would seem to be unimportant in the present work.

Mulliken[23] has concluded that the normal $^2\Pi$ state of nitric oxide should separate adiabatically into a normal oxygen atom (^3P) and a normal nitrogen atom (^4S) at the convergence limit of its vibration levels. He gives the value of 7.9 volts for the energy of dissociation. This value is certainly subject to a large uncertainty. The heat of dissociation of nitrogen is fixed at a probable value corresponding to 9–9.5 volts,[25] while that of oxygen is subject to an even greater uncertainty,[26] but may be placed between the

[24] Mulliken, *Phys. Rev.*, 33, 508 (1929).

[25] Birge, *ibid.*, 34, 1062 (1929).

[26] Birge and Sponer, *ibid.*, 28, 267 (1926); Herzberg, *Z. physik. Chem.*, 4B, 223 (1929); Copeland, THIS JOURNAL, 52, 2581 (1930); Rodebush and Troxel, *ibid.*, 52, 3467 (1930); Sommer, *Naturwissenschaften*, 18, 752 (1930); Herzberg, *Z. physik. Chem.*. 10B, 189 (1930).

limits of **5.1** and 7 volts, with the probability that the correct value is near the lower limit. The heat of formation of nitric oxide from the elements corresponds to 0.94 volt.[27] We may now set up the following relationships:

$$\begin{array}{lll} NO = {}^1/_2\,N_P + {}^1/_2\,O_2; & AE = +0.94\text{ v.} & \\ {}^1/_2\,N_2 = N; & AE = -4.5\text{ to }-4.75\text{ v.} & \\ {}^1/_2\,O_2 = O; & AE = -2.55\text{ to }-3.5\text{ v.} & \\ \hline NO = N + O; & \Delta E = -6.1\text{ to }-7.3\text{ v.} & (3) \end{array}$$

Since the minimum energy of dissociation of nitric oxide exceeds the 4.9 volt energy of excitation of 2^3P_1 state of mercury by **1.2** volts, the reaction

$$Hg\ (2^3P_1) + NO = Hg\ (1^1S_0) + N + O \qquad (4)$$

may be considered as impossible. However, if the heat of vaporization of mercury is taken as equivalent to 0.55 volt, the heat of formation of mercuric oxide from the elements as 0.93 volt, the reaction

$$Hg\ (2^3P_1) + NO = HgO + N \qquad (5)$$

is found to be exoenergetic to the extent of **2.6** to **2.8** volts. This value is too large by an amount corresponding to the heat of sublimation of mercuric oxide. The latter is not known but certainly should not exceed one volt. Reaction 5 should, therefore, be considered as thermodynamically possible.

Two other possible primary steps may be considered: **(1)** that represented by the equation

$$Hg\ (2^3P_1\text{ or }2^3P_0) + NO = NO^{\circ} + Hg\ (1^1S_0) \qquad (6)$$

where NO° represents an excited nitric oxide molecule. Since the lowest excited electron level of nitric oxide lies 5.45 volts above the normal, NO° would, in all probability, represent a molecule in the normal electron level but in a high vibration-rotation state. **(2)** An excited or metastable mercury atom may stay associated with a nitric oxide molecule a sufficient length of time to render the equivalent of a triple collision possible. The reaction could then be represented by

$$Hg^{\circ} + 2N0 = N_2 + 20 + Hg \qquad (7)$$

or some other reaction of this general type.

The effect of various gases in quenching the fluorescence of mercury vapor has been the subject of several recent investigations.[28,29,30] The quenching may be ascribed to three different types of process: **(1)** loss of energy by the mercury atom due to a simple collision of the second kind with the production of a normal 1^1S_0 atom. This probably occurs when the spectra of thallium and of silver are produced.' **(2)** A definite chemical reaction

[28] Stuart, *Z. Physik*, 32, 262 (1925).

[29] Gaviola, *Phys. Rev.*, 33, 309; 34, 1049, 1373 (1929); 35, 1226 (1930)

[30] Zemansky, *ibid.*, 31, 812 (1928); 36, 919. 219 (1930).

may take place. This may be the case with oxygen and hydrogen.[31] (3) Loss of only a small amount of energy (0.218 volt) with the production of a 2^3P_0 mercury atom. This small amount of energy may appear as energy of vibration and rotation of the quenching molecule. Using the ideas of Kallmann and London,[32] Zemansky[30] has shown that quenching is most apt to occur by this mechanism when the quenching molecule has a vibration level differing from the normal by approximately $(0.218 + {}^1/_2\, kT)$ volt. This process is of importance for such molecules as CH_4, H_2O, CO, CO_2 and N_2.

The first vibration level of nitric oxide lies 0.231 volt above the zero vibration level.[33] This differs from 0.218 volt by 0.013 volt and, according to Zemansky,[30] this should mean that NO would have an exceedingly large "effective cross section for quenching." In fact the cross section should be larger than for any gas given in his diagram.

In the experiments described above, nitric oxide was shown to quench the resonance radiation of mercury to the extent of 72% at a pressure of 2 mm. and 85% at 6 mm. The method used was not capable of the highest precision; moreover the optical arrangement was different from that used by Zemansky,[30] so that a direct comparison with other gases is impossible. A rough calculation shows that the effective cross section for quenching is approximately $2 \cdot 10^{-16}$ sq. cm., not as high as for NH_3, C_4H_{10}, CO and CO_2, but larger than for H_2O, C_2H_6, CH_4 and N_2. The pressure for half quenching would be slightly less than one millimeter, which is lower than the values for other gases studied by Stuart[2*] with the exception of H_2, O_2 and CO. Hydrogen used in the same apparatus showed a quenching of 95%, which agrees within about 1% with the value calculated by the method of Gaviola.[29]

If the quenching in nitric oxide is due to $2^3P_1 \longrightarrow 2^3P_0$ transitions, at higher temperatures the quenching should be noticeably less because there are more collisions capable of causing the reverse process.[34] This experiment was tried, using a cell made entirely of fused quartz. There was much more scattering in this cell than in the one used previously. After proper corrections the results at room temperature agreed fairly satisfactorily with those obtained with the other cell. At a temperature of from 600 to 700°, 7 mm. of nitric oxide gave approximately 10% less

---

[31] *Cf.* Zemansky, Ref. 30. A slight error seems to have crept into his consideration of the possibility of the reaction $Hg^0 + O_2 = HgO + O$. This reaction should be exoenergetic to the extent of about 3 volts, a value which is in error by an amount corresponding to the heat of sublimation of mercuric oxide. For other arguments against this mechanism see Dickinson and Sherrill, Ref. 5 and Noyes, Ref 6.

[32] Kallmann and London, *Z. physik.* Chem , 2B, 207 (1929)

[33] "International Critical Tables," McGraw-Hill Book Co., Inc., New York, 1929, Vol V, p. 415.

[34] See Cario and Franck, *Z. Physik,* 17, 202 (1923)

quenching than at room temperature. This is an average value obtained in seven different runs. At similar temperatures Cario and Franck[34] found nitrogen to be practically without effect in quenching the fluorescence of mercury vapor. Due to the possibility of introducing impurities it was not advisable to try high pressures of nitric oxide and there is, therefore, the probability that part of the 2^3P_0 atoms are removed by the walls. Moreover nitric oxide quenches the fluorescence of mercury vapor much more effectively than nitrogen. It is questionable whether the quenching should become zero at the temperatures used even if it were due entirely to the production of 2^3P_0 atoms. For reasons to be given later it seems certain that this mechanism is not the only one, but the results do not disprove the presence of some collisions of this type. In fact it seems probable that part of the quenching is to be ascribed to the production of 2^3P_0 atoms.

At 25° the following distribution of nitric oxide molecules among the various vibration states is obtained[35] (neglecting A-type doubling)

$^2\Pi_{1/2}$	$v = 0$	65.04%
$^2\Pi_{1/2}$	$v = 1$	0.477%
$^2\Pi_{1/2}$	$v = 2$	0.004%
$^2\Pi_{3/2}$	$v = 0$	34.23%
$^2\Pi_{3/2}$	$v = 1$	0.250%
$^2\Pi_{3/2}$	$v = 2$	0 0021%

Thus a small but definite fraction of the molecules have a vibrational quantum number of 1. If the majority of the quenching is ascribed to the process NO ($^2\Pi$, $v = 0$) + Hg (2^3P_1) = NO ($^2\Pi$, $v = 1$) + Hg (2^3P_0), certain of the facts presented above may be tentatively explained. At low pressures the 2^3P_0 atoms would diffuse largely to the walls and be converted to normal atoms. As the pressure is increased, the chance for reversal of the above process before the metastable atoms reached the walls would be increased. Thus the quenching at higher pressures could not be calculated by a simple formula from that at low pressures. This would be independent of any effect due to broadening of the absorption line, etc. The qualitative results presented above indicate this to be the case. The lower quenching at higher temperatures could also be explained in this manner.

It is impossible, however, to assume that nitric oxide molecules with a vibrational quantum number of 1 are appreciably more reactive than those with $v = 0$. Otherwise reaction would take place at room temperature and would have a very high temperature coefficient. There must, therefore, be some other process involved.

The 26th vibration level of nitric oxide lies 4.90 volts above the zero level and the 24th is found at 4.61 volts.[36] In optical absorption the forma-

---

[35] See Ref. 9, p 3212.

[36] See Ref 33. This value is calculated by means of the formula $\bar{\nu} = v(\omega'' - \omega''x''v)$, where 5 is the vibrational energy in cm.$^{-1}$ and v is the vibrational quantum number. w'' and $\omega''x''$ are constants, 1888.31 and 13.88, respectively. It is recognized that use of

tion of such high levels would be an exceedingly rare occurrence. One might expect their formation by collision of the second kind with 2^3P_1 (4.863 v.) and 2^3P_0 (4.645 v.) mercury atoms to be improbable in the absence of some special resonance effect. The first excited electron level of nitric oxide lies 5.45 volts above the normal and differs from 4.863 volts by an amount probably too large to be of importance in such an effect. However, 5.45 volts is only 5.22, 4.99 and 4.77 volts above the first, second and third vibration levels, respectively. One might expect, therefore, that molecules in vibration levels higher than the zero level would have some possibility of being excited to vibration levels as high as the 26th or 27th. Thus 4.81 volts will raise the first vibration level to the 27th and this differs by only 0.05 volt from the energy 2^3P_1 mercury atoms may give up. Calculations concerning this type of collision may only be made by approximate methods, but is it possible that the paramagnetic characters of the two bodies entering into the collision might be a determining factor in the type of resonance effect obtained?

There are two arguments against the mechanism represented by Equation 5. (1) Mercuric oxide is not deposited in the reaction vessel in the zone of illumination. (2) No bands could be detected which might be ascribed to either HgO or HgN molecules. This last argument should be given little weight since bands, if emitted, might lie in the infra-red. In the absence of a radiative process, such an exoenergetic mechanism would be improbable. Equation 5 would, however, satisfy the rate equations obtained.

Reaction 7 would seem to be excluded by the fact that only the first power of the nitric oxide pressure occurs in the rate equation. Other information concerning this mechanism is lacking.

It seems probable, therefore, that the mechanism is correctly represented by Equation 6. In order for this to be true, the life of NO^0 must be appreciably longer than the average time between collisions even at low pressures. From what is known of the life of molecules in high vibration states, this would not be unexpected.

It can now be shown that the rate of activation of nitric oxide should be given by the equation

$$+\,d(NO^\circ)/dt = c_1c_2Ip/(c_1c_2p + c_3) \qquad (8)$$

(NO°) = total number of activated molecules
I = number of quanta of resonance radiation absorbed per second
p = pressure of nitric oxide in millimeters
c_1 = number of collisions per second per excited mercury atom at 1 mm. pressure
c_2 = fraction of these collisions which lead to activation
$c_3 = 9.7\cdot10^6$ = constant for fluorescent decay of excited mercury

---

this formula for such high values of v is approximate, for higher powers of v should undoubtedly be included, Comparison of the rate obtained at low pressures with the one obtained at 24 mm. shows that $c_1c_2 = 5\cdot10.^6$ Equation 8 satisfies all of the requirements of the data presented above, for at low pressures c_1c_2p will be small compared to c_3.

It is impossible to calculate c_1 and c_2 separately without introducing special assumptions. If c~ = 1, the radius of the nitric oxide molecule is found to exceed the kinetic theory radius by a small amount if the radius of the excited mercury atom is taken equal to the kinetic theory radius of the normal mercury atom. If nitric oxide molecules in vibration levels above the lowest are alone capable of reacting, their effective radius would be found to be much larger.

Equation **8** with the values of the various constants determined from reaction rate data gives lower values for the quenching of the fluorescence of mercury vapor than those found experimentally. Thus quenching should be 51% at **2** mm. and 75% at 6 mm. as compared to 72 and **85%** found experimentally. One would not expect precise agreement, however, due to the difference in optical arrangement between the reaction system and that used for the study of fluorescence, as well as on account of certain factors mentioned by Zemansky.[30] This is partial evidence that part of the quenching occurs by a process which does not lead to chemical reaction, presumably through the production of 2^3P_0 atoms.

Summary

1. The rate of pressure decrease in a system consisting of mercury vapor and nitric oxide illuminated with the resonance radiation of mercury has been studied.
2. The quenching of the fluorescence of mercury vapor by nitric oxide has been studied. It is probably to be ascribed to two processes.
3. Various mechanisms for the activation process are discussed. Probably a nitric oxide molecule in a high vibration state of the normal electron level is produced by collisions of the second kind.

ELECTRIC MOMENT AND MOLECULAR STRUCTURE. I. THE ETHYL ESTERS OF MONO- AND DICARBOXYLIC ACIDS

BY C. P. SMYTH AND W. S. WALLS

RECEIVED DECEMBER 3, 1930 PUBLISHED FEBRUARY 9, 1931

A series of ten papers has been published from this Laboratory under the general title, "The Dielectric Polarization of Liquids,"[1] but, the applicability of the Debye theory to liquids having been definitely established, dielectric investigations can now safely aim more directly at the problems of electric moment and molecular structure, some of which received preliminary treatment in earlier studies.[2]

Although it was obvious that the complexity of the carboxyl group would complicate the interpretation of the results, the ethyl esters of the dicarboxylic acids appeared to offer a means of investigating the effect upon the resultant electric moment of separating the component moments by a carbon chain of varying length. As this moment is the resultant of the moments of two $—COOC_2H_5$ groups, it seemed desirable to give this group more thorough investigation than it had hitherto received by measuring the ethyl esters of formic, acetic and propionic acids.

The dielectric constants of these substances in solution in benzene were measured by means of a heterodyne beat apparatus similar to those employed by several other investigators,[3] the wave length used being 1000 meters. As previous work[4] had shown that the values of large moments obtained from the temperature variation of the polarization did not differ greatly from those calculated from the difference between the polarization at one temperature and the molar refraction, the measurements were carried out at 25° and repeated at 50° as a means of ascertaining the presence of any complicating factors which would vary with temperature. The cell used to contain the liquid to be measured consisted of concentric gold-plated brass cylinders similar to those used in earlier measurements.[5] An Ostwald–Sprengel pycnometer fitted with carefully ground caps was used for the density measurements. The temperatures were maintained by means of two accurately adjusted thermostats. The refractive indices were measured with a Pulfrich refractometer at 25° for the calculation of the molar refraction and at 20° for comparison with the values contained in the literature, this comparison serving as a means of checking the purity of the materials.

Preparation of Materials

Benzene was purified as in earlier work.[6]

Ethyl Formate.—Material obtained from the Eastman Kodak Company (b. p. 54–55.5°) was dried with anhydrous sodium sulfate and distilled. The fraction boiling at 54.0–54.5° was redistilled and the fraction at 54.2–54.4° taken for use.

Ethyl Acetate.—Merck's ethyl acetate was shaken twice with concentrated potassium carbonate solution, washed with water, dried with fused potassium carbonate and then with phosphorus pentoxide, and fractionally distilled. The middle fraction was redistilled, b. p. 76.7–76.9°.

Ethyl Propionate.—Material obtained from the Eastman Kodak Company (b. p 98–100°) was dried with phosphorus pentoxide and distilled. The middle fraction (b. p. 99.05–99.15°) was redistilled and the fraction at 99.10–99.15° taken for use.

Dibasic Acid Esters.—With the exception of the diethyl ester of hexadecamethylenedicarboxylic acid, the materials were obtained from the Eastman Kodak Company. They were dried over anhydrous sodium sulfate or fused potassium carbonate and fractionally distilled under reduced pressure, the middle fraction being taken and redistilled.

Hexadecamethylenedicarboxylic ester was prepared from the acid, which was very kindly loaned to us by Dr. Wallace H. Carothers of E. I. du Pont de Nemours and Company. A solution of the acid in absolute ethyl alcohol was treated with dry hydrogen chloride and, after two hours of refluxing, the excess alcohol was distilled off. After cooling, the product was poured into ice water, treated with sodium carbonate, filtered, washed and dried, It was then recrystallized four times from absolute alcohol and dried in a vacuum desiccator; m. p. 48.3°.

The refractive indices of all the purified liquids are shown in Table I, their good agreement with the values in the literature giving evidence of purity. The molar refraction of the hexadecamethylenedicarboxylic ester given in Table III is calculated from measurements upon the substance in solution. It is only 0.1 higher than the value calculated as the sum of the atomic refractions.

Experimental Results

The data for the pure substances are given in Table I, in which the temperature coefficient of the refractive index for the D sodium line is calculated as the difference between the values at 20 and 25° divided by 5 and the coefficient of the density as the difference between the values at 25 and 50° divided by 25. The indices at 25° and the densities at 50° are omitted for the sake of brevity. In Table II the first column gives the mole fraction c_2 of the ester in the benzene solution and the succeeding columns give the values at 25 and 50° of the dielectric constants ϵ and the densities d of the solutions and the polarizations P_2 of the esters. P_2 is calculated by means of the usual equations

$$P_{12} = \frac{\epsilon - 1}{\epsilon + 2}\,\frac{c_1M_1 + c_2M_2}{d} \text{ and } P_2 = \frac{P_{12} - P_1}{c_2} + P_1$$

in which P_{12} is the polarization of the mixture, and c_1 and c_2, M_1 and M_2 and P_1 and P_2 are, respectively, the mole fractions, molecular weights and polarizations of the individual components. For dilute solutions the difference $P_{12}-P_1$ is so small that the error in P_2 may be large, sometimes,

---

[6] Smyth and Rogers, THIS JOURNAL. 52, 2227 (1930).

causing single values of P_2 to deviate markedly from a uniform variation with c_2. In some cases ten or more solutions have been measured in order to fix as accurately as possible the course of the P_2–c_2 curve, although only enough values are included in Table II to make possible the reproduction of the curve. A number of solutions in heptane also were run as a check on those in benzene, but the few data thus obtained are omitted as they are consistent with the results for the benzene solutions. The extrapolation of the P_2–c_2 curve to infinite dilution, that is, $c_2 = 0$, gives the value of P_∞, from which the electric moment μ is calculated by means of the equation

$$\mu = 0.0127 \times 10^{-18} \sqrt{(P_\infty - MR_D)T}$$

in which MR_D is the molar refraction calculated from the data in Table I, and T is the absolute temperature. In Table III the second column gives the carbon chain which holds the $—COOC_2H_5$ group or groups, the third column gives the molar refraction for the D sodium line, and the fourth and

fifth columns the differences between this refraction and the values of P_∞ at 25 and 50°. In the calculation of the moment this difference is treated as the orientation polarization, that is, the polarization due to the orientation of the molecular dipoles. This treatment neglects the small atomic polarization P_A, which probably increases somewhat with increase in molecular weight, but, in the case of such large polarizations, the error involved in regarding $P_\infty - MR_D$ as the measure of the effect of the dipole is small.[4] The molar refraction is, of course, the measure of the electronic contribution P_E to the polarization and increases regularly with increase in the size of the molecule. The absolute values of the moments are probably a few hundredths high because of the neglect of P_A, but, relative to one another, they should not be in error by more than $\pm 0.02 \times 10^{-18}$.

Discussion of Results

A few years ago the relative moments of the molecules of monocarboxylic acids and their esters were calculated[7] on the assumption of valences acting at the apices of regular tetrahedra with arbitrarily located charges and complete freedom of rotation about the single bonds. The conclusion reached was that the unsubstituted esters and acids should all have the same moment except for the secondary effects of induction and repulsion between groups. A similar type of calculation for the ketones indicated that they should have moments approximately 1.24 times those of the esters. These conclusions were supported by the values of the moments calculated from the dielectric constants by an approximate method, although, as was to be expected, the replacement of an acid hydrogen by an alkyl group altered the moment considerably. Subsequent work showed that this method of calculating the moment from a single value of the dielectric constant could not be relied upon for accurate results because of its failure to correct wholly for the effect of intermolecular action or association. This was evident to some extent at the time of the calculations on the esters, for ethyl acetate gave a value of 1.47×10^{-18} for the moment at room temperature and 1.62×10^{-18} at the boiling point. This latter value is not much lower than those in Table III for ethyl acetate, which are slightly higher than the unpublished value of Zahn for the vapor, 1.76×10^{-18}, and the value 1.74×10^{-18} found by Williams.[8] It is obvious now, however, that, because of intermolecular action, the small differences in moment calculated in the original investigation were without significance. Recent experimental determinations of the moments of the ketones[9] show that they are about 1.5 times those of the esters, instead of 1.24, as calculated.

Eucken and Meyer[10] have calculated the moments of molecules by assigning definite moments to chemical bonds. Assuming tetrahedral valences and considering the effect of rotation about the C—O bond in fatty

[10] Eucken and Meyer, ibid., 30, 397 (1929)

acids and their esters, they have concluded that there are two extreme positions possible, one giving a minimum moment and the other a maximum. These possibilities are evident in the following formulas, in which the principal moments are shown

(a) 
(b) 
For arrangement (a), in which the moments oppose and cancel one another to a considerable extent, Eucken and Meyer calculate a moment 1.1×10^{-18}. (b) is obtained from (a) by a rotation of 180° about the C—O bond. Here the R—O doublet acts in nearly the same direction as the C=O so that the total moment is 3.4×10^{-18}. Intermediate positions about the C—O bond would give intermediate values for the moment. Eucken and Meyer suppose that, in the acids, the tendency of the acid hydrogen to be attracted toward the carbonyl oxygen, the reason for which is evident in the distribution of charges in (a), renders (a) more probable than (b) under ordinary conditions. The moments of the fatty acids should thus be lower than they would be if, in the rotation about the C—O bond, all positions were equally probable. Eucken and Meyer encountered the difficulty that the value found in the literature for the moment of benzoic acid was lower than the minimum value 1.1×10^{-18} calculated for (a). This was also true of values found for several fatty acids.[11] The difficulty appears, however, to be removed by the finding of a value of 1.4×10^{-18} for acetic acid together with evidence that the low values found for other acids were in error because of molecular association.[12]

Although such speculation is necessarily uncertain, it is interesting to note that the tendency of an alkyl group to be attracted toward the carbonyl oxygen might be expected to be less than that of an acid hydrogen. This would make structure (a) represent a less probable position for an ester than for an acid so that the former would have a larger moment as shown by the values for the monocarboxylic acid esters in Table III when compared with the value 1.4×10^{-18} for acetic acid. As the energy of rotation about the C—O bond increases with rising temperature, the forces which render one position more probable than another have decreasing influence and a condition is approached in which all positions around the bond are equally probable. This reduction[13] in the probability of a structure approximating to (a) should result in an increase in moment with temperature, a phenomenon which has been observed by Zahn[12] for the

vapor of acetic acid. If the hypothesis just presented is correct, the esters should show a smaller temperature variation than the acids as their distribution about the C—O bond is a more nearly random one than that of the acids. Actually, Zahn, in measurements as yet unpublished, has found no temperature variation of the moment of ethyl acetate in the vapor state, although a variation might be expected in some region of temperature. The reduction of the mean moment because of the fact that all positions around the C—O bond are not equally probable offers a possible explanation of the high value calculated for the ester as compared to that of the ketone on the assumption of the equal probability of all the positions.

Meyer's calculation of the mutual potential energies of the moments in the —COOH group led to values so high that a temperature of 20,000° would have to be reached for fully excited rotation to occur within the group. If this is correct, the temperature variation which is experimentally possible might well be too small to produce a detectable variation in moment. Zahn attributed the change in the moment of acetic acid vapor which he observed between room temperature and 200° to a transition from one state to a higher state of vibration associated with the —OH group. Meyer calculated 3.5×10^{-18} to be the limiting value of the moment approached at the very high temperatures as the energy of rotation overcomes the mutual attraction of the doublets. This value is actually slightly higher than that calculated by Eucken and Meyer for the structure of maximum moment like that represented by (b). Evidently, attempts at exact calculation of the moments and their temperature changes are exceedingly uncertain, but the hypotheses which have been discussed may be used in a qualitative interpretation of experimental results.

The differences between the moments found at 25 and at 50° for the esters in Table III are no greater than the possible experimental errors except in the case of diethyl succinate. It does not appear significant that the three esters of monocarboxylic acids show a decrease in the values found for the moment from 25 to 50°, while the dicarboxylic acid esters generally show an increase. As it has been shown that any change in the moments of the former esters with rising temperature should be an increase and as Zahn has found no change in the moment of ethyl acetate vapor with temperature, the decrease observed in the moments of the fatty acid esters should be accidental, possibly arising from a small error in the calibration of the cell at the higher temperature. The increase in the moments of the other esters is what would be expected from the increased energy of rotation, but the observed change is too small to be significant without further experimental confirmation except in the case of diethyl succinate.

As the marked drop in moment on passing from the formate to the acetate and the slight drop on passing from the acetate to the propionate are analogous to the sharp drop in ionization constant on passing from formic to acetic acid and the smaller drop from acetic to propionic acid, it would appear that there is a slight variation in the polarity of the O—R bond with the nature of the group attached to the carboxyl carbon. Naturally, the change from hydrogen to methyl has a greater effect than that from methyl to ethyl. It may be noted that the moment of ethyl benzoate is 1.8 X 10^{-18},[14] which shows that the phenyl group has no markedly different effect upon the —$COOC_2H_5$. It seems reasonable to assign a value 1.8 × 10^{-18} to the moment of the —$COOC_2H_5$ group when it is attached to a carbon atom, but this moment cannot be treated like that arising from a simple atom or group such as chlorine or nitro because of the effects of the rotation within the group and of the rotation of the group itself. The mean effective moment of the group probably makes an angle with the direction of the bond connecting the group to the rest of the molecule not very different from the tetrahedral angle, but the complexity of the structure arising from rotation and the approximations which would be necessary, render useless an attempt to calculate this angle exactly. If the moment is treated as a fixed moment 1.8 X 10^{-18}, making the tetrahedral angle 110° with the direction of the bond of the group, the moment resulting from the joining of two groups to form diethyl oxalate may be calculated from the simple equation, $\mu = 1.41 \times 1.8 \times 10^{-18} \sin 70° = 2.4 \times 10^{-18}$,[15] in which the effect of the two groups upon each other is disregarded. This value is close to that observed for diethyl oxalate, in which, however, the fields of force of the two groups should so affect one another that some positions in the rotation of the groups about the connecting bond should be much more probable than others. In dimethyl terephthalate, two —$COOCH_3$ groups, which should have moments close to those of the —$COOC_2H_5$, though, perhaps, a little lower, are in para positions on the benzene ring. As the benzene valences lie in the plane of the ring directed out from the center,[16] this means that the two groups are placed relatively to one another just as in the oxalate, except that they are so far separated from one another by the benzene ring that all positions of rotation about the line joining the two carbonyl carbons should be equally probable. The moment found for this molecule,[17] 2.2 X 10^{-18}, differs from the calculated value by little more than the possible experimental error. The moment 2.5 X 10^{-18} found by the same investigators for dimethyl o-phthalate in which the two —$COOCH_3$ are attached to the ring in such a way that the group bonds make an angle of 60° with one another instead of pointing in opposite directions shows that the resultant

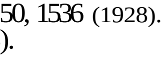
moment of the molecule is increased, but only to a small extent, by the introduction of this angle. This is in marked contrast to the behavior of simple groups, for the moment of *p*-dichlorobenzene is zero, while that of o-dichlorobenzene is 2.25 X 10^{-18}.[18]

In diethyl fumarate the two $—COOC_2H_5$ groups should point in opposite fixed directions and the moment happens to be identical with that calculated for such an arrangement. It must be remembered in considering all of these calculated values that, while, relative to one another, they are significant, absolutely, they can be expected to indicate little more than the order of magnitude. In diethyl maleate the groups make an angle with one another, perhaps acute, and the moment is 0.16×10^{-18} higher than that of the fumarate, the difference resembling qualitatively that between the ortho and para arrangements of similar groups on the benzene ring. That the force fields of the groups affect one another strongly in the cis form is shown by the fact that the first ionization constant of maleic acid is ten times that of fumaric, while the second ionization constant of fumaric is about one hundred times that of maleic. The moment of the maleate is probably influenced by the effects of the two groups upon one another, but, in view of the small differences in moment accompanying great differences in the angles between the groups, the effect of the groups upon one another's rotation about the group bonds should not alter the moment greatly. It is evident also that the moment of the molecule as a whole is little affected by possible effects upon the rotation about bonds within the $—COOC_2H_5$ groups.

The insertion of the $—CH_2—$ between the $—COOC_2H_5$ groups to form the malonate should introduce the tetrahedral angle between them, that is, set them at an angle of 110° to one another and so raise the moment slightly as observed in Table III. When another $—CH_2—$ is introduced to form the succinate, the effect is complicated by rotation about the bond between the $—CH_2—$ groups. However, it is customary to regard a carbon chain as a zig-zag arrangement and Vorländer[19] has found that the tendency to form liquid crystals, which is dependent, to a considerable extent, upon the linearity of the molecules, is greatly reduced by the introduction of a $—CH_2—$ group into the middle of the molecule of a liquid crystalline substance because of the angle thereby produced in the chain of the molecule. When a second $—CH_2—$ group is added, the tendency to form liquid crystals is largely restored, while the addition of a third $—CH_2—$ reduces the tendency once more, etc. The bending of the molecule is obvious if we write the carbon-to-carbon valences in the conventional fashion



---

[18] Smyth, Morgan and Boyce, THIS JOURNAL, 50, 1536 (1928).

[19] Vorländer, *Z. physik. Chem.*, 105,211 (1923).

It would appear that there is a tendency toward such a zig-zag arrangement, but rotation about the bonds in the molecules containing more than one carbon between the $—COOC_2H_5$ groups gives the opportunity for all possible arrangements, of which, perhaps, the zig-zag is the most probable. In considering the moments of the molecules containing the $—COOC_2H_5$ groups on the ends of these chains, one must bear in mind that not only the orientations of the two groups relative to one another, but also the removal of the two groups from one another's influence by the interposition of carbon atoms may affect the resultant moment of the molecule as a whole.

The rise in moment from the oxalate to the malonate is followed by a drop as expected on going to the succinate, but the magnitude of the drop shown in Table III is much greater than would be expected. When the result was first obtained, the presence of an abnormally large experimental error was suspected, but the purity of the material used was checked satisfactorily and additional measurements agreed with the first. It is possible that the apparent farther removal of the $—COOC_2H_5$ groups from one another's influence has some effect, but, if this were the principal cause of the drop, one would expect the moments of the higher members of the series to vary around 2.2×10^{-18} instead of rising again to above 2.4×10^{-18}. Actually, there is reason to believe that, instead of being farther removed from one another, parts, at least, of the $—COOC_2H_5$ groups in the succinate may be particularly close to one another, for the anhydride of succinic acid is formed with ease. Dunstan, Hilditch and Thole[20] found that the molecular viscosities of these esters gave a smooth curve when plotted against molecular weight except for a sharp hump at the value for the succinate, which lay above those for the malonate and the glutarate. This enhancement of the viscosity was attributed to contiguity of the groups at the ends of the carbon chain. It seems probable then that the structure with two carbons between the $—COOC_2H_5$ groups is particularly favorable to those positions of rotation about the bonds in which certain of the doublets are brought close together so as partially to oppose and cancel one another, the mean resultant moment of the molecule being thereby lowered. This idea receives support from the marked rise in moment when the temperature changes from 25 to 50°, for rising temperature, by tending to make all positions equally probable, would increase the moment. It would appear that the succinate is the only one of these esters which may be expected to show much variation of moment with temperature since, in the others, the influences of the $—COOC_2H_5$ groups upon one another have little effect upon the resultant moment of the molecule. It may be mentioned that, in examining the optical activity of the menthyl esters and the brucine salts of the fatty dibasic acids, Hilditch[21] found

---

[20] Dunstan, Hilditch and Thole, *J. Chem Soc.*, **103, 133** (1913).

[21] Hilditch, *ibid.*, 95, 1678 (1909).

an exceptionally large temperature coefficient for the rotatory power of dibrucine succinate. The temperature variation of the moments of these substances is being further investigated.

The moment of the glutarate should be approximately the same as that of the malonate if the zig-zag structure of the carbon chain and the consequent angle between the $—COOC_2H_5$ groups were maintained, but rotation about the bonds of the chain tends to destroy this arrangement and lower the mean moment. Because of this rotation and flexibility of the chain, the effect of an added carbon atom diminishes with increasing length of the chain. In fact, the fourth carbon added in going from the glutarate to the adipate has no observed effect. If, therefore, the chain does not bend around upon itself with increasing length to form something like a loose ring structure because of the attraction of the $—COOC_2H_5$ dipoles for one another, and if it is not so flexible as to bend in the electric field used in the measurement of the dielectric constant and so give partially independent orientation of the two ends of the molecule in the field, the value found for the moment should show little change with increasing length of the chain. The small apparent increase in moment from the adipate to the sebacate might be attributed in part to the neglected P_A of the four added $—CH_2—$ groups and in part to the effects just mentioned, but the absence of further change when the chain is lengthened by eight more $—CH_2—$ groups indicates that these effects must be very small. Indeed, if the atomic polarization, P_A, of the eight $—CH_2—$ groups were equal to that of octane,[22] 0.78, it would increase the apparent value of the moment by less than 0.01×10^{-18}. Although it has been shown that the orientation of the $—COOC_2H_5$ groups relative to one another does not have a large effect upon the moment of the molecule, the identity of the moment of the very long molecule of the diethyl ester of hexadecamethylenedicarboxylic acid with that of the shorter molecule of the sebacate and the closeness of this value to those for the relatively short molecules would seem to indicate that the long chains do not bend around upon themselves to form ring structures. It would further appear that the extended chains of the long molecules are not so flexible as to bend in the external fields applied in the measurements.

Summary

The dielectric constants and densities of the ethyl esters of a number of mono- and dicarboxylic acids have been measured in benzene solution and have been used, together with the refractions determined for the pure substances, to calculate the electric moments of the molecules. The ethyl esters of the monobasic fatty acids show a slight decrease in moment with increase in the size of the molecule analogous to the decrease in ionization constant.

---

[22] Dornte and Smyth, THIS JOURNAL, 52, 3546 (1930).

Because of rotation around the bonds the relative positions of the $—COOC_2H_5$ groups in the molecule do not have large effects upon the moment.

The absence of marked difference in moment between the long and the short-chain esters is regarded as indicating that the long-chain molecules have extended structures, which do not bend appreciably in small external electric fields.

THE RAPID COLORIMETRIC ESTIMATION OF POTASSIUM

BY EARLE R. CALEY

RECEIVED DECEMBER 4, 1930 PUBLISHED FEBRUARY 9, 1931

Some months ago the writer published a paper[1] setting forth the merits and demerits of the picric acid test for potassium from a qualitative point of view. Further experiments have since demonstrated that this reaction may be utilized for the colorimetric estimation of small amounts of potassium by separating the precipitated potassium picrate, dissolving it in water, and using the intensely-colored yellow solution thus obtained for the determination of the element.

Factors Influencing the Quantitative Precipitation of Potassium as Picrate by Alcoholic Solutions of Picric Acid.—In addition to the marked influence of the ratio of the volume of the reagent to that of the potassium solution on the sensitivity of the reaction, noted in the previous paper, it was found that the temperature during precipitation was of importance from the quantitative standpoint. In the accompanying graph are shown the results of several experiments (Fig. 1) in which the amount of potassium picrate precipitated at various room temperatures is compared colorimetrically with that precipitated at 20°. This effect is apparently due to the rapid increase in the solubility of the precipitate with rise in temperature. It is evident that for comparative quantitative results in any colorimetric method involving this reaction the potassium, in a single series of experiments where standards and samples are prepared for matching, they must be precipitated under like temperature conditions or, better, a definite temperature must be established for all precipitations. It is apparent from the graph that for the sake of greater completeness of precipitation this temperature should be nearer the lower limits of room temperature rather than the higher. A temperature of 20° was found to be satisfactory. Temperatures much below this, while resulting in the more complete precipitation of the potassium, are not satisfactory due to the precipitation of the picric acid from the reagent saturated at room temperature and to

---

[1] Caley, THIS JOURNAL, 52, 953 (1930).

increased interference from sodium. The influence of agitation and time of standing on completeness of precipitation were also studied. It was found that a forty-five-minute period of standing with occasional stirring was adequate in all cases providing the solution was stirred sufficiently at the beginning to start the separation of the precipitate when dealing with amounts of potassium near the lower limit of precipitation.

Experiments on Methods of Collecting and Washing the Precipitated Potassium Picrate.—The nature of the reagent introduced certain difficulties in the way of sharply separating the precipitate from the excess of reagent. Due to the direct dyeing action of picric acid, filtering mediums containing minute pores, such as filter paper and even asbestos, were found to be unsuitable. A number of experiments demonstrated that it was extremely difficult completely to wash out the picric acid from such filters, with any liquids suitable for this purpose, without applying an excessive number of washings, and yet on the subsequent dissolution of the precipitate in water variable amounts of the remaining picric acid went into solution, thus introducing sensible errors in the colorimetric comparison. It was found, however, that the use of a medium-porosity, sintered-glass filtering funnel or crucible permitted the sharp separation of the precipitate and excess reagent with ease. The picric acid is apparently not adsorbed in such glass filters and is readily removed with a few washings. Several washing mediums were tried, such as 95% alcohol, 95% alcohol saturated with potassium picrate and ethyl ether. It was found that the latter was the most satisfactory of these due to the ready solubility of picric acid and the high insolubility of potassium picrate in this liquid.

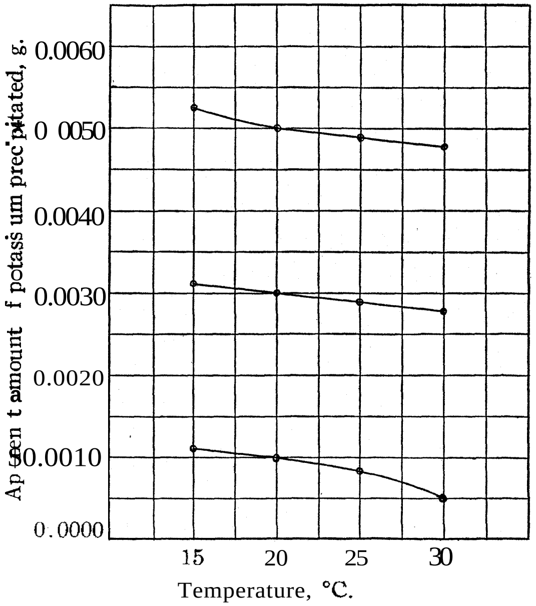

Fig. 1.—Showing the effect of temperature on completeness of precipitation in the reaction between potassium chloride solutions and saturated alcoholic solutions of picric acid.

Accuracy Obtainable in the Colorimetric Comparison of Potassium Picrate Solutions.—In order to ascertain the observational error inherent in matching solutions of potassium picrate, experiments were performed in which the same solution was divided and comparison made between the two parts in a plunger type colorimeter. The following table gives the results obtained with solutions of different concentration and shows the average values of the pairs of colorimeter readings after two, five and ten successive observations.

TABLE I

OBSERVATIONAL ERRORS IN THE COMPARISON OF IDENTICAL POTASSIUM PICRATE SOLUTIONS

Concn. of potassium, g./cc.	Averages of readings after two comparisons, mm.	Errors, %	Averages of readings after five comparisons, mm.	Errors, %	Averages of readings after ten comparisons, mm.	Errors, %
0.00002	L 29.0		L 28.2		L 28.9	
	R 28.2	2.8	R 27.9	1.1	R 28.6	1.0
.00010	L 10.7		L 12.1		L 11.1	
	R 10.6	0.9	R 12.0	0.8	R 11.1	0.0
.00020	L 11.1		L 9.9		L 9.4	
	R 10.4	6.3	R 9.7	2.0	R 9.5	1.1

From the above results it is evident that solutions of the concentrations shown may be balanced colorimetrically with an error of not more than about 1% providing at least ten separate observations are made and the results of these averaged. Solutions of potassium picrate much outside the range of concentration shown in the above table cannot be matched with this degree of accuracy. For amounts of potassium from one to ten milligrams the above experiments also indicated that a solution of the corresponding amounts of potassium picrate in fifty cubic centimeters of water would yield solutions of proper concentration for accurate matching. The best conditions for matching such solutions appear to be reached when depths of solution are used that show a strong straw color and when a strong white light is used as the source of illumination.

Recommended Procedure.—On the basis of the experiments outlined above the following method was evolved.

Procedure

Evaporate the solution, containing the potassium *as* the chloride, to dryness on the steam-bath in a 25-cc. beaker. Dissolve the residue in 1.00 cc. of water and add, with stirring, 7.5 cc. of a saturated solution of pure picric acid in 95% alcohol. Place the beaker in a dish containing water at 20° to maintain a definite temperature during precipitation and, if necessary, stir the solution until a precipitate starts to form. Let the mixture stand for forty to forty-five minutes and stir at five-minute intervals in order to promote complete precipitation. Filter off the separated potassium picrate in a medium-porosity, sintered-glass filtering funnel or crucible and, after the excess reagent has passed through the filter, transfer the small portion of precipitate remaining in the beaker to the filter by washing out with small portions of ether. Wash the precipitate with successive 1–2 cc. portions of ether until the washings are colorless and no trace of yellow color due to picric acid can be seen in the sintered glass disk or on any part of the filtering crucible or funnel. Usually five to ten washings will be required. Free the precipitate from ether by continuing the suction for about one-half minute after completing the washing and then dissolve the precipitate in successive small portions of water, catching the resulting solution in a 50-cc. volumetric flask. After mixing, compare the yellow solution with a standard potassium picrate solution representing approximately the same amount of potassium. The standards are prepared from a potassium chloride solution of known value by means of the above procedure. A convenient solution for this purpose is one containing 1.907 g. of pure potassium chloride per liter, 1.0 cc. of which represents 0.0010 g. of potassium.

Results Obtained with Known Amounts of Pure Potassium Chloride.—The comparison of samples and standards prepared by the above procedure was found to give satisfactory results in all cases when the amount of potassium present, in the sample and standard compared, was identical or nearly so, as the results in Table II show, while on comparing samples with standards containing different amounts of potassium the results were

	.0050	12.1	24.3	.0050	.0000

This divergence can be attributed to the fact that, due to solubility, a certain constant amount of potassium picrate remains unprecipitated, an effect that yields disproportionate variations in comparing samples containing the lower amounts of potassium with standards containing considerably higher amounts and *vice versa.* This source of error can be obviated entirely by making comparisons only between samples and standards containing approximately the same amounts of potassium as recommended in the procedure. In practice it was found that the use of a series of standards containing 0.0010, 0.0012, 0.0015, 0.0020, 0.0025, 0.0030, 0.0050 and 0.0100 g. eliminates this source of error and gives results on all amounts of potassium within this range as satisfactory as those shown in Table II, especially if care is taken to compare a given sample with the higher standard in cases where the sample is found to lie between two standards in the above series. Such a series of standards appears to be quite permanent, even over a period of a year, if care is taken to guard against loss by evaporation. This method is not suitable for the determination of amounts of potassium much greater than 0.0100 g., due to the increased difficulty in matching such intensely-colored solutions, nor is it suitable for amounts below 0.0010 g. by reason of the fact that precipitation of amounts below 0.0006 to 0.0007 g. does not occur with the volumes of test solution and reagent given in the procedure. By reducing these latter volumes in proportion, amounts below 0.0010 g. can be estimated but this modification is not advisable due to increased manipulative difficulties and to increased interference from sodium.

Effect of the Presence of Other Substances.—As pointed out in the previous paper[1] the potassium and other metals can be present only as chlorides by reason of the nature of the reagent. Sulfates can be transposed in the usual way by means of barium chloride. Small amounts of insoluble substances such as dehydrated silica and barium sulfate do not interfere. The influence of sodium and other metals likely to be associated with potassium is shown in Table IV. Experiments with ammonium, rubidium and cesium are not included in the table since these behave in practically the same manner as potassium. Such interference is not im-

portant, however, since ammonium is readily removed and rubidium and cesium are so rarely met with in weighable quantities. The interference from sodium is more serious and restricts the method to the examination of samples or residues weighing not more than twenty milligrams in cases where the sodium content is entirely unknown. Where the sodium content is approximately known, larger samples may, in many cases, be used. The other common metals usually associated with potassium apparently do not interfere even when present in larger amounts than shown in the typical experiments recorded in the table. This method is more particularly suitable for the rapid estimation of potassium in small residues of alkali and alkaline earth salts and is convenient where a series of determinations is to be made.

Summary

There has been described a rapid method for the colorimetric estimation of potassium depending upon its precipitation as potassium picrate by an alcoholic solution of picric acid with the subsequent solution of the separated precipitate in water, yielding a highly-colored solution suitable for colorimetric comparison with standard solutions prepared in a like manner from known amounts of potassium.

ELECTRIC MOMENT AND MOLECULAR STRUCTURE. II. TERTIARY BUTYL AND TRIPHENYLMETHYL CHLORIDES AND ALCOHOLS

BY C. P. SMYTH AND R. W. DORNTE

RECEIVED DECEMBER 6, 1930 PUBLISHED FEBRUARY 9, 1931

In an earlier paper[1] it has been shown that the relation between electric moment and chemical behavior is usually slight, but it has seemed desirable to pursue the investigation further for the case of a few closely related groups of markedly different chemical behavior. For this purpose, the n-butyl, *tert.*-butyl, and triphenylmethyl groups seemed particularly suitable. The n-butyl alcohol[2] and chloride[3] having already been investigated, the corresponding *tert.*-butyl and triphenylmethyl compounds were measured. While the determinations were being made, Parts[4] published values for the moments of the primary, secondary and tertiary butyl halides, which will be used in the subsequent discussion. It was hoped that the polariza-

tion–concentration curves obtained in the measurements would give qualitative information concerning the effects of the shapes of the groups upon the action of the molecular fields of force.

Preparation of Materials

Heptane and benzene were obtained as in previous work.[3]

***Tert.*-butyl** Chloride.—The material was prepared by Mr. George Rigby working with Professor James F. Norris at the Massachusetts Institute of Technology. It was made from a good grade of *tert.*-butyl alcohol by the action of concentrated hydrochloric acid, washed with a dilute solution of sodium bicarbonate and then with water, distilled and fractionated twice. The part boiling at 50.7° was shaken with anhydrous potassium carbonate for six hours and fractionated twice. After standing for twelve hours with phosphorus pentoxide, it was distilled, treated again with phosphorus pentoxide and redistilled; b. p. 50.7° with a maximum range of 0.05"; n^{20}_{D} 1.38528.

***Tert.*-butyl** Alcohol.—Material given us by Dr. H. B. Glass of Johns Hopkins University was redistilled, as it had stood for some time; b. p. 82.6–82.8°; n^{20}_{D} 1.38777.

Triphenylchloromethane.—Material obtained from the Eastman Kodak Company was twice recrystallized from carefully dried benzene and washed thoroughly with ether; m. p. 111".

Triphenylcarbinol.—Material prepared by Dr. R. H. Smith working with Professor Donald H. Andrews of Johns Hopkins University was loaned to us; m. p. 162°.

Method of Determination

The dielectric constants, ϵ, and densities, d, were measured with the apparatus used in previous work,[5] the former being determined at a wave length of 600 meters. The determinations were made at fixed temperatures with 10° intervals in the case of the *tert.*-butyl chloride and 20° intervals for the other substances. The polarizations, P_2, of the polar components of the solutions were calculated by means of the equations

$$P_{12} = \frac{\epsilon - 1}{\epsilon + 2}\,\frac{c_1M_1 + c_2M_2}{d} \quad \text{and} \quad P_2 = \frac{P_{12} - P_1}{c_2} + P_1$$

in which P_{12} is the polarization of the mixture, and c_1 and c_2, M_1 and M_2 and P_1 and P_2 are, respectively, the mole fractions, molecular weights and polarizations of the individual components. The values of P_2 have been plotted against those of c_2 (see Fig. 1 and Fig. 2) and extrapolated to $c_2 = 0$ to obtain the values of P designated as P_∞. The values of P_∞ when plotted against $1/T$ should give a straight line, as required by the Debye equation, $P = a + b/T$, in which $a = P_E + P_A$, the sum of the electronic polarization, P_E, and the atomic, P_A, and $b = 4\pi N\mu^2/9k$, N being the Avogadro number, 6.061×10^{23}, μ, the electric moment, and k, the molecular gas constant, 1.372×10^{-16}. In the case of *tert.*-butyl chloride, the intercept and slope of this straight line give values of a and b, from which the moment is calculated. However, the solutions of *tert.*-butyl alcohol in heptane, like those of the normal alcohol previously investigated,[2] are so strongly affected by association that the values obtained for P_∞ are not those for

---

[5] Smyth, Morgan and Boyce, THIS JOURNAL, 50, 1536 (1928); Smyth and Morgan, *ibid.*, 50, 1547 (1928); Dornte and Smyth, *ibid.*, 52, 3546 (1930).

molecules oriented at random and actually increase sharply with rising temperature instead of decreasing. As these values could not be used to determine the moment, the alcohol was also run in benzene solution, in which the effect of association was reduced. Because of their low solubility in heptane, the triphenylmethyl compounds also were measured in benzene solution. Unfortunately, the shorter temperature range within which benzene is liquid renders the location of the $P_\infty - 1/T$ curves inaccurate for these solutions. It has seemed best, therefore, to disregard P_A for these substances and use for P_E the molar refraction for the sodium D line, MR_D, which is slightly higher than P_E, a fact which partially compensates for the neglect of P_A. In the alcohol values, at any rate, the error caused by the effect of molecular association is greater than the small error due to neglect of P_A. Instead of using the constant $(P_\infty - a)T = b$ for the calculation of the moment as in the case of *tert.*-butyl chloride, we obtain an approximately constant value for the quantity $(P_\infty - MR_D)T$, calculate the moment from the value at each temperature by means of the relation $\mu = 0.0127 \times 10^{-18} \sqrt{(P_\infty - MR_D)T}$, which follows from the preceding equation, and take the mean of the values obtained.

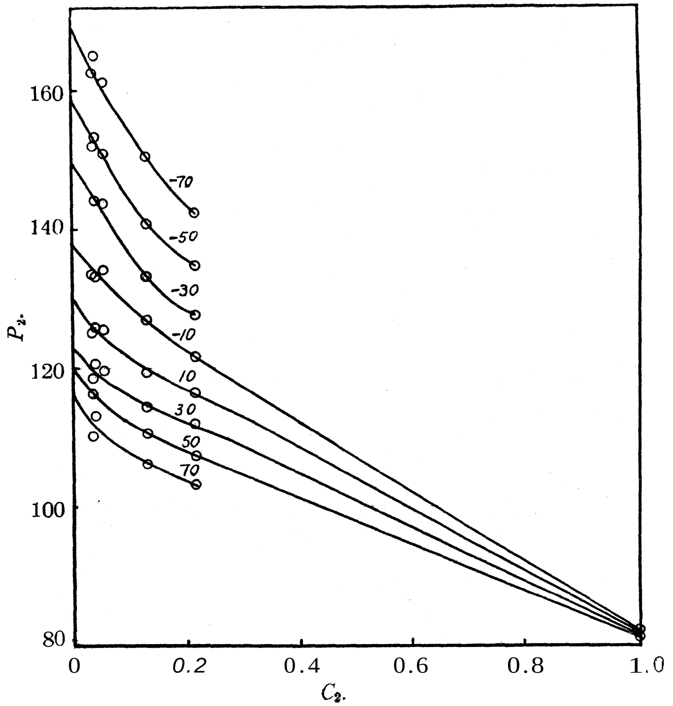

Fig. 1.—Polarizations (P_2) of *tert.*-butyl chloride in solution in heptane.

The experimental results and the values calculated from them are shown in Tables I and II. For the sake of brevity, half of the values obtained for *tert.*-butyl chloride are omitted, the data being given at 20° intervals only.

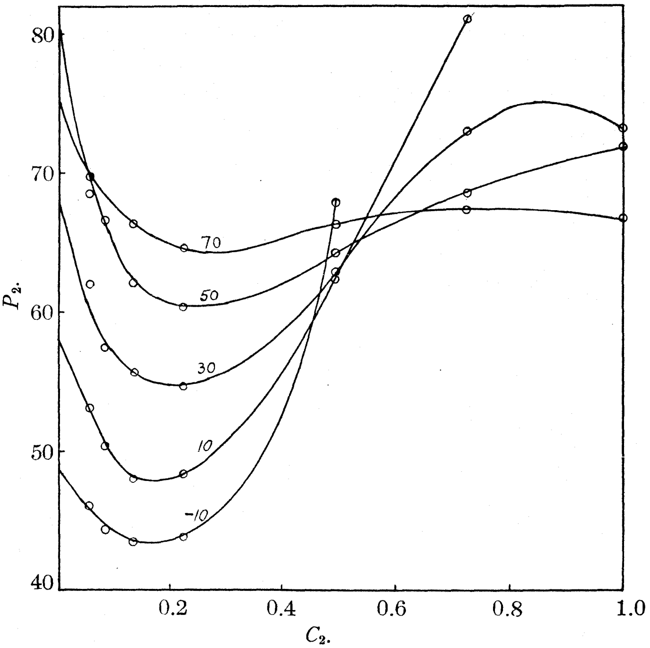

Fig. 2.—Polarizations (P_2) of *tert.*-butyl alcohol in solution in heptane.

Table III gives what appear to be the best values of the moments. The values for MR_D given in Table II are calculated from our measurements of the refractive indices of the pure liquids or of the substances in solution. The value of P_E for *tert.*-butyl chloride was obtained by extrapolation to infinite wave length.

Discussion of Results

The variation of P_2 for *tert.*-butyl chloride with temperature and concentration is very similar to that of the normal chloride. A 70° rise in temperature lowers the polarization of the pure liquid by only 1.2 in the case of both substances. The values of P_2 for the tertiary chloride are somewhat higher than those for the normal because of the higher moment and the P_2–c_2 curves (Fig. 1) are similar in shape to those for the normal,[3] but slightly steeper, the difference being that which the slightly higher moment should cause. In the study of the alkyl halides just referred to, it was found that there was a slight decrease in the slope of the P_2–c_2 curves in going from ethyl to n-butyl to n-heptyl bromide, although the moments of the three substances were the same This decrease was presumably due to the decrease in the effects of the molecular dipoles upon one another because of the increased screening effects of the larger alkyl groups. It had been thought that the branching of the carbon chain might give increased screening effect, but there is no evidence of such increase in the P_2–c_2 curves for *tert.*-butyl chloride.

The behavior of the alcohols resembles that of the chlorides in that the P_2–c_2 curves for the *tert.*-butyl compound in heptane (Fig. 2) are like those for the *n*-butyl,[2] showing the same peculiar maximum, which flattens with rising temperature, but a more pronounced minimum, also flattening with rising temperature. Intermolecular action is so strong that the apparent values obtained for P_∞ below 50°, not given in Table II, increase with rising temperature instead of decreasing as required by the Debye equation. At 50 and 70° the values of P_∞ agree satisfactorily with those obtained from the benzene solutions, which, as in the case of the benzene solutions of the normal alcohol, conform approximately to the Debye equation. The polarization of the tertiary alcohol at 20°, 75.4, is close to that of the normal compound, 77.3, at the same temperature, but the decrease for the tertiary compound with rising temperature is greater. The small differences in behavior must be due to the difference in the shapes of the carbon chains in the two molecules as the moments are the same. The general similarity in behavior is in accord with the conclusion of Stewart from the x-ray diffractions[6] that when the hydroxyl group is on the first or second carbon of the chain, the molecular arrangement is the same in different alcohols and different from what it is if the hydroxyl group is

---

[6] Stewart and Skinner, *Phys. Rev.*, 31, 1 (1928); Stewart, *Chem. Rev.*, 6, 483 (1929); Stewart, *Phys. Rev.*, 35, 726 (1930).

elsewhere. This is borne out by the measurements of Smyth and Stoops,[7] which showed that ethyl, n-butyl, and n-octyl alcohols were similar in behavior while 2-methylheptanol-3 gave P_2–c_2 curves very different in form. The mere assumption that the molecules lie end to end with the OH groups paired when the OH is on the first or second carbon and side by side when it is otherwise located is sufficient to explain the x-ray diffractions but insufficient to explain the dielectric behavior. The complex and unsatisfactory situation in regard to the latter has been discussed in other papers.[8]

The limited solubility of the triphenylmethyl compounds has made it impossible to run P_2–c_2 curves over a sufficient range to warrant their reproduction. However, the values in Table I show that the rates of change of the polarizations of triphenylchloromethane and triphenylcarbinol with concentration are lower than those of the *tert.*-butyl and *n*-butyl compounds, the intermolecular action being less. In other words, the screening effect of the large phenyl groups reduces the action of the molecular dipoles upon one another.

In Table III, 1.90×10^{-18} is given for the moment of n-butyl chloride as the weighted mean of the value 1.88×10^{-18} determined by Smyth and Rogers[3] and 1.97×10^{-18} obtained by Parts,[4] greater weight being attached to the former value because it was. obtained from measurements over a wide range of temperature in which P_A was determined. The value for *tert.*-butyl chloride, 2.14×10^{-18}, is in excellent agreement with the value 2.15×10^{-18} found by Parts. The value 1.65×10^{-18} assigned to n-butyl alcohol is the result of the accurate measurements of Miles upon the vapor [2] It is lower than the value 1.74×10^{-18} obtained from the measurements in benzene previously referred to, which is almost identical with the mean of the values given for the tertiary alcohol in Table II. Because of the agreement of this mean value, 1.75×10^{-18}, with the apparently too high value found for the normal alcohol in solution, and because of the tendency of the values to decrease with increasing temperature, which suggests the possible presence of a small error due to association at the lower temperatures, the value 1.65 is assigned to *tert.*-butyl alcohol. The values for the triphenylmethyl compounds are the means of the values at the different temperatures in Table II, which are in satisfactory agreement with one another.

The difference between the moments of n-butyl chloride and *tert.*-butyl chloride is interesting in view of the theory of induced moments which has been applied[1,3,8] to the alkyl halides. It was shown that the principal doublet in the molecule of a normal alkyl halide exerted an inductive effect upon the carbon chain sufficient to cause a small but appreciable moment in the second carbon of the chain, the moment of the ethyl halide being,

---

[7] Smyth and Stoops, THIS JOURNAL, 51, **3330** (1929).

[8] Smyth and Stoops, Refs. 2 and 7; Smyth, ***Chem. Rev.*, 6,** 549 (1929).

as a result, higher than that of the methyl. As lengthening of the chain beyond ethyl did not increase the moment of the molecule, it was concluded that the inductive effect of the principal halide doublet was not sufficient to produce a detectable moment at a distance greater than that of the second carbon atom. In n-butyl chloride, then, only the first and second carbons have sufficient moments induced in them to contribute appreciably to the total moment of the molecule, but, in *tert.*-butyl chloride, there are three carbons approximately at the distance of the second carbon in the normal compound. The small moments induced in each of these three carbons should contribute appreciably to the total moment, which should thus be greater than that of n-butyl chloride. The same should, of course, hold for the bromides and iodides, and this is evident in the values found by Parts, the moments of the tertiary compounds being considerably higher than those of the normal. In the *sec.*-butyl halides, the two carbons next to the first should be affected by the principal doublet so that the total moment should be larger than that of the n-butyl halide and smaller than that of the tertiary. The actual values found by Parts for the *sec.*-butyl halides are between those for the normal and those for the tertiary. In the isobutyl halides the branching of the chain is two carbons away from the principal doublet, so that only two carbons are appreciably affected by the principal doublet just as in the case of the normal compounds. The identical values found by Parts for the n-butyl and the isobutyl compounds are, therefore, to be expected. This view of the effect of induction receives support from the moments found for the heptyl halides by Errera and Sherrill.[9] When the halogen in a heptyl halide is moved from the end of the chain to the second carbon, to which two other carbons are, of course, attached, the moment rises because both of these carbons are now affected by induction. However, moving the halogen farther along the chain to give the 3- or 4-halogenated heptane produces no more effect because the carbons beyond the first two from the halogen in each direction are not affected sufficiently to contribute to the moment.

The absence of an appreciable difference between the moments of n-butyl and *tert.*-butyl alcohols is consistent with the moments of the other alcohols, as there is no significant difference between the values of methyl and ethyl alcohol or of the higher normal alcohols. The moment of the alcohol molecule is the resultant of the moment in the neighborhood of the C–O bond and that in the neighborhood of the H–O bond and this resultant makes a considerable angle with the general direction of the carbon chain,[10] which may account for the absence of inductive effect along the chain. In any event, in the absence of a difference between methyl and ethyl alco-

---

[10] See Eucken and Meyer, *Physik. Z.*, 30, 397 (1928).

hols, one would not expect the attachment of an increased number of carbons to the first to make much difference in the moment.

The moments found for the triphenylmethyl compounds are difficult to explain. The difference between n-butyl chloride and triphenylchloromethane is too small to be significant. The three benzene carbons attached to the first carbon of the latter compound appear to be less affected by the principal doublet than the three aliphatic carbons in *tert.*-butyl chloride. This is in harmony with the fact that the moment of chlorobenzene, 1.52 × 10^{-18},[5] is lower than those of the higher normal alkyl chlorides. However, this does not account for the high moment of triphenylcarbinol. This might be explained by supposing that the electropositive character of the triphenylmethyl group increases the moment at the C–O bond and thereby increases the total resultant moment. If, however, this is true, why is not the moment at the C–Cl bond increased so as to give triphenylchloromethane a moment higher than that of *tert.*-butyl chloride? The question may be complicated by the existence of the supposed benzenoid and quinonoid structures in the triphenylmethyl compounds, but this tautomerism does not appear to offer any satisfactory explanation of the observed differences.

As before,[1] we thus see very little relation between electric moment and chemical activity. The chemical behavior of n-butyl and *tert.*-butyl compounds, which should depend to a considerable extent upon the nature of the group bond, is markedly different in the two classes of compounds, but the moments of the two alcohols are the same and it is probable that the moments associated with the group bonds in the chlorides are the same, the differences in total moment being due to differences within the groups. The very different triphenylmethyl radical gives no indication of a very different moment associated with the group bond in the chloride, although the high moment of the triphenylcarbinol suggests a difference in the alcohol. The moments of the normal and tertiary butyl compounds can evidently be explained in terms of spatial considerations and induction. It must be remembered that we do not know the cause of the small moment of toluene or of the differences between the moments of the monohalogenated benzenes and the alkyl halides, although they seem quite natural and to be expected. It is not surprising, therefore, that the differences between the triphenylmethyl and the alkyl compounds do not as yet lend themselves to explanation. It may be concluded, however, that the triphenylmethyl compounds show no radical differences in moment corresponding to their different chemical behavior.

Summary

The dielectric constants and densities of solutions of *tert.*-butyl and triphenylmethyl chlorides and alcohols in heptane or benzene have been determined over varying ranges of temperature, and the data have been

used to calculate the polarizations of the substances and the electric moments of their molecules.

The polarizations show that the branched carbon chain of the *tert.*-butyl group has no measurably greater screening effect upon the force field of the dipole than the straight chain of the n-butyl group, while the larger triphenylmethyl group has a greater screening effect.

A theory of induced moments has been applied to explain the values here obtained, together with those of other investigators of alkyl halides. The moments of the molecules increase from the normal to the secondary to the tertiary compound because of the increase in the number of carbon atoms subjected to the inductive influence of the principal dipole, while the moment of the iso compound is the same as that of the normal if the branch in the chain is at least two carbons away from the halogen because only these two carbons are measurably affected by the principal dipole.

As previously observed, the moments do not show differences corresponding to the differences in chemical behavior.

DIFFERENTIAL POTENTIOMETRIC TITRATION.
IV. (a) AN ADAPTATION OF THE METHOD TO THE USE OF HYDROGEN ELECTRODES.
(b) A TEST OF STANDARDS FOR PRECISE ACIDIMETRY

BY DUNCAN A. MACINNES AND IRVING A. COWPERTHWAITE

RECEIVED DECEMBER 6, 1930 PUBLISHED FEBRUARY 9, 1931

In the third paper of this series[1] an improved apparatus for differential potentiometric titrations, involving a simple gas lift pump, was described, and data were given showing the usefulness of the method for measurements of high precision. We are, however, in this Laboratory, much interested in solutions of acids. Until recently our measurements on conductances, transference numbers, etc., have been hampered by the lack of precise (0.01% or better) methods for acidimetry. This has been especially true with regard to solutions of weak acids. Our attempts to use the quinhydrone electrode for acidimetry were not successful. This was probably due to the rapid oxidation of this substance as soon as the solutions approach the neutral point. An effort was also made to get the desired accuracy by means of indicators, using color standards, without greater success. Either of these methods might, with further investigation, have been developed to give adequate precision. It was, however,

---

[1] The papers already published in this series are (a) MacInnes and Jones, THIS JOURNAL, 48, 2831 (1926); (b) MacInnes, *Z. physik.* Chem. (Cohen Festband), 217 (1927); (c) MacInnes and Dole, THIS JOURNAL, 51, 1119 (1929).

decided to adapt the differential potentiometric method to the use of hydrogen electrodes. With such electrodes the results are more nearly unambiguous than when some indicating substance is added, since no allowance need be made for such an addition.

The Apparatus

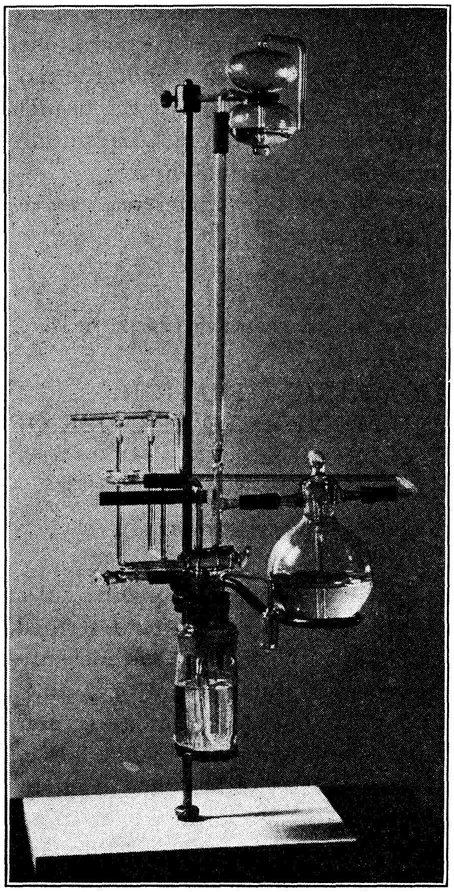

Fig. 1.

The apparatus now in use utilizes the gas lift pump described in a previous paper,[1] operated by a stream of hydrogen. It was found in our early tests that for correct results when using hydrogen electrodes two conditions are essential. First, the apparatus must exclude oxygen during the titration, and, second, no dissolved oxygen should be added with the titrating fluid. The apparatus as finally developed is shown in Fig. 1 and a diagrammatic sketch of the principal parts in Fig. 2. The solution to be titrated is placed in the vessel represented by A, of the latter figure. This is of about 150 cc. capacity. It is closed by a ground-glass joint a-a, into which fits a glass cover containing three openings shaped to hold rubber stoppers. These three openings are at the angles of a triangle in the actual apparatus instead of being in a line as shown. The two hydrogen electrodes E and E' are mounted in a single rubber stopper which is inserted into one of the holes in the cover. One of these electrodes, E', enters the tube G of the gas lift pump L. This pump is operated by a stream of hydrogen gas which flows through the tube h_2, which enters through a stopper in the second hole in the cover. The other hydrogen electrode, E, is in the body of the solution in the vessel A. The solution is stirred, and at the same time saturated with hydrogen, by a stream of that gas through the tube h_1 which, in the actual apparatus, reaches to the bottom of the vessel A. The tip of the buret B and the gas exit tube leading to the trap T pass through the third rubber stopper. In operation pure hydrogen gas is passed through tubes h_1 and h_2 until no difference in potential is observed between the electrodes E and E'.[2] Under these conditions

---

[2] In order to cause hydrogen to flow from more than one outlet at the same time about 20 cm. of 0.5 mm. capillary tubing are inserted in the lines h_1, h_2 and h_3. This tubing can be seen in Fig. 1. Without this tubing bubbles will appear at only one place unless the gas pressure is very high.

both electrodes are saturated with hydrogen, and the solution in the tube G is uniform with that in the body of the solution due to circulation through this tube caused by the gas lift pump L. Now if the stopcock S is given a turn of about 45° this gas stream is stopped, causing an isolation of the solution in the tube G from the body of the solution. A further turn of the stopcock S causes the titrating fluid to flow into the solution from the tip of the buret B. On turning the stopcock back far enough to stop the flow of fluid, but not far enough to start the gas, a potential ΔE will exist between the electrodes E and E'. This potential is due to the concentration difference between the solution in the tube G and that in the body of the solution.

As already stated it has been found necessary to have all the oxygen removed from the titrating fluid. In fact, the addition of one or two drops of an oxygen-bearing solution from the buret B, after the electrodes are saturated with hydrogen, causes a very large and rapidly changing potential to develop between E and E', quite obscuring the potentials due to hydrogen and hydrogen ions. Oxygen is kept out of the titrating solution as follows. The titrating fluid (a solution of a base in these experiments) is placed in the special flask, F. This type of flask was described in a previous paper.[1e] With the head H turned in the direction indicated, a stream of hydrogen through tube h_3 will bubble through the liquid, displacing the oxygen in the solution in the flask and saturating it with hydrogen. From the flask the gas passes through the buret B and out of the special trap R. This is designed so that the first few cubic centimeters of the gas force the water in the lower bulb into the upper one, after which the gas bubbles through the tube J. After the air is sufficiently removed from the system, the buret may be filled from the flask by turning the head H in the reverse direction to that shown in the diagram, allowing the gas to flow through h_3. The flow of gas and fluid may then be stopped by turning the head H through 90°. If the fluid is now run into the vessel A from the buret tip B, the volume of titrating fluid is replaced by hydrogen from the trap R. It is usually necessary to sweep gas out of the tip of the buret B and to reject some titrating fluid in order to start the buret reading at a convenient point. This rejected liquid is prevented from entering the solution in the vessel A by swinging the bent tube M under the buret tip by means of the trap T to which it is attached. In this position the rejected fluid will be forced by the gas stream from tube h_1 into the trap. The tube M may then be swung out of the way of the fluid from the buret.

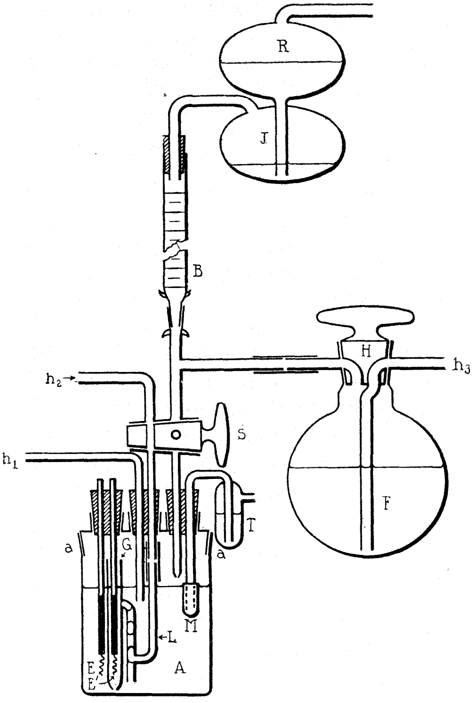

Fig. 2.

The Electrodes.—At first sight it would appear likely that, since the two electrodes are exposed to the solution under very nearly the same conditions, the readings should be independent of the purity of the hydrogen gas, because the effect of impurities, for example oxygen, would be expected to be about the same on both electrodes. Quite the contrary was found to be true. We have found it necessary to bring the hydrogen to a very high purity before the two electrodes will have the same potential with the circulating pump operating so that both electrodes are bathed with the same solution. Ordinary tank hydrogen gave differences of potential between 5 and 50 millivolts. These conditions were but slightly improved, and occasionally were made worse by passing the gas through alkaline pyrogallol. After passing over a nickel catalyst prepared as described by Latimer, Buffington and Hoenschel[3] and which, according to these authors, leaves less than 0.01% of oxygen in the gas, a difference of several millivolts between the electrodes persisted. A hot wire filament, as recommended by Lewis, Brighton and Sebastian,[4] had no perceptible effect. However, by using a reduced copper catalyst, at a relatively high temperature (650 to 700°), the two electrodes will show a zero difference of potential. The copper catalyzer used consisted of reduced copper oxide, in wire form, filling 20 cm. of a quartz tube of about 2.5 cm. diameter. To prevent channeling of this material, plugs of copper gauze were placed at the ends and at intervals in the catalyst. In order to keep out oxygen it was found necessary to avoid rubber tubing as far as possible, as the behavior of the electrodes gave definite evidence of the effect of the diffusion of oxygen through it. Such rubber connections as were unavoidable were made "glass to glass" with thick rubber tubing, impregnated with a paraffin–vaseline mixture.

The explanation of this surprising effect of very small amounts of oxygen in the hydrogen in preventing the two hydrogen electrodes from reaching the same potential is almost certainly as follows. The platinizing on the electrode tends to remove the last traces of oxygen by catalyzing its reaction with hydrogen. However, the electrode in the body of the solution in the vessel A of Fig. 2 is bathed by a constantly changing solution which is supplied with traces of oxygen from the tube h_1, and the electrode is therefore not permitted to come to equilibrium. The electrode in the tube *G*, on the other hand, is furnished with a relatively small portion of the solution which flows over it slowly. The catalysis of the reaction of the hydrogen with the oxygen has thus the opportunity to proceed further and the electrode thus reaches a potential nearer to the true equilibrium value than is possible with the electrode in the body of the solution.

The observations just described on the effect of traces of oxygen on the potentials at the electrodes appear to be important as they indicate clearly that as ordinarily used a platinized platinum electrode has, in addition to its generally recognized function of bringing the reaction between hydrogen gas, hydrogen ions and electrons to equilibrium, the responsibility of catalyzing the reaction between hydrogen and traces of oxygen, which, as we have seen, have decided influence on the potentials observed. It seems probable, therefore, that potentials measured with hydrogen electrodes which have gas flowing over them may be in error, even if constant readings are obtained, unless extraordinary precautions are taken to make certain that the hydrogen is pure.

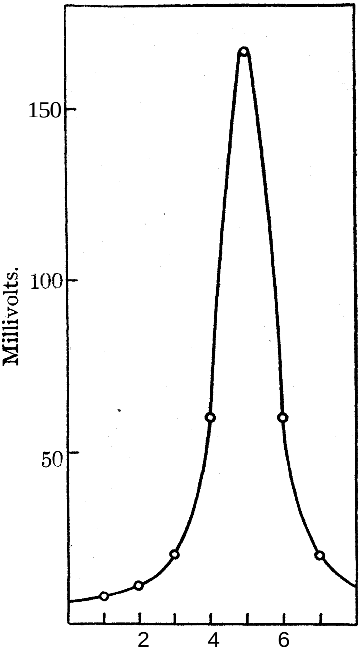
A Test of Standards for Precise Acidimetry.—Since, as has already been stated, it has been necessary for us to know the concentrations of acid solutions to high precision, a comparison of three different standards for

---

[3] Latimer, Buffington and Hoenschel, THIS JOURNAL, 47, 1571 (1925).

[4] Lewis, Brighton and Sebastian, *ibid.*, 39, 2245 (1917).

acidimetry was made, employing the electrometric method in each case to find the end-point.[5] A solution of sodium hydroxide with which the acid solutions could be titrated was prepared. The first solution of base used was calibrated, using (a) constant boiling acid, and (b) potassium acid phthalate. The constant boiling acid was prepared as described by Foulk and Hollingsworth,[6] using the slight modification of their procedure described by MacInnes and Dole,[7] who checked, very closely, Foulk and Hollingsworth's value for the composition of this material. A dilution of this acid was made by weight to approximately the concentration of the base. This diluted acid was then placed in a weight buret and about sixty grams was weighed out into the vessel A of the apparatus shown in Fig. 2. Then, from another weight buret, enough of the solution of the base, the titer of which was desired, was added to bring the acid within about 0.2 g. of neutralization. (To do this a preliminary rough titration, using phenolphthalein, was necessary.) The vessel A was put into place in the apparatus and the currents of hydrogen started through tubes h_1 and h_2. When equilibrium was established (shown by a zero or nearly zero potential between electrodes E and E') the titration was completed from the buret B, using the solution of the base diluted in the proportion one to ten. This had previously been saturated with hydrogen in the flask F. The solution from B was added usually a drop at a time and the corresponding readings of the potentials between E and E' were made. One drop is, of course, equivalent to 0.1 drop of the original solution. A typical plot of the readings thus obtained is shown in Fig. 3, the e. m. f. values in millivolts appearing as ordinates and drops of solution as abscissas. The sharpness with which the end-point can be located is shown by the fact that the last drop, representing about 0.01% of the total titer, produced in this case a potential difference of 167 millivolts, whereas the previous and following



Drops of diluted base solution.
Fig. 3.

---

[5] Such comparisons, using ordinary indicators, have been made by Morey, THIS JOURNAL, 34, 1027 (1912), and by Hendrixson, *ibid.*, 37, 2352 (1915). These workers have not, however, attained quite the accuracy we have desired

[6] Foulk and Hollingsworth, *ibid.*, 45, 1220 (1923)

[7] MacInnes and Dole, *ibid.*, 51, 1119 (1929).

drops produced potentials lower than this by over 100 millivolts. The curve shown in Fig. 3 happens to be symmetrical about the maximum ordinate. In this case the drop producing this maximum potential exactly completes the titration. However, if the adjoining ordinates were of unequal heights it was possible by a simple interpolation to compute the portion of the last drop added that would have finished the titration. The interpolation was carried out with sufficient accuracy by drawing lines through the last two points on each side of the end-point, and noting the point at which they cross.

The solution of base was also standardized, using potassium acid phthalate furnished by the Bureau of Standards. We followed the directions for drying the material, and used the factor (0.9997) for its purity, as given in a circular from that Bureau. In this case the solid salt was weighed out into vessel A and the solution of the base was added from a weight buret within one or two tenths of a gram of the computed amount, after which the titration was finished as described above. The end-point was quite as definite, as in the preceding case, although the potentials were much lower. Table I, based on determinations made by the junior author, gives the results of standardizations, made by the two methods outlined above, of the solution of base. The constant boiling acid which, as collected, had a composition of 20.214% HCl was diluted in the proportion of 48.3299 grams of acid in 987.203 grams of final solution. The table is mostly self-explanatory. However, the column headed "Correction to weight of base" is computed from the weight of diluted base solution added from the buret in the final electrometric titration carried out in the apparatus shown in Figs. 1 and 2.

TABLE I

STANDARDIZATION OF SODIUM HYDROXIDE SOLUTION BY MEANS OF CONSTANT BOILING HYDROCHLORIC ACID AND POTASSIUM ACID PHTHALATE

Standard	Weight Standard	Weight Base	Correction to weight of base	Normality of base
Constant boiling HCl	2.90026	47.2977	0.0645	0.33945
Constant boiling HCl	2.70567	44.1365	.0471	.33946
Potassium acid phthalate	4.0238	57.9822	.0990	.33948
Potassium acid phthalate	4.2204	60.7734	.1446	.33948

It will be observed that the two standards yield the same result with a high degree of accuracy. This test was repeated by an assistant, Mr. Valik, using a solution of sodium hydroxide having another strength. In this series another standard, pure benzoic acid from the Bureau of Standards, was also used. Since the addition of alcohol to dissolve this acid, as recommended by Morey,[8] has an unfavorable effect on the hydrogen electrodes and on the end-point, the following procedure, which does not involve the

---

[8] Morey, THIS JOURNAL, 34, 1027 (1912); see also Weaver, *ibid.*, 35, 1309 (1913).

use of that solvent, was adopted. About 1.4 g. of the solid acid was placed in a bottle of about 100-cc, capacity and the solution of base, the strength of which was approximately known, was added within 0.1 to 0.2 g. less than the amount necessary for neutralization and the flask was tightly stoppered. With sufficient shaking all the benzoic acid went into solution. The resulting solution, which was slightly acid and would therefore not absorb carbon dioxide, was washed into the vessel A of Fig. 2, and the titration was completed electrometrically with dilute base as already described. The results obtained for the standardization of the second. solution of sodium hydroxide are given in Table 11. All weights given in these tables have been reduced to vacuum standard. The weight of the potassium acid phthalate is that of the material of 0.9997% purity. The constant boiling acid in the second series of determinations contained 20.224% of HCl.

TABLE II

STANDARDIZATION OF SODIUM HYDROXIDE SOLUTION BY MEANS OF CONSTANT BOILING HYDROCHLORIC ACID, POTASSIUM ACID PHTHALATE AND BENZOIC ACID

Standard	Weight Standard	Weight Base	Correction to weight of base	Normality of base
Constant boiling acid	1.56523	41.2528	0.1483	0.20967
Constant boiling acid	1.56055	41.1483	.1364	.20963
Constant boiling acid	1.55804	41.1090	.1424	.20959
Potassium acid phthalate	2.1118	49.1500	.1833	.20963
Potassium acid phthalate	2.0194	47.0256	.1453	.20965
Potassium acid phthalate	2.0892	48.7370	.0684	.20963
Benzoic acid	1.4713	57.3510	.1538	.20963
Benzoic acid	1.4389	56.0079	.2263	.20965
Benzoic acid	1.4387	56.1074	.1271	.20962

It is evident from the data presented in Tables I and II that, in the first place, the electrometric method as outlined is capable of giving results of high precision, and, also, that the three methods tested for standardizing solutions of bases are equally accurate. Of these three methods the use of potassium acid phthalate is probably the most convenient. An empirical factor for the purity of the material must, however, be used. The constant boiling acid method involves a distillation which must be carefully carried out at a barometric pressure which must be constant and accurately known. Although it is hard to get into solution, benzoic acid is unquestionably the best material to use as a standard for precise acidimetry, since its use depends only on the stoichiometric relations, and no analytical results of other workers have to be accepted. Furthermore, it can be obtained in a state of highest purity.

A paper which will follow shortly will deal with the question of the equivalence of the electrometric and stoichiometric end-points, and with the titration of mixtures of acids.

Summary

1. The differential electrometric method for titration has been adapted to the use of hydrogen electrodes.

2. The usefulness of the method has been shown by its application to precise acidimetry. Three standards for use in acidimetry: constant boiling hydrochloric acid, potassium acid phthalate and benzoic acid, have been tested and have been shown to be suitable for accurate work (0.01% or better).

THE PHOTOCHEMICAL INTERACTION OF ETHYLENE AND AMMONIA

BY HUGH S. TAYLOR AND HARRY J. EMELÉUS[1]

RECEIVED DECEMBER 8, 1930 PUBLISHED FEBRUARY 9, 1931

The present work had its origin in some experiments carried out by J. R. Bates at the suggestion of one of us (H. S. T.) in December, 1926, during our studies of photosensitized decompositions by excited mercury.[2] In this work it was found that, in the decomposition of ammonia, both photochemically and by excited mercury, the non-condensable gas first received in a flowing system was mainly hydrogen. This suggested a primary decomposition of ammonia into NH_2 and H, and experiments were undertaken to determine whether evidence for this could be obtained from reactions initiated by such atomic hydrogen. This was readily forthcoming, since we showed that the photochemical decomposition of ammonia in presence of hydrogen and carbon monoxide led to very much larger yields of formaldehyde than were obtained under the same arc conditions in the absence of ammonia. This latter fact was also proof that we were not producing the formaldehyde by reason of the presence of excited mercury in the system. The reaction was sufficiently rapid that a solid residue was quickly laid down on the vessel walls; the solid was assumed to be hexamethylenetetramine. We have not yet examined the reaction further, and therefore confine ourselves to recording at this time the free solubility of the solid product in water.

In the following year Hill and Vernon,[3] at Princeton, also showed that the illumination of ammonia in the far ultraviolet and at low partial pressures, in quartz vessels, in contact with tungstic oxide gave an immediate reduction to the blue oxide. This again pointed to atomic hydrogen, but not so directly, since hydrazine might have been the product to

[3] Unpublished experiments.

which such reduction was to be attributed. Further work in this very promising field had to be postponed pending the erection of a new laboratory in which facilities were available for the development of light sources of high intensity in the region absorbed by ammonia. These were obtained last year, and the present program was then initiated.

During the latter part of 1929 an apparatus was assembled to study the sensitization of the hydrogen-ethylene reaction by atomic hydrogen produced in the photo-decomposition of ammonia. Before the release of the high tension spark sources from other work,[4] a communication by Farkas, Haber and Harteck[5] on the photosensitization of the oxidation of hydrogen and carbon monoxide by means of ammonia indicated that the field of ammonia sensitization was being pursued elsewhere. We have, therefore, utilized, in the present work, the available mercury light sources of the laboratory in continuation of the program initiated as described above.

Our choice of the ethylene–hydrogen reaction for study was dictated by several reasons. In the presence of excited mercury the reaction has been very fully investigated,[6] and the various possible reactions identified. The reactions are fast, and their progress can be followed manometrically. With oxygen as one of the reactants in the system, there is always the possibility that the primary interaction of ammonia with oxygen might influence the results. The deposition of solid products in the hydrogen–carbon monoxide reaction ascertained in the first experiments was the principal factor in our choice of the hydrogen–ethylene reaction. We anticipated straightforward gas reactions in the case of hydrogen and ethylene but our experiments have shown that the deposition of liquid products is the principal reaction, and these inhibit, in part, the reactions occurring.

We shall present first the nature of the experimental procedure and the experimental results. A general discussion of the data obtained will then be given.

Experimental Details

Ethylene was prepared by washing the gas from a cylinder with sulfuric acid and condensing in liquid air, dissolved non-condensable gases being then removed by melting in vacuum, freezing, and re-evacuating. Approximately one-quarter of the condensate was pumped off at its melting point, and the bulk of the liquid was then distilled at −100° in vacuum directly into the storage globe. Ammonia was prepared similarly, the gas from a cylinder being frozen in liquid air, freed from dissolved gases and a middle fraction collected by distilling from a bath at −100°. Commercial electrolytic hydrogen was purified by passing over heated platinized asbestos, and drying with phosphorus pentoxide. Gas mixtures were prepared by admitting the gases in turn into the previously evacuated reaction vessel up to the required pressure, as indicated by a mercury manometer.

The mercury arc was of the vertical type, uncooled and normally operated at about 2.5 amp. from the 110-volt d. c. circuit. The region absorbed by ammonia lies almost at the limit of transmission of quartz, and the available radiation of this wave length was found to fluctuate from one experiment to another. For this reason the results of different experiments cannot, in general, be compared with one another. In some cases, however, as, for example, in the comparison of the decomposition of ammonia with and without ethylene, comparable conditions were maintained for two sets of observations.

Two reaction vessels were employed. **A** cylindrical bulb of quartz (Vessel **A)** 16 cm. long by *2.5* cm. diameter was used when temperature conditions were of secondary importance. It was illuminated from one side by the vertical arc. Reaction vessel B was an annulus of quartz, of 7.5 cm. external diameter, 4.5 cm. internal diameter and 10.5 cm. long, which was immersed in a constant-temperature water-bath and illuminated by a vertical arc placed co-axially within the annulus. The reaction vessels were cleaned between successive experiments by evacuating, filling with oxygen, and heating to a red heat. The film of oil deposited during the reaction was completely removed in this way.

Experimental Results

General Course of the Reaction.—A mixture of ethylene and ammonia when illuminated in quartz reaction bulb A, with the mercury arc placed at a distance of 1 cm., showed a steady decrease of pressure, the reaction being followed by interrupting the illumination, and measuring the pressure with the bulb immersed in a bath at 20° and in liquid air. Such a series of observations is recorded below.

TABLE I

PRESSURE VARIATION ON ILLUMINATION OF 10.05 CM. OF ETHYLENE AND 2.23 CM. OF AMMONIA

Time of illumination	Total pressure, cm.	Pressure of non-condensable gas (corrected to 20°), cm.
0 Minutes	12.28	0.00
25	9.32	.16
50	7.45	.00
80	5.95	.39
105	5.17	.58
170	4.45	.80
316	4.38	1.54
496	4.50	1.71
760	4.72	2.15
27 Hours	5.13	2.77
32'	5.62	3.25
34 5	5.87	3.89
62 5	6.07	4.05

[a] At this point the position of the arc was shifted to the opposite side of the reaction vessel, and its distance altered from 1 cm. to 0.5 cm.

As the reaction progressed a light brown oil was deposited, which was found to retard the reaction, due, probably, to a reduction of the effective light intensity. This is shown by the following measurements. An ethylene–ammonia mixture ($p_{C_2H_4}$, 9.97 cm.; p_{NH_3}, 10.45 cm.) was illuminated for 160 minutes, and gave a pressure reduction of 2.84 cm. After evacuating the reaction bulb (the oil not being appreciably volatile), a fresh gas mixture was admitted ($p_{C_2H_4}$, 9.80 cm.; p_{NH_3}, **10.21** cm.). Continuing the illumination under the same conditions, the decrease in pressure in fifty minutes was only **0.24** cm. Moreover, the reaction rate at the beginning of the second experiment was approximately the same as that at the point where the first was interrupted.

On illuminating ammonia in the reaction vessel in which an ethylene–ammonia mixture had reacted with a pressure reduction of 1.86 cm., the ammonia decomposition resulted in a pressure increase of 0.07 cm. in ten minutes, whereas the average value for ammonia under the same conditions in a clean vessel was **0.24** cm. in ten minutes, showing that the oil also retarded the decomposition of ammonia.

Illumination of Ethylene Alone.—On illuminating ethylene alone with the mercury arc in vessel A illuminated at 1 cm. distance there was a reaction, the rate of decrease of pressure being approximately 20–30% of that observed with ammonia present. This is shown by the following measurements.

TABLE II

COMPARISON OF PHOTOCHEMICAL ACTION WITH AND WITHOUT AMMONIA

$p_{C_2H_4}$, cm.	p_{NH_3}, cm.	Time of illumination, min.	Pressure decrease, cm.
30.53	..	45	1.97
33 22	6.66	45	6.17
17.87	..	30	0.63
18.01	3.68	30	4.14

With a hot arc this reaction cannot be due to a mercury sensitized reaction, and probably represents a direct polymerization following absorption by the ethylene itself. Using reaction vessel B the polymerization of ethylene without ammonia becomes inappreciable. Thus, with this vessel and with $p_{C_2H_4} = 14.64$ cm.. the pressure decrease on illuminating for **140** minutes was **0.12** cm.; with $p_{C_2H_4} = 32.57$ cm., the pressure decrease on illuminating for ninety minutes was **0.10** cm.

In experiments with reaction vessel A the reaction of ethylene alone was neglected, these runs being made mainly in the investigation of the products of the reaction. Reaction vessel B was used in studying the kinetics of the reaction, and in that case the reaction of ethylene alone was some 5% of that in the presence of ammonia.

Formation of Saturated and Unsaturated Hydrocarbons in the Reaction.—To determine whether saturated hydrocarbons were formed in the course of the reaction, an ethylene–ammonia mixture was illuminated in vessel A and the non-condensable gas pumped off with the bulb immersed in liquid air. The residue was then distilled in vacuum into a bulb containing gas-free **10%** sulfuric acid to absorb ammonia and amines. The moist residue was returned to the reaction vessel and the pressure remeasured. The percentage of unsaturated hydrocarbon in this residue was then determined by absorption with fuming sulfuric acid. Where the quantity of gas was sufficient, a sample was pumped off and oxidized over copper oxide heated to a red heat, the increase in pressure on oxidation and the decrease on treating the residue with potash giving the number of carbon atoms in the molecule. Two experiments were also made in which hydrogen was introduced to determine whether this caused an increase in the amount of saturated hydrocarbon formed. These results are recorded below. Those in which hydrogen was present are discussed later.

TABLE III

FORMATION OF SATURATED AND UNSATURATED HYDROCARBONS

	$p_{C_2H_4}$	p_{NH_3}	p_{H_2}	Δp in reaction, cm.	Time, hours	% of residual gas absorbed by fuming H_2SO_4	Carbon value
1	38.80	6.17	...	10.88	10.5	94	...
2	32.67	5.47	...	12.11	15	93	2.0
3	24.72	7.00	11.89	11.12	16	89	...
4	30.33	8.33	13.73	12.01	15	93	2.1
5	33.68	5.92	...	12.18	5.25	92	...

These results show that in the course of the reaction a small amount of gas not absorbed by fuming sulfuric acid was formed, which must be saturated hydrocarbon. It is very probable that this residue consists of ethane. The approximation of the carbon value for the total residue to the value C_2 shows that the residue contained no appreciable amounts of the higher homologs of ethylene—it must have consisted in the main of unchanged ethylene.

Influence of Hydrogen on the Reaction.—The mercury sensitized reaction between ethylene and hydrogen was proved not to occur under the conditions of illumination used by radiating an ethylene–hydrogen mixture (p_{H_2}, 15.66 cm.; $p_{C_2H_4}$, 5.43 cm.) in the reaction vessel B. Mixtures of ethylene, hydrogen and ammonia were next illuminated in the simple cylindrical bulb to determine if, under these conditions, the hydrogen reacted, the hydrogen pressure being measured before and after each run by immersing the reaction bulb in liquid air.

TABLE IV

INFLUENCE OF HYDROGEN ON THE REACTION

	p_{H_2}, cm.	p_{NH_3}, cm.	$p_{C_2H_4}$, cm.	Time, min.	Total Δp, cm.	Initial p_{H_2} at −180°, cm.	Final p_{H_2} at −180° cm.
1	10.06	2.34	10.05	72	−4.09	3.29	3.41
2	10.06	10.03	10.08	38	−2.43	3.36	3.34
3	20.12	9 90	10 09	97	−8.53	6.98	6.97

From the last two columns it is evident that the amount of hydrogen used in the reaction is negligible. Further support for this conclusion is obtained from the analyses recorded above, where it was shown that, in presence of hydrogen, there was no difference in the amount of saturated hydrocarbon formed.

Reaction of Ammonia.—In the presence of ethylene, ammonia might be expected either to undergo its normal decomposition into nitrogen and hydrogen, or to react with the hydrocarbon, giving amines as the main product. To determine the extent to which the normal decomposition occurred, ammonia was illuminated in the quartz reaction bulb A with the mercury arc for a definite time and the amount of non-condensable gas formed determined by immersing the bulb in liquid air at the end of the run. An ethylene–ammonia mixture with the same pressure of ammonia was then illuminated for the same time under identical conditions, and the non-condensable gas again determined.

TABLE V

AMMONIA DECOMPOSITION WITH AND WITHOUT ETHYLENE

	p_{NH_3}, cm.	ΔP, cm.	Time of illumination, min.	$p_{l.a.}$, cm.	p_{NH_3}, cm.	$p_{C_2H_4}$, cm.	ΔP, cm.	Time, min.	$p_{l.a.}$, cm.
1	5.17	+1.42	45	1.02	5.03	14.75	−5.38	50	0.05
2	4.95	1.30	40	0.76	5.11	15.26	..	40	.03
3	10.00	0.95	63	.65	10.03	15.00	−4.29	63	− .01

The readings under $p_{l.a.}$ refer to the pressure of non-condensable gas at liquid air temperatures. Other pressure measurements were made at 20°. These readings show that in the presence of ethylene the simple decomposition of ammonia was reduced to less than 10% of its normal value.

The second possibility, namely, the formation of a simple compound, should be indicated by a definite relation between the amount of ammonia which would normally have decomposed under the conditions of illumination used, and the amount of ethylene used. The total decrease in pressure in the reaction has been used as a measure of the latter quantity; actually this measures the minimum value of this quantity, for the true pressure decrease will be reduced by the formation of other volatile products (such as amines, and saturated and unsaturated hydrocarbons).

A series of observations of this type was conducted in reaction vessel B maintained at room temperature. The ammonia decomposition rate was first determined over a period of forty to eighty minutes, the residue being then pumped out and an ammonia–ethylene mixture introduced, the arc conditions remaining unchanged. The decrease in pressure over the first ten to twenty minutes was determined, this short period of illumination minimizing the error due to the accumulation of oil.

The average value of r is 5.0. This measures the ratio of the pressure decrease in presence of ethylene to the pressure increase due to the simple ammonia decomposition. That is, for every one molecule of ammonia which would have decomposed, at least five molecules of ethylene disap-

TABLE VI

AMMONIA DECOMPOSITION WITH AND WITHOUT ETHYLENE

1	4.77	0.095	4.86	15.15	−0.42	4.4
2	5.03	.098	5.06	15.15	− .46	4.7
3	5.08	.085	5.00	15.15	− .44	5.2
4	5.05	.052	5.00	15.13	− .28	5.4
5	5.05	.049	5.11	15.07	− .235	4.8
6	4.95	.045	5.07	15.07	− .245	5.4

pear. The high value of this ratio is strongly against the formation of a simple compound, such as a volatile amine. Even for a tertiary amine the ratio would be only 3, and it appears very probable that the ethylene has undergone a polymerization, resulting in the deposition of the non-volatile oil.

As a further check on the disappearance of ammonia in the reaction, four runs were made in which the residual ammonia (+ amines) was determined, after varying times of illumination, by admitting 1–2 cc. of 30% sulfuric acid directly into the reaction vessel from a side tube, the observed decrease in pressure being corrected for the vapor pressure of the acid.

TABLE VII

RESIDUAL AMMONIA (OR AMINES) AFTER ILLUMINATION

	p_{NH_3}	$p_{C_2H_4}$	Time of illumination, min.	Δp, cm.	Gas absorbed as % of original ammonia
1	5.50	19.59	30	− 3.71	96
2	5.25	19.93	60	− 5.30	92
3	5.75	19.95	120	− 9.20	78
4	5.62	19.76	210	−11.68	62

If a part of the ethylene had formed a volatile amine, then, for every ammonia molecule decomposed, one molecule of amine should have been formed, and the gas absorbed by sulfuric acid should have remained constant throughout a run. The above table shows that such is not the case; that is, volatile amine formation must have occurred to a very much smaller extent, if at all.

Finally, an attempt was made to determine whether the amount of ammonia decomposed in the presence of ethylene was the same as that which would be observed on illuminating ammonia alone under the same conditions. Ammonia was first illuminated, the pressure change in a definite time being measured. An ethylene–ammonia mixture was then illuminated under the same conditions, and for the same time, and the residual ammonia determined by introducing 10% sulfuric acid directly into the reaction bulb. The following values were obtained.

These results show that within the probable error of the experiments the ammonia decomposition proceeded normally in presence of ethylene,

TABLE VIII

AMMONIA DECOMPOSITION WITH AND WITHOUT ETHYLENE

Expts. IIIa and b	1.08	.97

the products of the reaction alone being different. The non-condensable gas formed in the reaction was pumped off in two experiments, and analyzed for hydrogen and nitrogen by burning over copper oxide. With $p_{C_2H_4}$ = 15.01 cm., p_{NH_3} = 10.05 cm., and with a pressure decrease of 10.36 cm. in the reaction, the pressure of non-condensable gas formed, measured at liquid-air temperatures, was 0.33 cm., and 84% was found to be absorbed by heated copper oxide. In a repetition of this run the value 83% was obtained

The oil deposited during the reaction was not available in sufficient quantity for further examination. It was insoluble in water and acids, and soluble with difficulty in ether. A similar oil was formed in the polymerization of ethylene sensitized by excited mercury.[6] In the present case, however, it is impossible to account for the nitrogen from the decomposed ammonia except by supposing it to be present in the oil in the form of compounds of low volatility. Vapor pressure measurements made on the residue in the reaction bulb after pumping off all gas volatile at −100 to −90° were as follows.

TABLE IX

VAPOR PRESSURES OF OILY RESIDUE

Temperature, °C.	−76	−58	−44	−30
V. p., cm.	0.05	0.10	0.19	0.34

It is obvious that such measurements have minor value since the residue is undoubtedly complex. We believe the evidence presented indicates polymerization of the ethylene with the participation of the NH_2 radical at some stage of the total process later than the first stage, since this would involve volatile amine production.

Reaction Kinetics

Influence of Ethylene Concentration on the Reaction Rate.—These experiments were made in vessel B at room temperatures. A measured pressure of ammonia was admitted to the bulb, and then a small pressure of ethylene, the decrease in pressure on illumination for ten minutes being determined. After introducing a further quantity of ethylene the rate was re-determined, and so on for a series of ethylene pressures. The retardation of the reaction due to the deposition of oil was determined by working with fixed amounts of ethylene and ammonia, and measuring the pressure at ten-minute intervals (Expt. 1). By comparing this set of readings with those in which the ethylene concentration was varied, it was possible to determine if the latter had any influence on the rate.

TABLE X

INFLUENCE OF ETHYLENE CONCENTRATION ON REACTION RATE

Expt. 1. $p_{C_2H_4}$, 32.47 cm. p_{NH_3}, 5.17 cm.

Time, min.	10	20	30	40	50	60
Δp in 10 min., cm.	−0.26	−0.30	−0.24	−0.23	−0.22	−0.20

Expt. 2. p_{NH_3}, 4.98 cm.

$p_{C_2H_4}$, cm.	4.7	9.35	14.4	19.1	28.3
Δp in 10 min., cm.	−0.44	−0.42	−0.40	−0.38	−0.38

Expt. 3. p_{NH_3}, 10.03 cm.

$p_{C_2H_4}$, cm.	1.0	4.4	9.6	22.3
Δp in 10 min., cm.	−0.27	−0.24	−0.29	−0.26

Expt. 4. p_{NH_3}, 18.8 cm.

$p_{C_2H_4}$, cm.	0.9	2.3	5.25	13.9
Δp in 10 min., cm.	−0.12	−0.12	−0.10	−0.14

These results show that over a wide concentration range the rate of reaction is independent of the ethylene pressure.

Influence of Ammonia Concentration on the Reaction Rate.—The same method was used in studying the influence of ammonia concentration on the reaction rate, a fixed pressure of ethylene being used while the ammonia concentration was varied. As the reaction progressed the ethylene concentration decreased, but it has already been shown that this does not influence the rate. Similarly, in the previous set of observations, the ammonia concentration must have decreased; this effect has been neglected, a course which is justified by the results given below.

TABLE XI

INFLUENCE OF AMMONIA CONCENTRATION ON REACTION RATE

Expt. 1. $p_{C_2H_4}$, 20.99 cm.

p_{NH_3}, cm.	0.9	3.1	9.0	12.0
Δp in 10 min., cm.	−0.13	−0.22	−0.22	−0.18

Expt. 2. $p_{C_2H_4}$, 10.03 cm.

p_{NH_3}, cm.	0.3	0.8	1.8	4.4	9.6
Δp in 10 min., cm.	−0.08	−0.15	−0.21	−0.19	−0.20

Expt. 3. In this experiment the ammonia was introduced as a mixture with hydrogen containing 16% of ammonia. $p_{C_2H_4}$, 10.08 cm.

p_{NH_3}, cm.	0.04	0.12	0.22	0.38	1.14
Δp in 10 min., cm.	−0.05	−0.08	−0.11	−0.13	−0.18

These results show that above a certain pressure the rate of reaction is independent of the ammonia pressure. This pressure is approximately equal to 1.5 cm., and may be interpreted as being the pressure at which the active light is completely absorbed. Below this point the reaction rate increases with increasing ammonia concentration, but the accuracy of the measurements does not justify any attempt to formulate a relation between the two.

Temperature Coefficient of the Reaction.—The approximate temperature coefficient of the reaction was determined by working with reaction vessel B placed in a water-bath which could either be maintained at 15° or heated at 98°. The radiation emitted by the arc was found to be very sensitive to temperature for the wave length region absorbed by ammonia, and the decomposition of ammonia itself, for which the temperature coefficient is known, was used as a method of calibration. The ammonia decomposition was found to have an apparent temperature coefficient of 3.1 for a temperature increase of 83°. From Kuhn's value of 1.05 per 10°, the factor should be 1.4. Taking this discrepancy as due to a change in the condition of the arc, the observed values for the temperature coefficient (of the ethylene–ammonia reaction) were divided by the factor $3.1/1.4 = 2.2$, to give the true values.

Ammonia Decomposition.—In a series of runs in which the pressure of ammonia was varied from *3* cm. to 18 cm., the following values were obtained for the ratio of the decomposition rate at 98° to that at 15°: 3.4, 3.7, 3.9, 2.4, 3.9, 2.9, 2.8, 2.4, 2.7; average, 3.1.

Ethylene–Ammonia Reaction.—The following measurements were made with ethylene–ammonia mixtures, the reaction vessel being cleaned and the arc reset between the measurements at the two temperatures.

15°				98°				
p_{NH_3}, cm.	$p_{C_2H_4}$, cm.	Δp, cm.	Time, min.	p_{HN_3}, cm.	$p_{C_2H_4}$, cm.	Δp, cm.	Time, min.	r
3 03	15 **13**	−0.94	30	3.09	14 94	−2.48	30	**2.64**
5 08	15.24	−1.29	40	5.05	15.40	−2.03	25	**2.52**
5 41	15.05	−1.67	60	5.40	14 96	−1.85	20	**3.33**
5.02	15.10	− 186	60	5.05	15.05	−1.90	20	**3.06**

The value of r in the last column is the ratio of the pressure decrease at 98° to that at 15° calculated for equal times of reaction.

The average value of r is 2.9, **i.** e., dividing by the factor 2.2, the temperature coefficient for 83° is 1.32 or 1.04 per 10°. Taking into account the low degree of accuracy of the determinations, this value does not differ sensibly from that for the photo-decomposition of ammonia.

Discussion of Results

A survey of the data obtained in the preceding sections justifies the general conclusion that the photochemical decomposition of ammonia induces the low-temperature polymerization of ethylene. We ascribe this induced polymerization to the liberation, in the reaction system, of atomic hydrogen formed in the decomposition of ammonia. At some stage in the process, however, the nitrogen fragment of the dissociation enters the reaction and is removed not as a volatile amine, but as a liquid, non-volatile, nitrogen carbon compound of undetermined composition.

The polymerization of ethylene with the aid of atomic hydrogen is a familiar process by reason of earlier work on excited mercury. In the latter case, however, polymerization is always accompanied by hydrogenation, which, with hydrogen-rich mixtures, may even be practically the exclusive reaction.[6] This result is in striking contrast to the present work with ammonia as the source of atomic hydrogen. Here we find the hydrogenation occurring to be of the order of 20% of the ethylene polymerized. It is evidently necessary, therefore, to account for such a divergence of behavior. The reaction with ammonia is as much a process of polymerization as that found by Taylor and Jones,[7] in which ethyl radicals liberated from decomposing metal ethyls in mixtures of hydrogen and ethylene at 250° produced mainly ethylene polymers with only small amounts of saturated hydrocarbons.

Experimentally, the outstanding divergence between the processes with ammonia and with mercury is probably associated with the concentration of atomic hydrogen produced. In the case of mercury, as has frequently been pointed out, the reaction volume is mainly confined to a very thin element of volume adjacent to the vessel surfaces receiving illumination by resonance radiation, owing to the extremely high absorption coefficient of mercury atoms for this light. Comparatively, in the case of ammonia, the concentration of atomic hydrogen produced is very much less.

That saturated hydrocarbon formation is small with ammonia in hydrogen–ethylene mixtures at room temperatures and is subordinate with metal alkyls even at 250° suggests definitely that a reaction $C_2H_5 + H_2 = C_2H_6 + H$,[8] postulated in earlier communications[2,6] on this subject to account for ethane formation, must in reality be a reaction of low collision efficiency. This conclusion is in agreement with a wide variety of experience accumulated in the past year,[4,9,10,11] concerning the reactivity of the atoms and radicals, O, Cl, F, CHO with hydrogen molecules. The formation of hydrogen peroxide to the exclusion of water at ordinary temperatures from atomic hydrogen and oxygen molecules[2] also points to the inefficiency of collisions in the process, $OH + H_2 = H_2O + H$. We are led, therefore, to reject the reaction $C_2H_5 + H_2 = C_2H_6 + H$ as the process producing saturated hydrocarbon at ordinary temperatures. At 250° and higher

[8] The production of ethyl from hydrogen atoms and ethylene is an association reaction $H + C_2H_4 = C_2H_5$ to be achieved by means of a three-body process

[9] Frankenburger, *Z. Elektrochem.*, 36, 767 (1930).

[10] Farkas, Haber and Harteck, *ibid.*, 36, 714 (1930).

[11] Franck and Rabinowitsch, *ibid.*, 36, 794 (1930).

such a process may have a measurable efficiency. Even there, however, it must play a subordinate role to processes of polymerization involved in collisions between C_2H_5, C_4H_9, etc., and unsaturated molecules, $C_2H_5 + C_2H_4 = C_4H_9$. Such association reactions must be three-body processes to produce stabilized products. They are, however, more frequent than another three-body process producing amine $C_2H_5 + NH2 = C_2H_5NH_2$, owing to the high concentration of C_2H_4 compared with that of NH_2. This accounts for the absence of the lower volatile amines in the gas phase, a circumstance which is aided by the fact that such amines are themselves photochemically decomposed. The presence of nitrogen compounds in the liquid deposit indicates, however, that processes such as $C_nH_{2n+1} + NH_2 \longrightarrow C_nH_{2n+1}NH_2$ occur at later stages in the polymerization processes.

There remains the problem as to the mechanism of saturated hydrocarbon formation in excited mercury systems at ordinary temperatures. If we exclude the reaction $C_2H_5 + H_2 = C_2H_6 + H$ for reasons already set forth, we are left with the following possibilities already discussed in an earlier communication,[6] (a) $C_2H_4 + H_2 + H = C_2H_6 + H$ and (b) $C_2H_5 + C_2H_5 = C_2H_6 + C_2H_4$, together with one additional possibility not hitherto noted, (c) $C_2H_5 + HgH = C_2H_6 + Hg$. Concerning these we can make the following additional observations in the light of the new results. A reaction of type (a) should occur equally efficiently with a hydrogen atom from an ammonia molecule as with one from excited mercury and hence, in view of our experimental data with ammonia indicating low conversion to saturates, is to be considered of minor importance. Reactions of the type (b) and (c) are only to be expected in regions of high concentration of atoms or the resultant radicals and thus may be anticipated in the mercury systems and not in the ammonia system. It is to be noted that reaction (b) is a strongly exothermic process involving the evolution of some 70 kg. cal.,[12] with probably a very low activation energy. That both reactions (b) and (c) are bimolecular and are not association reactions gives them a higher degree of probability than similar reactions of two radicals involving three-body processes, e. g., $C_2H_5 + C_2H_5 + X = C_4H_{10} + X$.

Summary

The photochemical decomposition of ammonia in the presence of ethylene or ethylene–hydrogen mixtures induces a polymerization of the ethylene, even at room temperatures, to form a liquid product.

The formation of saturated hydrocarbons in the reaction system with varied ratios of hydrogen to ethylene is subordinate to the polymerization process.

The presence of ethylene reduces the formation of nitrogen and hydrogen from photo-decomposition of the ammonia. The nitrogen content of the

---

[12] Mecke, *Z. Elektrochem.*, **36.** 595 (1930).

ammonia decomposed must be present mainly in the oil produced, in the form of compounds of low volatility.

The velocity of reaction is independent of the ethylene pressure over a wide concentration range and of the ammonia pressure when light absorption is complete.

The temperature coefficient of the total process is determined by that of the photo-decomposition of ammonia.

The experimental results lead to definite conclusions with regard to the efficiency of various possible methods of producing saturated hydrocarbons from ethylene and atomic hydrogen.

AN EFFECT OF THE BREADTH OF JUNCTION ON THE ELECTROMOTIVE FORCE OF A SIMPLE CONCENTRATION CELL[1]

BY GEORGE SCATCHARD AND T. F. BUEHRER

RECEIVED DECEMBER 8, 1930 PUBLISHED FEBRUARY 9, 1931

It is generally assumed that the electromotive force of a simple concentration cell, such as M, MX(m_1), MX(m_2), M, is independent of the method of making the junction between the two solutions, and that this fact has been demonstrated both theoretically and experimentally. The same theoretical argument may be extended to any cell involving a liquid junction to show that the electromotive force is independent of the thickness of the boundary layer provided that any element of the solution may be duplicated by taking x parts of the solution surrounding one electrode and $(1 - x)$ parts of that surrounding the other electrode.[2] Such a boundary is known as a "mixture boundary" and is obtained in practice when the boundary is made without diffusion. A simple concentration cell must always give a "mixture boundary" regardless of diffusion.

The electromotive force of a cell with electrodes reversible to the k'th ion, when the temperature and pressure are constant throughout the cell, is given by

$$E = \sum_{i=1}^{n} \int_B^A t_i \mathrm{d}E_{ik} = \frac{RT}{F} \sum_{i=1}^{n} \int_B^A t_i \,\mathrm{d} \ln \frac{(m_i\gamma_i)^{1/z_i}}{(m_k\gamma_k)^{1/z_k}}$$

where R is the gas constant, T the absolute temperature, F the faraday, t_i is the transference number of the i'th type of ion, z_i is its valence (taken negative for a negative ion), m_i its molality, and γ_i its activity coefficient.[3]

---

[1] Presented before the Physical and Inorganic Chemistry Section at the Cincinnati Meeting of the American Chemical Society, September 10, 1930.

[3] P. B. Taylor, *J. Phys. Chem.*, 31, 1478 (1927).

A is the solution surrounding one electrode and B that surrounding the other. E_{ik} is the electromotive force of a cell without liquid junction with one electrode reversible to the i'th ion, the other to the k'th ion. Although the "individual ion activities" appear in the second part of the equation, their use is only formal for they appear in such a way that they may always be replaced by the mean activity of some salt, or by the difference in mean activities of two salts. This is shown sufficiently by the fact that in the first expression they are reduced to the electromotive forces of realizable cells. For a mixture boundary each m, and therefore the composition, is a function only of x. If the mobilities and activity coefficients are functions of the composition, independent of its gradient, they are also functions of x, and the integral is single-valued. That is, for any cell the electromotive force is independent of the thickness of the junction for a mixture boundary, and for a simple concentration cell it is independent of the method of making the boundary.

We believe that the flowing junction gives a "mixture boundary" not over 0.01 cm. in breadth, and that the Clark type of junction,[4] when properly made, also gives a "mixture boundary," but about 1 cm. broad. If so, they should give equal electromotive forces for any pair of solutions if the conditions given above are fulfilled. However, when one solution is saturated potassium chloride and the other 1 M hydrochloric acid, the difference between the two types of junction is about 0.5 mv.[5] We therefore undertook the study of a simple concentration cell to attempt to determine whether this is due to one type failing to give a "mixture boundary" or to a failure of real junctions to meet the other conditions of the thermodynamic equation. In a simple concentration cell it is not possible to obtain a difference in concentration comparable to that of the potassium or hydrogen ion in the above cell. We considered, however, that the cell Hg, HgCl, HCl (m_1), HCl (m_2), HgCl, Hg might give a measurable effect because of the large difference in the mobility of the ions. And we did find a small but indubitable effect.

Materials and Apparatus

The measurements were made in the flowing junction apparatus previously described,[6] and the junction was allowed to increase in breadth by diffusion on standing after the flow was stopped. The calomel half-cells were the same as there pictured except that the end of the goose-neck arm was sealed off, instead of being constricted, and a hole about one millimeter in diameter was blown in the perpendicular side of the tube a few milli-

[5] H. W. R. Biers, Thesis, M. I. T. (1927), confirmed by our own measurements.

[6] G. Scatchard, THIS JOURNAL, 47, 696 (1925).

meters from the end. The glass around the edge of this hole projected slightly, but not enough to prevent passing the tube easily through a rubber stopper. This simple device reduced considerably the entry of air bubbles into the goose neck. Of course, any dipping electrode should be used only where the solutions inside and out are the same.

The materials were prepared and purified as in the previous paper, except that each acid solution was boiled and cooled in a stream of nitrogen, and the composition was determined by a gravimetric chloride analysis; the calomel–mercury paste and the cell solutions were equilibriated for twelve hours on a shaking machine in an atmosphere of nitrogen, and introduced into the half cells in the absence of air. These precautions were rather more harmful than helpful, for it was not found possible to keep oxygen excluded from such half-cells, with their openings often exposed to the air, so that the cells did not give a constant electromotive force over a period of days. The absolute values of the cell potentials are therefore uncertain to several tenths of a millivolt. Probably the variations during a day's run would also have been somewhat smaller without this precaution.

The Results

Measurements were made with three sets of cells. The average results are given in Table I, where the first two columns give the concentrations of the two solutions in moles per 1000 g. of water; the third the average electromotive force in millivolts when the flow was stopped; the fourth gives the average increase of electromotive force, also in millivolts, when the solutions were flowing and the probable error of the average; the last gives the number of measurements of ΔE. About half these measurements were made on starting the flow and half on stopping it. For the latter the first measurements were made about one minute after the flow was stopped. Within the experimental error the change was complete within this time, and the electromotive force then remained constant for hours.

TABLE I

HYDROCHLORIC ACID CONCENTRATION CELLS AT 25°

m_1	m_2	E (stop)	ΔE (flow)	No. of observations
7.29	0.1047	238.0	0.028 ± 0.005	22
7.29	.01117	331.0	.058 ± .019	17
1.091	.01117	194.7	.005 ± .019	6

The averages are given to 0.001 mv. although the individual measurements were made generally only to 0.01 mv. and never beyond 0.005 mv. All conditions must be kept very constant to maintain the electromotive force of a cell constant to a hundredth of a millivolt. Perhaps our conclusions are better shown by a single run of somewhat more than six hours' duration when conditions were very good. The run was with the first cell, and E' is the observed electromotive force minus 237.00 mv. The values given are the minimum and maximum readings during a period of flow or of

TABLE II

HYDROCHLORIC ACID CONCENTRATION CELL. RUN NO. 6

0	19	0.88	0.89		
20	204			0.85	0.86
205	229	.88	$.88_5$		
230	302			.84	.85
304	336	.89	.89		
338	368			.85	$.85_5$

cessation of flow. During six hours the value flowing varied only 0.01 mv. and that stopped varied only 0.02 mv. The difference between the minimum flowing value and the maximum stopped value is 0.02 mv. There can be no doubt of the reality of the effect.

From the Debye–Hückel interionic attraction theory we should expect that both the activity coefficients and the mobilities should depend slightly upon the concentration gradient, but we would scarcely expect to obtain a sufficient gradient in practice to show a measurable effect. There is another effect which should appear with much smaller gradients. Although the process is carried out in a thermostat, it cannot be isothermal. The mechanical mixing of the two solutions gives a heat effect and a resultant change of temperature in the boundary layer. These effects tend to be increased by the diffusion of ions through the boundary due to their Brownian motion. The temperature difference is dissipated, both along the axis of the tube and transversely to the walls, by the Brownian movement of all the molecules including those of the solvent. The temperature difference will be a complicated function of the concentration gradient and the time, and the effect on the electromotive force might be expected to be even more complicated and also to depend to a greater extent upon the ratio of the concentrations. Qualitatively the effect should depend upon the concentration as do our experiments. The fact that it disappears so rapidly shows that it must be very small except for a very steep gradient. Although the equation given above applies strictly to constant temperature, and therefore only to an infinitely wide boundary layer, the deviations must be immeasurably small for a breadth of even less than a millimeter.

Practically the effect of a sharp boundary in this cell is so small as to be negligible for all except the most precise work. Our results do show that a broad boundary, made by mixing rather than by diffusion if there are two electrolytes involved, should be preferable to **a** sharp boundary.

Summary

The electromotive force of hydrochloric acid concentration cells was found to increase a few hundredths of a millivolt when the liquid junction was made very thin.

A probable cause is the change in temperature at the boundary produced by the heat of mixing of the two solutions.

THE ACTIVATION ENERGY OF ADSORPTION PROCESSES

BY HUGH S. TAYLOR

RECEIVED DECEMBER 13, 1930 PUBLISHED FEBRUARY 9, 1931

The rapid development, during the last decade, of the experimental study of adsorption phenomena at solid surfaces having catalytic activity has served to emphasize those adsorption processes in which a high degree of specificity is manifest. This work has centered attention on the operation of valence forces in determining adsorption and has indicated the existence of adsorption processes not markedly different from chemical reactions. The accumulation of experimental material has yielded, however, a number of data which, from the standpoint of classical adsorption theory, are abnormal. There has been considerable discussion of types of adsorption and distinctions drawn between "primary" and "secondary" adsorption.[1] In other cases there has been a tendency to speak of "reversible" and "irreversible" adsorption and to recognize only the former as conforming to true adsorption, to ignore the latter in the theoretical treatment of the subject. This latter attitude[2] undoubtedly arose from the lack of a general theory applicable to all types of adsorption. At the same time, owing to the orientation of experimental work, the data in conflict with the simplified theoretical treatment have grown so rapidly that it may now be stated that the experimental literature of adsorption dealing with the abnormal cases is now as extensive as that conforming to the simple theory. There are now numerous data showing abnormal variations in the extent of adsorption with both temperature and pressure, abnormal variations of the heats of adsorption with temperature and pressure, large variations in the velocity of attainment of equilibrium in different adsorption systems and in the velocity of evaporation of adsorbed gases inconsistent with present adsorption theory. Since these several factors in part determine the velocity of chemical processes at surfaces, the lack of a general theory covering such phenomena has resulted in an inadequate, and, in some cases, an incorrect treatment of the theory of chemical reactions at surfaces. It is the object of the present communication to point out the inadequacy of the classical theory of adsorption and

---

[1] Benton, THIS JOURNAL, 45, 887, 900 (1923).

[2] Hückel, "Adsorption und Rapillarkondensation," Akademische Verlagsgesellschaft. 1928.

to indicate how it may very simply be modified to yield a general theory covering all types of adsorption.

It has been quite generally assumed on the basis of both theoretical considerations[3] and practical experience that the velocity of adsorption is great. There has been a constant tendency to ascribe any variation from a rapid process to the operation of secondary factors not essentially connected with the adsorption process. As one example, we may cite the assumption of diffusion processes, either in solutions or through the minute cavities or fissures in porous solid adsorbents, as responsible for the failure to establish equilibrium conditions rapidly in adsorption processes. Whatever importance may, in individual cases, be assigned to the operation of such secondary factors, it is the object of the present paper to propose and to establish by experimental evidence that the adsorption process per se is not necessarily a rapid process, may indeed be a very slow process, too slow to be measurable, and that for each adsorption process there is a characteristic velocity which is determined by the same factors which govern the velocity of chemical reactions, and therefore by temperature, pressure, concentration and the nature of the adsorbing surface. Since, as is now usual in discussions of chemical kinetics, we speak of the activation energy of a given chemical process we may, in the same sense, speak of the activation energy of an adsorption process. We shall show that, paralleling the enormous variation in activation energy of chemical reactions, there is a similar large variation in the activation energies of adsorption processes. Furthermore, we shall demonstrate that it is to this variability in activation energy of the adsorption process that the abnormalities we have already discussed are to be ascribed.

General Theory of Activation Energy in Adsorption Processes

The consequences of the concept of activation energy in adsorption processes may best be examined by a general consideration of the adsorption of a gas at a plane surface composed of a definite number of elementary spaces. The conditions governing adsorption equilibrium at such surfaces have already been detailed by Langmuir.[4]

(1) Equilibrium in Processes Involving Activation Energy.—Extending this treatment of equilibrium to processes involving activation energy, we shall consider the adsorption of a diatomic gas (X_2) which may be adsorbed on the surface (S) in question in two forms (a) as molecules, (b) as individual atoms. We may represent the two processes by means of the equations

$$\text{(a)} \quad S + X_2 \rightleftharpoons S(X_2)$$

$$\text{(b)} \quad S + X_2 \rightleftharpoons S\begin{pmatrix}-X\\-X\end{pmatrix}$$

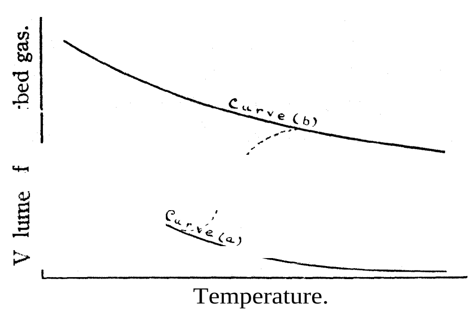
---

[3] **Lenard,** *Sitzb.* **Akad.** *Heidelberg, 5A, 16* **(1914).**

[4] **Langmuir, THIS JOURNAL, 38, 2221 (1916).**

We shall assume that, in a particular case, the heats of adsorption for the two processes (a) and (b) are respectively Q_a and Q, and that Q_b is greater than Q_a. We shall further assume that the activation energies are different and that the activation energy of process (a), E_a, is small, but that the activation energy of (b), E_b, is markedly higher. Under these conditions the activation energies of the reverse processes of vaporization are, respectively, E_a f Q_a and $E_b + Q_b$.

It is a consequence of the Langmuir concept of adsorption as due to the time lag between condensation and evaporation that the average time which molecules occupy the surface depends upon the ratio of the rates of adsorption and desorption and, therefore, accepting the above assumptions, on the ratio A, $e^{-E_a/RT}/B_a\ e^{-(Q_a + E_a)/RT} = (A_a/B_a)\ e^{+Q_a/RT}$ in the one case and on $(A_b/B_b)\ e^{+Q_b/RT}$ in the other case. Since the variations in A, and A_b, B_a and B_b are minor[5] as compared with the variation of the exponential for different values of Q_a and Q_b, it follows that the relative magnitudes of Q_a and Q_b largely determine the positions of the adsorption–temperature isobars for the two processes. For the case assumed, $Q_b > Q_a$, the isobar for (b) will lie above that for process (a) (Fig. 1). If the heats of adsorption for the two processes were equal the two curves would more nearly coincide. The differences would depend only on differences in A„ A_b, B_a and B_b. Were Q_b less than Q_a the curve for the isobar would lie below that of Q_a. There is no experimental evidence as yet of such a case.



Pig. 1.—Schematic representation of adsorption isobars with two activation energies for the adsorption processes.

(2) Extent **of Adsorption** and Temperature.—It may happen, by reason of the respective magnitudes of E_a and E_b, that, over a given range of low temperatures, the velocity of process (b) will be negligibly slow compared with that of (a). Under such circumstances the experimental results obtained will follow curve (a). As the temperature is raised there will be the normal decrease in adsorption of X_2 with temperature, but, simultaneously, there will be an increase in the velocity of process (b) so that, at sufficiently high temperatures, the experimental values obtained

---

[5] In the simple Langmuir theory A_a and A_b are the rates at which molecules strike unit surface inelastically and are identical. The B factors in the evaporation process are similar to the factor C in the equation for a unimolecular reaction $dx/dt = C\,e^{-E/RT}$. Polanyi and Wigner [Z. *physik.* Cham., 139, 439 (1928)] have shown that, in this latter case, the variation of the C values in the available experimental data is very small.

will be due practically exclusively to the adsorption process (b). Between the two extremes of temperature there will be a region in which the results obtained will be intermediate between (a) and (b) and determined by the relative magnitudes of Q_a, Q_b, E_a and E_b. This intermediate stage may reveal itself by rising values of the adsorption at a given pressure with increasing temperature. This condition is indicated by the dotted line in Fig. 1. The location of the two adsorption curves with respect one to another will determine the magnitude of the increase in adsorption (if any) due to such causes.

(3) Adsorption Equilibrium and Nature of the Activation Process.—The conclusions thus reached with respect to the two adsorption processes involving, respectively, molecular and atomic adsorption are not limited to such processes but are applicable to any two processes of adsorption of a given molecular species producing any two forms of adsorbed product, the two processes differing in their activation energies. Dissociation of the molecule to yield atoms on the surface represents only one particular case of the general principle. It is apparent that adsorption may involve a plurality of types of change, in which case there will be a corresponding number of possible curves in Fig. 1 and a corresponding complexity in the observed adsorption–temperature relations. Thus, if a third type of adsorption occurred involving a higher activation energy E_c and a higher heat of adsorption Q_c, the isobar would lie above that of curve (b) and, in a given temperature range, there would be again a transition region of metastable adsorptions rising with increase of temperature. It should also be pointed out that if a case were found where Q_b was less than Q_a it is theoretically possible that the adsorption isobars experimentally realized would consist of two sections of decreasing adsorption with increasing temperature with an intermediate metastable region in which the decrease with temperature would be very much more pronounced. For simplicity, in the succeeding theoretical treatment only two types of adsorption will be discussed. It will be convenient to designate as type (a) the adsorption that occurs with low or negligible activation energies and as type (b) the adsorptions involving high activation energies. This in no sense, however, imposes on us the restriction that the adsorptions are of any particular type, for example, molecular and atomic. Any two adsorption processes of the same gaseous species may be involved.

(4) Activation Energy and Attainment of Equilibrium.—One further consequence of the present concept of activation energy on the results of experimental measurement may now be indicated. It is evident that because of the large activation energy, E_b, the portion of the curve (b) to the left of the dotted ascending curve cannot be experimentally realized by measurements conducted wholly at the lower temperatures involved. It is, however, also evident that values much higher than those correspond-

ing to curve (a) at the temperatures in question will be obtained if adsorption equilibrium is first established at higher temperatures, where both processes are occurring, and then the system be brought to the lower temperature. One can conclude from the theory that desorption of gas as far as curve (a) will not occur on cooling, that values considerably higher than those of curve (a) will be obtained and that these values will *approximate* to but will, in general, be somewhat lower than those for true equilibrium in the process (b) at the temperature in question.

(5) Effect of Varying Adsorbent.—Variation in the nature of the adsorbent with a given adsorbate will yield variations in the adsorption dependent on the values of Q_a, Q_b, E_a and E_b for the system in question. The discussion may be simplified if we assume that with every adsorbent the value of E_a is negligibly small. A variation in the value of E_b from case to case will involve a variation in the temperature at which the transition from adsorption along curve (a) to that along curve (b) occurs. For low values of E_b the transition will occur at low temperatures and may even result in the absence of all evidence of a transition. If E_b attains high values the transition will take place only at elevated temperatures. With a wide range of adsorbents these extremes of transition may be expected in practice.

(6) Effect of Concentration of Adsorbate.—The effect of increasing concentration of adsorbable gas may be indicated by again assuming that E_a is small and that the adsorption complex $S(X_2)$ is an intermediate stage in the formation of the second type of adsorption. The rate of the second stage will, therefore, be determined by the concentration of $S(X_2)$ and the activation energy E_b. The gas striking the surface will form initially complexes of type (a). Without the necessary activation energy, the molecules will re-evaporate. With increasing gas pressure the number of molecules striking the surface increases and, therefore, the probability of a collision with the necessary activation energy present at the place of collision will increase. The adsorption complex formed will become increasingly of the type (b). While this behavior will not be exhibited by the form of the adsorption isotherm it may be deduced from the values for the heat of adsorption (see below) at various equilibrium pressures.

(7) Effect of Non-Uniform Surface.—In actual practice adsorption studies are not made with uniform surfaces but with surfaces of varied activity. This reveals itself in the case of a single process of adsorption by a steadily falling value for the heat of adsorption. The adsorptions involving high heats of adsorption occur first and are succeeded by processes with lower and lower heat of adsorption. This factor introduces a constantly varying Q into the equations determining the evaporation process. Were the E factor constant, the effect of this falling Q would be to increase the rate of evaporation by increase in the term $e^{-(Q + E)/RT}$. There is

reason to believe, however, from analogy with the activation energy of chemical reactions at surfaces,[6] that the activation energy of adsorption processes should become larger and larger the less active the surface area. This increase in E with surface covered would tend, therefore, to offset to some extent the effect of diminishing Q.

In the case discussed in the preceding section where the extent of adsorption according to type (b) increases with increasing partial pressure of the gas, it is evident that the heat of adsorption–pressure (or amount of adsorbed gas) curve might show two descending sections corresponding mainly to types (a) and (b) with an intermediate section of transition values between. Such a possibility is shown diagrammatically in Fig. 2. It is also evident that, with suitable values for the activation energies and heats of adsorption, the preliminary fall in the first portion of the curve might be eliminated, leaving a curve showing a maximum. With low values for both E_a and E_b or, alternatively, at high temperatures, the curve would be entirely of the (b) type and show continuously falling values.

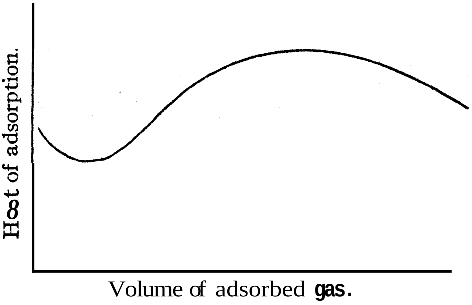


Fig. 2.—Variation of heat of adsorption with amount adsorbed for two adsorption processes having different activation energies.

(8) **Heat** of Adsorption **and** Temperature.—When, owing to a high value of E_b or the low temperature of operation, the adsorption is purely of type (a), the heats of adsorption measured will be characteristic of the adsorption process (a) and the extent of the surface covered. At high temperatures, where process (b) predominates, the heats of adsorption would in the same way be characteristic of that process. For this reason one can deduce a change in heats of adsorption with temperature. Since adsorption of the type (a) is the low temperature, non-specific, non-activated type, we can in general expect low heats of adsorption Q_a. For the specific adsorption involving activation and activation energy of adsorption, with the operation of valence forces at the surface, we should in general expect somewhat higher values for Q_b, of the order of magnitude familiar in chemical processes. It must be remembered, however, that since, for example, the activation process may involve in the case of a diatomic molecule a dissociation of the molecule into atoms, there is always the possibility of Q_b becoming a small magnitude.[7] At intermediate tempera-

[6] Taylor, *Z. Elektrochem.*, 35, 542 (1929); "Treatise on Physical Chemistry," Vol. II, D. Van Nostrand Co., New York, 1931, 2d ed., Chap. XV, pp. 1081–1086.

[7] Compare, for example, the chemical reaction $N_2 + O_2 = 2NO$; the net heat of

tures where both adsorptions are involved, values intermediate to Q_a and Q_b would be obtained. It is also to be remembered in this connection, as already emphasized in the preceding section, that the Q value obtained under a given set of conditions is also a function of the nature of the surface covered, highest with the most active areas, whether the adsorption is of the (a) or (b) type.

(9) Extent of Saturation of a Non-Uniform Surface.—From the preceding discussion it will be evident that, on a non-uniform surface, it can readily follow that the combined operation of the Q and E values may result in a set of conditions such that only on a fraction of the surface may the activating adsorption (b) occur. If the temperature be such that adsorption of the type (a) is negligibly small, it would follow that the adsorption isotherms obtained would show all the characteristics of saturation with, however, only a small fraction of the surface covered with adsorbed gas. Such a condition would be of first importance in those chemical reactions at surfaces where activation was a condition precedent to reaction.

(10) The Temperature Coefficient of Surface Reactions and the Concept of Activation Energy of Adsorption.—It is well known that, in surface reactions, the observed activation energy of the chemical reaction is identical with the true activation energy only in exceptional circumstances (actually, in the so-called zero order reactions) For other reactions the observed and true activation energies are related to one another by equations which involve also the heats of adsorption of the reactants and products. Thus, as has been indicated[8] by Polanyi[9] and Hinshelwood,[10] for a unimolecular process involving decomposition of a substance A, the true energy of activation of the reaction (E_t) is related to the observed value E_0 by the equation

$$E_0 = E_t - Q_A \qquad (1)$$

where Q_A is the heat of adsorption of the substance A For a similar process involving retardation by a reaction product B the relation is

$$E_0 = E_t - Q_A + Q_B \qquad (2)$$

where Q_B is the heat of absorption of the reaction product B.

As pointed out by Hinshelwood, these equations presuppose that the establishment of adsorption equilibrium is rapid in comparison with any disturbance of it due to the removal of the molecule in chemical change. When, however, owing to the operation of an activation energy term, E, the rate of adsorption leading to activation is very materially decreased, this

---

this reaction is **−43** kg. calories, as it involves the heat of dissociation of nitrogen and oxygen molecules, respectively, 200 and 120 kg. calories.

condition may no longer hold and the equations derived will be inapplicable. This consideration applies to both Equations 1 and 2 above.

(11) Velocity of Evaporation and Adsorption of Molecules.—It has been customary hitherto in treating the velocity of evaporation of adsorbed molecules to assume its proportionality to $e^{-Q/RT}$ where Q was the heat of adsorption. This is only true so long as the activation energy of the adsorption process is negligibly small. The correct expression for the evaporation process involves $e^{-(E+Q)/RT}$; it is evident that cases might arise in which great differences in the velocity of evaporation of two adsorbed gases were obtained, even though the Q's were identical, because the E's were markedly different. It is also not impossible that, owing to marked differences in the values of E in two cases, the velocity of evaporation in the process with a higher Q value should be more rapid than the velocity of evaporation with the lower Q. In the reverse process of adsorption the same principles apply.

With this review of the general principles involved in the application of the concept of activation energy to adsorption processes accomplished, we may now pass to an examination of experimental data in order to ascertain how far the general conclusions reached in the preceding may find experimental verification. We shall examine data with reference to adsorption processes for such gases as hydrogen, oxygen, carbon monoxide, nitrogen, sulfur dioxide and water vapor on a variety of surfaces. We shall find our theoretical conclusions abundantly verified by practical experience.

Experimental Data and the Concept of Activation Energy of Adsorption

It will be convenient to classify the experimental data with reference to the gas adsorbed, discussing in each case the various adsorbents studied.

Adsorption of Hydrogen.—There are pertinent data for hydrogen adsorption on the catalytically active metals, nickel, copper, platinum, palladium, as well as on charcoal and a few oxide surfaces.

NICKEL.—The most abundant data are available in this case on nickel surfaces. The recent research of Benton and White,[11] extending the earlier studies of Gauger and Taylor,[12] provide data for adsorption equilibria over the temperature range —209 to 305°. Benton and White's results show that the activation energies involved are low since the transition (Section (2) of General Theory) from a region of low adsorption to one of high adsorption occurs in the temperature range of —190 to —100°. Above this latter temperature, the activation process is rapid. Benton and White observed different amounts of adsorption at low temperatures according as one operated exclusively at low temperatures or saturated at high temperatures and then cooled down. This checks with the conclu-

---

[12] Gauger and Taylor, *ibid.*, 45,920 (1923).

sions of Section (4) in the General Theory. The increased adsorption obtained by cooling to −191° over that observed at 0° will be in part due to increased adsorption of the activated adsorbate in passing through the metastable region plus any additional hydrogen adsorbed with the low activation energy.

Benton and White's data on the velocity with which equilibrium is attained also conform to the requirements of the present theory. At the temperatures of −183 and −191°, "the pressure became constant almost immediately after admitting the gas;" at these temperatures we have type (a) adsorption with low values of E_a. In the higher[13] temperature range equilibrium was fairly rapidly established at very low pressures, slowly at moderate pressures and somewhat less slowly at higher pressures. These are consistent with an adsorption involving an activation energy as set forth earlier in Sections (6) and (11). Gauger and Taylor had earlier noted that an interval of ten minutes was insufficient at room temperatures and upward to establish equilibrium and that isotherms thus obtained were different from those obtained by de-sorbing gas from the surface. The work of Gauger and Taylor also showed the effect discussed in Section (9) of the varying extent of surface covered, with apparent saturation, at different temperatures.

An increase in the heat of adsorption with increase of surface covered has been shown in Section (8) to be a possible consequence of adsorption processes involving activation energy. Such an increase was demonstrated by Fryling[14] in the case of active nickel catalysts. In other cases with less active adsorbents this phenomenon was absent in the measurements at 0°. In all cases at this temperature the heats of adsorption were high (*ca.* 15,000 cal.) as compared with those involving only van der Waals forces.

One can summarize, therefore, the case of nickel–hydrogen by observing that it conforms closely to the conditions imposed by the general theory. In the system metal–hydrogen this constitutes the best investigated case. With other metals the data are scantier and, to economize space, they will only be recorded in bare outline.

PLATINUM.—Platinum shows the phenomenon of *diminishing* adsorption with decreasing temperature as noted with nickel above.[15] Apparently, the decreased absorption sets in at a higher temperature than in the case of nickel since de Hemptinne records diminished adsorption at −78°, whereas the decrease with nickel occurred below −110°. G. B. Taylor, Kistiakowsky and Perry[16] record high heats of adsorption at 0° of the order of 10,-

---

[13] We cannot explain why the equilibrium below −191° was slowly established unless it was due to the experimental difficulty of maintaining constant temperature.

000–30,000 calories. A determination of the heat of adsorption in the low temperature range would be revealing. On the present thesis it should be much lower than the values at 0°.

PALLADIUM.—De Hemptinne records a higher absorption of hydrogen by palladium at −78° than at 0°. On the other hand, there is excellent experimental evidence by Firth[17] that massive palladium foil will not take up hydrogen at liquid-air temperatures. Palladium saturated with hydrogen at ordinary temperatures did not evolve this gas on cooling to liquid-air temperatures. In a later communication, Firth[18] compares the absorption of palladium black samples which have been either (a) saturated at 110° with hydrogen and then cooled in hydrogen to the temperature of measurement or (b) have been saturated with hydrogen only at the temperature in question. In both cases there is a decrease in absorption with increase of temperature from liquid-air temperatures upward. Prior saturation at 110° always gave the higher values. The curve (b) shows a pronounced minimum around 20°, which indicates that an activation sets in around this temperature, leading to the increased adsorption represented by the difference in values of curves (a) and (b). A similar minimum sorption has also been found by Gutbier, Gebhardt and Ottenstein.[19] In the case of palladium conditions are complicated by the high solubility of the gas in the metal. This point will be treated subsequently in a special paragraph. There appear to be no data on heats of adsorption.

COPPER.—There is no evidence in the published data of adsorptions on copper similar to that cited in the preceding cases. Through the courtesy of Dr. R. N. Pease, however, some unpublished data by C. A. Harris may be quoted to the same effect.[20] On a particular sample of active copper, Harris found a pronounced maximum in the adsorption of hydrogen on copper between 0 and 100°. At 56.5° and 760 mm. pressure the adsorption was 35% greater than at 0°. At 100 and 155° the adsorption was slightly greater than at 0° but less again at 193° There is also good evidence in this work that by saturating at higher temperatures and then returning to 0° the adsorptions recorded could be increased many-fold (cf. Section (4)). These latter results should be accepted with reserve since the adsorbed hydrogen was not recovered from the surface after the experiment. There is, however, every reason to believe that such results are quite sound and in accord with those already recorded That such is the case is emphasized by the knowledge that Taylor and Kistiakowsky[21] found a pronounced

[21] Taylor and Kistiakowsky, *Z. physik. Chem.*, 125,341 (1927)

maximum in the curve for the heat of adsorption of hydrogen on an active copper catalyst. Some unpublished data by Washburn also indicate an activation energy for the hydrogen adsorption. Although the heat of adsorption is only 10,000 calories as compared with 15,000 calories for ethylene, it is a familiar experimental fact that it is easier to remove this adsorbed ethylene from the surface than it is to remove hydrogen (cf. the discussion of carbon monoxide on platinum later).

The evidence cited in this case would indicate that the activation energy necessary in the case of the copper–hydrogen system is markedly higher than with nickel, platinum and palladium.

CARBON.—There is indirect evidence that, with carbon, activation occurs at even lower temperatures than with nickel and palladium. At $-78°$ and at liquid air temperatures[22] the adsorption of hydrogen on charcoal is very much greater than at 0°, and greatest at the lowest temperature. Above $-200°$, therefore, there is no evidence of diminishing adsorption. There is, however, indirect evidence that even at liquid hydrogen temperatures adsorbed hydrogen is at any rate in part activated. Bonhoeffer and Harteck[23] showed that charcoal is an excellent catalyst for the conversion of ortho- to para-hydrogen at these low temperatures. There is good reason to believe that this interconversion of the two forms must occur through the atomic state, which, therefore, must be present at the surface.[24] If so, the activation energy of the adsorption process must indeed be small. It is pertinent to point out that the data presented above for nickel, platinum and palladium provide the reason for the inefficiency of these metals in the para-hydrogen conversion at liquid-air temperatures and lower, whereas they are good catalysts for the reconversion process at room temperatures. This peculiar behavior puzzled both Bonhoeffer and Harteck, who believed, however, that it might be due to some "triviale Ursache." Measurements of the heats of adsorption over a range of temperatures and pressures would be instructive in respect to the matters here raised.

OXIDE CATALYSTS.—It is known that series of oxides are efficient agents for hydrogenation–dehydrogenation processes and that these operate normally in a higher temperature range than the metal hydrogenation catalysts. On this basis one might anticipate that the phenomena discussed concerning adsorption by the metals in the low temperature range might be repeated with the oxide catalysts in a higher temperature range. Evidence is accumulating that this is true.

[24] The conversion of ortho- to para-hydrogen involves a change of the nuclear spin of one hydrogen atom. According to present accepted ideas this can only occur by a definite exchange of atoms. Cf. Farkas, Z. *Elektrochem.*, 36,782 (1930).

Garner and Kingman have recently reported[25] that hydrogen (or carbon monoxide) adsorbed at low pressures and room temperature on ZnO–Cr_2O_3 catalysts was given off at 100–120°, but after twenty to thirty minutes was readsorbed on the surface of the catalysts. This is precisely what is expected from *a* high temperature adsorption with high activation energy. Indeed, this concept of activation energy requires the evaporation and re-absorption as two independent processes, a phenomenon which appeared to Garner and Kingman as "curious." It is in accord with the experience of Taylor and Kistiakowsky[26] with zinc oxide and with zinc–chromium oxide catalysts which showed that desorption only occurs rapidly by evacuation above 300°. Further, on zinc–chromium oxides, Kistiakowsky and Flosdorf[27] have recently shown the presence of a maximum in the heat of adsorption–pressure curve as with hydrogen on nickel and copper. Garner and Kingman state that the phenomenon they observed with zinc oxide is given by copper oxide.

With hydrogen on manganous oxide some measurements by Williamson at present in progress in this Laboratory have shown a pronounced increase of hydrogen adsorption with temperature. At 0 and 100° negligible amounts of hydrogen are adsorbed. At 184° adsorption can just be demonstrated while at 305° as much as 10 cc. of gas has been adsorbed by the sample in question. Our work shows also that on saturating at the higher temperature and cooling to lower temperatures, complete desorption does not occur. These experiments, therefore, extend the region of transition from one type of adsorption to another, from temperatures below $-110°$ in the case of metals to above 200° in the case of oxides.

Dr. H. N. Alyea has directed my attention to the experiments of Bone and Wheeler[28] with quartz at 650° in which it was found that considerable quantities of hydrogen were taken up at this temperature. In view of the preceding examples a renewed investigation with glass and quartz in this region is desirable and is being undertaken by Dr. Alyea. One might observe that it seems doubtful that under the circumstances given the adsorption should be of atomic hydrogen since Langmuir has shown that glass surfaces loaded with atomic hydrogen at liquid-air temperatures readily yield this hydrogen in the molecular form on raising the temperature. The possibility of occlusion or solution of the gas in the preceding cases will receive separate discussion at a later stage.

Adsorption of Oxygen.—The data on oxygen adsorption which are of interest in respect to activation energy concern such varied surfaces as carbon, silver, gold, nickel, tungsten and platinum.

CARBON.—It has long been recognized that the adsorption of oxygen on carbon did not obey the simple general theory of adsorption at solid surfaces but no satisfactory treatment of the subject has hitherto been available. It may now be shown that the adsorption consists of more than one type and that activation energy is involved. There does not appear to be any evidence of an increase of adsorption with increase of temperature. There is definite evidence, however, of two types of adsorption similar to those discussed in the general theoretical portion of this paper. Dewar[29] showed that the oxygen adsorbed by charcoal at −185° was given off on heating to room temperature. Lowry and Hulett showed[30] with a given char that of the oxygen which saturated the sample at room temperatures, not more than 50% was recoverable as oxygen on evacuation. The residue could only be recovered as carbon oxides. The extent of oxygen fixation was a function of the char. Rhead and Wheeler showed that the oxygen retained by charcoal[31] at temperatures of 200° and upward could not be recovered as oxygen at all, only as carbon oxides. The influence of temperature on the fixation or activation process is evident not only from these several researches but also from the experimental data of Rhead and Wheeler in the temperature range of 300–600°.

The data for heats of adsorption on charcoal are also illuminating. At −185° Dewar obtained a value of 3744 calories per mole. At higher temperatures the principal data have been obtained by Garner and his coworker and by Keyes and Marshall.[33] The data of the latter showed a heat of adsorption at 0° of 72,000 calories per mole. More recently Marshall and Bramston-Cook show values falling from 89,600 calories at nearly zero concentration to 70,000 calories, at which value it flattens prior to the normal fall. The data of Garner and his colleagues all agree in indicating very low values on the earlier portions of the curve with values rising subsequently to a maximum and then a falling curve, as in the experiments with hydrogen on nickel, copper and zinc–chromium oxides. Whatever the ultimate explanation of these experimental discrepancies may be,[34] is immaterial to the present discussion. It is sufficient to

[34] See Bull and Garner, *Nature*, 124, 409 (1929). The simplest explanation would seem to be that the divergencies were due to the difference in methods employed. The ice calorimeter permits longer time intervals for the measurement during which time the activation process may have occurred, the high heat value being thereby obtained. The Garner method operates on shorter time intervals and so adsorption without activation is probably the major process whose heat effect was measured.

record the existence of rising heats of adsorption in yet another case of abnormal adsorption of a gas at a solid surface. On extending their measurements to high temperatures, Blench and Garner obtained heats of adsorption as high as 227,000 calories. The extraordinary increase in the heat data from liquid-air temperatures to high temperatures is striking evidence of a plurality of processes in the fixation of oxygen by charcoal.

SILVER.—Adsorption experiments by Benton and Elgin, with oxygen on silver,[35] are in excellent agreement with the concept of activation energy. Their measurements indicate an increasing adsorption in the region 26–110° and a great slowness in attaining equilibrium. At 110° a period of twenty-four hours was required before a constant value of 14.84 cc. adsorption was attained. The adsorption was rapid in the first stages but after the addition of each successive quantity a gradual and long-continued pressure decrease occurred. Furthermore, only a very small fraction of the total amount adsorbed could be recovered by evacuation. It would be interesting to extend such measurements to very low temperatures to see how low in temperature this irreversibility extends. A measurement of heats of adsorption over the same temperature range should also be instructive. In this same investigation the authors record an immeasurably small adsorption of hydrogen at 26 and 110°. Measurements with this gas above and below this temperature range would be instructive, especially since silver is known to possess a certain small activity as a hydrogenation–dehydrogenation catalyst.

GOLD.—Experiments by the same authors, with oxygen on gold,[36] are compelling evidence in support of adsorption with an activation energy. The authors find that "at about 650 mm. pressure the gold took up 3.57 cc. at 98°, 4.78 cc. at 130° and 5.73 cc. at 157°." Measurements were continued at a temperature of 130° for forty-eight hours after apparent equilibrium had been reached without altering the above value. Without removing the oxygen the temperature was raised to 157° and the system allowed to come to equilibrium, which also was the same as before. The temperature was then lowered to 130°. Although this temperature was maintained for eighty hours, no decrease occurred in the amount of gas adsorbed. This is convincing proof that it is the activation energy of the process which is determining the extent of adsorption at any temperature. Benton and Elgin observe that at 130° approximately twenty-four hours are required for attainment of apparent equilibrium, one hundred eight hours at 98°.[37] At 25° an adsorption of only 0.1 cc. had occurred in seven

[35] Benton and Elgin, THIS JOURNAL, 48, 3027 (1926). This and the example next discussed were called to my attention by my colleague, Dr. J. C. Elgin.

[36] Benton and Elgin, *ibid.*, 49, 2426 (1927).

[37] If one uses these times as a rough measure of reaction velocity at the two temperatures one obtains by insertion in the equation d ln $k/\mathrm{d}t = E/RT^2$ the value of $E =$

hours of contact. They further demonstrate that the rate of adsorption is nearly independent of the gas pressure, which indicates that the activation energy is supplied to adsorbed gas and hence by the surface. The rates of adsorption with gold were pronouncedly slower than with silver. The oxygen adsorbed at 130° was not recoverable by evacuation. Experiments at very low and at higher temperatures would be of great interest both with respect to adsorption, reversibility and heat of adsorption. On the gold sample, a scarcely measurable adsorption of hydrogen occurred at 130°. The study of higher temperatures should be of interest.

NICKEL.—A similar condition apparently holds with an active nickel surface but at somewhat lower temperatures. Russell[38] has recently found that oxygen is strongly, irreversibly and rapidly adsorbed by nickel in an ice-bath. The heat evolution is of the order of 100,000 calories per mole adsorbed.

Experiments with oxygen and nickel at liquid air temperatures are to be undertaken by Dr. Russell at the writer's request.

TUNGSTEN.—The retention of oxygen by clean tungsten filaments was demonstrated by Langmuir, who also showed that the stability of the oxide film was so great that no interaction with hydrogen occurred up to 1500°K. The film may be formed at room temperatures but its properties are somewhat different from that produced by heating the filament in oxygen at low partial pressures at about 1900°K. for a few seconds.[39] From its behavior toward cesium under these conditions there is reason to believe that the oxygen taken up at 1900°K. is then probably held as negative oxygen ions. The heat of adsorption of this oxygen has been estimated by Langmuir to be 160,000 calories per gram atom.[40] Dr. S. Dushman has kindly consented to ascertain whether this strong affinity between tungsten and oxygen manifests itself at liquid-air temperatures. Langmuir believes that oxygen may be adsorbed on tungsten surfaces in at least three different forms.

PLATINUM.—Langmuir similarly showed that oxygen was held tenaciously by platinum and could be removed by reaction with hydrogen. Recent experiments[41] have shown that the heat of adsorption may be as high as 163,000 calories per mole of oxygen adsorbed and that values in the neighborhood of 100,000 are usual. The adsorption process is fairly rapid

---

13,830 calories. To this value must be added the activation energy of the molecular absorption process since this influences the concentration of molecules at the surface at the two temperatures. The data, therefore, suggest in this case an activation energy of around 15,000 calories.

at 0° but detailed experiments at lower temperatures have not yet been performed. Langmuir states[42] that in some earlier work he observed that platinum at liquid-air temperatures took up a certain amount of oxygen. On warming the system some oxygen was evolved, but at higher temperatures this same oxygen was once more reabsorbed. This exper'imental fact indicates a change in the state of oxygen absorption between liquid air and room temperatures.

Adsorption of Carbon Monoxide.—Experimental evidence in support of the concept of activation energy of adsorption processes is available also in the adsorption of carbon monoxide by nickel, copper, platinum and palladium.

NICKEL.—Carbon monoxide in contact with nickel shows strikingly the function of temperature in the adsorption process. At ordinary temperatures, as is well known, carbon monoxide and nickel react to form nickel carbonyl. At 180° this reaction is suppressed and a truly reversible adsorption of carbon monoxide occurs.[43] At about 270° the carbon monoxide begins to be irreversibly adsorbed and a portion remains in contact with the surface on evacuation. It is this carbon monoxide which reacts with hydrogen to yield methane and water, or with other carbon monoxide gas to yield carbon dioxide and carbon. We might suggest that at this temperature the atoms of carbon monoxide are now attached to the nickel surface directly as Ni_3C and NiO. Indeed experimental evidence indicates the presence of nickel carbide as an intermediate stage in methane synthesis.[44] It is this last process, whatever its nature, that involves the high activation energy. Further, it can be demonstrated that this process of activation only occurs at 270° on the most active portions of the nickel surface since relatively small amounts of sulfur compounds poison the surface for the methane reaction. In this case, therefore, we have an experimental example of the case discussed in Section (9) of the general theory in which only a small fraction of the total surface is capable of effecting the activation in question.

COPPER.—On copper surfaces carbon monoxide showed a curve for heat of adsorption as a function of surface covered which first fell, then rose to a maximum and then once more showed falling values.[21] This is the case discussed in Section (7) of the general theory and illustrated in Fig. 2. It constitutes good evidence of a dual nature of the adsorption process on copper. The heats of adsorption measured were of the order of 10,000–20,000 calories. No evidence as to rising adsorptions over a temperature range has been located in the literature but a study of the region below 0° would be of interest. It is known that no such activation of the carbon

---

[42] Personal communication.

[43] Taylor and Burns, THIS JOURNAL, 43, 1283 (1921).

[44] Bahr and Bahr, Ber., 61B, 2177,2465 (1928).

monoxide molecule occurs on copper as takes place on nickel at 300°. Even up to higher temperatures no decomposition of carbon monoxide to carbon dioxide and carbon occurs on copper nor can methane be produced under ordinary conditions with copper. One may thus conclude that the activation energy of this latter adsorption on copper is very high indeed.

PLATINUM.—De Hemptinne records a less adsorption of carbon monoxide on platinum at −78° than at +15°. Taylor and Burns found smaller values at 25° than at 110°. It is well known that the reversibility of carbon monoxide adsorption on platinum is slight.[45] G. B. Taylor, Kistiakowsky and Perry obtained measured values of the heat of adsorption with as much as 21.7 cc. of adsorbed gas with heats of adsorption greater than 20,000 calories per mole. Of this only 0.7 cc. was removed by degassing at 350°. The significance of this is apparent when we find that on the same catalyst 5 cc. of hydrogen with heats of adsorption greater than 20,000 calories can be removed by degassing at 250° for four hours. Such results obviously suggested to the authors that "the true rate of evaporation from the surface must be influenced by other factors besides the heat of adsorption to a very considerable degree." The authors showed that differences in the rates of diffusion are too small to account for the observed phenomena, this being the reverse of the observation by Benton and Elgin cited above concerning oxygen on gold, namely, that the gas pressure was without influence on the rate of adsorption. It follows that in the case of carbon monoxide adsorption on platinum the activation energy of the adsorption process must be higher than that of hydrogen.

PALLADIUM.—De Hemptinne found an increase in carbon monoxide adsorption between −78 and +15°. Taylor and Burns found no change between 25 and 110°.

OXIDE CATALYSTS.—We have already referred to the observation of Garner and Kingman that carbon monoxide adsorbed on $ZnO-Cr_2O_3$ surfaces at room temperature was first evolved on heating to 110° and then readsorbed after twenty to thirty minutes. This is direct evidence of adsorption having an activation energy. The same conclusion is abundantly evident from the comprehensive paper by Benton[1] on the adsorption of gases by oxide catalysts. His data on the extent of "primary" and "secondary" adsorptions of carbon monoxide, their variation with temperature and pressure are all excellent material for a demonstration that the so-called "primary" adsorption is a process involving a high activation energy compared with that of the "secondary" adsorption. Indeed one might inquire how, without this concept of activation energy, one is to account for the fact that "secondary" adsorption, involving the weaker forces of adsorption, occurs at −78° in preference to "primary" adsorption which only becomes important at higher temperatures but in which the

---

[45] Langmuir, THIS JOURNAL, 40, 1361 (1918).

forces of adsorption are stronger. It is evident that secondary and primary adsorptions are in reality processes with low and with larger activation energies. None of Benton's data show an intermediate temperature range of increasing adsorption, a factor which is evidently to be attributed to the relative positions of curves (a) and (b) of Fig. 1 in these cases. Benton observes, however, that the carbon monoxide could be much more easily removed after a measurement at $-79°$ than at $0°$.

Adsorption of Nitrogen.—Adsorption of nitrogen with activation is of obvious importance in ammonia synthesis. The recent work of Frankenburger and Mayrhofer on iron surfaces laid down by condensation of iron vapor[46] along with ice or sodium chloride molecules on glass was successful in demonstrating a stoichiometric ratio $Fe:H_2$ of 1:1 for hydrogen adsorption. No similar adsorption of nitrogen could be detected although there were slight indications of a nitrogen adsorption if hydrogen was also present. This suggested to the authors that thermal activation of the nitrogen is also necessary. That such activation leads to nitrogen fixation on the iron surface at least in the presence of hydrogen is evident from the fact that in the dissociation of ammonia streaming over heated iron relatively large amounts of nitrogen are continuously present on the surface. It follows then, from the principle of "microscopic reversibility" or "entire equilibrium," that a nitrogen–hydrogen mixture passed over iron will lead to a fixation of nitrogen on the surface. In this case also, therefore, we are led to postulate activation energy of the adsorption process.

Adsorption of Water Vapor.—From what has preceded it is evident that we may expect dual processes of adsorption of water vapor on such surfaces as are active in hydration and dehydration processes, and hence on such surfaces as alumina, thoria and the like. This does not seem to have been directly tested. There is, however, one very instructive if indefinite piece of evidence that such dual activation occurs. Dohse and Kälberer[47] found that the decomposition of isopropyl alcohol on bauxite was a unimolecular reaction, inhibited by the product water and having an apparent activation energy of 39,000 calories. The true activation energy of the process, obtained from a study of the zero order reaction by constant removal of the water vapor or by investigation at low surface concentrations, gave a value of 26,000 calories. For a unimolecular process inhibited by a product, water, we saw in Section (10) of the general theory that the Polanyi–Hinshelwood equation gives

$$E_{\text{obs.}} = E_{\text{true}} - \lambda_{C_3H_7OH} + \lambda_{H_2O}$$

For low surface concentrations Dohse and Kalberer actually measured the heats of adsorption, finding $\lambda_{C_3H_7OH}$ to be 21,000 calories and $\lambda_{H_2O} = 13,000$ calories. From the equation, then, we have

---

[46] Frankenburger and Mayrhofer, *Z. Elektrochem.*, 35, 590 (1929).

[47] Dohse and Kälberer, *Z. physik. Chem.*, 5B, 131 (1929).

$$E_{\text{true}} = 39{,}000 + 21{,}000 - 13{,}000 = 47{,}000 \text{ calories}$$

in obvious disagreement with the value of 26,000 calories found for the uninhibited zero order reaction. This discrepancy is even more conspicuous when we note that water vapor with a measured heat of adsorption of 13,000 calories is inhibiting the decomposition of isopropyl alcohol with a measured adsorption heat of 21,000 calories. This shows that the heat of adsorption is no simple measure of the rate of evaporation, an additional example, therefore, of the point raised in Section (11) of the general theory and in the case of platinum–carbon monoxide adsorption. To account satisfactorily for inhibition by water in the present case we are forced to assume an activation energy of the order of at least 22,000 calories greater than that of isopropyl alcohol. Such a divergence would bring both types of experimental result into agreement.[48]

Adsorption of Sulfur **Dioxide.**—PLATINUM.—The data already cited with respect to reversibility in the adsorption of hydrogen and carbon monoxide on platinum may be supplemented by the case of sulfur dioxide. G. B. Taylor, Kistiakowsky and Perry showed that of 6.5 cc. of gas held with heats larger than 20,000 calories only 3.5 cc. is removed by degassing at 350°, whereas more than 5 cc. of hydrogen with heats greater than 20,000 calories could be removed at 250°. On another sample of platinum, sulfur dioxide with heats smaller than 20,000 calories could not be removed at 250° whereas, with hydrogen of higher heats of adsorption, removal was readily accomplished. It is thus necessary to postulate a high heat of activation for the adsorption of sulfur dioxide on platinum.

General Conclusions

It has been suggested that the slow process, requiring an activation energy, might be a solution process in the material and that the slowness of diffusion to the interior of the adsorbent was the rate-determining factor. The presence of palladium, in the list of examples cited, at once suggests this possibility. It ought to be emphasized, however, that this cannot be the general explanation. In many of the cases here dealt with the quantities of gas involved are of several orders higher magnitude than the known solubility of the gas in the substance concerned. The surface factor, too, is paramount in the cases we have been considering, whereas this factor is not of such importance where solubility is concerned. The variation of adsorption with pressure is not that to be expected on the basis of solubility.

It is obvious that the concept of activation energy for adsorption processes here developed is of great importance in the general problem of reactivity at surfaces. It is evident at once that adsorption per se need

---

[48] There is the additional possibility that, at the reaction temperature, the heat of adsorption of water is markedly greater than that recorded above. This would require a smaller spread between the activation energies.

not be related to catalytic activity. There should be, however, a closer concordance between reactivity and the adsorption processes occurring with marked activation energy. Limitations of space prevent such a discussion in this place but opportunity to treat this problem separately will be taken at a later date.

Summary

A general theory of adsorption involving several forms of adsorption at surfaces has been shown to lead to a number of conclusions capable of experimental verification. It has been shown, from abundant data in the literature, that these conclusions are already experimentally verified. It seems necessary, therefore, to abandon entirely the assumption implicit in older theories that the processes of adsorption are rapid. The assumption that all processes of adsorption possess their own characteristic activation energies permits a single general treatment of adsorption inclusive of processes which hitherto have been considered separate and unrelated. It has been shown that the only essential distinction between "secondary" and "primary" adsorptions or between "reversible" and "irreversible" adsorptions is that "secondary" or reversible adsorption processes are adsorptions normally with small heats of adsorption and small activation energies and that in the so-called "primary" or "irreversible" adsorptions, moderate or large energies of activation are involved, frequently with high heats of adsorption. The velocities of these latter processes may indeed be extremely slow. In general, it is the adsorptions with the higher energies of activation which are important in catalytic change.

THE QUINHYDRONE ELECTRODE. II

BY OLIVE M. LAMMERT, J. LIVINGSTON R. MORGAN AND MARGARET A. CAMPBELL

RECEIVED DECEMBER 16, 1930 PUBLISHED FEBRUARY 9, 1931

Introduction

While there have been a number of papers which included work more or less directly related to the effect of oxygen on the potential and to the use of nitrogen in the preparation of the quinhydrone half cell, we are not aware of any study having been made of the reproducibility of the electrode possible under conditions of preparation and use which excluded oxygen in acid solution. It is the object of this paper, then, to present the results of such a study made in 0.1 N hydrochloric acid and to compare the reproducibility of the quinhydrone electrodes prepared with nitrogen with those obtained with air and upon which we have previously reported.[1]

---

[1] Morgan, Lammert and Campbell, THIS JOURNAL, 53, 454 (1931).

Preparation and Purification of Materials.—The materials used have been described in the first paper of this series with the exception of the following.

Nitrogen.—Tank nitrogen from the Air Reduction Sales Company was reduced to the desired pressure and passed successively through solutions of alkaline permanganate, alkaline pyrogallic acid, distilled water, and the electrolyte used in the cell before it was conducted to the cell.

Oxygen.—Tank oxygen supplied by the Linde Air Products Company was purified by the same method as the compressed air.

Apparatus.—The electromotive force measurements were made with the apparatus and with the precision described in the first paper, to which reference has been made; the gases were conducted through the purifying solutions, kept at the same temperature, before being conducted to the cell solution containing the quinhydrone.

The electrodes and electrode vessels were identical with those used for the experiments in air except that in the stopper of the electrode vessel a gas inlet tube replaced the stirrer.

Procedure and Results.—The procedure adopted for the determination of the reproducibility of the quinhydrone electrode under circumstances which permit the use of nitrogen was in every respect identical with the procedure adopted in the first paper of this series[1] except that the electrodes were dried with nitrogen instead of with air and the solutions stirred with nitrogen instead of by a mechanical stirrer. The procedure was carried out in such a way that no air was admitted to the electrodes after they were immersed in alcohol. Nitrogen was bubbled through the alcohol for several minutes, the alcohol was forced out of the electrode vessel with nitrogen, and the flow of nitrogen was continued while the quinhydrone solution was being poured into the electrode vessel as well as during the time the electrodes were in the thermostat. Later results obtained when the electrodes were dried in air as described in the first paper and then stirred with nitrogen indicated that the more elaborate procedure of drying with nitrogen was unnecessary; these results will be discussed presently. In some cases oxygen or compressed air was substituted for nitrogen in both drying and stirring operations, the procedure being similar.

The results obtained with nitrogen-dried electrodes and nitrogen-stirred solutions are collected in Table I. The averages and deviations were calculated by the method used for the potentials measured in air, which results were presented in Table I of the first paper of this series.

In Table II are given the percentages of the total number of cells measured in nitrogen which lie within certain ranges.

A number of conclusions are obvious from the results collected in these tables. In the first place, quinhydrone electrodes prepared with nitrogen are far more reproducible than those prepared with air. The average

potential differences, the range of differences, and the average deviations obtained in nitrogen are much lower than those obtained in air.

Second, and a conclusion of perhaps the greatest importance, the quinhydrone electrode when prepared with c. p. platinum dipping into 0.1 N hydrochloric acid solution saturated with quinhydrone and stirred with nitrogen gives a half-cell which in our experience is more easily reproduced with great precision than any of the other half-cells used for reference. Even with the very small platinum wires (O,1–6) few potential differences (Table II) occur which are greater than 0.000010 volt; the medium sized platinum wires (A, 1–6; B, 1–6; Pt, 1–6) as well as the foils give excellent results, over 85% of the total number of cells measured giving potential differences less than 0.000005 volt and over 95% (in many cases 100%) giving differences less than 0.000010 volt. The smallest gold wires **(Au,** 7–12), as in the case of the results in air, gave erratic results and large differences; the two series of larger gold wires (Au, 1–6 and St, 1–6) and the gold foils were also less satisfactory than the platinum electrodes of the same dimensions. On the other hand, the gold electrodes purchased from Leeds and Northrup (L. & N. 1–4) were by far, as in the case of air, the most satisfactory electrodes we measured. The platinum–rhodium alloy, while less satisfactory than the pure platinum, was nevertheless more satisfactory than the platinum–iridium alloy.

Further, it is to be observed (Table I) that the potential differences obtained when the electrodes are short-circuited in pairs during pre-treatment and measurement are, in general, no smaller than when the electrodes are cleaned and dried singly. Moreover, the irregularity in the potential differences of the unshorted electrodes observed in air did not appear when the electrodes were measured in nitrogen.

What is not indicated in these tables is the very important point that whereas the cells composed of air-dried electrodes and mechanically-stirred solutions sometimes take as long as sixty minutes to reach an equilibrium potential difference, and unstirred solutions even longer, cells made with nitrogen-stirred solutions take up the equilibrium value almost immediately; the initial values are almost always very nearly the final values. That this is not due to a more efficient stirring with the nitrogen is indicated by the results obtained when air or oxygen is bubbled through the solution, results which will be discussed presently.

Our next efforts were in a direction to find out whether, if the electrodes were dried in nitrogen, it was necessary to stir the solutions with nitrogen throughout the time of measurement. We found that the average potential differences, the ranges and the average deviations were not as large as they were when the electrodes were air dried as well as measured in solutions stirred in air; on the other hand, neither were they as small as when they were measured in nitrogen-stirred solutions. This is due to the fact that when the electrodes are dried with nitrogen and the solutions mechanically stirred in the presence of air, they give small initial potential differences comparable to those obtained when nitrogen is used throughout, and larger final potential differences comparable to the equilibrium potential differences obtained when the electrodes are dried with air and the solutions mechanically stirred in the presence of air. The results which we calculated are the averages of the two types of results. Apparently, then, stirring the solution with nitrogen is of importance if the better reproducibility is desired.

Our next step was to dry the electrodes with air and to stir the solution with nitrogen. The results are given in Table III.

TABLE III

SUMMARY OF RESULTS OBTAINED WHEN THE ELECTRODES WERE DRIED WITH AIR BUT MEASURED IN SOLUTIONS STIRRED WITH NITROGEN. ELECTRODES SHORT-CIRCUITED; 0.1000 *N* HYDROCHLORIC ACID SATURATED WITH QUINHYDRONE USED

Electrode series	Electrodes in series	Values in average	Identical cleaning and drying opns. between meas.	Average equilibrium potential, volt	Ranges of difference, 0.000000 to —volt	Average deviation, millivolt

B, 1-6	6	28	2	.000002	.000010	.002
Pt, 1-6	6	32	2	.000000	.000003	.000
Au, 1-6	6	31	2	.000001	.000004	.001
St, 1-6	6	32	2	.000001	.000005	.001

Quite apparently electrodes dried in air and measured in solutions stirred with nitrogen give results fully as satisfactory as those obtained when the electrodes are dried in nitrogen as well as measured in solutions stirred with nitrogen. Consequently the more elaborate technique of drying electrodes with nitrogen may be discarded.

Some measurements were made as in the case of air with electrodes which were not dried but which were rinsed in some of the 0.1 N hydrochloric acid used and then measured in solutions stirred with nitrogen.

While the results were in general very satisfactory, they were not quite as consistent as those obtained when the electrodes were dried.

Still further measurements were made when the electrodes were dried with air and the solutions stirred with compressed air and when the electrodes were dried with oxygen and the solutions stirred with oxygen.

These methods do not give the same consistently low potential differences that are observed when nitrogen is used, which fact makes it obvious that it is the inert nitrogen which is instrumental in obviating the errors present when the half-cell is prepared in air and not an improved method of stirring the solution.

In conclusion, then, it seems fairly obvious that it is highly desirable that nitrogen be passed through the solutions during the measurements to eliminate errors which seem to arise as the result of the presence of oxygen in the solution. In the case of the gold and platinum alloys the desirability is not so marked; the action of these electrodes is erratic and demands some further study. It seems probable that the differences in air are due to the oxidation of the quinone, which introduces local disturbances in the hydroquinone–quinone equilibrium, but we are not at present able to offer any theory of the part the metal of the electrode plays in this disturbance.

Up to this time the work reported has been on the reproducibility of the different metals, in the course of which work comparisons have been made between electrodes of any one series, which is to say, in most cases, comparisons between similar specimens of the same metal. While from these results we can draw conclusions as to the relative precision with which different metals and different sizes reproduce the quinhydrone half-cell when different pieces of the same sample of metal or size are used, we cannot draw any conclusions as to whether a sample of one metal will give, within the precision of its own reproducibility when another sample of the, same metal is used, the same potential as a sample of another metal; the same may be said as to the comparative potentials of electrodes of two different sizes. Work is in progress to decide this point; it involves an intercomparison between the different series of electrodes. The results of this work will be published in the next paper.

This work was made possible by a grant from the Special Research Fund of Columbia University.

Summary

An investigation has been made of the effect of nitrogen upon the reproducibility of the quinhydrone electrode in 0.1 N hydrochloric acid, from which the following conclusions may be drawn.

1. The quinhydrone half-cell, when prepared with electrodes dried in nitrogen and with solutions stirred with nitrogen, or when prepared with electrodes dried with air and with solutions stirred with nitrogen, is far

more readily reproducible than when prepared with air-dried electrodes and solutions stirred either mechanically in the presence of air or with compressed air or oxygen.

2. In the preparation of the quinhydrone half-cell it is not sufficient to dry the electrodes with nitrogen; nitrogen must be passed through the solution. If; however, nitrogen is passed through the solution the electrodes need not be dried with nitrogen.

3. The 0.1 N hydrochloric acid quinhydrone half-cell, prepared as described in this and in the first paper of this series. is the most easily and readily reproducible electrode which the authors have used.

4. Electrodes prepared with nitrogen acquire a definite equilibrium potential much more quickly than those prepared with air.

5. Short circuiting the electrodes in pairs during pre-treatment does not affect the potential differences obtained in nitrogen.

Work is in progress which involves an inter-comparison of the electrodes of different series made up of electrodes of different metals and of different sizes of the same metal.

THE ATOMIC WEIGHTS OF NITROGEN AND SILVER. I. THE RATIO OF AMMONIA TO SILVER

BY GREGORY PAUL BAXTER AND CHARLES HERBERT GREENE

RECEIVED DECEMBER 18, 1930 PUBLISHED FEBRUARY 9, 1931

Because accurate, simple and direct methods are lacking, until recently the atomic weight of nitrogen has been less certainly known than most of those of elements of low atomic weight. But in view of recent gravimetric evidence, as well as gas density and mass spectrograph measurements, there now seems to be little doubt that the value of this constant is very nearly 14.008.

This paper describes an investigation of the ratio Ag: NH_3. The ratio NO_3: Ag is already known with a higher degree of precision than most gravimetric ratios.[1] By combining the two the ratio NH_3: NO3 may be obtained. This with the assumption of the atomic weights of hydrogen and oxygen makes possible the calculation of the atomic weight of nitrogen. In spite of the fact that the method of calculating the atomic weight of nitrogen is indirect, the result is not particularly sensitive to experimental error, for an uncertainty in the ratio NH_3: NO_3 affects the atomic weight of nitrogen by a proportion only 60% greater, while a given uncertainty in

[1] 0.57479, Richards and Forbes, Pub. *Car. Inst., No.* 69, 47 (1907); Honigschmid, Zintl and Thilo, *Z. anorg. allgem. Chem., 165,284 (1927)*

the atomic weight of hydrogen affects the atomic weight of nitrogen in a proportion one-third as large.

The outline of the experimental procedure was as follows. Ammonia was weighed while adsorbed on dehydrated chabazite in a closed tube. A suitable quantity of the ammonia was then caused to evaporate into dilute hydrochloric or hydrobromic acid until the acid was exactly neutralized. The halogen content of the solution was then found by nephelometric comparison with the purest silver in the usual way.

The first step in the investigation was to make certain that the end-point in the comparison of ammonia with hydrochloric and hydrobromic acids could be determined with the necessary degree of precision. We found that this could be accomplished by using either methyl red or litmus as indicator. Approximately one normal solution of ammonium chloride, which had been subjected to one, two, three and four crystallizations from conductivity water, gave the same tint with methyl red, as nearly as could be determined, provided the crystals had been centrifugally drained and thoroughly rinsed to remove the mother liquor. The mother liquor itself was always more acid owing to escape of ammonia formed by hydrolysis.

Furthermore, if the solutions of ammonium chloride were deliberately made slightly acid or basic by addition of small amounts of hydrochloric acid or ammonium hydroxide immediately before crystallization, the crystals, if thoroughly rinsed, gave solutions of the same acidity as those of salt which had been crystallized without such additions.

The color of the indicator in 100 cc. of a normal solution of the chloride was perceptibly altered by the addition of 0.1 ml. of 0.01 normal base or acid. Since this quantity of acid corresponds to only 0.001% of the salt present, it was evident that the comparison of ammonia with hydrochloric acid could be carried out with sufficient accuracy.

Although there seemed to be every reason to expect that ammonium bromide would behave in the same manner, similar experiments were made with carefully purified ammonium bromide, without disclosing any differences, except that corresponding solutions of the bromide seemed to produce a slightly pinker shade with methyl red.

Some of the later experiments were carried out with litmus instead of methyl red. In spite of the fact that the color change of the former indicator extends over a greater P_H range, the sensitiveness of the end-point was only slightly reduced.

Although the ratio of ammonia to silver found by comparing the halide solution with the silver solution is independent of the particular halogen involved, the hydrochloric and hydrobromic acids were carefully purified. Good quality hydrochloric acid was diluted with an equal volume of water, and after the addition of a small amount of potassium permanganate to liberate bromine and iodine if present, the nearly constant boiling solution was distilled through a quartz condenser. The first half of the distillate was rejected as well as a small residue in the still. The portion retained was a second time distilled in the same way. The middle portion of the distillate was preserved in a quartz flask.

Hydrogen bromide was produced by synthesis from pure hydrogen and bromine, and the solution was further purified by distillation. Bromine was freed in large part from chlorine by solution in aqueous potassium bromide, and distillation. A portion of the partially purified bromine was converted into potassium bromide by addition to a solution of recrystallized potassium oxalate and the remainder of the bromine was subjected to a second distillation from solution in this bromide. All the product was next converted to potassium bromide by reaction with three times crystallized potassium oxalate, and after evaporation of the solution the residual potassium bromide was fused in a platinum dish with the addition of small amounts of potassium permanganate to oxidize organic matter. A concentrated solution of the bromide was boiled with a small amount of permanganate and sulfuric acid to remove residual iodine, and then the solution was cooled and treated with a considerable excess of sulfuric acid which had been heated to fuming to remove volatile acids. The potassium sulfate which deposited was separated and bromine was liberated from the solution by adding about 80% of the theoretical amount of permanganate. After distillation from the solution the bromine was washed with water and once distilled.

Hydrogen bromide was prepared by saturating pure electrolytic hydrogen with bromine at 44° and passing the mixture over hot platinized asbestos. Any excess of bromine was removed by washing the gas with ferrous bromide solution and the washed gas was then absorbed in the purest water. Two distillations of the resulting solution through a quartz condenser followed, only the middle portions of the constant boiling distillate being retained. The acid was preserved in a pyrex flask, and remained colorless.

Another specimen of hydrobromic acid was prepared by distilling a solution which resulted from work on nickelous bromide carried on by Professor S. Ishimaru.[2] The bromine used in this preparation had been subjected to the same treatment as ours. The acid seemed to have a slight tendency to decompose on standing.

Pure ammonia was prepared by fractional distillation of liquid ammonia in an all-glass apparatus constructed for the purpose by Dr. E. K. Haviland in connection with another research. The original material was commercial synthetic liquid ammonia supplied in a steel cylinder. McKelvey and Taylor[3] have shown that the important impurities in such material are

[2] Baxter and Ishimaru, THIS JOURNAL, 51, 1729 (1929).

[3] McKelvey and Taylor, *Bur. Standards, Sci. Pub. 365.*

moisture and non-condensing gases. The cylinder A (Fig. 1) was connected by means of a copper tube B to the glass purifying apparatus by means of hard de Khotinsky cement. The mercury relief valve D was long enough to permit evacuation of the apparatus. After passing through the mercury bubbler E and the trap F the gas was passed over fused potassium hydroxide in the two towers C, and through the tube H filled with the dehydrated adsorbent gmelinite, both for the removal of water, and through the sintered glass dust filter H_1 The first portion of ammonia was condensed by chilling with ether–solid carbon dioxide in L. The succeeding portions of gas were caused to bubble through the liquid ammonia in L before condensation in M. The material in L was then rejected by evaporation through the safety tube I, or through the line K, into a bottle containing dilute sulfuric acid. From M a light fraction was distilled into N which had previously been evacuated, and the remainder of the ammonia in M was condensed in O after bubbling through the liquid in N. A third similar distillation from O to Q followed. A large proportion of non-condensing gaseous impurities must have been eliminated in the three distillations. The removal of the remainder was secured by the method used by McKelvey and Taylor of condensing the ammonia as a solid by chilling S with liquid air. Uncondensed gases were then removed by exhausting S. Two more similar distillations from S to U, and from U

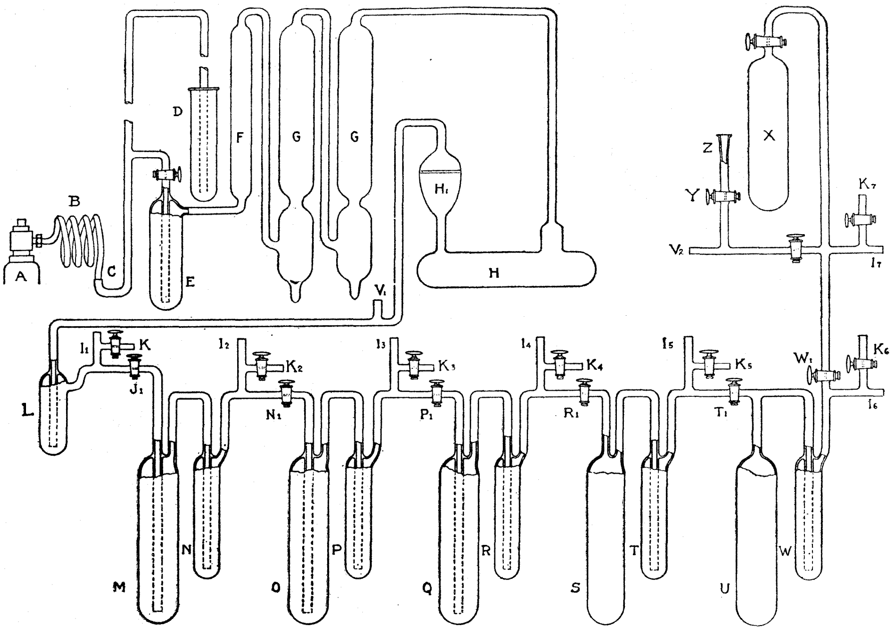

Fig. 1.—Ammonia purification train.

to X followed. In each of these distillations a light and a heavy fraction were rejected. The purified ammonia was stored in X at room temperature under pressure.

The silver used in the comparison with the ammonium halide was purified by standard methods by Dr. William *C.* Cooper for the analysis of germanium halides.[4]

The ammonia was weighed in a tube containing dehydrated chabazite (Fig. 2), provided with a well ground stopcock lubricated with rubber grease, and a sintered glass dust filter to prevent loss of chabazite powder during the expulsion of the ammonia. This chabazite had been previously employed in other experiments on adsorption. Before use in the ammonia tube it was heated to 575° in a high vacuum to eliminate so far as possible residual water and other gases to which it had previously been exposed. In the course of our experiments it was many times saturated with pure ammonia and the ammonia expelled by heating. This treatment undoubtedly removed any important amount of other gases which might not have been expelled in the initial treatment. The experiments described below to determine whether the purified ammonia still contained moisture would not have differentiated between water contained in the ammonia and that given off by the chabazite during the expulsion of the ammonia.

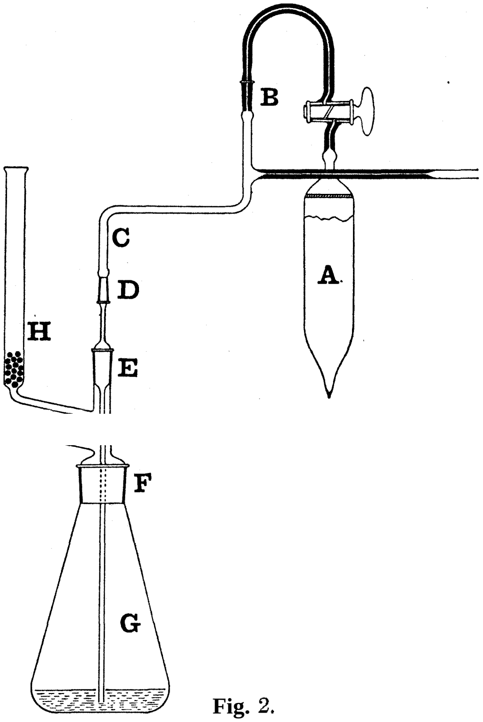

Fig. 2.

The determination of the apparently very small water content of the ammonia was a far from simple task. The method followed was to pass the ammonia expelled from the chabazite tube through a weighed tube containing freshly fused potassium hydroxide. Baxter and Starkweather[6] have found the efficiency of this substance as a drying agent to be very high, for a liter of air dried with freshly fused hydroxide even at 50° con-

tains only 0.006 mg. of water, while at 25° the residual amount of water per liter can hardly exceed 0.002 mg. In spite of the fact that McKelvey and Taylor reject this method of determining moisture in ammonia as unreliable, we feel that it is fully as satisfactory as the one advocated by them of evolving acetylene from calcium carbide. Possibly the difficulty experienced by them with potassium hydroxide may have come from incomplete dehydration of the hydroxide at the start.

Since preliminary experiments in which rubber connections were included in the apparatus exhibited irregularities which disappeared when rubber was eliminated, the final apparatus had only sealed or ground connections. The results of the experiments in which rubber was used were not on the whole different from those with the final improved apparatus.

The procedure in the moisture determinations was as follows. A glass-stoppered U-tube containing potassium hydroxide was provided with a ground joint and a counterpoise of similar construction, volume and weight, but containing no caustic. After being wiped with first a damp and then a dry cloth, both the adsorption tube and the counterpoise were hung on a balance and left for several hours. One stopcock on each was then carefully opened and after about an hour the differences in weight were determined. The average difference between duplicate weighings was 0.014 mg. and the algebraic sum of fifteen such differences was 0.01 mg. In order to prevent diffusion of moisture into the potassium hydroxide tube while open to the air, the orifice of the outlet tube was constricted to a fine capillary. Even this did not prevent a slow but steady gain of 0.01 mg. per hour; therefore, a correction of this magnitude was applied for the period during which the tube remained open.

Both the chabazite tube containing ammonia and the absorption tube in that order were connected by greased ground joints to a line through which was flowing air which had been finally dried by means of fused potassium hydroxide.

The stopcocks of the absorption tube were then opened and ammonia was expelled from the chabazite tube through the absorption tube. Finally the chabazite tube was closed and the ammonia swept out of the absorption tube with the **air current.** Twelve similar runs in which no ammonia was involved yielded only 0.29 mg. of water in all. An average correction of −0.024 mg. was therefore applied in each experiment with ammonia. The results of the three final experiments with ammonia are given in the following table.

Wt. of NH_3	Wt. of H_2O	Wt. of H_2O corrected for blank	Per cent. of H_2O
3.14	0.00014	0.00012	0.0038
4.66	.00009	.00007	.0015
2.27	00013	.00011	.0048
Total 10.07	.00036	.00030	.0030

Another experiment with 1.42 g. of the residual liquid ammonia from a fractional distillation yielded 0.0056% of moisture.

McKelvey and Taylor[3] state that the most nearly anhydrous ammonia prepared by them contained 0.004%. At any rate it seems unlikely that any appreciable amount of water was introduced from the chabazite itself.

The quantitative comparison of ammonia with silver was conducted in the following manner. The chabazite tube charged with ammonia was carefully compared with a similar sealed counterpoise of similar exterior volume by suspending them on opposite arms of a balance in a balance room kept thermostatted within a degree or two to prevent alteration in the ratio of the lengths of balance arms. By means of the greased ground joint B (Fig. 2) the chabazite tube was connected with the tube C delivering into the Erlenmeyer flask G which contained the acid (1 normal, containing indicator) to be neutralized. Just before use this acid was further twice freshly distilled through a quartz condenser, only the middle portion being retained. The tube C delivering into the Erlenmeyer flask was connected with a supply of the purest electrolytic hydrogen. The ground joints E and F were wet with water and the guard tube H containing a few glass pearls was wet with tenth normal acid. The ground joint D was lubricated with grease.

After the apparatus had been filled with hydrogen, the chabazite tube was warmed gently with an electric oven and ammonia was allowed to flow into the hydrogen stream, except in Analysis I when the hydrogen was shut off. It was possible to determine very closely when the acid was neutralized and as soon as the end-point was nearly reached the stopcock of the chabazite tube was closed and the ammonia in the connecting tubes was swept into the flask by passing the hydrogen current for some time. The guard tube was then rinsed into the flask.

The chabazite tube was next disconnected, the ground joint cleaned with ether, and the tube again compared with the counterpoise by adding weights to the side of the balance on which the tube was hung, so that the ammonia was weighed by substitution.

To find the exact neutral point all parts of the stopper and tubes were rinsed with freshly distilled and boiled water and then the ammonium halide solution was brought to the desired shade by adding hundredth normal acid and barium hydroxide. The barium hydroxide solution had been analyzed by exactly neutralizing with hydrobromic acid and precipitating silver bromide.

In the first five experiments the standard color was produced in an acetate buffer solution which had been brought to the same shade as that given by a solution of the ammonium halide (normal). In the later experiments the standard color produced by a solution of carefully recrystallized ammonium halide was used. In Experiments 1, 2, 3, 5 and 6 methyl red dissolved in redistilled alcohol was employed, while in Experiments 10, 12, 14 and 16 a saturated aqueous solution of methyl red was substituted. For Experiments 7, 9 and 11, litmus was prepared by extracting commercial powder with hot alcohol, dissolving in water, precipitating with alcohol and dissolving in water for use. None of the indicator solutions used gave any precipitate with silver nitrate. As nearly as possible the same amount of indicator was added to the solution being titrated and to the standard color solution, and the volumes and concentrations of both were made very closely the same.

After the neutralization was complete the solution of the ammonium halide was transferred to the precipitating vessel, a 3-liter Erlenmeyer flask with a carefully ground stopper or an 8-liter bottle, and diluted. A very nearly equivalent amount of the purest silver was carefully weighed by substitution and dissolved in chlorine-free nitric acid, with especial precautions to avoid loss of spray. This solution of silver was diluted to approximately the same volume as the halide solution and then added in small portions with gentle agitation to the halide solution. The exact end-point was then found with the use of a nephelometer, by testing the supernatant liquid occasionally with equivalent amounts of halide and silver, and making up a deficiency of either by means of hundredth normal halide and silver solutions. This process always was continued for a month or more in order to allow salts occluded by the silver halide to be leached out so far as possible.

The weight of silver actually equivalent to the ammonia was found by subtracting the silver equivalent of the barium hydroxide used in the neutralizing and adding the net amount of silver used in the halide–silver comparison.

The loss in weight of the ammonia tube was corrected for buoyancy of the air on the weights and the weight of silver for buoyancy of the air on both silver and weights. For this purpose the density of the weights was assumed to be 8.3 and that of silver 10.49. The density of the air was calculated from the conditions at the time of each weighing.

In the following table the weights of ammonia are corrected for moisture content by subtracting 0.003% (page 609). The ratio $NO_3:NH_3$ is calculated assuming $NO_3/Ag = 0.57479$.'

After the earlier experiments in the above table had been completed (Analyses 1 to 7), it was evident that the ratio of silver to ammonia was lower when hydrobromic acid was used for neutralization than when hydrochloric acid was used. A search for the cause of this difference revealed the fact that in the case of hydrobromic acid the more concentrated the solutions during the precipitation, the lower the ratio. Since the silver solution was poured into the bromide solution in these experiments, a possible cause of the difficulty apparently lay in occlusion of soluble bromide by the silver bromide. To test this hypothesis in the following

Average of analyses 1, 3, 7, 8, 9, 10, 11, 12									6.33420	3.64083	14.0078

experiments with hydrobromic acid (Analyses 8, 10, 11, 12) the concentration of the solutions during precipitation was made from one-half to one-third that previously used. These experiments yielded results concordant with those of the earlier chlorides as well as with Experiment 9 in which the chloride solution also was made more dilute before precipitation. In Analyses 10 and 12 the bromide solution was added to the silver solution.

If the correction for water in the ammonia is omitted the ratios $Ag:NH_3$ and $NO_3:NH_3$ become 6.33401 and 3.64073, respectively, and the atomic weight of nitrogen 14.0085.

This investigation was interrupted before it was completed. It is unfortunate that a larger number of experiments could not have been carried out. The purity of the ammonia needs further investigation, especially as regards water, although the synthetic material which we used as the starting point is unlikely to be seriously contaminated with any impurities except permanent gases and moisture. On the whole the final outcome may be looked upon as valuable corroborative evidence that the atomic weight of nitrogen is very close to 14.008. The uncertainty of the method is apparently less than 0.001 unit, which compares very favorably with that of all other methods at present available for the purpose.

If nitrogen is taken as 14.0078, the atomic weight of silver may be calculated to be 107.879, while the value for nitrogen of 14.008 gives 107.880 from the $Ag:NH_3$ ratio and 107.879 from the $Ag:NO_3$ ratio.

KINETICS OF THE POLYMERIZATION OF ETHYLENE AT PRESSURES ABOVE ONE ATMOSPHERE[1]

BY ROBERT N. PEASE[2]

RECEIVED DECEMBER 22, 1930 PUBLISHED FEBRUARY 9, 1931

Previous work[3] has indicated that the only important primary reaction of ethylene when heated in glass to 400–600° at 1 atmosphere initial pressure is one of polymerization to higher mono-olefins (C_nH_{2n}). The point has not been conclusively demonstrated, however, as would be done if a considerable portion of the ethylene could be caused to polymerize without

---

[1] This paper contains results of an investigation carried out as a part of Project No. 7 of American Petroleum Institute Research. Financial assistance in this work has been received from a research fund donated by Mr. John D. Rockefeller. This fund is being administered by the American Petroleum Institute with the cooperation of the Central Petroleum Committee of the National Research Council. Professor Hugh S. Taylor of Princeton University is Director of Project No. 7.

[3] Day, *Am. Chem. J.*, **8,** 153 (1886); Bone and Coward, *J. Chem. Soc.*, **93,** 1197 (1908); Hague and Wheeler, *ibid.*, 390–391 (1929); Pease, THIS JOURNAL, 52, 1158 (1930); Wheeler and Wood, *J. Chem. Soc.*, 1823 (1930).

the formation of appreciable quantities of by-products such as hydrogen, methane, ethane and carbon. Examination of the experimental data reveals that the polymerization reaction at 1 atmosphere is excessively slow and apparently limited, and that it is accompanied by decomposition of the product, and probably also of ethylene itself. The indications are that the polymerization reaction is fundamentally second order, whereas the decompositions are presumably first order. The former should be favored if the initial pressure is increased. It was proposed, therefore, to study the reaction at pressures somewhat higher than 1 atmosphere. A series of experiments was carried out in which ethylene was heated in a copper bomb ta 350–500° at initial pressures of 2.5, 5 and 10 atmospheres. These experiments, the results of which are here reported, demonstrate that as much as 50% of the ethylene can be polymerized without the formation of more than 1 or 2% of hydrogen and methane. The importance of the polymerization reaction is, therefore, confirmed.

The apparatus consisted of a cylindrical copper bomb to which was connected (by means of copper tubing and suitable valves) a pressure gage, a tank of compressed ethylene and a mercury gasometer. The bomb was *20* cm. long with an outside diameter of *5* cm. Its walls were 5 mm. thick. Its volume was *250* cc. The copper tubing was **3.2** mm. internal diameter. The bomb was heated in an electric tube-heater. Temperature was measured with a double-junction chromel–alumel thermocouple, and was controlled by hand regulation of the heating current.

The bomb was flushed out five times with ethylene before and after each run. In starting a run, ethylene was allowed to flow through the bomb. The outlet was closed, and the pressure was allowed to rise to the value desired, the starting time being taken at the mid-point of filling. After some definite time interval was completed, the gases were released into the mercury gasometer. The gas was then passed through a trap at 0° to condense liquid products. A sample was analyzed for higher olefins by absorption in ordinary concentrated sulfuric acid; for ethylene by absorption in dilute bromine water; and for hydrogen plus saturated gaseous hydrocarbons by difference. The total volume of off-gas was then measured. The percentage of ethylene reacting was calculated from the volume in the off-gas, and the volume required to fill the bomb. This was compared with the amounts of higher olefin, and of hydrogen plus hydrocarbons formed.

The reaction is believed to be homogeneous as carried out, although no direct tests of the effect of increased copper surface were made. The conclusion is based on the fact that the rates are comparable with those obtained in empty pyrex glass reaction vessels, the surface of which has been shown to have a small though definite repressive action. Thus, at 500° and 1 atmosphere in glass, it was found that 14% of the ethylene reacted in twelve minutes and 19% reacted in tweoty-four minutes. In the copper bomb. at 500° and 2.56 atm. pressure, 41% reacted in fifteen minutes. This is about the expected relation if the reaction is second order (as it appears to be). Further, there was no evidence of a "drift" in the results such as might have occurred if a gradual change in the surface of the bomb due to carbonization were affecting the reaction rate.

Results

Results of the experiments appear in Table I. For each experiment there are given the temperature, the initial **pressure** of ethylene in atmospheres

(corrected for the nitrogen present), the time of heating in hours, and the volume in cc. (S. T. P.) of ethylene reacting, of higher gaseous olefins formed, and of hydrogen plus gaseous paraffins formed for each 100 cc. (S. T. P.) of pure ethylene introduced. The figure for ethylene is in effect the percentage of ethylene reacting. In the last column are given second order velocity constants. The numerical value of k_2 is the fraction of the ethylene which would react in one hour if the pressure of that gas were maintained constant at one atmosphere, and the reaction were actually second order. The constant is based on the following. If p is the pressure of ethylene in atmospheres and t is the time in hours

$$-\frac{dp}{dt} = k_2p^2$$

If x is fraction of ethylene converted, and p_0 is initial pressure of ethylene

$$p = p_0(1 - x)$$

Then

$$-p_0\frac{d(1 - x)}{dt} = k_2(1 - x)^2p_0^2$$

$$-\frac{d(1-x)}{(1-x)^2} = k_2p_0dt$$

$$k_2 = \frac{1}{p_0t}\cdot\frac{x}{1-x}$$

The results show clearly that it is possible to polymerize more than 50% of the ethylene to higher members of the C_nH_{2n} series without the formation of appreciable quantities of other products. The polymer is in part gaseous and in part liquid, the tendency being to form a greater proportion of the latter as reaction proceeds. In one or two favorable cases the yield of gaseous C_nH_{2n} was that to be expected from the reaction

$$2C_2H_4 \longrightarrow C_4H_8$$

It is reasonable to conclude from this fact that butylene is the primary product of the reaction.[4]

This conclusion is strengthened by an analysis of the kinetics of the reaction. If the primary reaction is that shown above, and occurs as a result of a collision in the gas phase, one would expect it to be kinetically of second order. Actually it is found that the second order constant holds reasonably well when comparisons are made between corresponding conversions at different initial pressures. Nevertheless, the constants for the most part increase as the total conversion increases. This can be qualitatively accounted for by a secondary reaction between ethylene and the butylene first formed

$$C_2H_4 + C_4H_8 \longrightarrow C_6H_{12}$$

The primary product offers an outlet for the reaction of an additional quantity of ethylene. This reaction, and the reaction

$$2C_4H_8 \longrightarrow C_8H_{16}$$

would account for the formation of the liquid products.

Bimolecular gas reactions are of special theoretical interest because it has, in general, been possible to show that the heat of activation as calculated from the temperature coefficient of the rate

$$\frac{d\ln k}{dT} = \frac{E}{RT^2}$$

can be simply interpreted as the excess of energy which two colliding molecules must possess before reaction is possible. The rate of reaction is given by the rate of collision between molecules possessing the requisite excess energy.

The case of ethylene polymerization is an exception to the rule. From the temperature coefficient of k_2, the energy of activation is calculated to be 35,000 cal.

If $Z_{\text{eff.}}$ = number of collisions per cc. per sec. between molecules possessing 35,000 cal. over the average
n = number of molecules per cc.

---

[4] *See* Wheeler and Wood, *J. Chem. Soc.*, 1823 (1930), for confirmation.

σ = molecular diameter in cm.

$\bar{c}$ = root mean square velocity in cm. per sec.

then $Z_{\text{eff.}} = \sqrt{\frac{2}{2}}\, n^2 \pi \sigma^2 \bar{c}\, e^{-35,000/RT}$

k_2 = fraction of molecules reacting per hour when the pressure is maintained at 1 atm.

$k_2 = 2.3600 \cdot Z_{\text{eff.}}/n$

n = number of molecules per cc. at 1 atm. press.

$k_2 = 3600 \sqrt{2}\; n\; \pi \sigma^2 \bar{c}\, e^{-35,000/RT}$

The observed value of k_2 at 425° is 0.1. The calculated value is

$$k_2 = 3600 \cdot \sqrt{2} \cdot 1.058 \times 10^{19} \pi\, (3.78 \times 10^{-8})^2\, 78810\, e^{-35,000/4.58 \cdot 698} = 215.$$

The observed value is thus only $^1/_{2000}$ of that calculated. If, instead of calculating k_2 at 425°, we use the observed value of k_2 at 425° to calculate the heat of activation, the latter comes out to be 45,650 cal. This corresponds to a temperature coefficient of 3.1 per 25°, whereas the observed value is *2.3* per 25°.

There is no question as to the existence of a wide discrepancy between the observed rate and that to be expected on the basis of the collision theory. It is true that the variation in the values of k_2 at each temperature allows some latitude of choice of temperature coefficient, but even the extreme value would not be sufficiently high. The low rate of formation of product cannot be due to a reverse reaction because the discrepancy between observed and calculated rate is far too large. The reverse action would have to be more than 1000 times the faster, under which conditions no reaction whatever would be observed.

The cause of the discrepancy is undoubtedly to be sought in the type of reaction under investigation. The ethylene polymerization is an association reaction taking place in the gas phase. It is not immediately obvious how such a reaction can be of second order at all. Theoretical considerations based on the older quantum mechanics rule out the possibility that a stable product molecule can be formed as the immediate result of a collision between two active reactant molecules.[5] The argument is simple. The energies of the reacting molecules and the heat of reaction must be suitably represented in the product molecule. However, the translational energy of the latter with respect to that of the reactant molecules is limited by the requirements of the law of conservation of momentum, while its rotational and vibrational energy is limited by quantum restrictions. Since the energy to be accommodated in the product molecules may have any value whatsoever, the chance that it can be exactly accommodated in any particular collision under these restrictions is negligible. Hence, reaction is highly improbable. Prior to the introduction of the quantum theory there would have been no such difficulty. Now with the development of the uncertainty principle, the above argument

---

[5] See, *e. g.*, Born and Franck, *Ann.*, [4] *76, 225 (1925).*

seems to lose some of its force. If, by specifying that two molecules collide, we virtually specify their positions, then their momenta become to a degree uncertain, and as a consequence there will always exist a finite though usually small probability of accommodation and therefore of successful reaction between suitably activated molecules. The average of these probabilities over all activating collisions would be given by the ratio of the reaction rate to the rate of occurrence of such collisions. In the case of ethylene polymerization, the latter has been calculated to be about 1 to 2000.

There are three alternatives to the mechanism just presented. The difficulty as to the accommodation of the energy of reactant molecules plus the heat of reaction in the product molecule may be solved by radiation of a part of the energy, or by transfer at the reaction vessel walls, or by a suitable distribution of energy between the product molecule and a third molecule which enters into the collision. Radiation by molecules of this type has not a high degree of probability. Wall reaction seems to be ruled out by the observation that a glass packing diminishes the rate somewhat. This leaves us with the possibility of termolecular collisions. The immediate objection to this latter is that it would appear to require that the reaction be of third order rather than second. However, this may not be a disadvantage since at 1 atmosphere there is some evidence of a fall in rate more rapid than would be expected of a second order reaction. Professor H. S. Taylor has suggested a mechanism which appears capable of presenting this view of the reaction. This is given below.

Assume that a quasi-molecule, C_4H_8, is formed as a result of collision between two ethylene molecules. This complex can have only an excessively short life. It may immediately resolve itself into two ethylene molecules, or it may be decomposed by collision with an ethylene molecule, or finally it may be stabilized by a collision with an ethylene molecule. We thus have

$$2C_2H_4 \xrightarrow{k_1} C_4H_8'$$

followed by

either, $C_4H_8' \xrightarrow{k_2} 2C_2H_4$

or, $C_4H_8' + C_2H_4 \xrightarrow{k_3} 3C_2H_4$

or. $C_4H_8' + C_2H_4 \xrightarrow{k_4} C_4H_8 + C_2H_4$

For the rates of these reactions, we write

$$+\frac{d[C_4H_8']}{dt} = k_1[C_2H_4]^2$$

$$-\frac{d[C_4H_8']}{dt} = k_2[C_4H_8'] + k_3[C_4H_8'][C_2H_4] + k_4[C_4H_8'][C_2H_4]$$

If we assume that the concentration of C_4H_8' has a steady-state value, we can write

$$k_1[C_2H_4]^2 = k_2[C_4H_8'] + k_3[C_4H_8'][C_2H_4] + k_4[C_4H_8'][C_2H_4]$$

Whence

$$[C_4H_8'] = \frac{k_1[C_2H_4]^2}{k_2 + k_3[C_2H_4] + k_4[C_2H_4]}$$

Finally

$$+\frac{d[C_4H_8]}{dt} = k_3[C_2H_4][C_4H_8']$$

$$= \frac{k_1k_3[C_2H_4]^3}{k_2 + k_3[C_2H_4] + k_4[C_2H_4]}$$

When the ethylene concentration is high, this reduces to

$$+\frac{d[C_4H_8]}{dt} = \frac{k_1k_3}{k_3 + k_4}[C_2H_4]^2$$

which is the second order form. With suitable values of the temperature coefficients of the various velocity constants involved, the experimentally observed coefficient could be fitted. At very low concentrations of ethylene, the equation becomes

$$+\frac{d[C_4H_8]}{dt} = \frac{k_1k_3}{k_2}[C_2H_4]^3$$

that is, the reaction is third order.

Summary

The rate of polymerization of ethylene has been measured at 2.5, 5 and 10 atmospheres from 350 to 500°. At least 50% of the ethylene may be polymerized to gaseous and liquid mono-olefins without the formation of more than a few per cent. of hydrogen and saturated hydrocarbons.

The reaction is of second order and has an abnormally low temperature coefficient. This is discussed in the light of the fact that the reaction is of the association type.

PRINCETON, NEW JERSEY

NOTES

A Note on Diffusion in Gelatin Gels.—In a recent paper on the diffusion of non-electrolytes in gelatin gels, Friedman and Kraemer[1] have observed that the coefficient of diffusion is diminished by an increase in the concentration of the gel. A similar diminution was observed by Stiles and Adair,[2] who found that the coefficient of diffusion of sodium chloride decreased from 0.675×10^{-5} in a 4% gel to 0.483×10^{-5} in a 16% gel.

The results of Friedman and Kraemer are consistent with the formula we published, to show the relation between coefficient of diffusion and gel concentration. The formula is

$$k = a(1 - bc)$$

where k is the diffusion constant of sodium chloride in the gelatin gel, c is concentration of gelatin in percentage by weight, a is a constant = 0.74

---

[1] L. Friedman and E. O. Kraemer, THIS JOURNAL, 52,1295 (1930).

[2] W. Stiles and G. S. Adair, *Biochem. J.*, 15,621 (1921).

$\times 10^{-5}$ at 0°, and 1.35 $\times 10^{-5}$ at 20°, and b is a constant, approximately 0.018.

The range of application of this formula is restricted to systems containing from 2 to 16% of gelatin. The constant b is a measure of the effect of the gelatin in arresting diffusion. In our experiments with sodium chloride the term b appeared to be practically constant. The values calculated from the data for urea, given by Friedman and Kraemer, show very considerable irregularities; one experiment gave a result for *b* which was the same as ours, but another gave a higher value, nearly 10 times as great. Their experiments with glycerol and with sucrose gave values for b of about 0.034 and 0.058, respectively. It is interesting to note that the values of b obtained with non-electrolytes are of the same order of magnitude as those obtained by us with sodium chloride.

It seems desirable to draw attention to the essential agreement of the results obtained in both investigations, because the following passage occurs in Friedman and Kraemer's paper: "A decrease in the rate of diffusion of 20% as the concentration of the gel increased from 2.5 to 5% is shown, contrary to the statement by Stiles and Adair that above 2% there is very little change." Their abbreviated quotation conveys an entirely different meaning from the actual statement of Stiles and Adair, namely, "with concentrations above 2% the curve connecting the coefficient of diffusion and concentration is approximately a straight line, the rate of decrease of the diffusion coefficient with increasing concentration of the gel being less than with concentrations less than 2%."

Glass Electrode Measurements by Means of a Galvanometer with Condenser Attachment.—Due to the high resistance of glass electrodes and to a possible polarization of their membranes on the passage of a direct electrical current, e. m. f. measurements of glass electrode potentials have hitherto not been carried out with the ordinary galvanometer–potentiometer systems. Jones and Kaplan have recently invented a condenser galvanometer system which enables potential measurements on cells of high resistance to be made with a ballistic galvanometer.[1] By means of

---

[1] Grinnell Jones and B. B. Kaplan, THIS JOURNAL, 50, 1853 (1928); see W. E. L. Brown, J. *Sci. Instruments*, 2, 12 (1924), for a brief mention of a similar arrangement. H. T. Beans and E. T. Oakes, THIS JOURNAL, 42, 2116 (1920), and H. T. Beans and G. H. Walden, Jr., *ibid.*, 50, 2673 (1928), have used a condenser for making potential measurements, but as their method is not a null-point method it was not used here.

this instrument it is now possible to test the applicability of galvanometers to glass electrode measurements and to test the question of membrane polarization.

Through the courtesy of Professor Jones, the same apparatus that he and Kaplan used was made available for this research; the details of operation and manipulation are fully described in their paper and need not be repeated here. Similarly, the glass electrode technique has already been given by MacInnes and Dole.[2] In Table I a typical example of a cell reading is given. There was no indication of any drift of potential due to polarization of the electrodes by the current charging the condenser.

TABLE I

MEASUREMENT OF A GLASS ELECTRODE CELL USING THE CONDENSER ATTACHMENT

Potentiometer setting. volt	Time allowed for condenser to charge, seconds	Galvanometer deflections on scale, millimeters
0.44	15	L, 10.0
.43	15	L, 2.0
.42	15	R, 3.0
,427	30	L, 1.0
.426	30	L, 0.1
.4258	60	0
.4258	120	R, 0.2
.4260	120	L, .2

Accepted potential 0.4259 L = left. R = right

In Table II are given the asymmetric potentials and resistances of the glass electrodes used in the final measurements. One electrode was prepared from glass furnished by the Corning Glass Company (their 0.012 glass) and the other from glass made in the manner described by MacInnes and Dole.

TABLE II

ASYMMETRIC POTENTIALS AND RESISTANCES OF GLASS ELECTRODES USED

	Asymmetric potentials, volt	Resistances, megohms
Corning glass	−0.0010	51.5
MacI.–D. glass	− .0020	21.1

The hydrogen half-cell and the glass electrode half-cell were measured in two solutions of different PH against a saturated calomel reference electrode at 27.3°. The solutions were made up only approximately.

The final measurements are given in Table III. The hydrogen–calomel cell was measured without using the condenser. From the last column of Table III it is evident that both Corning glass electrodes and MacInnes and Dole glass electrodes give the correct hydrogen electrode potential changes as measured with the ballistic galvanometer–condenser system.

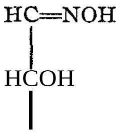
THE REACTIVE FORM OF GLUCOSE OXIME[1]

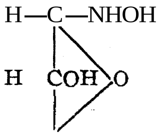
BY M. L. WOLFROM AND ALVA THOMPSON

RECEIVED JUNE 23, 1930 PUBLISHED FEBRUARY 9, 1931

The fact that glucose reacts with hydroxylamine to form an oxime has been used as proof for the presence of an aldehyde group in the molecule of this sugar. Glucose oxime was first prepared in crystalline form by Jacobi[2] and its structure was tacitly assumed to be of the true oxime type, R—CH=NOH. The establishment of the ring or cyclic hemiacetal structure for the crystalline forms of glucose raised the question whether this ring opened or remained intact in the nitrogen condensation products of the sugar. In the case of the oxime, these two possibilities are illustrated as follows



True oxime



Ring type oxime

Each of the above types could exist in two isomeric forms, *syn* and *anti* in the true oxime structure and alpha and beta in the other. In the latter case, the formation of more than one ring would indeed give rise to further isomers, but this possibility is not pertinent to the following discussion

---

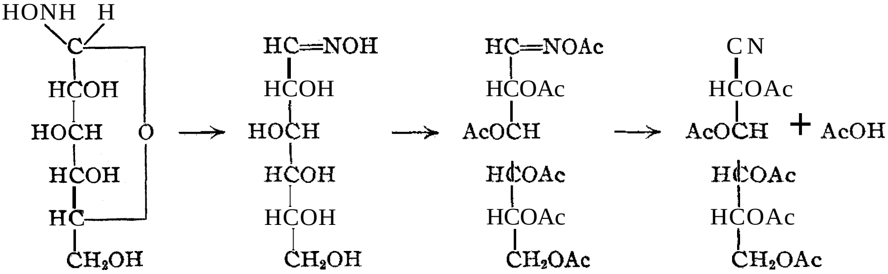
[1] (a) Constructed from a thesis presented by Alva Thompson in candidacy for the degree of Doctor of Philosophy in Chemistry at The Ohio State University. (b) Presented before the Division of Organic Chemistry at the 79th Meeting of the American Chemical Society, Atlanta, Georgia, April 7 to 11, 1930.

[2] H. Jacobi, *Ber.*, 24, 697 (1891).

and may be disregarded. Furthermore, the exact location of the lower end of any oxygen bridge present need not concern us.

Evidence as to the type of structure of the one known crystalline form of glucose oxime was produced by Miller and Plöchl,[3] who found that glucose oxime did not add hydrogen cyanide, as is characteristic of a true oxime. The objection may be raised that this result is based upon negative experimental data, but positive evidence pointing to the same conclusion was obtained by Irvine and Gilmour.[4] These workers found that on methylation and hydrolysis of this compound, crystalline tetramethylglucose of the lactal or ring structure was obtained instead of the open-chain pentamethylglucose,[5] as would be the case if the substance were a true oxime.

Although the lactal structure for glucose and its derivatives explains many of the reactions of this important compound, it has been postulated by one of us[6] and by others that in many reactions, and especially in those of a deep-seated nature, the glucose molecule reacts in the open-chain form. The lactal structure may then be considered as a resting or passive phase in these reactions, the ring opening to produce the highly reactive open-chain form as needed. The importance of this molecular behavior in biological reactivity is obvious. In the work herein reported we have verified this assumption by working with a nitrogen derivative, the oxime. The deep-seated reaction we have chosen to study is the formation of the acetylated nitrile from the oxime. This is the first step in the well-known Wohl sugar degradation. The agents used for this change are sodium acetate and acetic anhydride at relatively high temperatures. The end result of this reaction is, of course, an open-chain compound, but the point in question is whether the lactal structure opens to form the straight chain or true oxime as an intermediate, as follows



It is to be noted that the first reaction above is in the nature of a hydrogen shift and would probably be a prototropic change. Whether this is

a true tautomeric phenomenon or whether it is a definite change is still open to question.

The isolation of the open-chain or aldehydo form of glucose penta-acetate[6] has made possible the synthesis of the third compound represented above, as a reference substance for the study of this reaction.[7] Aldehydo-glucose penta-acetate[8] gave a crystalline oxime penta-acetate on reaction with hydroxylamine. Further acetylation yielded the crystalline hexa-acetate, which was isolated in two forms with melting points of 79 and 119.5°, respectively. The lower-melting compound was the form obtained first. This was very unstable and changed spontaneously into the other, after which all attempts to gain the 79° isomer failed. This latter substance showed a characteristic behavior on melting, first fusing at 79°, then, on continued heating, re-solidifying and again melting at about 119°. We believe that these isomers are probably syn and anti forms, although the possibility of an unstable pseudomorph has not been excluded, due to the fact that we failed to obtain the optical rotation of the 79° form.

In his classical work on the degradation of glucose, Wohl[9] isolated an oxime hexa-acetate in the mother liquor from the crystallization of the acetylated gluconic acid nitrile. He gave the melting point of 109–110° for this compound and stated that it did not undergo nitrile formation. He considered this to be the anti form of the acetylated oxime and happily attributed the rather low yield of acetylated nitrile to the fact that half of the oxime was in this form which did not give the nitrile. Behrend[10] obtained this same hexa-acetate by low temperature acetylation of glucose oxime with acetic anhydride and pyridine. He gave the melting point of 110–111° for this compound and showed that it possessed a normal molecular weight. We have repeated and confirmed the work of these two investigators. On rigorous purification of this compound we have obtained for this substance the melting point of 113–115° and the specific rotation of +7° in U. S. P. chloroform solution. The rotation of this substance has not been previously recorded. Behrend and Roth[11] had used this method of mild acetylation to correlate the two lactal penta-acetates of glucose with the two alpha and beta forms of the free sugar, which indicates that this treatment did not alter the lactal nature of the compound. Since Irvine and Gilmour[4] have later shown that glucose oxime has a ring

[7] Recently P. Brigl and H. Muehlschlegel, ***Ber.***, 63, 1551 (1930), have prepared aldehydo-d-glucose pentabenzoate mono-ethyl alcoholate from glucose mercaptal pentabenzoate by hydrolysis with formic acid. These authors use the prefix *al-* to denote the aldehydo form.

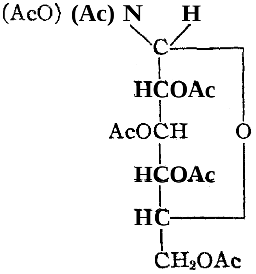
[10] R. Behrend, ***Ann.***, 353, 106 (1907).

[11] R. Behrend and P. Roth, ibid., 331, 359 (1904).

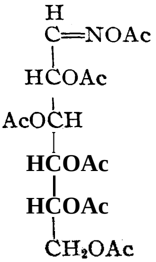
structure, then it follows that this hexa-acetate also is the ring form. From their low rotations, these substances are very probably the beta isomers, according to the general classification of Hudson.[12] The constants of glucose oxime are given by Irvine and Gilmour[4] as follows: m. p., 138°; specific rotation in aqueous solution, −7.8°, changing to the final value of —0.8'. By rigorous purification we have found the melting point of 142–143° and the specific rotation in 4% aqueous solution of −8.9°, changing to the final value of −2°.

The second oxime hexa-acetate of glucose which we have now obtained has widely differing constants from the one previously known. The melting point is 119.5° and the specific rotation in U. S. P. chloroform solution is +46°. From its method of synthesis it possesses the true oxime structure. On heating with acetic anhydride and sodium acetate it readily yielded the acetylated nitrile. On heating this hexa-acetate in the solid form to 135–140°, it began to decompose into acetic acid and acetylated nitrile. The sirup so obtained was colorless and gave a good yield of pure gluconic acid nitrile penta-acetate. These experiments show that this form of acetylated glucose oxime can lose acetic acid to form the acetylated nitrile, whereas the acetylated ring form of the oxime does not possess this property. It is of interest to note here that the penta-acetate of aldehydo-glucose oxime does not form the acetylated nitrile on heating. This indicates that acetic acid and not water is split out in the reaction.

To distinguish the ring form of the acetylated oxime from the open-chain form, the name 0-glucose oxime hexa-acetate is suggested for the former, the prefix denoting the beta ring structure. In a parallel way, the prefix aldehydo is suggested for the other isomer, this prefix denoting the open-chain form. The differing structures for these two substances are illustrated by the following formulas



β-Glucose oxime
hexa-acetate



Aldehydo-glucose
oxime hexa-acetate

On repeating Wohl's[9] procedure, we have confirmed his finding that at 135° or slightly above the reaction produces gluconic acid nitrile penta-acetate in about 40% yield, together with a small amount of the 0-glucose

---

[12] C. S. Hudson, This Journal, 31, 66 (1909).

oxime hexa-acetate. In this latter compound it is seen that the active hydrogen atom that is attached to nitrogen and is concerned in the shift to the aldehydo structure is here replaced by an acetyl group, which in this case blocks any change to the open-chain form. This compound is thus produced by direct acetylation of the ring form of glucose oxime before the ring has opened.

Gluconic acid nitrile penta-acetate has been rigorously purified and we have found the melting point of 83–84' and the specific rotation in U. S. P. chloroform solution of +48°. This optical rotation has been recorded for the first time.

By using Wohl's procedure, but keeping the reaction temperature below 90°, aldehydo-glucose oxime hexa-acetate, melting point 119.5°, was formed from *β*-glucose oxime and was isolated along with a low yield of acetylated nitrile. This would seem to be definite proof that this open-chain acetate is an intermediate in the reaction. The ring form of glucose oxime then opens and undergoes acetylation, followed by the loss of acetic acid from the acetylated open-chain or true oxime form.. We believe the experimental data reported confirm this statement. The reaction as a whole is a complicated one, as is indicated by the low yield, 40%, of acetylated nitrile formed under the best conditions known. The above mechanism may not account for the entire reaction, but it would certainly appear that it accounts for some of this yield of acetylated nitrile and perhaps for the major part of it. We are not interested in explaining the exact mechanism of this reaction, but only in proving that a shift from a lactal structure to the aldehydo or open-chain form does take place.

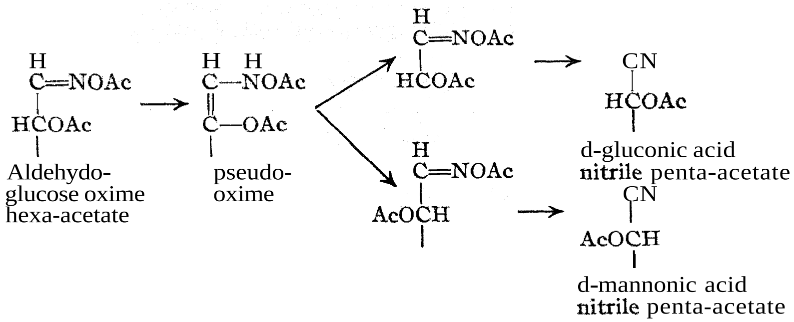
The question of the stability of the non-acetylated aldehydo-glucose oxime is of interest. Aldehydo-glucose oxime penta-acetate underwent hydrolysis on acid de-acetylation. A basic de-acetylation using methyl alcohol and ammonia produced only the previously known @-glucose oxime, thus showing that when the hydrogen atom concerned in the change between the two forms is not blocked, the solid phase separating from the solution is the ring form. In this connection it is to be noted that *β*-glucose oxime undergoes mutarotation, whereas none of the oxime acetates we have studied mutarotate, even in the presence of dry hydrogen chloride. In the case of these acetates the mobile hydrogen atoms are replaced by acetyl groups.

Recently, Busch and Kämmerer[13] have isolated the crystalline pseudo oxime form of phenacyl-p-toluidine oxime, $C_6H_5C(NHOH)=CHNH-C_6H_4CH_3$. This is analogous to an enolic form. The possibility of such a pseudo oxime being a factor in the work herein reported is easily eliminated with sugar derivatives. Such a substance should produce both gluconic and mannonic acid nitrile penta-acetates, as it is known that the shift from

---

[13] M. Busch and R. Kämmerer, *Ber.*, 63, 649 (1930).

a double bond linkage to a new asymmetric carbon atom would produce both forms,[14] as is illustrated below



The acetate of mannonic nitrile was not known. It was accordingly synthesized and found to be readily distinguishable from the acetate of gluconic nitrile. It was not found in the reactions studied and it then follows that no consideration of pseudo oxime forms need be made.

Further work on the synthesis and reactivity of the open-chain forms of sugar acetates is in progress in this Laboratory.

Experimental

A.—Synthesis and Preparation of Reference Compounds

Aldehyde-glucose **Oxime** Penta-acetate.—Ten grams (1 mole) of aldehydo-glucose penta-acetate was added quickly to 100 cc. of boiling water, the solution filtered and cooled as rapidly as possible to room temperature. To this solution was added a mixture of 2.3 g. (1.3 moles) of hydroxylamine hydrochloride and 5 g. (2 moles) of potassium acetate in the dry form. In a few minutes the solution became milky and the oxime separated as an oil. The mixture was allowed to stand at room temperature and was then placed in the ice box to crystallize. The crystalline material was filtered and washed with water; yield, 7.3 *g.*; m. p. 95–97°. It was recrystallized by dissolving in the smallest possible quantity of methyl alcohol and adding water to opalescence. Crystals separated after standing overnight in the ice box. These were filtered and washed with cold water, m. p. 95–97". After another recrystallization in the same manner, the substance melted at 97–98° and gave a polarization value of $[a]^{28}_{D}$ +57.4° (0.2104 g. of subs., 10.06 cc. of U. S. P. chloroform soln., α = +1.32°, 1.1-dm. tube). After two more recrystallizations the m. p. was 99–99.5° and $[\alpha]^{24}_{D}$ +57.2° (0.2096 g. of subs., 10.06 cc. of U. S. P. chloroform soln., α = +1.31°, 1.1-dm. tube) was obtained. No rapid or appreciable mutarotation was observed in methyl alcohol solution containing 0.005% of dry hydrogen chloride. Under these conditions the anilides of tetramethylglucose and tetramethylmannose will mutarotate to a constant value.[14] The polarization value of the substance in pure methyl alcohol was $[\alpha]^{24}_{D}$ +49.9° (0.3487 g. of subs., 10.02 cc. of methyl alcohol soln., α = +1.91°, 1.1-dm. tube). A second value was $[\alpha]^{24}_{D}$ +49.7° (0.3456 g. of subs., 10.06 cc. of methyl alcohol soln., **a** = +1.71°, 1.0-dm. tube).

The substance at room temperature is soluble in ethyl alcohol, very soluble in methyl alcohol, acetone and chloroform, but is practically insoluble in water and petro-

---

[14] M. L. Wolfrom and W. Lee Lewis, THIS JOURNAL, 50, 837 (1928).

leum ether. It is soluble in hot water but is practically insoluble in hot petroleum ether. It crystallizes in massive six-sided plates.

Anal. Subs., 0.2635: N_2, 9.03 cc. (749.5 mm., 23"). Calcd. for $C_6H_8O_5N(CH_3CO)_5$: N, 3.45. Found: N, 3.76. Calcd. for acetyl, 0.2000: 24.7 cc. 0.1 *N* NaOH. Found: 24.7 cc.

Aldehyde-glucose Oxime Hexa-acetate.—Thirty cubic centimeters of acetic anhydride was added to a solution of 10 g. of aldehydo-glucose oxime penta-acetate in 60 cc. of dry pyridine at 0°, and allowed to stand in an ice-bath for one hour. It was then poured into five times its mass of ice and water and stirred until all the acetic anhydride had been hydrolyzed. The mixture was then extracted with 50 cc. of chloroform. The chloroform solution was washed successively with a 3% sulfuric acid solution, saturated sodium bicarbonate solution and water, all solutions being kept near ice temperature. The chloroform solution when evaporated left a thick sirup which was crystallized by dissolving in the smallest possible volume of 95% ethyl alcohol and adding water to opalescence. The crude yield was 8.9 g. After one recrystallization the substance melted sharply at 79°; as the bath was heated, it solidified and melted again at 119°. After two recrystallizations, it melted at 119.5°. After four recrystallizations it melted at 119.5" and gave a polarization value of $[\alpha]_D^{28}$ +46.3° (0.4043 g. of subs., 10.06 cc. of U. S. P. chloroform soln., a = +2.05°, 1.1-dm. tube). After five recrystallizations the m. p. was 119.5° and the polarization value $[\alpha]_D^{25}$ +45.9° (0.4022 g. of subs., 10.06 cc of U. S. P. chloroform soln., a = +2.02°, 1.1-dm. tube) was obtained. The polarization value of the pure substance in methyl alcohol was $[\alpha]_D^{26}$ +40.9° (0.2010 g. of subs., 10.06 cc. of methyl alcohol soln., α = +0.90°, 1.1-dm. tube). A second value was $[\alpha]_D^{24}$ +41.0° (0.2029 g. of subs., 10.06 cc. of methyl alcohol soln., a = +0.91°, 1.1-dm. tube). No rapid or appreciable mutarotation was observed in methyl alcohol solution containing 0.005% of dry hydrogen chloride.

The substance is soluble in hot ethyl alcohol and hot water. It is practically insoluble in cold alcohol, water, petroleum ether and ether but is soluble in cold acetone.

Anal. Subs, 0.3030: N_2, 9.4 cc. (760 mm., 26°). Calcd. for $C_6H_7O_6N(CH_3CO)_6$: N, 3.14. Found: 3.42. Calcd. for acetyl, 0.1000: 13.4 cc. 0.1 *N* NaOH. Found: 13.6 cc.

The acetyl value was determined by distilling 0.5 g. of the substance with 50 cc. of 20% sulfuric acid, water being added to replace that lost by distillation. The acetic acid was then determined in the distillate by titration.

For purposes of identification, a crystallographic description of this compound was made by Doctor V. H. Morris of the Ohio Agricultural Experiment Station.

Crystallographic Description of **Aldehydo-d-glucose-oxime** Hexa-acetate (119.5° Form).—The crystal is observed as colorless elongated prisms belonging to the orthorhombic system. The elongation is in the direction which is taken as crystallographic *c*. The crystal is characterized by the common occurrence of pyramid faces on one or both ends. The optical sign of the crystal is negative; the indices of refraction are a = 1.460, β = 1.497 and γ = 1.504. Interference colors vary from first order gray when the acute bisectrix emerges, to third and fourth order colors when the optic normal emerges. The crystal shows parallel extinction in all positions. Since the vibration direction of (γ) is parallel to the direction of elongation, the sign of elongation is positive. The optic plane is parallel to the direction of crystallographic *c* and normal to one of the edges between two prism faces. When the crystal is observed lying on one of the edges between two of the prism faces, the acute bisectrix emerges; in this position beta (β) can be measured across the crystal and gamma (γ) along the elongation. When the crystal is observed lying on the edge between the other two prism faces, the optic normal emerges; in this position alpha (a) can be measured across the crystal and gamma (γ) along the elongation. The optic angle is small. The vibration direction of the obtuse bisectrix is the direction of crystallographic c, the direction of elongation.

Properties of β-Glucose Oxime Hexa-acetate.—&Glucose-oxime hexa-acetate was prepared by the method of Behrend.[10] It was crystallized by dissolving the thick sirup obtained in ethyl alcohol and adding water to opalescence. After three crystallizations the m. p. was 113–115° and the polarization value was $[\alpha]^{25}_{\mathrm{D}}$ +7.3° (0.4014 g. of subs., 10.06 cc. of U. S. P. chloroform soln., a = +0.32°, 1.1-dm. tube). After four crystallizations the m. p. was 113–115°, and the polarization value was $[\alpha]^{25}_{\mathrm{D}}$ +7.3° (0.4018 g. of subs., 10.06 cc. of U. S. P. chloroform soln., a = +0.32, after forty-eight hours, 1.1-dm. tube). In methyl alcohol the rotation of the pure substance was $[\alpha]^{24}_{\mathrm{D}}$ −1 3° (0.4026 g. of subs., 25.00 cc. of methyl alcohol soln., α = —0.04". 2-dm. tube). Another determination gave the value $[\alpha]^{27}_{\mathrm{D}}$ —1.3' (0.4042 g. of subs , 25.00 cc. of methyl alcohol soln., a = −0.04°, 2-dm. tube). From its low rotation the substance is probably the beta form. No rapid or appreciable mutarotation was observed in a methyl alcohol solution containing 0 005% of dry hydrogen chloride.

The substance is soluble in methyl alcohol, ethyl alcohol, chloroform and acetone, but is practically insoluble in ether, petroleum ether and water at room temperature. It is slightly soluble in hot water, but insoluble in hot petroleum ether. It crystallizes in fine needles. The substance was analyzed, as no analysis was found recorded in the literature.

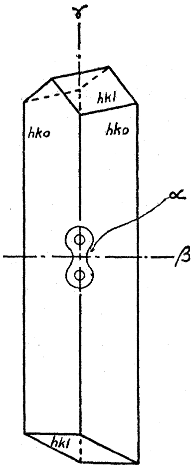


Fig. 1.—Optical orientation of aldehydo-*d*-glucose oxime hexa-acetate, 119.5" form.

Anal. Subs., 0.3045: N_2, 9.8 cc. (731.3 mm., 32°). Calcd. for $C_6H_7O_6N(CH_3CO)_6$: N, 3.14. Found: N, 3.28. Calcd. for acetyl, 0.5004: 67.0 cc. 0.1 N NaOH . Found: 67.3 cc. The acetyl value was determined as described for aldehydo-glucose oxime hexa-acetate.

Preparation of **Mannose Oxime.**—The directions of Fischer and Hirschberger[15] were slightly modified to give a more convenient method of preparation. Ten grams of mannose was dissolved in 15 cc. of water. To this solution was added a mixture of 15 g. of potassium acetate and 7 g. of hydroxylamine hydrochloride. The solution was warmed very gently for a few minutes and then placed in an ice–salt bath for one-half hour. The mannose oxime crystallized immediately upon scratching the sides of the flask with a glass rod. The crystals were filtered and washed with a little ice water; yield, 7.8 g.; m. p. 175–177°.

Mannonic Acid Nitrile Penta-acetate.—Six grams of mannose oxime was treated with 40 cc. of acetic anhydride and 6 g. of fused sodium acetate, by heating the reaction mixture to 85–90°. At this point the flask was removed from the source of heat and the reaction started with a rapid increase in temperature to the boiling point of the mixture. After the reaction was apparently over, the mixture was heated at its boiling point for one minute. It was then cooled and poured upon four times its volume of cracked ice with stirring. The sirup which separated was washed repeatedly with ice water and placed in the ice box. After four or five hours the sirup crystallized. This material had a very dark color which was removed by dissolving in boiling water and treating with norite. The water solution upon cooling gave a crop of almost white product This material was recrystallized four times from a few cubic centimeters of alcohol; yield, 2.5 g.; m. p. 92–93". This material gave a polarization value of $[\alpha]^{29}_{\mathrm{D}}$ −1.8"

---

[15] E. Fischer and J. Hirschberger, *Ber.*, 22, 1155 (1889).

(0.3878 g. of subs., 10.06 cc. of U. S. P. chloroform soln., α = −0.07°, 1.0-dm. tube). After one further recrystallization the m. p. 92–93', and the polarization value $[\alpha]_D^{30}$ −1.1° (0.3525 g. of subs., 10.06 cc. of U. S. P. chloroform soln., a = −0.04°, 1.0-dm. tube), were obtained.

The substance is soluble in cold chloroform, slightly soluble in cold alcohol, insoluble in cold water, slightly soluble in hot water, very soluble in hot alcohol and insoluble in petroleum ether. It crystallizes in plates.

Anal. Subs., 0.3030: N_2, 10.3 cc. (748.2 mm., 27°). Subs., 0.1993: CO_2, 0.3617; H_2O, 0.0993. Calcd. for $C_6H_6O_5N(CH_3CO)_5$: C, 49.56; H, 5.46; N, 3.61. Found: C, 49.49; H, 5.58; N, 3.68.

Measurement of Constants of Gluconic Acid **Nitrile** Penta-acetate.—Ten grams of gluconic acid **nitrile** penta-acetate which had been recrystallized once, after three further recrystallizations from the smallest possible volume of hot alcohol, had a melting point of 82.5–84°. After three more recrystallizations its melting point was 83–84°. The polarization value of the pure substance was $[\alpha]_D^{29}$ +47.8° (0.9354 g. of subs., 24.88 cc. of U. S. P. chloroform soln., α = +1.80°, 1.0-dm. tube). A second determination gave the value $[\alpha]_D^{31}$ +48.3° (0.3505 g. of subs., 10.02 cc. of U. S. P. chloroform soln., a = +1.69°, 1.0-dm. tube). The substance crystallizes in plates.

Measurement of Constants of **β-Glucose Oxime.—We** have been able to recrystallize glucose oxime in one-gram lots from 60% methyl alcohol by boiling with 15 cc. of the solvent for not more than one-half minute, decanting the supernatant liquor, and cooling it rapidly. If the solution is kept hot too long the glucose oxime will not crystallize. After two recrystallizations in this way the material gave a melting point of 139–140°, an initial polarization value of $[\alpha]_D^{25}$ −8.9° and a final value of $[\alpha]_D^{25}$ −1.9° (1.0260 g. of subs., 25 cc. of water soln., initial a = −0.73°, final a = −0.07°, 2.0-dm. tube). A melting point of 142–143" was obtained for this substance when prepared by de-acetylation of aldehydo-glucose oxime penta-acetate. In this case an initial specific rotation of −8.3" and a final value of −3.0" were obtained.

B.—**Reactivity** of Glucose Oxime and its Acetates

De-Acetylation of Aldehydo-glucose Oxime Penta-acetate.—An attempt to de-acetylate aldehydo-glucose oxime penta-acetate in acid solution resulted in splitting the oxime linkage. The compound was successfully de-acetylated in alcoholic ammonia. Five grams of aldehydo-glucose oxime penta-acetate was dissolved in 25 cc. of methyl alcohol and dry ammonia bubbled through the solution for fifteen minutes at 0°. The solution was placed in the ice box for twenty-four hours. It was then evaporated under reduced pressure at 35° to a thick sirup, which was dissolved in 10 cc. of ethyl alcohol, nucleated with known glucose oxime and placed in an oven at 37°. Glucose oxime slowly separated out, taking several days to crystallize completely; yield, 0.85 g., m. p. 135–138°. A mixed melting point with known glucose oxime (m. p. 139°) was 135–138°. After one crystallization from 80% ethyl alcohol the melting point was 142–143" and a mixed melting point with known material was 140–141°. It gave an initial polarization value of $[\alpha]_D^{29}$ −8.3" and a final value of $[\alpha]_D^{29}$ −3.0° (0.3380 g. of subs., 10.06 cc. of water soln., initial α = −0.28°, final α = −0.10°, 1.0-dm. tube).

Aldehyde-glucose Oxime Penta-acetate.—On heating aldehydo-glucose oxime penta-acetate slowly to 200°, it began to decompose. The heating was stopped at this point and the product dissolved in hot water. Only unchanged material was isolated.

Aldehyde-glucose Oxime Hexa-acetate, **Nitrile** Formation.—Two grams of aldehydo-glucose oxime hexa-acetate (m. p. 119.5") was carefully melted and then heated to 135–140°. At this point the substance began to decompose and on removal from the source of heat the reaction continued spontaneously with a rapid rise in temperature.

After the reaction was completed, the resulting sirup was poured into cold water. It crystallized almost immediately. On one recrystallization from dilute alcohol, 1.4 g. of material melting at 82–83° was obtained. One further crystallization gave material melting at 83–84° and showing no depression when mixed with an authentic specimen of gluconic acid nitrile penta-acetate (m. p. 83–84°). It gave a polarization in chloroform of $[\alpha]^{27}_{D}$ +47.8° (0.4040 g. of subs., 10.06 cc. of U. S. P. chloroform soln., $\alpha = +1.92°$, 1-dm. tube), in exact agreement with the value determined for the nitrile acetate.

Two grams of aldehydo-glucose oxime hexa-acetate (m. p. 119.5°), 2 g. of fused sodium acetate and 8 cc. of acetic anhydride were heated at the boiling point of the mixture for ten minutes and then poured on cracked ice. The resulting sirup was washed several times with cold water, recrystallized from water and then twice from dilute alcohol. The melting point was 83–84° and showed no depression on admixture with an authentic specimen of gluconic acid nitrile penta-acetate (m. p. 83–84°). The polarization value in chloroform was $[\alpha]^{27}_{D}$ +46.8° (0.2269 g. of subs., 10.06 cc. of U. S. P. chloroform soln., $\alpha = +1.06°$ 1-dm. tube). The rotatory value previously determined for the acetylated nitrile was +47.8°.

6-Glucose Oxime Hexa-acetate.—This substance did not form gluconic acid nitrile penta-acetate when heated alone to high temperatures or with acetic anhydride and sodium acetate. The compound underwent profound decomposition when heated alone to high temperatures. If treated according to Wohl's procedure for the formation of the acetylated nitrile, the material was recovered unchanged in high yield.

β-Glucose Oxime: **Nitrile** Formation **and** Isolation **of** Intermediate Form.—Ten grams of β-glucose oxime, 10 g. of fused sodium acetate and 40 cc. of acetic anhydride were heated to a temperature of 75–80° for one hour. These conditions were identical with those used by Wohl except that the reaction was run for a longer time at a lower temperature. The solution was then poured into 200 cc. of ice water and allowed to stand overnight. The solid material from four such runs was combined, dissolved in the smallest possible volume of hot ethyl alcohol and water added to opalescence at room temperature. The material which separated was recrystallized four times from hot ethyl alcohol. It yielded 16 g. of gluconic acid nitrile penta-acetate, m. p. 83–84° and giving a polarization value of $[\alpha]^{29}_{D}$ + 47.6° (0.4227 g. of subs., 10.06 cc. of U. S. P. chloroform soln., $\alpha = +2.00°$ 1-dm. tube). The constants determined for the pure substance are m. p. 83–84°, $[\alpha]_{D}$ +47.8°. The ice water used to hydrolyze the acetic anhydride solution was extracted with chloroform, the extract evaporated and the residue crystallized by dissolving in hot ethyl alcohol and adding water to incipient opalescence. The filtered material was recrystallized from alcohol-free ether. The alcohol mother liquor from the first recrystallization of the nitrile was diluted to 400 cc. with water, extracted with chloroform and the extract treated as above. The filtered material from these two sources was combined and recrystallized four times from alcohol-free ether and finally from dilute ethyl alcohol. The yield was 0.2 g. of material, m. p. 119°. A mixed melting point with an authentic specimen of aldehyde-glucose oxime hexa-acetate (m. p. 119.5°) was 119.5°, while on admixture with β-glucose oxime hexa-acetate (m. p. 113–115°) the melting point was depressed to 103–106°. The isolated material gave a polarization value of $[\alpha]^{31}_{D}$ +45.9° (0.2150 g. of subs., 10.06 cc. of U. S. P. chloroform soln., $\alpha = +0.98°$, 1-dm. tube). The polarization value determined for the pure substance in this solvent was $[\alpha]_{D}$ +46°. Doctor V. H. Morris of the Ohio Agricultural Experiment Station has made a comparison of the optical properties of the above isolated material with those of aldehydo-glucose oxime hexa-acetate synthesized through aldehydo-glucose penta-acetate and states that "the optical constants of the two samples are identical."

The yield of 0.2 g. reported above is probably not representative of the total amount of this substance in the acetylation mixture, since its separation is difficult and most of the material is lost in purification.

β-Glucose Oxime Hexa-acetate. Isolation from **Wohl's Acetylation** Mixture.—Since Wohl[9] merely reported a melting point for the oxime acetate obtained by him and gave no directions for its isolation, it was thought advisable to repeat this work. It was also of interest in our work to determine that when the acetylation of the oxime had gone to completion, no trace of the aldehydo-oxime acetate could be found. Five grams of glucose oxime was acetylated according to Wohl's procedure and the reaction mixture poured into 300 cc. of cold water. The liquid decanted from the sirup formed was extracted with chloroform and the evaporated extract dissolved in a small quantity of ethyl alcohol. To this solution was rapidly added about four volumes of water and the solution decanted from the sirup precipitated. A crop of crystals appeared in the decanted solution. After one recrystallization from alcohol and water the melting point was 113–115° and showed no depression on admixture with an authentic specimen of β-glucose oxime hexa-acetate (m. p. 113–115°) and gave a melting point of 100–105" on mixing with aldehydo-glucose oxime hexa-acetate (m. p. 119.5")

Summary

1. The penta-acetate and hexa-acetate of the open-chain form of glucose oxime have been synthesized in pure crystalline condition.

2. Evidence is given that the ring form of glucose oxime shifts to the open-chain form on undergoing nitrile formation. This evidence is based upon the direct isolation of the intermediate open-chain oxime acetate from the reaction mixture when the reaction is stopped before completion.

3. Acetic acid and not water is split out on nitrile formation from glucose oxime.

4. The acetylated oxime isolated by Wohl and considered to be the *anti* form of glucose oxime hexa-acetate is shown to be a ring form, corresponding in structure to glucose oxime. It is shown that these ring forms are probably the beta isomers.

5. The open-chain form of glucose oxime penta-acetate yields the ring form of glucose oxime on de-acetylation.

6. A nomenclature is suggested which distinguishes between the ring forms and the open-chain forms of sugar oximes.

7. Evidence is given that glucose oxime does not react in the pseudo oxime form on undergoing nitrile formation.

8. Mannonic acid nitrile has been synthesized in pure crystalline condition.

9. Constants are given for β-glucose oxime hexa-acetate, β-glucose oxime, and gluconic acid nitrile penta-acetate.

THE IODINE CONTENT OF SHRIMP WASTE

BY HAYWOOD PARKER, JR.,[1] AND FRANK C. VILBRANDT[2]

RECEIVED JULY 30, 1930 PUBLISHED FEBRUARY 9, 1931

The recent investigation of Vilbrandt and Abernethy[3] on the utilization of the waste products of the shrimp fisheries has shown that a high protein stock feed, rich in vitamins, can be produced economically from the shrimp waste. Since practically all marine life contains comparatively large quantities of iodine, the above wastes from shrimp have been examined for iodine content.

Source of Material.—The shrimp waste used in this investigation was taken from the composite of a number of brine cooks prepared by Vilbrandt and Abernethy[3] during the summer of 1928 at Brunswick, Ga. The waste from the shrimp picking tables had been boiled in brine, then removed from the cooking liquor and dried to a moisture content of 4.4%. This material had been kept in this condition for twenty-two months with no indication of deterioration. The methods of Baumann,[4] Paolini[5] and McClendon[6] were used to reduce the shrimp waste to a condition whereby extraction could be accomplished efficiently.

Methods for Determining Iodine.—The analytical method used in this investigation was the Tressler and Wells[7] modification of the von Fellenberg extraction method. In the case of the extracts prepared and analyzed, one gram of the shrimp waste was used as a base to distribute and support the extract. This procedure added a definite constant amount of iodine to the extraction values; a correction was made for this iodine added.

Experimental Data.—The treatment of the shrimp waste to ascertain the distribution of the iodine was varied by using several solvents and methods of extraction. The extraction data and the iodine content of the various extracts are given in Table I.

Of the various treatments used, simple extraction with ethyl alcohol, water and ethyl ether, in the order named, gave the most efficient separation of iodine. The ether extract contained the lipoid iodine, while the water and alcohol extracts contained considerable quantities of organically combined iodine as well as the inorganic iodine.

TABLE I

IODINE CONTENT OF EXTRACTS OF SHRIMP WASTE

Treatment	Solvent	Concn., %	Sample, g.	Nature of residue	Iodine in sample, P. P. m. Sol.	Insol.	Total	Iodine, % Sol.	Insol.	Iodine found, %
1	...	...	..	....	..	...	16.90	..	...	100.0
2	Alcohol	96	30	Brown tar	4.68	2.78	7.46	62.7	37.3	44.1
3	Ether	100	30	Greenish brown oil	3.45	5.95	9.40	36.7	63.3	55.6
4	Water	...	60	Brown tar	9.15	7.65	16.80	54.5	45.5	99.4
5	HCl	5	30	Putrid brown mass	..	10.10	10.10	0.0	100.0	60.0
6	NaOH	5	30	Putrid brown mass	8.00	8.94	16.94	47.2	52.8	100.0

The results of the acid hydrolysis indicated that coagulation of protein matter caused by the acid tended to render the iodine compounds insoluble. The alkaline hydrolysis showed that a large fraction of the iodine is held in some organic combination, probably protein, quite resistant to decomposition. It will be noticed that the values for total iodine, obtained by adding the extract iodine and residue iodine, are low in the samples treated with alcohol and with ether. It is possible that some of the loss of iodine is due to volatilization of some organic iodides, possibly ethyl iodide formed with the alcohol itself or the alcohol present in the ether.

These experiments show that the shrimp waste contains a relatively large proportion of iodine. The majority of this iodine is held in organic combination, 26.7% being combined with the lipoid material, and the rest probably occurring in protein combination.

Examination for Thyroxine.—An attempt was made to isolate thyroxine from the shrimp waste by means of Kendall's[8] method of hydrolysis, modified slightly in the extraction procedure due to the peculiar nature of the waste. Upon proper extraction the Kendall precipitate, which should normally contain the thyroxine if any were present, was so small that it was deemed inadvisable to make a direct iodine determination; instead, the substance in solution, slightly yellow in color, was tested for the presence of thyroxine according to the nitrous acid method cited by Kendall,[8] with negative results. The addition of ammonium hydroxide to the resultant solution also produced no color change, thus indicating that thyroxine could not be detected in the extract of shrimp waste by the Kendall method.

Summary

1. The wastes of shrimp fisheries showed a content of **16.9** parts per million of iodine calculated on the dry basis.
2. Alcohol extraction indicated the presence of **44.14%** of organic plus inorganic iodine.

---

[8] E. C. Kendall, Thyroxine, American Chemical Society Monograph Series, No. 47.

3. Ether extraction indicated the presence of 55.86% of lipoid iodine.

4. No thyroxine could be detected in the extract of shrimp waste when tested by the Kendall method.

THE REDUCING ACTION AND CONSTITUTION OF THE GRIGNARD REAGENT

BY C. R. NOLLER

RECEIVED SEPTEMBER 10, 1930 PUBLISHED FEBRUARY 9, 1931

A. Reducing Action

The occurrence in the literature of over fifty references to the reduction of various compounds, chiefly aldehydes, ketones and esters, brought about by Grignard reagents indicates the frequency with which this side reaction is encountered. During the past year alone, from papers and a note have appeared dealing primarily with this subject.[1]

An examination of the various experiments leads one to the conclusion that the reduction may be due to a number of causes. It may be brought about by the action of unused magnesium and the magnesium halide which is always present,[2] by the action of magnesium alcoholate on an excess of the aldehyde or ketone,' or by the action of the Grignard reagent itself. It would seem that, strictly speaking, only the last type of reduction should be considered as the reducing action of the Grignard reagent, but even in this case reduction may be brought about in at least two ways. Where dissociation of the Grignard reagent into the free hydrocarbon radical and magnesious halide may take place, the latter may cause reduction.*

In other cases reduction takes place at the expense of the hydrocarbon radical with the formation of unsaturated hydrocarbon.[5] It should be

[4] Gilman and Fothergill, THIS JOURNAL, 51,3149 (1929).

[5] Of the several theories that have been proposed for this last type of reduction, the assumptions (1) that after a primary addition of RMgX to the aldehyde or ketone, unsaturated hydrocarbon is lost and the remaining HMgX adds to the carbonyl group [Hess and Rheinboldt, *Ber.*, 54,2043 (1921); Hess and Wustrow, *Ann.*, 437, 256 (1924); Rheinboldt and Roleff, *Ber.*, 57, 1921 (1924); Meisenheimer, *Ann.*, 442, 180 (1925); Rheinboldt and Roleff, *J. prakt. Chem.*, 109, 175 (1925)] and (2) that the free radicals RR'C(OMgX)— and R''— are intermediate products in the reaction of a ketone RCOR'

noted that the products of these various types of reduction are not the same. Magnesium halide or magnesium and magnesium halide seem to lead to the formation of pinacols, whereas magnesium alcoholate and undissociated Grignard reagent yield alcohols.[5,6]

With the appearance of the excellent work of Schlenk and Schlenk[7] on the composition of the Grignard reagent in which direct evidence was advanced for the equilibrium

$$2RMgX \rightleftharpoons R_2Mg + MgX_2 \qquad (1)$$

it seemed desirable to determine whether solutions of R_2Mg alone would cause reduction. In choosing a reaction for study it was thought advisable to use one that normally caused a very large amount of reduction. The reaction of isobutylmagnesium iodide and benzophenone reported by Blicke[1c] to give a 74% yield of benzhydrol satisfied this condition, and the ease with which the reduction product was isolated seemed to be an added advantage. Isobutyl bromide was used in place of isobutyl iodide because it is more readily prepared and probably rearranges to the tertiary halide less readily.

Schlenk's method[7] was used for preparing solutions of di-isobutyl magnesium. It was found that the equilibrium *(1)* is shifted so far to the right in the Grignard reagent prepared from isobutyl bromide that approximately 75% of the active Grignard reagent is present in the form of di-isobutyl magnesium. Precipitation of the halogen-containing compounds with 1,4-dioxane therefore gave a ready means of obtaining fairly concentrated solutions of di-isobutyl magnesium (0.1–0.14 equivalent or 0.05–0.07 mole per 100 cc. of solution). These solutions could be prepared containing less than 0.1 equivalent per cent. of the active Grignard reagent combined with halogen, as determined by analysis for halogen.[8] In all of

---

with $R''MgX$ (Biicke, Ref. 1c) seem to be the most satisfactory. The latter theory, however, leads one to predict the formation of pinacols in the absence of excess of magnesium. Until recently, the only case where this occurred was with triphenylmethylmagnesium chloride.[4] Recently, Davies, Dixon and Jones[10] report the isolation of benzpinacol from the reaction of amylmagnesium halides with benzophenone. Unfortunately. they siphoned or decanted their solutions from the excess magnesium. That this may not be sufficient is shown by the experiments of Gilman and Fothergill (Ref. 4, note g) with *tert.*-butylmagnesium chloride. Since the appearance of the work of Davies, Dixon and Jones, we have re-examined 60 g. of the combined solid fractions obtained in the reaction of isobutylmagnesium bromide and benzophenone and have been unable to find any indication of the presence of benzpinacol.

[6] An entirely different type of reduction seems to take place in the action of Grignard reagents on azobenzene [Rheinboldt and Kirbig, *J. prakt. Chem.*, [2] 118, 1 (1928)] and in the reaction of certain bromides with magnesium [Krestinsky, Ber., 55, 2770 (1922)].

[7] Schlenk and Schlenk, *ibid.*, 62, 920 (1929); see also Gilman and Fothergill, Ref. 4.

[8] One of the referees has pointed out that a small amount of MgX_2 because of the equilibria involved might suffice to convert a large amount of R_2Mg to $RMgX$. We do

the work reported in this paper, perfectly clear filtered solutions of the Grignard reagent were used and always in 10% excess.

We have found that solutions of di-isobutyl magnesium reduce benzophenone to benzhydrol to the extent of at least 64% of the theoretical amount. The high percentage of di-isobutyl magnesium present in the original Grignard solution (approximately the same as the amount of reduction reported by Blicke) seemed to indicate that it was the sole reducing agent. However, when benzophenone in benzene solution is added to the original Grignard reagent, a copious precipitate is soon formed from which the reduction product is isolated; when added to a solution of di-isobutyl magnesium, no precipitate is formed and the reduction product is obtained on decomposing the solution and crystallizing the benzhydrol from the other reaction products. On comparing the relative amounts of benzhydrol isolated in each case, it would appear that more reduction takes place when the original Grignard reagent is used (83.5%) than when a solution of di-isobutyl magnesium is used (64.2%). Because of the greater difficulty in isolating the benzhydrol in the second case, however, the amount formed is undoubtedly larger than was actually isolated. Whether or not the amount of reduction was identical, it was certainly greater than 64% in both cases.

Blicke assumed the precipitate from which the benzhydrol was isolated in the first case to have the formula $(C_6H_5)_2CHOMgBr$, having shown that a similar precipitate is formed on adding a solution of benzhydrol to the Grignard reagent prepared from ethyl bromide. No analyses were given. We have determined the ratio of the benzhydrol to the basic hydroxyl groups and to the halogen after the precipitate is decomposed with water, and find that it agrees with this formula. It would appear therefore that solutions containing only di-isobutyl magnesium can cause reduction of benzophenone to the extent of at least 64%, the reduction product probably existing in the form $(C_6H_5)_2CHOMgOCH(C_6H_5)_2$, which is soluble in ether. When, on the other hand, the original Grignard reagent is used, only isobutylmagnesium bromide causes reduction, the reduction product precipitating entirely in the form $(C_6H_5)_2CHOMgBr$, and this in spite of the fact that 75% of the active Grignard reagent is in the form of di-isobutyl magnesium.

B. Constitution of the Grignard Reagent

In order that reduction may be brought about entirely by means of isobutylmagnesium bromide, the equilibrium (1) must shift very rapidly,

not feel that this is likely, however, because Gomberg and Bachmann (Ref. *2)* and more recently Bachmann [THIS JOURNAL, 52,4412 (1930)] find that in reactions depending on similar equilibria the rate is slower when only a small amount of MgX_2 is present than when an equivalent quantity of MgX_2 is present, whereas in our experiments reaction always takes place very rapidly. The suggestion is, nevertheless, one to be kept in mind since the rates of attaining equilibrium may be vastly different in different reactions.

because so far as one can tell by the evolution of heat and immediate precipitation of the reduction product (after precipitation once starts), the reduction is practically instantaneous. This would not be a serious drawback, however, because Schlenk[7] has shown that although the equilibrium in the case of ethylmagnesium iodide is only slowly attained, the equilibrium in the case of phenylmagnesium bromide must be reached quite rapidly. The reduction of benzophenone by di-isobutyl magnesium, however, must also, as evidenced by the evolution of heat, be practically instantaneous. It is difficult to see, therefore, why the original Grignard reagent which is in the form of di-isobutyl magnesium to the extent of 75% should shift entirely to the form isobutylmagnesium bromide during the reduction when either compound may cause reduction.

At this point it occurred to us to determine what would happen if a solution of anhydrous magnesium bromide in absolute ether were added to the solution containing the reduction product formed by the action of di-isobutyl magnesium. It was found that a compound is rapidly precipitated (again after precipitation once starts) which so far as can be determined from analysis, appearance and behavior is identical with that formed when benzophenone is added to the original Grignard reagent. This would mean, assuming Blicke's formula to be correct, that the reaction

$$(C_6H_5)_2CHOMgOCH(C_6H_5)_2 + MgBr_2 \rightleftharpoons 2(C_6H_5)_2CHOMgBr \qquad (2)$$

is likewise a very rapid one.

Considerable work has been done in attempts to decide between the formulas RMgX and $R_2Mg{\cdot}MgX_2$ for the Grignard reagent.[9] The majority of this work seems to favor the RMgX formula, but with the possible exception of the results of Job and Dubien[10] on the order of the reaction

$$C_2H_5MgBr + C_2H_5Br \rightleftharpoons C_2H_4 + C_2H_6 + MgBr_2 \qquad (3)$$

of which no experimental details are given, the writer does not believe that any of the work gives conclusive evidence for either formula. Until such evidence is presented, it would appear that the reactions discussed in this paper are best explained by assuming that no isobutylmagnesium bromide exists in the original Grignard solution, that the equilibrium existing in this solution is best represented as

$$R_2Mg{\cdot}MgX_2 \rightleftharpoons R_2Mg + MgX_2 \qquad (4)$$

and that the insoluble compound has the composition $[(C_6H_5)_2CH{-}O]_2$-$Mg{\cdot}MgBr_2$, where the dots simply represent some form of molecular complex. Such reactions involving the formation of simple addition products would be expected to take place more rapidly than metathetical

reactions in a slightly ionizing solvent such as anhydrous ether, **and a** single compound, the dialkyl magnesium, would be responsible for reduction.

Experimental

Isobutyl Bromide.—Isobutyl alcohol, b. p. 106–107.5°, was mixed with a 50% excess of constant-boiling hydrobromic acid and the mixture slowly distilled through a 1-m. column until the temperature reached 120°. The distillate was saturated with salt, the bromide layer separated, returned to the flask containing the residue of hydrobromic acid and distilled again. This operation was repeated until the bromide layer had a specific gravity of approximately 1.2. It was then washed twice with concd. sulfuric acid, once with 5% sodium carbonate solution, then with water and dried over calcium chloride. This product was carefully fractionated three times through a 1-m. column, the main portion boiling at 91–93'. Analysis according to the method of Michael[11] showed 5.1% of tertiary butyl bromide. After vigorously stirring this product for thirty minutes at 25° with fifty times its weight of water, drying over anhydrous potassium carbonate, and distilling, analysis showed 0.96% tertiary butyl bromide.

Grignard Reagent.—The entire preparation and filtering operations were carried out in an atmosphere of hydrogen. About 10 cc. of a mixture of 137 g. (1 mole) of isobutyl bromide and 150 cc. of absolute ether was added to 24.5 g. of fine, bright magnesium turnings in a one-liter three-necked flask fitted with condenser, stirrer and dropping funnel. The reaction started almost immediately without the addition of iodine and 100 cc. of absolute ether was rapidly added. The balance of the bromide–ether mixture was then added slowly from the separatory funnel with stirring over *a* period of three hours. During this time the solution was under hydrogen at a pressure only slightly greater than atmospheric. Another 100 cc. of ether was added and the solution filtered under hydrogen pressure into a graduated cylinder and diluted to a total volume of 590 cc. The apparatus was so arranged that the solution could be transferred from the three-necked flask to a Biichner funnel with slight hydrogen pressure, filtered under a pressure of 10 pounds into the graduated cylinder, diluted to the desired volume and transferred from the graduated cylinder to a measuring buret entirely in the absence of air. The Biichner funnel had a Jena glass filter disk of porosity 3 and a 3-mm. layer of tightly packed ignited kieselguhr was used as a filtering medium.

The filtered solution was perfectly clear but still had the pale brownish-gray color characteristic of Grignard reagents. Analysis of 5-cc. portions by titration[12] with standard 0.2 N acid showed 0.001325 mole per cubic centimeter of solution. This corresponds to a total yield of Grignard reagent of 78.2%. (The actual yield of Grignard reagent, as determined in other runs in which the filtration was omitted and hence losses avoided, was approximately 86%)

Analysis **of** the Grignard Solution for Di-isobutyl **Magnesium.**—A *3G3* Jena-Biichner funnel with sintered glass filter disk was fitted through a cork with a 60-cc. glass-stoppered separatory funnel and a stopcock for applying hydrogen pressure. The apparatus was swept out with hydrogen, 5 cc. of absolute ether run into the funnel to moisten the glass filtering disk (no other filtering medium was used) and 5 cc. of the Grignard reagent run into the separatory funnel from a buret. To this was quickly added 1.5 cc. of a solution of pure 1,4-dioxane in absolute ether (1 g. per 2 cc. of solution). The separatory funnel was closed with a well-greased stopper and shaken. The mixture was then run into the Biichner funnel and filtered with hydrogen pressure. The sepa-

[11] Michael, *Ann.*, **379, 287** (1911).

[12] Gilman and co-workers, THIS JOURNAL, 45, 150 (1923); 51, 1576 (1929).

ratory funnel and precipitate were washed three times with 5-cc. portions of ether, filtering each time with pressure. The filtrate was decomposed with 50 cc. of water, the ether removed by heating on a hot-plate, and the magnesium hydroxide titrated with standard acid.[13] The average amount of acid, calculated *as* 1 N, was 4.967 cc., indicating that approximately 75% of the active Grignard solution was in the form of di-isobutyl magnesium.

Preparation of Di-isobutyl Magnesium Solution.—Three hundred cubic centimeters of the Grignard reagent from isobutyl bromide was placed in a 500-cc. glass-stoppered flask previously swept out with hydrogen, and cooled in an ice–salt bath to 0°. To this was added with shaking 66 cc. of a solution of dioxane in ether (50 g. per 100 cc.). The temperature did not rise above 20°. After thorough shaking the mixture was poured into four 100-cc. centrifuge tubes and tightly stoppered. After centrifuging for fifteen minutes at about 2000 r. p. m., a clear upper layer had formed. This still gave a slight precipitate with dioxane solution and a total of 7 cc. more was added to each tube, when practically no more precipitate formed. The tubes were again centrifuged and then decanted into a hydrogen filled bottle. This solution is perfectly clear and water white, being entirely free from the grayish color of the original Grignard solution. The concentration of active Grignard reagent as determined by titration with standard acid was 0.00101 equivalent per cubic centimeter. The solution gave a weak test for halogen. To 10 cc. of the solution was added 100 cc. of water and then 10 cc. of 6 N nitric acid. This solution was titrated with an approximately 0.1 N standard silver nitrate solution. An amount equivalent to 0.0079 cc. of N silver nitrate was required, indicating 0.078% of the Grignard reagent combined with halogen.

Reducing Action of the Original Grignard Solution.—In an Erlenmeyer flask fitted with a thermometer and a 50-cc. dropping funnel was placed 41.5 cc. (0.055 equiv.) of the Grignard solution and this diluted with 13.5 cc. of absolute ether to make the equivalent concentration of active Grignard reagent the same as that of the di-isobutyl magnesium solution prepared above. The flask was placed in an ice–salt mixture and when the temperature had dropped to 0°, a solution of 9.1 g. (0.05 mole) of benzophenone dissolved in 10 cc. of dry benzene was slowly added, shaking after each addition. The rate of addition was such that the temperature was kept between 0 and 5°. With the addition of each drop of benzophenone solution, a deep wine red color was imparted to the solution, which soon disappeared. After a short time a white precipitate began to form which settled out very readily. The formation of a red color each time the solution of benzophenone was added took place at the end of the reaction just as at the beginning. The mixture was allowed to warm up to room temperature and then filtered on a Büchner funnel with suction, washing the precipitate three times with 10-cc. portions of dry benzene. The filtrate and precipitate were decomposed separately with a saturated solution of ammonium chloride and extracted three times with 50-cc. portions of ether. The ether solutions were evaporated in a tared beaker placed on a watch glass, at first over a warm hot-plate and finally in a vacuum desiccator over phosphorus pentoxide.[14] There was obtained from the precipitate 7.7 g. of benzhydrol melting at 65–67° or 83.5% of the calculated amount. The filtrate yielded 1.3 g. of an oil from which nothing could be crystallized. Assuming this to be diphenyl isobutyl carbinol, it would correspond to 10.8%, making the total recovery 94.3%.

Reducing Action of Di-isobutyl Magnesium Solutions.—The procedure followed

---

[13] Whenever an appreciable amount of ether is present it is necessary to remove it in order to get a satisfactory end-point with phenolphthalein. This is in agreement with the work of Hall [*Ind. Eng. Chem., Anal. Ed.*, 2, 244 (1930)] on the analysis of ether.

[14] Excessive heating must be avoided to prevent the formation of dibenzhydryl ether which seems to take place at times even at temperatures near 100°.

was the same as in the previous experiment, using 110 cc. (0.11 equiv.) of di-isobutyl magnesium solution and 18.2 g. (0.10 mole) of benzophenone in 20 cc. of dry benzene. As in the preceding experiment, a deep red color developed after each addition of benzophenone, which soon disappeared on shaking. This reaction differed from the preceding one, however, in that no precipitate formed. After all of the benzophenone had been added, the solution was allowed to warm up to room temperature and a clear pale yellow solution resulted. The entire solution was decomposed with a saturated ammonium chloride solution, extracted three times with 50-cc. portions of ether, and the ether and benzene removed as before. There was obtained 18.5 g. of an oil which partially solidified on standing. Filtration was rather difficult so the whole was dissolved in 10 cc. of 95% alcohol, cooled until crystallization was complete, and filtered with suction. The filtrate was cooled again in an ice–salt mixture and filtered. A total of 10.4 g., m. p. 59–64°, was obtained. The combined alcoholic solution, including alcoholic washings of funnel, beakers and filter papers, was evaporated at 25 mm. and finally heated at 100° for ten minutes at this pressure. After standing for several days crystals appeared and on stirring a paste of crystals resulted. On filtering, oily crystals were obtained which weighed 1.4 g. and after clay plating melted at 59–65°, making the total recovery of benzhydrol 11.8 g. or 64.2% of the calculated amount. The total amount of oil remaining was 3.8 g., so that a loss of 2.9 g. occurred. The difference between the original weight and the weight of benzhydrol is 6.7 g. Assuming this to be diphenyl isobutyl carbinol it amounts to 27.9% of the calculated amount, making the total yield of products 92.1%. The actual amount of benzhydrol formed must be considerably greater than was actually isolated.

Analysis of Precipitate Formed on **Adding** Benzophenone to the Original Grignard Reagent.—A Grignard solution was prepared as previously described except that one-third quantities were used and the final solution was less dilute. Analysis by titration with standard acid showed it to contain 0.001927 equivalent of active Grignard reagent per cubic centimeter. Two 20-cc. (0.0385 equiv.) portions of this solution were treated with solutions of 6.3 g. (0.0347 mole) of benzophenone in 10 cc. of dry benzene. The precipitates were centrifuged, the clear liquid decanted and the precipitate washed four times with 30-cc. portions of *dry* benzene, stirring the precipitate and centrifuging each time. After the last centrifuging the tube was swirled so as to remove an upper gelatinous layer with the benzene when the latter was decanted. No attempt was made to obtain all of the precipitate, the sole object being to get a pure product. Ether was added to the precipitate to facilitate removal and the whole transferred to an Erlenmeyer flask, where it was decomposed with 100 cc. of distilled water. The solutions were extracted four times with 50-cc. portions of alcohol-free ether and the ether evaporated from the solution in a tared beaker, at first over a warm hot-plate and finally in a vacuum desiccator over phosphorus pentoxide.

The aqueous layers were boiled to remove ether and after cooling titrated with approximately 0.5 N standard nitric acid. These same solutions were then diluted to 500-cc. and 50-cc. portions acidified with nitric acid and titrated with approximately 0.1 *N* standard silver nitrate solution. The results are given in Table I.

TABLE I

ANALYSIS OR PRECIPITATE FROM ORIGINAL GRIGNARD REAGENT AND BENZOPHENONE

Sample	G.	Benzhydrol equiv.	M. p., °C.	*N* HNO_3, cc.	Equiv. of basic OH	*N* $AgNO_3$, cc.	Equiv. of halogen
1	4.28	0.0233	66–67.5	23.02	0.0230	23.20	0.0232
2	4.17	.0227	67.5–68	22.80	.0228	22.81	.0228

These results show that on decomposing the precipitate with water there is obtained one equivalent of benzhydrol for one equivalent each of basic hydroxyl and halogen.

Analysis of the Precipitates Formed on Adding a Solution of Anhydrous Magnesium Bromide to a Solution of the Reaction Product of Benzophenone and Di-isobutyl Magnesium.—Anhydrous magnesium bromide was prepared according to the method of Lerch.[15] On allowing the powdered fused salt to stand for several hours under absolute ether with occasional shaking, a lower yellow layer formed which according to Menschutkin[16] contains around 40% of magnesium bromide at room temperature. By dissolving **35** cc. of this lower layer in a mixture of 45 cc. of dry benzene and 30 cc. of absolute ether, a solution was obtained which could be diluted with a considerable quantity of ether without causing the separation of two layers, and a clear solution resulted when small amounts were mixed with a large volume of ether. Analysis for halogen showed it to contain 0.00089 mole of magnesium bromide per cubic centimeter.

When this solution was added to a solution of the product of the reaction of benzophenone and di-isobutyl magnesium prepared as above, an immediate precipitate was formed. On carrying out a fractional precipitation and analyzing the precipitates, it was found that the first precipitate after decomposition with water gave practically no benzhydrol or basic hydroxyl but a large amount of halogen. The second precipitate gave a considerable quantity of benzhydrol (0.0082 equiv.) and a practically equal amount of basic hydroxyl (0.0098 equiv.) but a somewhat higher amount of halogen (0.0147 equiv.). This indicated that an excess of dioxane had been present in the di-isobutyl magnesium solution.

A solution of di-isobutyl magnesium was then prepared using a smaller excess of dioxane. To 100 cc. of the Grignard solution containing 0.001927 equivalent of active Grignard reagent per cubic centimeter was added 20 g. of dioxane dissolved in 20 cc. of ether. After centrifuging, the clear solution still gave a slight precipitate when more dioxane was added. Analysis for active Grignard reagent showed 0.00141 equivalent per cubic centimeter and for halogen 0.0000198 equivalent per cubic centimeter or 1.4 equivalent per cent.

To 65 cc. (0.092 equiv.) of this solution was added 15 g. (0.082 mole) of benzophenone dissolved in 25 cc. of dry benzene under the conditions previously given. A clear pale yellow solution resulted. This solution should require 51.5 cc. of the solution of anhydrous magnesium bromide prepared above to give an amount equivalent to the active Grignard reagent present in the di-isobutyl magnesium solution. On adding a small amount of the magnesium bromide solution, no precipitate formed, indicating that no excess dioxane was present. On adding 30 cc. of the anhydrous magnesium bromide solution, a heavy precipitate formed. The total mixture was divided into two parts and centrifuged. The clear liquids were decanted and combined and a second 10 cc. of magnesium bromide solution was added. The precipitate was centrifuged and another 10-cc. portion of magnesium bromide solution added. Only a small precipitate formed

[16] Menschutkin, *Z. anorg. Chem.*, 49,207 (1906).

this time and it was entirely different in appearance from the previous precipitates in that it was yellow and gelatinous rather than white and crystalline. A final addition of magnesium bromide solution gave no further precipitate. The various precipitates were each washed four times with 20-cc. portions of a mixture of 150 cc. of dry benzene and 100 cc. of dry ether. All washings were discarded and any gelatinous layer on top of the crystalline precipitates was removed and discarded. The precipitates were then analyzed as before. The results are given in Table II.

Table II

Analysis of Precipitates from Magnesium Bromide and the Reaction Product of Benzophenone and Di-isobutyl Magnesium

Precipitate	Benzhydrol G.	Benzhydrol equiv.	Benzhydrol M. p.	*N* HNO_3, *cc.*	Equiv. of *basic OH*	*N* $AgNO_3$, *cc.*	*Equiv.* of *halogen*
1—Part A	Lost	....	.....	15.62	0.0156	15.85	0.0158
1—Part B	3.47	0.0189	65–66.5	18.56	.0186	18.69	.0187
2	2.62	.0142	62–66.5	14.04	.0140	14.13	.0141
3	0.01	.00005	.....	1.469	.0015	3.20	.0032

The main portion of the precipitate, therefore, gives analytical results identical with the precipitate formed from the original Grignard reagent and benzophenone.

Summary

1. Solutions of di-isobutyl magnesium which are practically halogen free have been shown to reduce benzophenone to benzhydrol, as well as the original Grignard reagent containing halogen.

2. The Grignard reagent prepared from isobutyl bromide at a concentration of about 1.3 molar exists to the extent of 75% in the form of di-isobutyl magnesium.

3. When the original Grignard reagent is used to reduce benzophenone, the reduction product precipitates as a white crystalline compound which yields, on decomposition with water, one mole of benzhydrol, one equivalent of basic hydroxyl, and one equivalent of halogen. When a solution of di-isobutyl magnesium is used, the reduction product remains in solution presumably in the form $[(C_6H_5)_2CHO]_2Mg$, but which can be precipitated by the addition of a solution of anhydrous magnesium bromide to give *a* compound identical by analysis with that obtained from the original Grignard solution.

4. It is believed that the constitution of the Grignard reagent represented by the equilibrium

$$R_2Mg{\cdot}MgX_2 \rightleftharpoons R_2Mg + MgX_2$$

best fits these facts and that the ether-insoluble benzhydryl magnesium salt has the composition $[(C_6H_5)_2CHO]_2Mg{\cdot}MgBr_2$.

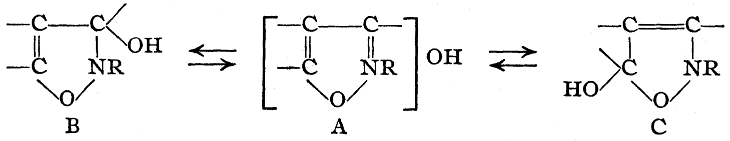
PSEUDO BASES IN THE ISOXAZOLE SERIES. FOURTH PAPER

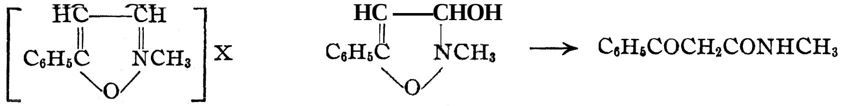
BY E. P. KOHLER AND W. F. BRUCE

RECEIVED SEPTEMBER 18, 1930 PUBLISHED FEBRUARY 9, 1931

In earlier papers of this series it has been shown that when the salts which are obtained by alkylating various isoxazoles are treated with bases they give rise to a great variety of products. All these products can be traced to two fundamental reactions which differ in the positions assumed by the hydroxyl group in the rearrangement from the true to the pseudo bases

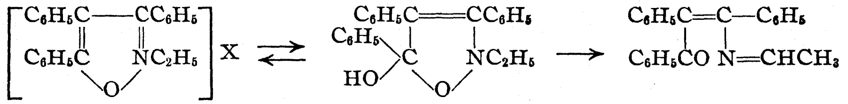


The rearrangement from **A** to B, in which the hydroxyl group ends in the 3-position, has heretofore been observed only when both the **3**- and the 4-positions were occupied by hydrogen alone, as, for example[1]



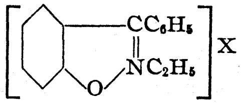
Salt *Pseudo* base *Acid amide*

In all other cases the hydroxyl group entered the 5-position and the sequence of reactions was as follows



Salt *Pseudo base* Anhydro *compound*

Before concluding our studies in this series it was desirable to investigate a case in which the **3**- and 4-positions are occupied by hydrocarbon residues but in which there is also a pronounced hindrance to the shift of linkage that is essential to a rearrangement from **A** into C. To this end we have alkylated 3-phenyl benzisoxazole and studied the behavior of the resulting salts



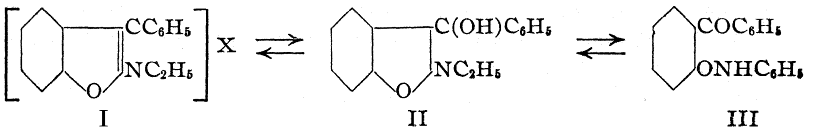
Except in their solubilities these salts differ but little from those obtained by ethylating triphenyl isoxazole. Even their behavior toward bases bears a certain superficial resemblance to that of the monocyclic salts, be-

---

[1] Mumm and Münchmeyer, *Ber.*, *43*, 3340 (1910).

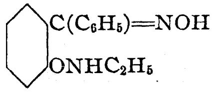
cause like these they yield, first, a pseudo base from which they can be regenerated, and finally an anhydro compound from which they cannot. Here, however, the resemblance ceases.

The pseudo base from the dicyclic salts reacts readily both with hydroxylamine and with phenyl isocyanate; it therefore behaves like an open-chained compound containing an active hydrogen atom and a carbonyl group. Such a substance manifestly can be formed only by a rearrangement of the type $A \rightarrow B$, and the relations must be represented as follows

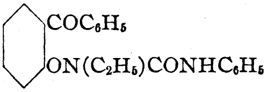


I II III

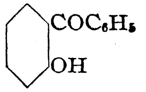
In acid solutions all transformations are toward the left, in alkaline solution they are toward the right; hence the ease with which the salts are regenerated and the inability to secure a methyl ether of II in the usual manner; hence also the ability to react with hydroxylamine and phenyl isocyanate and the readiness with which the pseudo base is oxidized to *o*-hydroxy benzophenone



IV



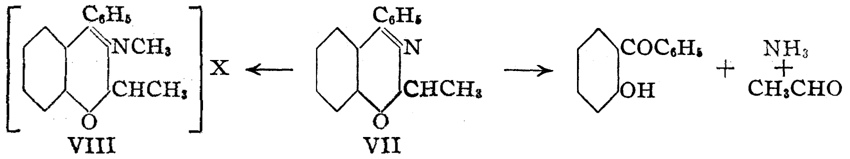
V



VI

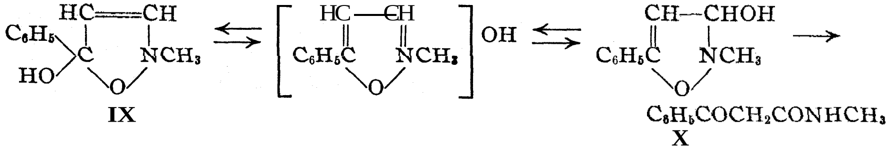
The formation of this open-chained pseudo base shows that when the hindrance to every other type of rearrangement is sufficiently great, isoxazolinium bases may rearrange to form 3-hydroxy isoxazolines even though the 3-position is occupied by a hydrocarbon residue and the lack of hydrogen in the 4-position prevents the usual adjustment to a stable acid amide. The open-chained formula, however, gives no clue to the structure of the anhydro compound. The pseudo base loses water rapidly when heated, and it even slowly passes into the anhydro compound when it is left to itself at the ordinary temperature. Despite the ease with which the process occurs, however, it must nevertheless represent a major change in structure because it cannot be reversed.

For determining the structure of the anhydro compound the following facts are available. The substance is a base, capable of forming salts that are isomeric with those derived from the pseudo base. It combines with dimethyl sulfate to form a salt in which one methyl group is in combination with nitrogen. And, finally, the anhydro compound is hydrolyzed, both by acids and by bases, to o-hydroxy benzophenone, acetaldehyde and ammonia. When these facts are assembled they lead to the metoxazine derivative VII



Doubtless there are a number of ways in which the metoxazine derivative might be formed from.the pseudo base, but whatever the route, its formation demonstrates anew the instability of all pseudo bases in the isoxazole series. In view of this great instability, it seems doubtful whether these bases can serve the main purpose of this series of investigations, namely, to ascertain the factors which determine the mode of addition of an ion to the unsaturated nucleus.

As a result of the investigations, it is now possible to predict the outcome of a reaction between a base and any isoxazolinium salt which has no substituents other than hydrocarbon residues; but in nearly all cases, there is a measure of uncertainty about the structure of the intermediate pseudo bases. In most cases the structure, of necessity, is inferred from the nature of the products into which the pseudo bases pass by spontaneous rearrangement or degradation. Since the base and the pseudo base are connected by a reversible process, inferences drawn from subsequent products are not necessarily reliable, and the fact that the final products always represent the most stable substances that could be formed leads to a suspicion that the outcome of these reactions may depend more upon the stability of the final products than upon the mode of addition. Thus the pseudo base obtained from the alkylation product of 5-phenyl isoxazole might have the structure represented by formula IX even though the final product can be reconciled only with X.



Experimental Part

Phenyl benzisoxazole was prepared as usual by converting *o*-chlorobenzophenone into its oxime and heating the oxime with bases, but it was found advantageous to combine the two steps into a single operation. The procedure was as follows.

A solution of 290 g. of hydroxylamine hydrochloride in 100 cc. of warm water was poured into a mixture of 350 g. of o-chlorobenzophenone and 300 cc. of alcohol contained in a two-liter flask. The flask was then connected with an inverted condenser and through the condenser a solution of 280 g. of sodium hydroxide in 300 cc. of water was added as rapidly as the refluxing permitted. The flask was heated for seven hours on a steam-bath and then most of the alcohol was removed by distillation. To the residue in the **flask was** added a solution of 220 g. of potassium hydroxide in 500 cc. of water.

The mixture was heated on a steam-bath for three days, then cooled to about 6° and shaken vigorously. It deposited a pale yellow solid which was thoroughly washed with water and recrystallized from methyl alcohol. It gave **220** g. of phenyl benzisoxazole, pure white in color, and melting at 81–82°—a yield of 70%.

Ethylation.—The isoxazole is ethylated less readily than those which have been studied heretofore. **A** mixture of **30** g. of the substance and **33** g of freshly distilled diethyl sulfate was heated in an oil-bath at 130–140°. The liquid darkened somewhat and there was a slow evolution of sulfur dioxide. After it had been heated for fifteen hours the mixture was cooled, treated with **50** cc. of **6** N hydrochloric acid and heated on a steam-bath for two hours. On cooling it deposited. **5** g. of unchanged isoxazole and a little more was obtained when the solution was thoroughly extracted with ether.

For the purpose of preparing the ferric chloride double salt the sirupy aqueous solution was treated with concentrated ferric chloride solution in excess. After two hours the light yellow precipitate was collected on a filter, washed with dilute hydrochloric acid and with ether, then recrystallized from **60–70** cc. of glacial acetic acid. The yield was 47 g. or 87%.

Anal. Calcd. for $C_{15}H_{14}ONCl_4Fe$: C, **42.7;** H, **3.4.** Found: C, **42.7;** H, **3.3.**

The ferric chloride double salt is readily soluble in water, very sparingly soluble in ether, ethyl bromide and cold acetic acid. It crystallizes in pale yellow platelets and melts at 134°.

Other Salts.—For the purpose of comparison with the isomeric salts derived from the metoxazine a few other salts were prepared. These were obtained most easily by forming the pseudo base from the ferric chloride salt and then converting the pseudo base into the new salt.

The Chloride.—An ethereal solution containing about **1** g. of the pseudo base was saturated with dry hydrogen chloride, whereupon it gradually separated into two clear liquid layers. The top layer was decanted, the bottom layer washed, by decantation, with dry ether, then placed in a vacuum over solid potassium hydroxide. It slowly solidified, first to a glassy, finally to an opaque solid. This was dissolved in chloroform. The chloroform solution, when cooled in a freezing mixture deposited colorless needles melting at **95–97°.** The chloride is difficult to handle because it is very hygroscopic. With ferric chloride solution it forms the double chloride melting at 134°

Anal. Calcd. for $C_{15}H_{14}ONCl$: Cl, **13.6.** Found: Cl, **13.3.**

The Mercuric Chloride Salt.—This salt was made both by adding excess of saturated mercuric solution directly to the ethylation product and by adding a similar solution to the pseudo base dissolved in hydrochloric acid. It is more soluble than the ferric chloride double salt. From glacial acetic acid it crystallizes in white fluffy needles melting at **119–120°.**

Anal. Calcd. for $C_{15}H_{14}ONCl_3Hg$: Hg, **37.8.** Found: Hg, **37.8.**

With picric acid ethereal solutions of the pseudo base yielded a picrate crystallizing in yellow needles which melt at **132–133°**, and with 60% perchloric acid similar solutions formed a perchlorate melting at 183–184°.

Anal. Calcd. for $C_{21}H_{16}O_8N_4$: C. **55.8;** H, **3.6.** Found: C, **55.6;** H, **3.6.**

The Pseudo Base (III).—The pseudo base was first obtained by the usual procedure of shaking the ferric chloride double salt with sodium hydroxide in the presence of ether but it is more easily prepared directly from the ethylation mixture. For this purpose the mixture is as usual digested with hydrochloric acid and thoroughly extracted with ether. Fresh ether is then stratified on top of the sirupy liquid, the mixture is cooled with ice and sodium hydroxide solution is slowly added in excess with constant shaking. The alkaline layer is drawn off and again extracted with ether.

The ethereal extracts are combined, washed with water, dried over sodium sulfate and evaporated by suction. It leaves a pale yellow oil. This oil is dissolved in low-boiling petroleum ether and the solution is cooled to 0°. The pseudo base has a tendency to separate as oil but vigorous rubbing of the walls of the vessel with a glass rod usually induces the formation of a granular precipitate. This is recrystallized by solution in benzene and addition of petroleum ether.

Anal. Calcd. for $C_{15}H_{15}O_2N$: C, 74.6; H, 6.3. Found: C, 74.8; H, 6.3.

The pseudo base crystallizes in small prisms and melts at 79–80°. It is soluble in the usual organic solvents except petroleum ether. All operations with it must be carried out at low temperatures and as rapidly as possible because in solution it soon changes into the anhydro compound. The solid base likewise changes into the anhydro compound. At the ordinary temperature the process is relatively slow but in the course of a month all preparations turn from colorless solids to yellow oils interspersed with small droplets of water. At $-10°$, however, a sample which had been kept for a year had changed but slightly; it was pale yellow in color and its melting point had dropped two degrees.

Attempts to Prepare a Methyl Ether.—Since the ability to form methyl ethers in basic media is one of the most characteristic properties of pseudo bases of all sorts, we made many attempts to prepare such an ether. To this end we treated the ferric chloride double salt with methyl alcoholic sodium hydroxide, the chloride with sodium methylate and the pseudo base with various concentrations of alkali in methyl alcohol. All methods gave only pseudo base or, in case the experiments were too prolonged, the anhydro compound.

The Oxime (IV).—To a solution of 1.5 g. of the pseudo base in 10 cc. of methyl alcohol was added 1.5 g. of hydroxylamine hydrochloride and then 4 cc. of a 40% solution of potassium hydroxide. The mixture was left to itself for an hour, then poured into 80 cc. of water. The solid precipitate was washed with water, dried and recrystallized from benzene. It separated in long felted needles and melted with decomposition at 135.6°.

Anal. Calcd. for $C_{15}H_{16}O_2N_2$: C, 70.3; H, 6.3. Found: 70.4; H, 6.3.

The oxime is readily soluble in acetone, methyl alcohol and acetic acid, slightly soluble in benzene and in chloroform. To prove that it is really an oxime of the pseudo base, it was treated with dilute hydrochloric acid. It dissolved at once and when ferric chloride was added to the solution it precipitated the double salt melting at 133–134°.

The Urea Derivative (V).—To a solution of 2.4 g. of the pseudo base in 7 cc. of benzene was added 1.4 g. of phenyl isocyanate. The temperature of the solution rose rapidly to 55–60°. On cooling, the solution slowly deposited a crystalline solid. After three days the solid was recrystallized from methyl alcohol. It separated as a granular deposit which melted at 128°.

Anal. Calcd. for $C_{22}H_{20}O_3N_2$: C, 73.3; H, 5.6. Found: 73.6; H, 5.7.

The Oxime of the Urea Derivative,  $C_6H_4\left\langle\begin{array}{l}C(=NOH)C_6H_5\\ON(C_2H_5)CONHC_6H_5\end{array}\right.$.—In order to distinguish between the two possible phenyl isocyanate addition products—the urethan and the urea derivative—the substance was treated with hydroxylamine. To this end 2.2 g. of the substance and an equal weight of hydroxylamine hydrochloride were dissolved in 100 cc. of hot methyl alcohol. To this solution was added gradually 6 g. of potassium hydroxide dissolved in 8 cc. of water. The light yellow mixture was immediately cooled under the tap and set aside for twenty-four hours.

A small quantity of unchanged material was removed by filtration. The solution was diluted with 300 cc. of water and filtered again to remove a small quantity of impure product. The filtrate on acidification deposited 2.0 g. of a colorless product which was dried and recrystallized from benzene. It was thus obtained as long filmy needles resembling those of the oxime of the pseudo base. The substance melted with decomposition between 145 and 150°, depending upon the method of heating.

Anal. Calcd. for $C_{22}H_{21}O_8N_3$: C, 70.4; H, 5.6. Found: 70.5; H, 5.6.

The Anhydro Compound: **2-Methyl-4-phenyl-5,6-benzometoxazine (VII).**—As has been stated, the pseudo base spontaneously loses water and passes into the metoxazine derivative. In solution the process is rapid, hence all filtrates from the pseudo base are rich in this derivative. For preparation from the pure pseudo base the substance was heated to 95° under diminished pressure. Under these conditions bubbles of water vapor began to appear at about 60° and became brisk as the temperature rose. The residue was purified either by vacuum distillation or by transforming it into its hydrochloride, which was readily purified, and then regenerated by treatment with bases.

Anal. Calcd. for $C_{15}H_{13}ON$: C, 80.7; H, 5.9. Found: C, 80.8; H, 5 9.

When perfectly pure, the metoxazine derivative crystallizes in colorless needles melting at 33–35°. It is. however, extremely difficult to obtain it in crystalline form. It is readily soluble in all organic solvents and can be crystallized only from petroleum ether at low temperatures. It distils at 175–177° under a pressure of 11 mm. The distillate is a viscous oil which partially solidifies when its solution in petroleum ether is cooled in a freezing mixture and inoculated with solid.

The Hydrochloride.—.The hydrochloride can be made by dissolving the base in concentrated hydrochloric acid, but a better yield and a purer product are obtained by operating with dry hydrogen chloride in ether. Thus when dry hydrogen chloride was passed into a solution of 2 g. of the substance in 20 cc. of ether, a pale yellow precipitate began to form immediately. The solution was saturated, set aside for an hour, then filtered. The hydrochloride was washed thoroughly with ether, then dissolved in 4 cc. of methyl alcohol at 50° and this solution was very gradually diluted with ether to 120 cc. It deposited 2.2 g. of the hydrochloride in pale yellow needles.

Anal. Calcd. for $C_{15}H_{14}ONCl$: C, 69.3; H, 5.5; Cl, 13.6. Found: C, 69.2; H, 5.6; Cl, 13.6.

When it is heated rapidly the salt melts at 104°, but it decomposes slowly even at 110°. It is soluble in water but the solution soon becomes cloudy as it deposits the anhydro compound as a yellow oil. The metoxazine derivative itself is most easily obtained in a perfectly pure condition by adding sodium hydroxide to a solution of the hydrochloride and extracting the base with ether. The first crystals of the base were obtained by evaporating such an ethereal solution, dissolving the residual oils in petroleum ether, and keeping the mixture at −13° for several days.

The Ferric Chloride Double Salt.—Ferric chloride in excess was added to a clear solution of 3 g. of the chloride in 4 cc. of concentrated hydrochloric acid. The mixture was cooled to 6° for an hour during which it deposited the double salt in large, well-formed needles, darker in color than those of the corresponding salt of the pseudo base. The salt melted at 139–140°. When it was treated with sodium hydroxide it regenerated the metoxazine derivative.

Anal. Calcd. for $C_{15}H_{14}ONCl_4Fe$: C, 42.7; H, 3.4. Found: C, 42.7; H, 3.5.

The Picrate.—An ethereal solution of the anhydro compound was added, drop by drop, to a saturated ethereal solution of picric acid. A bright yellow solid appeared after the addition of the first few drops. After washing with ether the solid melted at 128–129°.

Anal. Calcd. for $C_{21}H_{16}O_8N_4$: C, 55.8; H, 3.6. Found: C, 55.5; H, 3.5.

The Mercuric Chloride Double Salt.—The salt was prepared like the preceding one and was purified by crystallization from acetone. It crystallized in yellow needles and melted at 180–181°.

Anal. Calcd. for $C_{15}H_{14}ONCl_3Hg$: Hg, 37.7. Found: Hg, 37.3.

Hydrolysis of the Metoxazine Derivative.—In dilute acids the metoxazine derivative is slowly hydrolyzed. Thus when 1 g. of the substance was suspended in 25 cc of water containing one equivalent of hydrochloric acid, the color of the oil gradually became lighter and after two weeks an ethereal solution of it no longer gave a solid hydrochloride with dry hydrogen chloride. The aqueous solution, from which the oil had been removed, had a strong odor of acetaldehyde. A few drops were therefore added to a β-napthol solution and condensed according to the directions of Mulliken.[2] A precipitate formed which melted at 169°. The remainder of the aqueous solution, when evaporated to dryness, left a residue of ammonium chloride

These products—acetaldehyde and ammonium chloride—indicated that the oily hydrolysis product was probably ortho hydroxy benzophenone. The oil was therefore recovered and treated with 0.5 g. of hydroxylamine hydrochloride and 4 cc. of 40% potassium hydroxide. It turned yellow and deposited a yellow solid—a behavior which is characteristic of ortho hydroxy benzophenone.[3] The yellow color disappeared when the solution was acidified. The melting point of the crude product was 127–128". After several recrystallizations from ether it had risen to 135°, the melting point of ortho hydroxy benzophenone oxime found by Meisenheimer and Meis.[4]

Anal. Calcd. for $C_{13}H_{11}O_2N$: C, 73.2; H, 5.1. Found: C, 73.5; H, 5.2.

Cleavage with Phenylhydrazine.—Although the metoxazine derivative is very resistant to the action of aqueous alkalies it is very easily cleaved with phenylhydrazine. A mixture of 2 g. of the substance and 1.1 cc. of phenylhydrazine was heated to 130–150° for half an hour. The gas which was given off had the odor of ammonia and was identified by conversion into the picrate and into ammonium chloride. The residue in the tube was dissolved in methyl alcohol and the solid obtained in this manner was recrystallized from the same solvent. It melted at 154–155° and was identified as the phenylhydrazone of ortho hydroxy benzophenone by comparison with a sample made from the ketone obtained by acid hydrolysis. It was observed incidentally that this phenylhydrazone like a number of others is phototropic,[5] turning orange in the light and reverting to yellow in the dark.

Methylation.—Since the metoxazine derivative is an unsaturated cyclic tertiary amine, it can be methylated in the usual manner. The resulting salts are, however, extremely unstable. Even the ferric chloride double salt is rapidly hydrolyzed by water at the ordinary temperature, and the process does not stop either with the formation of the base or that of the pseudo base. It involves the metoxazine ring and proceeds until the substances are completely degraded to ortho hydroxy benzophenone, acetaldehyde and methylamine.

[5] Chalkley, *Chem. Reviews,* 6, 233 (1929).

The Ferric Chloride Double Salt.—A mixture of 5 g. of dimethyl sulfate, which had been freed from acid by thorough washing with sodium bicarbonate and then dried over sodium sulfate, and 4.7 g. of the metoxazine derivative was heated on a steam-bath for five minutes The light brown solution was diluted with 10 cc. of concentrated hydrochloric acid and left to itself for fifteen minutes, during which time the two layers disappeared. To the clear homogeneous solution very concentrated ferric chloride was added in excess A dark brown oil precipitated. After cooling the mixture to 6° for three hours the top layer was decanted, the oil washed rapidly with cold 6 *N* hydrochloric acid, and dried over solid potassium hydroxide in a vacuum desiccator. The residue was almost completely soluble in chloroform and the solution gradually deposited 8 g. of the solid salt in deep yellow hexagonal plates. The pure salt melted at 119–120°.

Anal. Calcd. for $C_{16}H_{16}ONCl_4Fe$: C, 44.1; H, 3.7. Found: C, 44.3; H, 3.8.

Hydrolysis.—When the salt is shaken with cold dilute sodium hydroxide, or even with water, the odor of acetaldehyde appears almost immediately. For the purpose of identifying all the products of hydrolysis, one gram of the salt was shaken with 15 cc. of water until the salt was completely disintegrated. After the precipitated ferric hydroxide had been dissolved by addition of a little dilute hydrochloric acid, there remained a clear aqueous solution and a pale yellow oil.

The aqueous layer was decanted into a distilling flask and distilled to two-thirds its volume. The distillate, when treated with a solution of β-naphthol in glacial acetic acid in the usual manner, gave a precipitate of ethylidene β-dinaphthyl oxide melting at 173–174°, and therefore contained acetaldehyde. The remainder of the aqueous solution was diluted with 10 cc. of water, treated with 3 cc. of 40% potassium hydroxide and cautiously heated. The distillate was collected in 6 *N* hydrochloric acid. On evaporation it left a hydrochloride which melted at 226–227° and when this was added to a 1% solution of picric acid it formed a flaky yellow picrate which melted at 208–211°. The aqueous solution therefore contained methylamine.

The pale yellow oil was dissolved in ether. The washed and dried ethereal solution contained ortho hydroxy benzophenone, which was identified by conversion into its hydrazone and oxime.

Summary

When the salts that are obtained by alkylating 3-phenyl benzisoxazole are treated with bases they yield a pseudo base which readily loses water, and passes into an anhydro compound. The anhydro compound is a metoxazine derivative.

Since the anhydro compound can be formed only from a pseudo base which has the hydroxyl group in the 3-position, its formation shows that in the rearrangement from a base to a pseudo base the hydroxyl group may enter this position when the hindrance to every other type of rearrangement is sufficiently great.

4-PARA-TOLYLTHIOSEMICARBAZIDE AND ITS REACTIONS WITH KETONES

BY R. W. BOST AND W. F. SMITH

RECEIVED SEPTEMBER 25, 1930 PUBLISHED FEBRUARY 9, 1931

In spite of the fact that many substituted semicarbazides have been studied with aldehydes and ketones, it appears that the substituted thiosemicarbazides have received little attention. In view of this, we have chosen for study a substituted thiosemicarbazide which is easy to prepare, gives a good yield, and whose raw materials are fairly cheap. It was condensed with the following ketones: acetone, methyl ethyl ketone, acetylacetone, ethyl acetoacetate, cyclohexanone, acetophenone, benzophenone, benzoylacetone, benzoin, benzil and carvone.

Experimental

Di-*p*-tolylthiourea.—A method similar to that of Sell[1] was used to prepare di-*p*-tolylthiourea. An alcoholic solution of *p*-toluidine was heated under reflux for five hours with an equivalent of carbon disulfide. The pure product melted at 177°; yield, 95%.

***p*-Tolyl Mustard Oil.**—The di-*p*-tolylthiourea was converted into p-tolyl mustard oil by heating the former with acetic anhydride under reflux for fifteen minutes. The product was poured into water, steam distilled, extracted with ether and redistilled; b. p. 237°; yield, 72%.

4-*p*-Tolylthiosemicarbazide.—The method of Guba and Ray[2] was adopted. An alcoholic solution of *p*-tolyl mustard oil, cooled in an ice-bath, was treated with 42% hydrazine hydrate. The bottle containing the mixture was stoppered and shaken for a few minutes. The product was filtered and purified from alcohol. The pearly white needles melted at 137°; yield, 90%.

4-p-Tolylthiosemicarbazide Hydrochloride.—Two grams of the semicarbazide was dissolved in 20 ml. of alcohol and 5 ml. of concentrated hydrochloric acid added. On cooling, long white needles separated; m. p. 173°; yield, 90%.

Anal. Calcd. for $C_9H_{12}N_3ClS$: HCl, 16.60. Found: HCl, 16.46.

Condensation Products

To 0.01 mole of 4-p-tolylsemicarbazide dissolved in 10 ml. of alcohol was added an equivalent of the ketone. In the case of benzophenone, benzoin, benzil and carvone, 1 ml. of glacial acetic acid was added at this point. The solution was placed under reflux and heated with a hot-plate. The time of heating of the mixture depended upon the ketone. The reaction product was cooled, filtered, dried and recrystallized from alcohol. With the exception of methyl ethyl ketone and benzoylacetone, the products on cooling formed solids; even the products from these ketones, when dried and recrystallized, gave definite solids. The condensation products are also soluble in benzene and chloroform. All are soluble in ether with the exception of those from acetylacetone, benzophenone and benzoylacetone.

[2] Guba and Ray, THIS JOURNAL, 47, 385 (1925).

Alcoholysis of Acetylacetone-4-*p*-tolylthiosemicarbazone.—Wheeler and Norton[3] have shown that acetylacetone phenylsemicarbazide yields 3.5-dimethylpyrazole and phenylurethan when refluxed with absolute alcohol. It was found that acetylacetone-4-*p*-tolylthiosemicarbazone behaves similarly when subjected to alcoholysis.

Three-tenths gram of acetylacetone-4-p-tolylthiosemicarbazone was dissolved in 10 ml. of absolute alcohol and refluxed for one hour. The alcohol was evaporated on a steam-bath, leaving a colorless oil which crystallized on cooling. The residue was extracted with 5 ml. of water. A small quantity of yellow oil was insoluble. The water solution was evaporated to 1 ml. on a steam-bath. On standing overnight, small colorless flakes of 3.5-dimethylpyrazole appeared. They melted at 105–106°. The oil insoluble in water was crystallized from petroleum ether, whereupon a small quantity of a crystalline substance melting at 69–74" was obtained. It possessed an odor similar to that of anisole. The substance was undoubtedly *p*-tolylthiourethan. No analysis could be made because of a lack of sufficient material.

TABLE I

DATA ON DERIVATIVES

No.	Ketone	Form	Solvent	M. p., °C.	Time heated, minutes	Formula	Sulfur analyses, % Calcd.	Sulfur analyses, % Found
1	Acetone	Colorless plates	Alcohol	142[4]	1	$C_{11}H_{15}N_3S$	14.48	14.65[4]
2	Methyl ethyl	Colorless plates	Alcohol	75	10	$C_{12}H_{17}N_3S$	13.52	13.68
3	Acetylacetone	Fine white needles	Alcohol	100	5	$C_{13}H_{17}ON_3S$	12.09	11.99

Conclusions

1. 4-*p*-Tolylthiosemicarbazide has been prepared in good yields.
2. It was condensed with the following ketones: acetone, methyl ethyl ketone, acetylacetone, ethyl acetoacetate, cyclohexanone, acetophenone, benzophenone, benzoylacetone, benzoin, benzil and carvone.

THE INFLUENCE OF THE HALOGENS ON THE COLOR OF AZO DYES. THE SPECTRAL ABSORPTION OF CERTAIN MONO-AZO DYESTUFFS

BY DUNCAN GRAHAM FOSTER

RECEIVED OCTOBER 28, 1930 PUBLISHED FEBRUARY 9, 1931

Introductory

Some years ago the author participated in one of a series of investigations on the relation of molecular structure to the color of azo dyes.[1] The influence of o-, *m*- and p-substitution of sulfur and oxygen was studied,[2,3,4] and the preparation of dyes containing selenium is now under way.[5]

In all of this work color comparisons were made simply by the inspection of dyed samples. Recently the method of color analysis made possible by the development of the spectrophotometer has reached a stage where it is particularly valuable for this kind of study, and we hope that eventually all of the many dyes prepared in the investigations mentioned above may be quantitatively compared by means of this instrument.

This paper reports measurements of the spectra of dyes containing another group of the periodic system, the halogen family, with the spectrophotometer, to show the effect of o-, m- and p-substitution of chlorine, bromine and iodine. We attempted also to measure their absorption in the near ultraviolet with a quartz spectrograph and a densitometer, but because of the crudity of the apparatus were not able to obtain accurate results, and so have postponed this work until better instruments shall be available.

Preparation of the Dyes.—In order to preserve continuity with the dyes already studied, we selected dyes prepared by coupling an amine containing the halogen atom with R-salt. These compounds had the structure I, in which X is the halogen atom, shown here in the *p*-position. The o-, *m*- and *p*-chloro-, bromo- and iodo-anilines used were either bought on the market (Eastman Kodak Co.) or made by reduction of the corresponding halogeno nitrobenzene. In the latter case the amine was isolated as the hydrochloride.[1]

The purity of these compounds was established by the sharpness of the melting or boiling points. Solid compounds were recrystallized and liquid ones redistilled, if necessary, to melt or boil over a range of not more than one degree, and in most cases the melting or boiling range was less than this. Further purification was effected in the double (in some cases triple) recrystallization of the dyes themselves. There is, of course, no way of estimating the presence of a para compound in its ortho analog or *vice* versa, but this purification was felt to be amply sufficient to prevent the spectrum from being affected. Meta dyes, because of the different method of preparing the intermediate, could not be contaminated with the other isomers.

The amines were diazotized and coupled with R-salt by the standard method previously employed.[2] The dye made by coupling aniline with R-salt, which is the parent substance of the whole group, was prepared for use as a control. These compounds were all twice (at least) recrystallized from hot water. Because they were sodium salts and had no melting points, there was no criterion of purity, but sodium chloride, from the salting-out of the dye, is the only impurity likely to be present and this would not interfere with the spectral absorption. For purposes of making up standard solutions, the analyses gave us the amount of pure dyestuff present, and in point of fact it later developed that water was the chief contaminant of the solid dyes.

Analysis of the Dyes.—The dyes were analyzed both as dried samples and as indeterminate solutions made from the same samples. These indeterminate solutions were then used as stock solutions to make up the final solutions examined by the spectrophotometer. The method used was that of titration with titanous chloride, which is both rapid and accurate.[6]

Quantities sufficient to make 1 liter of $M/50$ solution were weighed roughly, dissolved in hot water and made up to 1 liter in a volumetric flask; 25-ml. titers were measured with a Bureau of Standards pipet and an excess of standard titanous chloride solution added from a buret. The excess was then determined with standard ferric ammonium sulfate solution, using ammonium thiocyanate as an indicator. This gave the amount of dyestuff in the solution and enabled us to calculate the volume that must be taken to make an exactly 5×10^{-5} molar solution, when diluted to one liter.

All the data thus obtained are given in Table I, in which the figures are the average of three determinations in each case.

The low percentages of dyestuff in each dry sample were due to the fact that the dyes are highly hygroscopic and took up moisture perceptibly

TABLE I

ANALYTICAL DATA

Dye	Wt. of dye for 1 liter of 5×10^{-5} *M* soln.	Dry dye found, %	Stock solution for 1 liter of 5×10^{-5} soln., ml.
Aniline	0.0229	87.20	23.20
o-Chloro	.0243	87.37	25.51
m-Chloro		90.80	23.15
p-Chloro		80.20	26.88
o-Bromo	.0266	92.40	20.78
m-Bromo		85.24	24.30
p-Bromo		90.28	26.92
o-Iodo	.0289	90.80	21.87
m-Iodo		97.10	22.52
p-Iodo		86.57	30.36

while being weighed. The m-iodo dye, for example, after drying for one hour at 85° and cooling in a desiccator, gained 4 mg. while weighing. The same sample, dried for one hour at 100°, cooled in a desiccator and rapidly weighed gave 97.10% of dye, the highest percentage obtained. All the others were exposed to the air for twenty-four hours to insure that their aqueous tension had reached that of the atmosphere. These samples were not used in making up our solutions for examination, so that the high moisture content has no effect on the final concentration.

Preparation of the Solutions.—Preliminary trials showed that a concentration of 5×10^{-5} molar was the most satisfactory to use in the spectroscopic examination. These solutions were made by measuring from a Bureau of Standards buret exactly (to 0.02 ml.) the quantity of the stock solutions described above required by the analysis to give this concentration when diluted to one liter. These quantities were diluted, with careful adjustment for temperature, in a Bureau of Standards volumetric flask, first adding from a pipet 10 ml. of a buffer solution of sodium acetate and acetic acid. This buffer was kept in stock in such concentration that 10 ml. would give a solution 0.01 N in both sodium acetate and acetic acid in the final volume of 1 liter. These solutions were freshly prepared within three to four hours before using.

That this method of analysis and preparation of solutions was of satisfactory accuracy was checked by repeating the spectral measurements in two cases with solutions made up freshly from dry dyestuff, analyzed separately and diluted to give the necessary concentration. These "repeat experiments" gave spectral absorption curves coincident with the originals, within the limitations of the instrument (see below).

Determination of the Spectral Absorption.—For the color analysis a Keuffel and Esser Color Analyzer was used,[7] modified for use only with

---

[7] This instrument and its accessories were put at the author's disposal through the kindness of the Technical Laboratory of the E. I. du Pont de Nemours Company, which the author hereby gratefully acknowledges.

solutions and reading directly the negative logarithm of the transmittancy. The cells were a special open-topped type made wholly of optical glass and were especially easily cleaned and filled. They offered a solution thickness of 10 mm. They were filled with a broad-tipped pipet and both pipet and cell were washed three times with solution before filling. Readings were taken at intervals of 10 millimicrons, first setting the wave length scale at the desired figure. Three readings agreeing within the limit of accuracy were made for each setting. This limit varies with the wave length and runs from about 0.002 of a unit at 700 millimicrons to about 0.1 of a unit at 450 millimicrons, the range over which determinations were made. Whenever it seemed necessary, particularly at the peaks and shoulders of the absorption bands, readings were taken at intervals of 5 millimicrons.

To check the accuracy and guard against personal error, a standard glass No. G. **586-A** was measured and checked after measurement against figures published by the Bureau of Standards. The measurements were found to agree with the Bureau of Standards figures within the above limits. The instrument itself was also checked for adjustment at maximum and minimum transmittancy before each half-day's work.

Calculation of Results and Plotting of Graphs.—The values determined and plotted are the negative logarithms of the transmittancy of the dye solution at given wave lengths. The *transmittancy* is defined as the ratio of the *transmittance* of the solution to that of the solvent, or $T_{\text{sol.}}/T_{\text{sov.}} = \mathbf{T}$.[8] The negative logarithm of this value represents as nearly as possible the way the color appears to the eye. In this paper these values are plotted from the top downward as abscissas, against the wave length as ordinates.

Discussion of Results

Examples of the spectral absorption curves obtained are given in the figures. Because no striking differences were observed, we are publishing one set of curves only and one "analyzed" curve, in order to economize space. In Fig. 1 the isomeric *o*-, *m*- and *p*-chloro derivatives are plotted together to show the difference between them. The color of all the dyes was red, with the chief absorption band in the violet portion of the spectrum, at almost the same wave length in every case. When dyed to 2% dyeings on wool flock they showed differences in shade easily visible to the naked eye, in the same directions but of a lesser magnitude than had been shown by the corresponding dyes containing sulfur.

It was obvious from the graphs that the color difference is a complex phenomenon, not due to a simple change in the magnitude or position of the chief absorption band. Thus a color that appears deeper red to the

---

[8] *For detailed definitions see Brode, Bureau of Standards Journal of Research,* 2, *502* (1929).

eye than another may have a lesser absorption in the red portion of the spectrum or a deeper absorption in the violet, or both. It may also have quite different characteristics in the yellow or green or even a uniform difference throughout the entire range preceding the chief absorption band. This last effect is shown most strikingly by the three bromo dyes, which exhibit absorption curves parallel but of slightly different depth throughout the whole of this range.

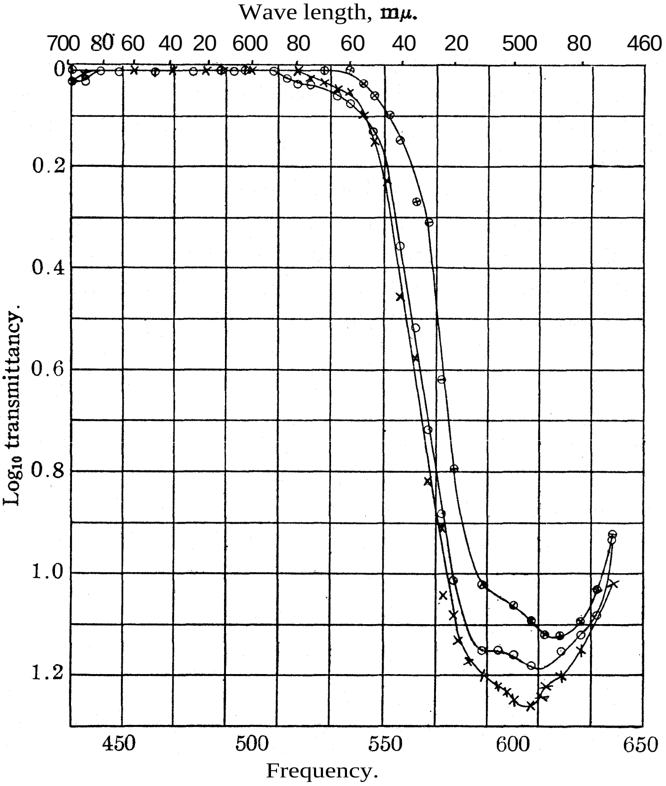

Fig. 1.—Chlorine dyes: O, ortho; ⊕, meta; ×, Para.

There is no uniformity even in the influences of position isomerism, for the depth of the absorption band for the chloro and bromo dyes increases in the order meta, ortho, para; while with the iodo dyes this sequence is ortho, meta, para. From the data obtained it is extremely difficult to make any generalizations.

The irregularities appearing near the peaks of the absorption bands appear as well in all the other dyes not shown in the figures. The iodine dyes, in fact, show two of them, one on either side of the peak of the band. We do not believe that these are accidental, since repetitions of the measurements in two instances, made two days apart with fresh solutions, gave the same results.

Rrode has observed the same effect with other dyes and has suggested that it is due to the presence of two or more component bands partly superimposed upon each other.[9] According to him these component bands are

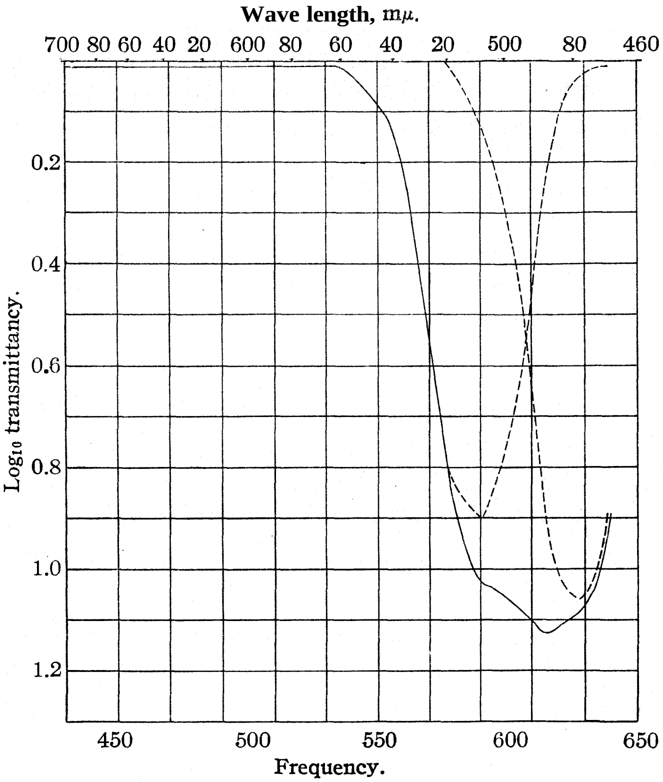

Fig. 2.—Analysis of the spectral curve of the *m*-chloro dye into its components. The solid curve is the experimental curve, the dotted curves the components, so drawn that the sum of the abscissas of the component curves at any point equals the abscissa of the experimental curve at the same point.

caused by two or more color-absorbing constituents of the dye molecule in equilibrium with each other, and the absorption curves can be analyzed to show their position and shape. Such an analysis for the *m*-chloro dye is shown in Fig. 2.

In general, the shift in the magnitude of the chief absorption bands due to position isomerism is in accord with the observations to be found in the literature. *p*-Substitution brings about a marked increase in depth, *o*-

---

[9] Reference 8 above, p. 520.

substitution a decrease and m-substitution a less marked decrease. The only exception to these rules are our m-chloro and m-bromo dyes, which show a greater decrease than the corresponding o-compounds.

Summary

1. A series of dyes containing the three halogens in the o-, *m*- and **p**-positions have been prepared, their spectral absorptions in water solution determined and compared with that of a parent dye containing no halogen.

2. The results show no simple relationship between the dyes attributable to variations in molecular weight but a complicated effect distributed in different portions of the spectrum.

3. The effect of position isomerism is for the most part the same as that observed by other workers.

4. The chief absorption bands appear to be composed of two or more constituent bands. These have in one instance been calculated.

RESEARCHES ON THIAZOLES. XVI. THE SYNTHESIS AND STUDY OF NEW AMINOTOLUTHIAZOLES AND DERIVATIVES FROM 2,5-DIAMINOTOLUENE-4-THIOSULFURIC ACID

BY MARSTON TAYLOR BOGERT AND MANASSEH G. SEVAG

RECEIVED NOVEMBER 6, 1930 PUBLISHED FEBRUARY 9, 1931

Following up the work already reported[1] from these laboratories on benzothiazole dyes, incidental and related compounds, it seemed to us desirable to ascertain the tinctorial properties of such dyes when they carried also free amino groups in the molecule, and the present paper is a contribution to the solution of the problem, in that it describes a method by which the necessary intermediates may be synthesized and records some preliminary experiments in the preparation therefrom of dyes of the Columbia Yellow (Colour Index No. 814) class.

The initial material was the 2,5-diaminotoluene, which was converted into a monothiosulfuricacid by the method of Bernthsen.[2] Theoretically, such a derivative might possess any one of the structures I, II or III, all of which are capable of yielding benzothiazoles. Thus, if condensed with *o*-nitrobenzaldehyde, they should give the thiazoles IV, V and VI, respectively, elimination of whose amino groups should result in the production of VII, VIII and IX.

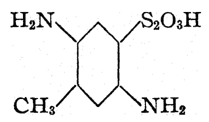
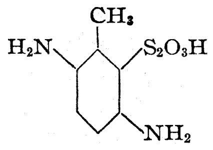
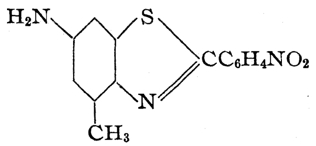
I



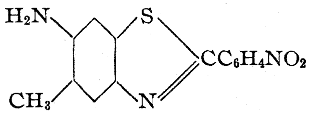
II



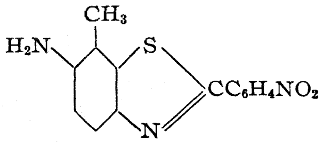
III



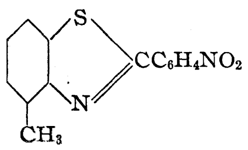
IV



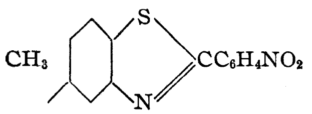
V



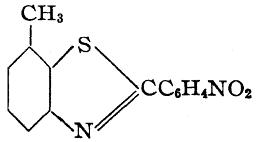
VI



VII



VIII
(M. p. 91–92°)



IX
(M. p. 108.5°)

Of the last three compounds, VII has not yet appeared in the literature, but VIII and IX have been described by Bogert and Allen.[3]

When this series of reactions was carried out with our 2,5-diaminotoluene thiosulfuric acid, the nitrotoluthiazole obtained as the final product proved to be identical with VIII. Hence the —SSO_3H group in the initial acid must have been in Position 4, *i. e.*, the acid must have had structure II.

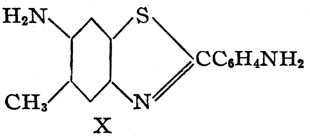
Potentiometric titrations were carried out with the acid and the results plotted graphically. From these results, the ionization constant of the acid was calculated as 5.56×10^{-6} at 25°.

Condensation of the thiosulfuric acid with *o*-, m- and *p*-nitrobenzaldehydes, or with 2,4-dinitrobenzaldehyde, led to the formation of the expected toluthiazoles, except in the case of the *p*-nitro compound where two moles of the aldehyde participated in the reaction, resulting in the production of a p-nitrobenzalamino, instead of a simple amino group, in Position 6 of the benzothiazole nucleus.

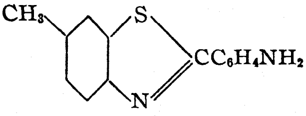
This p-nitrobenzalamino group was remarkably resistant to hydrolyzing agents, and this stability was associated in some manner with the presence of the nitro groups, for when the compound was treated with tin and hydrochloric acid, the nitro group on the 2-phenyl nucleus was reduced and the p-nitrobenzalamino at 6 simultaneously hydrolyzed to the 6-amino, giving the 2-(*p*-aminophenyl)-5-methyl-6-aminobenzothiazole.

[3] Bogert and Allen, THIS JOURNAL, 49, 1320 (1927).

The other 2-aminophenyltoluthiazoles were secured by reduction of the corresponding 2-nitrophenyl derivatives, save the m-amino compound, which could not be isolated in sufficient purity for analysis. These products are analogous to the well-known dehydrothio-*p*-toluidine, and the intention is to use them in similar ways as dye intermediates:



X



XI

The 2-(*p*-aminophenyl) derivative (X), for example, differs from dehydrothio-*p*-toluidine (XI) only in the location of its methyl group, a difference which we have shown in a previous communication'' to be without any great effect upon the shade, and in the presence of an additional amino group upon the benzothiazole portion of the molecule.

Preliminary experiments have shown that the 2-(*o*- and *p*-aminophenyl) derivatives can be converted into direct cotton dyes of the Columbia Yellow class, in which the amino group in Position 6 remains intact: and that these amino Columbia Yellow dyes, when diazotized and coupled, yield azo dyes which are also substantive for cotton.

Experimental Part

2,5-Diaminotoluene-4-thiosulfuric Acid, $CH_3(1)(NH_2)_2(2,5)C_6H_2SSO_3H\text{-}(4)$.—The 2,5-diaminotoluene which served as initial material for this research was generously supplied by the Fales Chemical Co. of Cornwall, N. Y., and was an exceptionally high-grade product which, when freshly distilled, formed colorless needles, m. p. 64°, b. p. 273" It was preserved in the form of its hydrochloride and used as such in the experiments.

For its conversion into the thiosulfuric acid, the method used by Bernthsen[2] for the preparation of *p*-phenylenediamine thiosulfuric acid was utilized, with one or two modifications. The best results were obtained when the materials were used in the proportion of seven moles of the diamine hydrochloride, seven moles of sodium thiosulfate ($Na_2S_2O_3{\cdot}5H_2O$), one mole of potassium dichromate, and 50 g. of aluminum sulfate.

To a solution of 50 g. of diaminotoluene hydrochloride in 120 cc. of water. there was added 50 g. of powdered aluminum sulfate, and then a solution of 64 g. of sodium thiosulfate ($Na_2S_2O_3{\cdot}5H_2O$) in 120 cc. of water was stirred in slowly. A copious white precipitate separated, which was probably the thiosulfate of the diamine.[4] To this mixture, a solution of 10 g. of potassium dichromate in 120 cc. of water was added gradually (during about one minute). The precipitate largely redissolved and the solution turned green at first, changing finally to a dark purplish-green.

After standing for a few minutes, it was filtered and the filtrate, after six to ten hours, separated a small quantity of a dark red amorphous solid, which was likewise filtered out. From the filtrate so obtained, the diamine thiosulfuric acid crystallized after forty-eight to seventy-two hours' standing, in dark steel-gray rhombic crystals; yield, 15%.

This product was purified by suspending the finely powdered material first in alcohol and then in ether for several hours, repeating the treatment until the decanted washings were nearly colorless. This removed the organic impurities. The product

---

[4] Wahl. *Compt.* rend., 133, 1216 (1902).

so purified was washed several times with tepid water and a solution of citric acid, to eliminate any traces of iron which might have been present in the initial diamine, since iron if present is likely to be carried down and retained by the diamine thiosulfuric acid.

The purified compound, when heated in an open crucible, decomposed without melting, swelling up and taking fire.

Anal. Calcd. for $C_7H_{10}O_3N_2S_2$: C, 35.88; H, 4.27; S, 27.40. Found: C, 35.88; H, 4.42; S, 27.64.

In carrying out the above method of preparation, it was found necessary to work with small batches only, since when quantities were used much larger than those stated, the yields were lower and the products less pure.

The location of the thiosulfuric acid group in this compound was proved, as described heyond, by condensing it with o-nitrobenzaldehyde to the 2-(*o*-nitrophenyl)-aminotoluthiazole, removal of whose amino group yielded the 2-(*o*-nitrophenyl)-5-methylbenzothiazole, from which it follows that the —SSO_3H group must have been in Position 4.

Potentiometric Titration of 2,5-Diaminotoluene-4-thiosulfuric Acid.—In a 100-cc. volumetric flask containing 100 cc. of distilled water there was suspended 0.1 g. of the thiosulfuric acid and this was brought into solution by shaking. This solution was transferred to a pyrex hydrogen gas electrode vessel, the flask being rinsed out with 25 cc. of water and this rinsing added to the main solution. The cell was connected to the saturated calomel electrode by a glass-stoppered salt bridge filled with saturated potassium chloride solution. The titration was conducted at 25° in a gas-tight apparatus, using a Type K potentiometer, in an atmosphere of hydrogen which had been purified by passing over heated copper oxide. The calomel and hydrogen electrodes were standardized by determining potentiometrically the P_H of a 0.104 *N* hydrochloric acid solution. Calculated P_H for 0.104 *N* HCl, 1.01; found, 0.99.

The titrations were carried out by means of a 0.0202 *N* sodium hydroxide solution, the stoichionietrical point for which was 21.3 cc. For reasons explained in what follows, a reverse titration also was conducted using 0.0202 N hydrochloric acid. The results of these titrations are presented graphically in the curves shown.

In the course of titration it was noticed that, after reaching a certain stage in the experiment, the potential began to drop to a final equilibrium much lower than the initial one. This phenomenon occurred only within the range of P_H 7.66 (0.6988 volt) to P_H 9.58 (0.8124 volt). These figures represent the initial readings. Final equilibrium corresponding to P_H 7.66, after seventy-five minutes, was 7.51 (or 0.6908 volt), and that corresponding to P_H 9.58 after twelve hours was 9.36 (or 0.7993 volt). The drop of potential took place at every point within this range after the addition of sodium hydroxide, and was a minimum at either of these two points, and maximum at P_H 8.71 (or 0.7612 volt). The final equilibrium corresponding to P_H 8.71 was P_H 7.97 (or 0.7177 volt), after thirty hours, a drop of 0.74 P_H unit (or 0.0435 volt).

The final neutralization equilibrium was easily attained at all points corresponding to measurements up to *P*H 7.66 (or 0.6988 volt), and above PH 9.58 (or 0.8124 volt).

The phenomenon within the above mentioned range may be due to one of the following causes: (1) decomposition of the diamine thiosulfuric acid with formation of sulfuric acid; (2) poisoning of the electrode by some impurity present in either the thiosulfuric acid or the sodium hydroxide (3) liberation of hydrochloric acid occluded by the electrode during the process of platinizing in chloroplatinic acid, or occlusion of the diamine thiosulfuric acid in which the electrode was immersed.

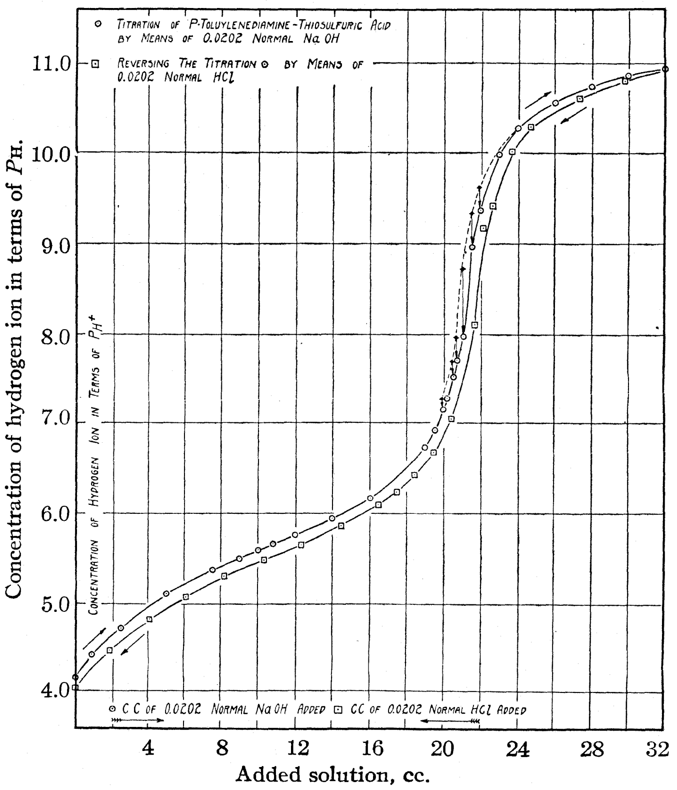


Fig. 1.

It was shown that there was no decomposition of the diamine thiosulfuric acid with formation of sulfuric acid because the final equilibrium remained constant for sixty-three hours and because practically no barium sulfate could be obtained from the solution after standing for twenty-four hours. Poisoning of the electrode was proved not to occur as shown by the smoothness of the curve, the similarity of the reverse titration curve and the constancy of the electrode after eighty hours' standing in solution.

'The third hypothesis concerning the drop in potential suggested the liberation of the hydrochloric acid occluded by the electrode during the process of platinizing in chloroplatinic acid solution, and the diamine thiosulfuric acid occluded by the electrode during the period before reaching the neutralization region. In order to determine whether the electrode contributed to the occurrence of this phenomenon, a new electrode was platinized under similar conditions and used to titrate 25 cc. of 0.1 *N* hydrochloric acid solution diluted to 125 cc. with distilled water. The steady neutralization equilibrium was obtained immediately at each point and no indication of drop of potential was observed during the entire course of titration. The curve plotted from the results was a typical hydrochloric acid titration curve. However, due to the fact that in the measurements of hydrogen electrode potentials in inorganic solutions which are strongly acid, strongly alkaline, or well buffered, it is difficult to observe this phenomenon,[5] it was necessary to study the measurements of the hydrogen electrode potentials of an organic acid whose ionization constant approximated that of the diamine thiosulfuric acid.

According to Ostwald,[6] *Ka* for propionic acid from the conductivity measurements is 1.34 X 10^{-6}. One hundred cubic centimeters of 0.0052 normal propionic acid was titrated by means of 0.0197 normal sodium hydroxide solution. In the course of the titration it was noticed also in this case that after reaching a certain point in the titration, the potential began to drop to a final equilibrium which was much lower than the initial potential. This drift of potential occurred within the range of PH 7.85 (0.7104 volt) to 8.91 (0.7730 volt) The final reading of potential corresponded to 0.7104 at 0.6504, a drop of 0.0170 volt. Beyond this point if any drift of potential was noticed it was upward in trend. A comparison of these results with those obtained from the measurements of the hydrogen electrode potentials of the diamine thiosulfuric acid will at once show a close resemblance and point to a common cause. Beans and Hammett,[5] from their studies on the hydrogen electrode, conclude that the greatest single cause of this phenomenon is the overwhelming tendency of platinum to occlude substances of an acid nature and to give up the occluded acid slowly but continuously. Therefore, in the light of these observations, the phenomenon observed in this investigation may be attributed to the occlusion of acids.[7] The molecular weight calculated from the stoichiometrical point of the final equilibrium curve is the one that approximates

---

[6] Ostwald, Z. *physik. Chem.*, **3**, 170, 241, 369 (1889).

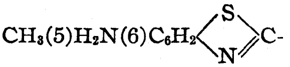
[7] From the conductivity measurements at 25°, the ionization constant for propionic acid, according to White and Jones [THIS JOURNAL, 44, 197 (1910)], is 1.4 X 10^{-5}; Franke [*Z. physik. Chem.*, **16**, 463 (1895)], 1.3 X 10^{-5}; Drucker [ibid., 52, 641 (1905)], 1.3 × 10^{-5}. The shape of the titration curve plotted from our measurements is similar to that of acetic acid with an ionization constant of 1.86 X 10^{-5}.

most satisfactorily to the true molecular weight. This relationship is suggestive of the possibility of the diamine thiosulfuric acid having been occluded by the electrode to a greater extent than the hydrochloric acid from the chloroplatinic acid solution during the process of platinizing the electrode.

Ionization Constant of **2,5-Diaminotoluene-4-thiosulfuric** Acid.—It has been found that the hydrogen-ion concentration in a weak acid 50% neutralized by a strong base is equal to that of the acid provided the salt is practically completely ionized; that is, the middle point of the titration curve of a given acid lies near the point where the hydrogen-ion concentration is numerically equal to the dissociation constant.

In the titration of the diamine thiosulfuric acid, the middle portion of the titration curve corresponds to 10.65 cc. of the sodium hydroxide, or P_H 5.64, or $C_H = 5.56 \times 10^{-6}$. Hence $Ka = 5.56 \times 10^{-6}$.

2-(*o*-Nitrophenyl)-5-methyl-6-aminobenzothiazole,



$CH_3(5)H_2N(6)C_6H_2<^{S}_{N}>C-C_6H_4NO_2(o\text{-})$.—A mixture of 10 g. of the diaminotoluene thiosulfuric acid, 8 g. of o-nitrobenzaldehyde and 80 cc. of glacial acetic acid was refluxed gently for twenty to thirty minutes and then more strongly for an hour longer. The color of the mixture gradually turned to *a* dark red, and considerable bumping occurred due to the separation of a cream-colored precipitate, which was possibly the acetate of the desired product. The mixture was filtered hot and more of the precipitate separated from the filtrate as the latter cooled and was added to the original precipitate. Warmed on the water-bath with caustic alkali, this cream-colored substance was changed to a yellow solid. Seven grams of the former gave 5 g. of the latter, which proved to be the compound sought

The filtrate from the cream-colored precipitates was diluted carefully to incipient turbidity and concentrated at laboratory temperature by allowing a stream of dry air to impinge upon its surface. The thiazole separated gradually and nearly completely. Crystallized from 90% alcohol, it was obtained in yellowish needles, m. p. 144° (corr.); yield 36%.

Anal. Calcd. for $C_{14}H_{11}O_2N_3S$: C, 58.94; H, 3.86; S, 11.24. Found: C, 58.86; H, 3.99; S, 11.38.

The alcoholic solution of these crystals exhibited a very faint purplish-red fluorescence.

A small amount (*0.5* g.) of this thiazole was diazotized at 0° and after the diazotized mixture had stood for thirty minutes at that temperature it was filtered and the precipitate suspended in 30 cc. of concentrated formic acid and exposed for three hours to direct sunlight. This suspension was refluxed for ten minutes and the resulting solution poured into cold water. The pale yellow precipitate which separated was removed and crystallized from 60% alcohol in lustrous pale yellow needles, m. p. 91.5–92°, which is the melting point recorded by Bogert and Allen[3] for 2-(*o*-nitrophenyl)-5-methylbenzothiazole.

Anal. Calcd. for $C_{14}H_{10}O_2N_2S$: N, 10.37. Found: N, 10.59.

2-(m-Nitrophenyl)-5-methyl-6-aminobenzotoe was synthesized from the diamine thiosulfuric acid and m-nitrobenzaldehyde in much the same way as just described for the o-nitro isomer.

During the refluxing of the initial mixture, some bumping also occurred, caused by the separation of by-products. Upon the completion of the heating, the mixture was filtered hot and as the filtrate cooled most of the thiawle separated, due to its sparing solubility in cold glacial acetic acid. The filtrate from this thiazole was diluted to moderate turbidity and then heated. This caused the impurities to redissolve and by filtering the hot solution more thiazole was recovered. Too large dilution during this latter step obviously precipitated more tarry impurities than could be redissolved on heating. The crude thiazole was refluxed in a large volume of glacial acetic acid in the presence of a decolorizing charcoal, to remove tarry impurities, and then crystallized from toluene, from which it separated very slowly in orange-yellow needles, m. p. **233** 5° (corr.); yield, 58.5%. In toluene solution it showed a yellowish-red fluorescence.

Anal. Calcd. for $C_{14}H_{11}O_2N_3S$: C, 58.94; H, 3.86. Found: C, 58.76; H, 3.99

2-(*p*-Nitrophenyl)-5-methyl-6-(*p*-nitrobenzalamino)-benotazole $CH_3(5)(N=C_6H_4NO_2)(6)C_6H_2$  $C_6H_4NO_2)(6)C_6H_2\langle{}^{S}_{N}\rangle CC_6H_4NO_2(p)$.—When a mixture of 11 g. of the diamine thiosulfuric acid, 15 g. of *p*-nitrobenzaldehyde and 75 cc. of glacial acetic acid was refluxed, the reaction seemed to proceed in the same way as noted for the *o*- and m-isomers A dark red solid precipitated which, when removed and crystallized from xylene, yielded fine dark red needles, m. p. 279" (corr.), the xylene solution exhibiting a greenish-yellow fluorescence. More of this materiai was precipitated from the original acetic acid mother liquor by diluting the latter with alcohol and warming.

Anal. Calcd. for $C_{21}H_{14}O_4N_4S$: C, 60.30; H, 3.32; N, 13.4; S, 7.65. Found: C, 60.00, 60.15, 60.22; H, 3.91, 3.94, 3.68; N, 13.24; S, 7 67.

While these analytical results are reasonably satisfactory so far as C, N and S are concerned, it is not clear why the figures for hydrogen should run so high.

A determination of the molecular weight gave the figures 405.1 and **411.4;** calcd., 418.

A careful search for 2-(*p*-nitrophenyl)-5-methyl-6-aminobenzothiazole in the mother liquors from the *p*-nitrobenzal derivative resulted in the isolation, finally, through repeated fractional crystallization, of a very small amount (0.005 *g.)* of fine bright orange needles, m. p. 312–315°, whose analysis indicated that they were probably the impure amine. but the quantity remaining after the analysis was insufficient for further purification.

Anal. Calcd. for $C_{14}H_{11}O_2N_3S$: C, **58.94;** H, 3.86. Found: C, 57.72; H, 3.00.

Attempts to prepare this amine by varying the proportions of initial materials, temperature, length of heating, and other factors, gave only the *p*-nitrobenzal derivative.

This *p*-nitrobenzal derivative was surprisingly stable to hydrolysis, for it was unaltered when refluxed for several hours with either 30% sulfuric or concentrated hydro chloric acid. This stability was evidently associated with the presence of the nitro group for, as described beyond, when subjected to the action of tin and hydrochloric acid, the reduction of the nitro groups was accompanied also by hydrolysis of the *p*-nitrobenzalamino group.

A small amount (1.0 g.) of the 2-(*p*-nitrophenyl)-5-methyl-6-(*p*-nitrobenzalamino)-benzothiazole was treated with 25 cc. of cold concentrated nitric acid for one or two minutes and the mixture then diluted with water. The precipitate separated crystallized from xylene in fine reddish orange needles, which melted at 247.5° (corr.), then congealed and remained unmelted at 300°. The product was apparently an impure mononitro derivative of the *p*-nitrobenzalamino compound

Anal. Calcd. for $C_{21}H_{13}O_6N_5S$: C, 54.42; H, 2.67. Found: C, 54.24; H, 3.41.

2-(*o,p*-Dinitrophenyl)-5-methyl-6-aminobenzothiazole was prepared by refluxing for an hour and a half a mixture of the diamine thiosulfuric acid (10g.), 2,4-dinitrobenzaldehyde (15 g.) and glacial acetic acid (80 cc.) and filtering hot. The small quantity of insoluble material filtered out was composed largely of the acetate of the thiazole, from which the thiazole itself was recovered by treatment with alkali.

The main portion of the thiazole was obtained from the filtrate by concentrating it cold with the aid of a current of air, adding alcohol to the concentrate, collecting the precipitate and crystallizing it from benzene. Fine red needles resulted, m. p. 239.2' (corr.); yield, 30%. A benzene solution of the compound possessed a greenish fluorescence.

Anal. Calcd. for $C_{14}H_{10}O_4N_4S$: C, 50.90; H, 3.03 Found: C, 51.03; H, 3 12.

2-(*o*-Aminophenyl)-5-methyl-6-aminobenzothiazole.—The 2-(*o*-nitrophenyl)-5-methyl-6-aminobenzothiazole (4 g.) was dissolved in concentrated hydrochloric acid (25 cc.) and refluxed for two hours with tin (10 g.), after which the excess of tin was filtered out, the filtrate diluted with an equal volume of water, then made strongly alkaline with sodium hydroxide solution and allowed to cool. The precipitate was removed and rubbed to a paste with strong sodium hydroxide solution, to liberate the amine, which was purified by crystallization from 65% alcohol. Fine yellowish or reddish-violet needles were obtained, m. p. 251° (corr.); yield 70%; bluish-violet fluorescence in alcoholic solution.

Anal. Calcd. for $C_{14}H_{13}N_3S$: C, 65.88; H, 5.13. Pound: C, 6.5.47, 65.63; H, 5.25, 5.21.

2-(*m*-Aminophenyl)-5-methyl-6-aminobenzothiazole.—Attempts to prepare this by reduction of the 2-(m-nitrophenyl) derivative, in the same way as the o-aminophenyl isomer, were unsuccessful, for no product of satisfactory purity could be isolated.

2-(*p*-Aminophenyl)-5-methyl-6-aminobenzothiazole.—When the 2-(*p*-nitrophenyl)-5-methyl-6-(p-nitrobenzalamino)-benzothiazole was similarly reduced with tin and hydrochloric acid, and the crude amine crystallized from 50% alcohol, orange-yellow or greenish-yellow needles were obtained, m. p. 255.5° (corr.); purplish fluorescence in alcoholic solution

Anal. Calcd. for $C_{14}H_{13}N_3S$: C, 65.88; H, 5.09. Found: C, 65.98; H, 5.22.

In the course of the reaction, therefore, the *p*-nitrobenzalamino group was hydrolyzed.

Preparation of a Columbia Yellow Dye from **2-(*o*-Aminophenyl)-5-methyl-6-aminobenzothiazole.**—Some of this thiazole was sulfonated and an aqueous solution of the sodium sulfonate was oxidized with a freshly prepared sodium hypochlorite solution, to obtain a dye of Columbia Yellow (Colour Index No. 814) type. Analysis of the black amorphous product gave figures which indicated that it was probably a mixture of the di- and tetra-sulfo acids.

Anal. Calcd. for $C_{28}H_{20}N_6S_2(SO_3H)_2$: *C*, 50.45; H, 3.34. For $C_{28}H_{18}N_6S_2(SO_3H)_4$: C, 40.67; H, 2.66. Found: C, 46.02; H, 3.33.

It dyed unmordanted unbleached cotton a deep orange-tan, of approximately the same fastness as other dyes of this type. Diazotizing and coupling experiments with β-naphthol led to the conclusion that the dye still retained free amino groups and that probably only the amino groups on the 2-phenyl participated in the formation of the Columbia Yellow dye. The azo dyes so produced were likewise direct dyes for cotton.

Preparation of a Columbia Yellow Dye from **2-(*p*-Aminophenyl)-6-aminotoluthiazole.**—The thiazole (2.5 *g.)* was heated for fifteen hours at 75–85' with a mixture of 20 cc. of concentrated and 25 g. of fuming (50%) sulfuric acid. The solution was poured upon cracked ice, the precipitate collected, dissolved in ammonium hydroxide solution, the solution reprecipitated by hydrochloric acid, this solution and precipitation repeated once or twice and the product dried at 120°.

Anal. Calcd. for $C_{14}H_{12}N_3S(SO_3H)$: C, 50.14; H, 3.88; S, 19.16. For $C_{14}H_{11}N_3S(SO_3H)_2$: C, 40.48; H, 3.13; S, 23.13. Found: C, 41.10, 40.83; H, 3.82, 3.94; S, 19.16, 20.5.

The product is hence a mixture of the mono- and di-sulfonic acids.

It was dissolved in sodium carbonate solution, and mixed with a freshly prepared sodium hypochlorite solution. The solution rapidly turned dark red and, after standing for twenty-four hours, was precipitated by the addition of concentrated hydrochloric acid. The precipitate was collected, dissolved in ammonium hydroxide solution and reprecipitated with hydrochloric acid, then dissolved in water and reprecipitated with concentrated hydrochloric acid, and finally dissolved in water and the solution evaporated on the water-bath. The dye was left as a lustrous black solid.

Anal. Calcd. for $C_{28}H_{20}N_6S_2(SO_3H)_2$: C, 50.45; H, 3.34. For $C_{28}H_{18}N_6S_2(SO_3H)_4$: C, 40.67; H, 2.66. Found: C, 44.90; H, 2.63.

The product was therefore a mixture of di- and tetra-sulfo acids. Its tinctorial properties, as well as its behavior when diazotized and coupled with β-naphthol, were much the same as those stated for the dye from the 2-(*o*-aminophenyl) isomer, except that the dyeings with the latter were of lighter shade.

2-(*o,p*-Diaminophenyl)-5-methyl-6-aminobenzothiazole, secured by reduction of the dinitrophenyl compound in similar manner, crystallized from 50% alcohol in fine orange needles, m. p. 285.5°; yield, 70%; sky-blue fluorescence in alcoholic solution.

Anal. Calcd. for $C_{14}H_{14}N_4S$: C, 62.22; H, 5.18. Found: C, 62.11; H. 5.36.

An attempt to prepare a **thiosulfuric** acid of **2,4-diaminotoluene,** by the process used for the preparation of the 2,5-diaminotoluene-4-thiosulfuric acid, proved unsuccessful.

Summary

1. A method for the preparation of 2,5-diaminotoluene-4-thiosulfuric acid is described. A potentiometric titration of this acid shows its ionization constant to be 5.56×10^{-6} at 25°.

2. Condensation of this acid with nitrobenzaldehydes gives the corresponding 2-nitrophenylaminotoluthiazole, except in the case of the *p*-nitrobenzaldehyde, when the thiazole obtained carries also a *p*-nitrobenzal group on the 6-amino.

3. Certain of these nitro derivatives were reduced to the corresponding amines, and with some of the latter preliminary studies were made of their conversion into dyes of Columbia Yellow type.

[Contribution from the Chemical Laboratory of the Washington Square College of New York University]

STUDIES IN THE DIARYL ACYL HYDRAZINE SERIES. II. SALT FORMATION IN THE BENZIDINE AND SEMIDINE REARRANGEMENTS

By John J. Ritter and Frank O. Ritter

Received November 12, 1930 Published February 9, 1931

In a previous paper[1] the authors described several unsymmetrical diaryl acetyl hydrazines, with a method for determining their structures based upon reduction with phenylhydrazine. The present communication treats of additional new members of this series, the determination of their structures by oxidation with potassium dichromate in glacial acetic acid solution, and the bearing of this work upon the problem of salt formation in the benzidine and semidine rearrangements.

The oxidation of diaryl acetyl hydrazines has been investigated by Goldschmidt and Euler,[2] who reported the formation of tetrazanes by the oxidation of mono-acetylhydrazobenzene and mono-acetylhydrazo-*p*-toluene in benzene solution with lead dioxide. We have carried out the oxidation of the latter hydrazo compounds and also those described in our previous paper[1] with potassium dichromate in glacial acetic acid at ordinary temperature, and have found that tetrazanes are not formed under these conditions in any case. Two kinds of behavior on oxidation were shown by the acetylhydrazo compounds examined by us. All of the mono-acetylhydrazines previously identified by phenylhydrazine reduction[1] were oxidized with dichromate and were found to divide themselves with reference to behavior on oxidation into two series. The N-acetyl[3] derivatives were oxidized in all cases to the corresponding azo compounds, while the N′-derivatives gave brilliant, intensely colored red or violet solutions from which highly colored crystalline products were isolated.

The production of the colored oxidation products appears to depend upon the presence of the group NH—, since the oxidation of mono-acetylhydrazo-*p*-toluene was found to yield, like the N-acetyl derivatives of the unsymmetrical members studied, the corresponding azo compound. The colored oxidation product derived from mono-acetylhydrazobenzene is under investigation in this Laboratory, and its structure has been established with some certainty. The oxidation of the N-derivatives probably takes place through the steps

---

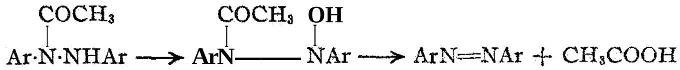
[2] Goldschmidt and Euler, *Ber.*, 55, 616 (1922).

[3] N designates the nitrogen atom attached directly to the unsubstituted benzene nucleus, N′, the nitrogen atom in direct union with the nucleus carrying a substituent group.



$$Ar\cdot\overset{COCH_3}{N}\cdot NHAr \longrightarrow Ar\overset{COCH_3}{N}—\overset{OH}{N}Ar \longrightarrow ArN{=}NAr + CH_3COOH$$

Having discovered this relationship between structure and behavior on oxidation in those cases where the structures were already determined by phenylhydrazine reduction, we were able to extend it to the determination of the structures of the compounds described in this paper, since each member studied had a *p*-substituent in one nucleus. We have in this way determined the structures of the two isomeric mono-acetyl-*p*-iodohydrazobenzenes, of the single acetyl derivative of *p*-acetoxyhydrazobenzene, which is the N-derivative, of the single mono-acetyl-*p*-carboxyhydrazobenzene, which is also the N-derivative, and of the single mono-acetylbenzenehydrazo-*p*-phenetole, which proved to be the N′-derivative.

The subjoined table summarizes the mono-acetyl hydrazines studied in this and in our previous paper, with the findings as to structure

TABLE I

Substituent group	Position	CH_3CO- attachment	Method of structure-determination	M. p. (corr.), °C.
CH_3	2	N	Red.	78
CH_3	4	N′	Ox. + red.	140–141
CH_3	4	N	Ox. + red.	124
Cl	4	N′	Ox. + red.	111–112
Cl	4	N	Ox. + red.	123–124
Br	4	N′	Ox. + red.	83
Br	4	N	Ox. + red.	117–118
I	4	N′	Ox.	156–157
I	4	N	Ox.	135–136
COOH	4	N	Ox.	207–208
$OCOCH_3$	4	N	Ox.	105–106
OC_2H_5	4	N′	Ox.	108

The symbol "Ox." signifies dichromate oxidation, and "Red.," phenylhydrazine reduction.

The formation of highly colored products on oxidation of the mono-acetylhydrazo compounds appeared, superficially, to bear a relationship to the behavior of certain hydrazo compounds on treatment with mineral acids. Jacobson and Kunz[4] reported the significant fact that *p*-acetamidohydrazobenzene in acid solution became deep blue in color. We have noticed that other hydrazo compounds behave in this manner. Hydrazobenzene, hydrazo-p-phenetole, *p*-methyl-, *p*-chloro-, *p*-bromo- and *p*-iodohydrazobenzene suspended in 10% hydrochloric acid at room temperature, and then exposed to the air for several days, yield blue or violet solutions.

[4] Jacobson and Kunz, *Ann.*, 303, 363 (1898).

The formation of these colored products is undoubtedly caused by air oxidation of the original unrearranged products, since hydrazobenzene, even after the development of color when treated in this manner, contains no detectable amount of benzidine. A solution containing the rearranged products of hydrazobenzene developed no color when similarly treated. The colors can be developed in much shorter time by the addition of hydrogen peroxide.

The oxidation of the hydrazo compounds in the presence of hydrochloric acid, furthermore, was found to be quite parallel with the oxidation of their acetyl derivatives by potassium dichromate; the hydrazo compounds which yielded N-acetyl derivatives were found to give brown solutions on air oxidation, presumably representing the formation of the corresponding azo compounds, while those which gave the N′-acetyl derivatives were readily oxidized to deep red or violet colored products. This behavior is most readily explained by assuming that the hydrazo compounds in acid solution form mono salts, which may involve the N- or N′-atom, and oxidize to new colored substances on the one hand, or to the azo compounds, on the other, depending upon the nitrogen atom involved in salt formation, in a manner analogous to the behavior of their acetyl derivatives. The formation of mono salts in the hydrazo series is in harmony with the fact that hydrazine and many of its simple derivatives function chiefly as mono-acid bases. Acylation and salt formation of amines, furthermore, appear in the present work to be quite parallel, as in the previously reported cases of phenylhydrazine[6] and methylhydrazine.[6]

It may therefore be said with some assurance that some of the unsymmetrical hydrazo compounds studied by us yield only one mono salt when treated with strong acids, while others yield two isomeric mono salts in approximately equal amounts.

Consideration of the products of rearrangement of the seventy-eight hydrazo compounds described by Jacobson[7] reveals the interesting fact that they show a marked tendency to yield exclusively semidines on the one hand, or diphenyloids on the other. There appear to be only eight outstanding exceptions to this rule, comprising a group in which each member yields both diphenyloids and semidines simultaneously, and in nearly equal amounts; among the eight exceptions occur the members each of which this research has shown to yield two isomeric acetyl derivatives in nearly equal amounts. Thus, benzenehydrazo-+-toluene, *p*-chloro-, P-bromo- and *p*-iodohydrazobenzenes each yield both diphenyloids and semidines. These facts suggest that the salts of hydrazo compounds are involved in their rearrangement, and, further, that the formation of a

---

[5] E. Fischer, Ann., **190**, 131 (1878).

[6] Von Brüning, *ibid.*, **253**, 10, 12 (1889).

[7] Jacobson, *ihid.*, **428**, 90–97 (1922).

salt of definite structure precedes the formation of a definite type of rearrangement product. Examination of Jacobson's[7] summary of the rearrangement of the various symmetrical hydrazo compounds (the structures of whose mono salts are known), supplemented by our own observations as to the structures of the salts of various unsymmetrical hydrazo compounds, discloses the following interesting relationship: when salt formation takes place on a nitrogen atom attached to an aryl nucleus in which the *p*-position is open, diphenyloids result, while semidines are formed when the salt in question involves a nitrogen atom attached to a nucleus carrying a *p*-substituent.

Considering the problem from this point of view, it seems that the type of rearranged product is determined by the structure of its mono salt. The tendency to rearrange to one type is so strong that it will often occur even with displacement of para groups already in the ring. However, the character and position of groups (other than para) undoubtedly have an influence, and determine the details within the two main types. It is in the latter sense that Jacobson's[7] rules apply.

It is planned to study other members of the group to determine whether their behavior on acetylation and on oxidation in acid solution is in harmony with the above generalizations. Table II illustrates the relationship between salt structure and type of rearrangement undergone by those hydrazo compounds the structure of whose mono salts is established by this investigation.

TABLE II

Substituent group	Position	Salt formation on	Type of rearrangement
COOH	(4)	N	Diphenyloid
$OCOCH_3$	(4)	N	Diphenyloid
CH_3	(2)	N	Diphenyloid
OC_2H_5	(4)	N'	Semidine
Cl	(4)	N + N'	Diphenyloid + semidine
Br	(4)	N + N'	Diphenyloid + semidine
I	(4)	N + N'	Diphenyloid + semidine
CH_3	(4)	N + N'	Diphenyloid + semidine

By extending this relationship to benzenehydrazo-p-toluene, *p*-chloro-, *p*-bromo and *p*-iodohydrazobenzenes, it may be concluded that diphenyloid rearrangement is preceded by formation of the N-salts, and semidine rearrangement by the formation of N'-salts.

A criticism of the hypothesis of Frantzen and Furst,[8] may also be offered. These authors suggest that the benzidine and semidine rearrangements involve the formation of mono salts which then separate into the corresponding amine and halamine

---

[8] Frantzen and Furst, *Ann.*, **412**, 19 (1917).

$$\mathrm{ArNH_2Cl{-}NHAr'} \longrightarrow \mathrm{ArNHCl + Ar'NH_2}$$

The latter are supposed to react, either as such or with intermediate rearrangement of the halamine to the o- or p-quinol form, to yield the final rearrangement products. Jacobson[9] has pointed out that this scheme does not harmonize with the "maintenance of the aryl combination" in the rearranged products, *i. e.*, the fact that the products of rearrangement always contain the original combination of aryl groups. He says that salt formation and breakdown in only one sense must be assumed in order that the aryl combination remain fixed. Our work has shown that this assumption cannot be made in those cases where the formation of two acetyl derivatives shows the ability of the compound in question to form two different salts. In those cases where only one acetyl derivative is formed, and hence only one salt, the hypothesis is on surer ground. Here only one type of amine and halamine is possible and the aryl combination is maintained.

Experimental Part

The preparation of the azo compounds, their reduction and the formation and separation of their acetyl derivatives were carried out as outlined in an earlier communication.[1] The experimental details of these operations will therefore be omitted in the present report.

Azo Compounds.—p-Iodoazobenzene, m. p. 105°, in agreement with Noelting and Werner;[10] *p*-carboxyazobenzene, made by condensation of *p*-aminoethylbenzoate with nitrosobenzene followed by saponification of the ester with alcoholic potassium hydroxide, m. p. 237–238° (corr.), in agreement with Jacobson and Steinbrenk;[11] *p*-acetoxyazobenzene, m. p. 82–83°. Wallach and Kiepenheuer[12] reported 84–85°; benzeneazo-*p*-phenetole, m. p. 77–78°, in agreement with Jacobson and W. Fischer.[13]

Hydrazo Compounds.—p-Iodohydrazobenzene, m. p. 105–106°, in agreement with Noelting and Werner;[10] *p*-carboxyhydrazobenzene, m. p. 192–193° (corr.), in agreement with Jacobson and Steinbrenk;[11] *p*-acetoxyhydrazobenzene, pearly plates from 95% alcohol, m. p. 117–118° (corr.).

Anal. Calcd. for $C_{14}H_{14}N_2O_2$: N, 11.57. Found: (micro Dumas) N, 11.14.

Acetylhydrazo Compounds.—The more important characteristics of the new acetyl compounds are listed below. N-Acetyl-p-iodohydrazobenzene, clusters of needles from 95% alcohol, m. p. 135–136° (corr.).

Anal. Calcd. for $C_{14}H_{13}N_2OI$: N, 7.95. Found: (micro Dumas) N, 7.45.

N'-Acetyl-benzenehydrazo-*p*-phenetole.—This compound was difficult to prepare from the corresponding hydrazo compound because the latter underwent self-oxidation–reduction in the presence of acetic anhydride. The acetyl derivative was obtained in good yield by reduction of benzeneazo-p-phenetole with zinc dust and glacial acetic acid in acetic anhydride solution; colorless nodules composed of fine needles, m. p. 108".

Anal . Calcd. for $C_{16}H_{18}N_2O_2$: N, 10.37. Found: (micro Dumas) N, 10.54.

N-Acetyl-*p*-acetoxyhydrazobenzene, fine colorless needles from alcohol, m. p. 105–106°.

Anal. Calcd. for $C_{16}H_{16}N_2O_3$: N, 9.86. Found: (micro Dumas) N, 9.22.

Oxidation of the Acetyl Derivatives.—The acetyl derivatives (one mole) were dissolved in glacial acetic acid to form a 10–15% solution, and then shaken for twenty-four hours on a mechanical bottle-shaker with finely ground potassium dichromate (0.66 mole). The N-derivatives yielded deep violet solutions immediately under these conditions, although the completed reaction required ten or more hours. The N-derivatives yielded brown solutions. The solutions were filtered after oxidation to remove any unused potassium dichromate, and then diluted with about five volumes of cold water. After standing overnight, the oxidation products appeared as precipitates which were separated by filtration. The brown solutions yielded in each case the corresponding azo compounds, which were identified by their melting points, and by comparison with authentic samples. The violet solutions yielded dark red crystalline solids. The product so obtained from acetylhydrazobenzene has been recrystallized from petroleum ether and then from alcohol in large plates of dark red color melting at 163° (corr.).

Oxidation of the Wydrazo Compounds.—Small quantities (0.1–0.2 g.) of the hydrazo compounds were suspended in 10% hydrochloric acid at room temperature, and allowed to stand exposed to the air for several days. Those which were found to yield N'-acetyl derivatives were found also to impart a deep violet color to the acid solutions, while those yielding N-acetyl derivatives became brown in color. Benzenehydrazo-*p*-toluene, *p*-chloro-, p-bromo- and p-iodohydrazobenzenes gave violet solutions in which the brown oxidation products were presumably formed also, although their presence could not be detected visually because of the intense violet color of the solutions. *p*-Acetoxy-and p-carboxyhydrazobenzenes, under the same conditions, gave orange-colored solutions. To make certain that the colored products resulted from the oxidation of the hydrazo compounds and not their products of rearrangement, the following experiment was performed: 0.1–0.2 g. of hydrazobenzene was boiled for five minutes with 5 cc. of concentrated hydrochloric acid. A clear solution was obtained, which was diluted with water until the acid concentration was approximately 10%. The solution was exposed to the air for several days, and remained colorless. Further work upon the isolation and identification of these colored air-oxidation products is in progress.

Summary

1. Several new diaryl acyl hydrazines have been prepared.
2. A method for their identification by means of oxidation has been described.
3. The formation of highly colored products from hydrazo compounds in contact with acids has been shown to be caused by air oxidation.
4. A relationship between the salt-forming properties of the nitrogen atoms in hydrazo compounds and their rearrangement in acid solution has been established.
5. The oxidation of hydrazo compounds in acid solution has also been

investigated and correlated with the oxidation of their acetyl derivatives. The phenomena observed have been found to have intimate bearing upon the benzidine and semidine rearrangements.

THE REDUCTION OF TRIPHENYLMETHANE DYES AND RELATED SUBSTANCES WITH THE FORMATION OF FREE RADICALS

BY JAMES B. CONANT AND NEWELL M. BIGELOW

RECEIVED NOVEMBER 15, 1930 PUBLISHED FEBRUARY 9, 1931

The work of Clark and collaborators[1] has shown that the reduction of many different dyes by soluble reducing agents is a process analogous to the reduction of quinones in that the leuco compound and the dyestuff form a mobile oxidation–reduction system. The reduction and reoxidation occur rapidly at room temperature even in dilute solution and characteristic and significant oxidation potentials may be measured. The indigoids, many anthraquinone dyes, indophenols, indamines and methylene blue are all of this type. The reduction of azo dyes and triphenylmethane dyes is of a different sort; here, the reduction product (or products) are not rapidly reoxidized and no significant oxidation–reduction potentials can be measured by the usual methods. An examination of the behavior of the azo dyes has already been made in this Laboratory;[2] the present paper deals with the unraveling of the chemical reactions involved in the action of soluble reducing agents on triphenyl methane dyes; a quantitative study of certain of these reactions will be included in a later paper.

The color bases of the triphenylmethane dyes are substituted triphenylcarbinols; the dyes themselves are salts which are related to the halochromic salts of triphenylcarbinol. The exact method of formulating the structure of the colored positive ion of the triphenylmethane dyes and that of the halochromic salts has been the subject of much discussion. We shall not attempt to take sides in this controversy; the distinction between triphenylmethyl sulfate and malachite green appears to be one of degree rather than of kind as far as our work is concerned. It was shown some years ago,[3] that the halochromic salts of triphenylcarbinol and related substances are reduced by powerful reducing agents in appropriate solutions with the formation of the corresponding free radical (*e.g.*, triphenylmethyl). The free radical and halochromic salt form a mobile oxidation–

reduction system whose potential may be measured in the usual way. A similar situation would be expected in regard to the cations of the triphenylmethane dyes except that the resulting free radical would be expected to be even more unstable in acid solution than triphenylmethyl. (The sensitivity of free radicals toward acids is well known and particularly pronounced when "positive" groups like methoxyl are present in the molecule.) These expectations have been confirmed by experiment, and we may write the following general reactions in which R^+ stands for the positive ion of the dye and M^{++} stands for a soluble reducing ion such as titanous, vanadous or chromous.

(1) $\underset{\text{cation}}{R^+} \ 4 \ M^{++} \rightleftharpoons \underset{\text{free radical}}{R—} + M^{+++}$ (fast, reversible)

(2) $2R— \rightleftharpoons \underset{\text{"ethane"}}{R—R}$ (fast, reversible or irreversible depending on nature of R)

(3) $2R— + H^+ \longrightarrow \underset{\text{"methane"}}{RH} + R^+$ (irreversible)

(4) $2R— \longrightarrow \underset{\text{(Chichibabin compounds)}}{R_2}$ (irreversiblecatalyzed by acid)

The factors influencing the composition of the equilibrium mixture in Reaction 1 have been outlined in a previous paper;[3] they include in addition to the oxidation–reduction potentials of the system R+, R and M^{++}, M^{+++}, the hydrogen-ion activity and water activity of the medium, provided the reaction $R^+ + H_2O$ $ROH + H^+$ is mobile. Since Reactions **3** and 4 are irreversible and since the product of Reaction 2 may be very insoluble in the medium employed, the overall reaction may go rapidly to completion even if a very small amount of product is formed in the first reaction.

We have established the validity of the foregoing account of the reduction of triphenylmethane dyes by isolating the products of Reactions 2, **3** and 4 in the case of malachite green (a typical dye) and *p*-dimethylaminotriphenylcarbinol. The latter may be regarded as a transition compound between the dyes and triphenylcarbinol. Titanous, vanadous and chromous salts were employed as reducing agents.

In order to isolate the associated free radical (the "ethane") it is necessary to take advantage of its relative insolubility in aqueous solutions of *P*H value of about **3**; it is also necessary to avoid the irreversible decompositions which are brought about by strong acids (Reaction **3**). *Sym.-p,p*-tetramethyldiaminohexaphenylethane (I) and *p,p,p',p'*-octamethyltetraminohexaphenylethane (II) have been isolated as brown amorphous powders by the reduction of the corresponding chlorides in acetic acid and precipitation with water in the presence of sodium acetate. Extreme pre-

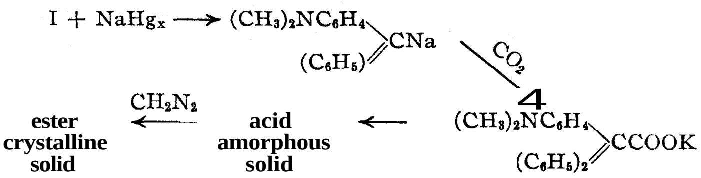
II

cautions must be taken in drying and handling the compounds. On exposure to a trace of oxygen the dry solids are decomposed with the evolution of formaldehyde. When first prepared in the moist state, the compounds are somewhat more stable. Crystallization was attempted without success and, therefore, no analyses can be reported. In spite of this the nature of the substances was established beyond question. Like all derivatives of hexaphenylethane, in solution they absorb oxygen very rapidly; as high as 89% of the amount corresponding to the formation of a peroxide was absorbed by a solution of the crude dried material. In the case of the diamino compound (I) a crystalline peroxide was isolated and analyzed. In this case also the substituted acetic acid could be obtained by the following series of reactions:



The sodium methide is unstable; on standing in ether suspension the characteristic color disappears and the corresponding methane is formed. This replacement of sodium by hydrogen may be the result either of the action of the ether (as in the case of sodium methyl) or some reaction involving one of the methyl groups on the nitrogen atom. This reaction is so rapid in the case of the ethane from malachite green (II) that only a fleeting color can be observed when an ethereal solution is shaken with sodium amalgam with the usual precautions; the solution was then found to contain the corresponding hydrogen compound (*p*, *p'*-tetramethyldiaminotriphenylmethane). Both ethanes (I and II) dissolve in neutral organic solvents with the formation of an orange solution indicating considerable dissociation into the free radicals. The significant difference in color between the solution of the free radical and the corresponding positive ion (cation of malachite green) has been discussed by Wieland, who prepared for this comparison solutions of the free radicals corresponding to a number of triphenylmethane dyes by the thermal decomposition[4] of azo compounds.

The decomposition of these dissociable ethanes by acid is easily demonstrated. For example, glacial acetic solutions of both ethanes slowly lose their oxygen-absorbing capacity. In concentrated hydrochloric acid both ethanes are at once decomposed. The nature of the decomposition product depends on the conditions; in a weakly acidic medium such as glacial acetic acid, the methane and the corresponding positive ion are formed; since the latter is, of course, further reduced (Equation 1), the prolonged action of reducing agents in acetic acid solutions yields only the substituted

---

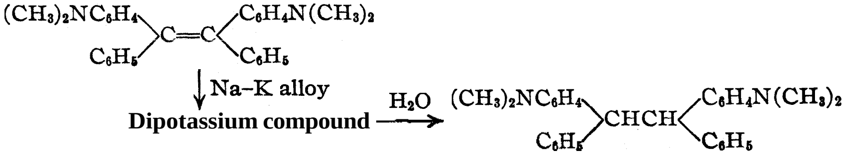
triphenylmethane, which is regarded as the leuco compound (Equations 1 and 3). The distinction between such leuco compounds and those corresponding to indigo and methylene blue is obvious; the free radical (or the corresponding ethane) should be regarded as the real leuco compound in the case of the triphenylmethane dyes. As would be expected, reducing agents such as zinc and acid reduce the ethanes to the corresponding methanes.

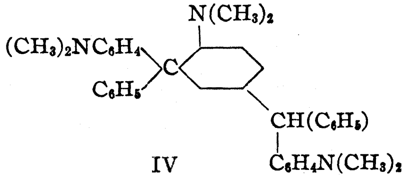
The action of concentrated hydrochloric acid on the free radicals appears to cause the irreversible formation of a dimer, isomeric with the dissociable ethane. Since this phenomenon is similar to the formation of p-benzhydryltetraphenylmethane from triphenylmethyl (a reaction first elucidated by Chichibabin), we shall designate these dimers as Chichibabin compounds. They were obtained by the use of chromous chloride in concentrated hydrochloric acid: analysis and molecular weight showed them to be isomeric with the dissociable ethanes; they are not affected by acids, oxygen or sodium–potassium alloy. Their structure has not been established, nor have they been isolated from the tarry material formed by the action of concentrated hydrochloric acid on the dissociable ethanes. Nevertheless, their mode of formation and empirical formulas show them to be dimolecular reduction products of the cations in question.

We have included in our study the mono-*p*-dimethylamino derivative of diphenyicarbinol. This substance is reduced in acetone solution containing hydrochloric acid by chromous chloride. The products are two isomeric dimers; the lower-melting and more soluble substance has been shown to be *p,p'*-tetramethyldiaminotetraphenylethane by its synthesis from the well-known ethylene by the reactions



III

The constitution of the higher-melting isomer has not been established; presumably it is a Chichibabin compound such as represented by formula IV, though it might be a diastereoisomeride of III. The formation of both isomers probably proceeds through the formation of the same free radical.



IV

In this case the normal association produces a tetraphenyl compound, and the reaction is therefore irreversible like the Chichibabin reaction.

The action of vanadous chloride or chromous chloride on the keto chloride of Michler's ketone (*p,p′*-tetramethyldiaminodiphenyl ketone) is similar to the reduction of the salts of the diphenylcarbinols. The keto chloride which is bright blue is undoubtedly a compound in which one chlorine is in the ionic condition and the cation has a structure similar to that of the triphenylmethane dyes (in regard to which there are many opinions.) On reduction one would expect to obtain the corresponding dichloroethane (V); the actual product, however, is the corresponding ethylene (VII). The steps involved in reaction appear to involve the initial formation of the dichloride V and its ionization to the corresponding salt.[5] This salt on reduction gives the ethylene, as we proved in a separate experiment

starting with the corresponding glycol. The mobility of the system VI–VII will be investigated by electrochemical methods.

Finally it may be noted that aryl-alkyl-carbinols may also undergo dimolecular reduction in acid solution with chromous chloride. Thus, *p*-dimethylaminophenylisopropylcarbinol is reduced to two isomeric dimers. Presumably one of these is *p,p′*-tetramethyldiaminodiisopropylethane and the other a Chichibabin hydrocarbon. However, their structure has not been elucidated.

Experimental

Preliminary Experiments on Reductions of *p*-Dimethylaminotriphenylcarbinol.—Six-tenths of a gram of *p*-dimethylaminotriphenylcarbinol was dissolved in the chosen solvent in a small flask directly joined to a larger one. In the larger chamber were placed 15 cc. of bromobenzene, 15 g. of crushed ice and 50 cc. of an aqueous solution containing 5.0 g. of sodium acetate and sodium hydroxide in quantity not quite equivalent to the acid in the reducing mixture. The system was swept with nitrogen, and the reducing agent was added through a stopcock in the neck of the smaller chamber. When the reduction was complete, judging from the disappearance of the halochromic color, the reduction mixture was allowed to run into the larger chamber; the apparatus was shaken vigorously until all of the bromobenzene was drawn from the bottom stopcock into a graduated test-tube filled with freshly distilled water; the organic layer displaced the water and did not come in contact with the air. It was found impossible to drain off all of the bromobenzene without including some of the aqueous layer; hence two-thirds of it was used, and the remainder allowed for in the calculation of the theoretical absorption.

Experiment showed that the "blank" absorption, as well as the errors due to deviations from the standard temperature and pressure, were within the limit of experimental error. These factors were accordingly overlooked.

The results of the preliminary reductions are tabulated:

Solvent	Time, min.	Temp., °C.	Absorption, cc.	Per cent. of absorption
15 cc. acetic acid	2	20	13.2	89
15 cc. acetic acid	10	20	11.2	75
15 cc. acetic acid	30	20	12.4	83
15 cc. acetic acid	120	20	9.3	62.5
15 cc. hydrochloric acid	2	30*	0	0
10 cc. acetone, 5 cc. hydrochloric acid	3	30*	0	0
20 cc. acetic acid, 5 cc. hydrochloric acid	3	0–5	4.2	28
20 cc. acetic acid, 5 cc. hydrochloric acid	6	0–5	4.2	28

* The heat of neutralization raised the temperature of the precipitating mixture to 30°.

Sym.-p,p-**tetramethyldiaminohexaphenylethane.**—Three grams of *p*-di-methylaminotriphenylcarbinol was dissolved in 45 cc. of glacial acetic acid in the large chamber of the reduction apparatus. The system was evacuated and filled with nitrogen; then, against a stream of nitrogen, 20 cc. of 1 N chromous chloride or vanadous chloride was pipetted into the smaller chamber. The system was stoppered and swept again with nitrogen; then the two reagents were mixed by tilting the apparatus. The deep red color of the carbinol salt disappeared in about thirty seconds, the apparatus being meanwhile shaken vigorously. Nitrogen was then forced into the system, and the mixture was allowed to flow from the bottom stopcock into a freshly boiled and chilled solution of 10 g. of sodium acetate in 800 cc. of water. On dilution, a flesh-colored amorphous precipitate of *sym.-p,p'*-tetramethyldiaminohexaphenylethane appeared. The suspension was stirred for a few seconds, and was then filtered by suction as rapidly as possible. The filter cake was washed rapidly, first with water and then dilute ammonia; it was transferred as rapidly as possible to a drying pistol. More than a few moments' exposure of the precipitate to the air caused the formation of a bright red crust of oxidized product to appear on its surface. Calcium chloride was used as the drying agent; the pistol was evacuated, filled with nitrogen and re-evacuated. About thirty-six hours were necessary to dry the precipitate thoroughly.

The dried product was a fluffy flesh-colored powder, colored bright red on its surface by a crust of oxidized material. On even momentary exposure to air it decomposed instantly to a deep red tar, evolving heat and an odor of formaldehyde. The oxygen absorption of the dried amorphous powder when dissolved in bromobenzene was 70–85% of the theoretical amount. Manipulations of the solid were in carbon dioxide. The apparent molecular weight of this material was determined in *p*-chlorotoluene (freezing point) and found to be 458–507 as compared with 572.5 for the ethane.

The attempts to crystallize the free radical were unsuccessful. The crude product was found to be readily soluble in ether and benzene. When alcohol was added to an ethereal solution of the compound, the solution became deep red in color. A red solid crystallized from this mixture; it was not the pure ethane, however, since its oxygen capacity was only half of the theoretical amount. The free radical was insoluble in petroleum ether and could be precipitated in an amorphous state when this solvent was added to an ethereal solution, but no crystalline product could be obtained. The ethane could not be crystallized from a mixture of acetone and water. When an ethereal solution of the ethane was evaporated to dryness in *vacuo,* the product was a brittle froth which filled the entire system.

Decomposition of the Ethane in Acid Solutions.—Small weighed bulb tubes with constricted necks were swept with carbon dioxide, stoppered and weighed. The stoppers were tied to the tubes to prevent mixing. The weighed tubes were transferred in an atmosphere of carbon dioxide and charged with 0.15–0.20 g. samples of the ethane. They were stoppered and reweighed. A small separatory funnel with a side tube just below the stopcock was fastened in the mouth of a bulb tube with a rubber stopper; the tube was at once evacuated and filled with nitrogen through the side tube. Five cubic centimeters of the chosen solvent was next drawn into the tube under a slightly diminished pressure. The bulb tube was sealed off at the constriction; just before the tube was closed off, the excess pressure in the bulb was relieved through the side arm of the separatory funnel. Bulbs so prepared were kept for varying lengths of time, and were then broken in the absorption apparatus. The amount of free radical left unattacked was calculated from the volume of oxygen absorbed. This method is not sufficiently accurate to warrant the assignment of quantitative significance to the results; it merely indicates the relative rates of decompositiori in acids of varying strength.

p-Dimethylaminotriphenylmethyl Peroxide.—When an ethereal solution of *sym.*-p,p'-tetramethyldiaminohexaphenylethane was exposed to the air, its color decreased momentarily, and then gradually turned to a deep red. The fine light brown crystals which appeared on the sides of the container were filtered off and washed with acetone. They were insoluble in all the ordinary low-boiling solvents, and decomposed to a red tar when heated in high-boiling solvents. The crude crystals melted with decomposition at 145–150°, dependent on the rate of heating of the melting point bath. The peroxide dissolved in concentrated hydrochloric acid; the solution, at first light red, rapidly turned deep red, at the same time developing a strong odor of phenol.

Anal. Calcd. for $C_{42}H_{40}O_2N_2$: C, 83.4; H, 6.7. Found: C, 82.2; H, 6.6.

Sodium p-Dimethylaminotriphenylmethide.—Two and one-half grams of *sym.*-p,p'-tetramethyldiaminohexaphenylethane was prepared by the usual procedure. The dry product was transferred in an atmosphere of carbon dioxide to a 100-cc. flask which was then closed with a rubber stopper bearing a straight glass stopcock. The container was swept with nitrogen; then 40 cc. of anhydrous ether and 15 cc. of 1% sodium amalgam was introduced through the stopcock. The flask was shaken by hand. After about one minute the color of the solution faded momentarily; then the bright orange-red color of the sodium salt appeared, and grew rapidly in intensity. The solution was shaken on a machine for four hours, at the end of which time the concentration of the sodium salt had reached its maximum. The solution was now deep orange-red; little or none of the solid methide could be seen in the mixture. If the shaking was continued overnight, the color of the solution disappeared. The resulting colorless ethereal solution, filtered from the amalgam and evaporated, yielded two crystalline products; these were separated by crystallization from a concentrated ethereal solution. The product which remained in solution was identified by a mixed melting point as *p*-dimethylaminotriphenylmethane. The product crystallizing from ethereal solution was a white solid melting at 138°; it was not identified

***p*-Dimethylaminotriphenylacetic** Acid.--Carbon dioxide was admitted to the flask containing the methide; decomposition took place rapidly. The ethereal layer was decanted from the amalgam, and the latter was washed several times with ether The combined ethereal layers were extracted several times with dilute sodium hydroxide, the combined aqueous layers were extracted once with ether. The aqueous solution of the sodium salt was boiled for a few minutes to expel the ether; it was then cooled and made exactly neutral with dilute hydrochloric acid, methyl orange being used as the indicator. A thick amorphous precipitate of p-dimethylaminotriphenylacetic acid separated. The precipitate was filtered, washed and dried *in vacuo* over calcium chloride. The crude product weighed 0.64 g., 29% of the theoretical amount. All attempts to crystallize *this* acid were unsuccessful.

Combining Weight with Sodium Hydroxide.—0.1850 g. of the acid neutralized 4.92 cc. of 0.1013 N sodium hydroxide; 0.2004 g. neutralized 5.30 cc. of 0.11113 N sodium hydroxide. Mol. wt. calcd. for $C_{22}H_{21}O_2N$: 331. Found: 371,373

Methyl ***p*-Dimethylaminotriphenylacetate.**—A solution of about 0.18 g. of diazomethane in 25 cc. of anhydrous ether was prepared. To this was added a solution of 0.46 g. of p-dimethylaminotriphenylacetic acid in 15 cc. of absolute methyl alcohol. The solution was allowed to stand for forty-five minutes; then 15 cc. of weakly acidulated water was added to destroy the excess diazomethane. The layers were washed with water, dried with sodium sulfate and concentrated to a volume of 4–5 cc. on a steam-bath. The addition of petroleum ether precipitated the ester in crystalline form. The yield was 0.31 g.; the product, after a second crystallization from the same solvents, melted at 141°.

Anal. Calcd. for $C_{23}H_{23}O_2N$: C, 80.0; H, 6.7. Found: C, 79.9, 80.0; H, 6.7, 7.0.

Molecular Weight, Micro Method.—Sample, 0.0134; camphor, 0.1219; average depression, 13 2. Calcd. for $C_{23}H_{23}O_2N$: 345. Found: 330.

“Chichibabin Product” from **Dimethylaminotriphenylcarbinol.**—A solution of 4.5 g. of p-dimethylaminotriphenylcarbinol in 90 cc. of acetone and 45 cc. of concentrated hydrochloric acid was treated in the absence of air with 25 cc. of 1 N chromous chloride. The solution was allowed to stand at room temperature for twenty-four hours; it was then poured into twice its volume of water and almost neutralized with sodium hydroxide. The mixture, still warm from the neutralization, was extracted several times with benzene. The united benzene layers were washed with water, dried with sodium sulfate and diluted with *n*-butyl alcohol. The benzene was driven off on a steam-bath. Two and six-tenths grams of the crude product separated after a few days' standing. The product, after two more crystallizations from the same solvent, weighed 1.5 g. and melted at 165°. This product dissolved in hydrochloric acid without coloration.

Anal. Calcd. for $C_{42}H_{40}N_2$: C, 88.1; H, 7.0. Found: C, 88.1; H, 6.8.

Molecular Weight, Micro **Method.**—Sample, 0.0132; camphor, 0.1109; average depression, 9 1°. Calcd. for $C_{42}H_{40}N_2$: 672 5. Found: 525.

The Long-Period Reduction of ***p*-Dimethylaminotriphenylcarbinol** with **Chromous** Chloride and **Titanous** Chloride.—Ten cubic centimeters of 1 N chromous chloride was added to a solution of 1.5 g. of p-dimethylaminotriphenylcarbinol in 30 cc. of acetic acid. The solution was allowed to stand for ninety-six hours and was then poured into 400 cc. of 10% sodium acetate solution. A white amorphous precipitate separated. The mixture was extracted with chloroform; the united chloroform layers were dried over sodium sulfate and concentrated. The solution was diluted with isopropyl alcohol and cooled; 0.5 g. of a white crystalline solid separated which was identified by a mixed melting point as p-dimethylaminotriphenylmethane.

One-half gram of p-dimethylaminotriphenylcarbinol and 3 g. of sodium acetate were dissolved in 18 cc. of acetic acid. To this solution 5 cc. of 20% titanous chloride was added in the absence of air. The reaction mixture was allowed to stand for forty-eight hours; it was then poured into 250 cc. of 10% sodium tartrate. The resulting suspension was filtered with suction, dried and recrystallized from benzene–isopropyl alcohol. The crystalline product weighed 0.25 g., 50% of the theoretical amount, and melted at 134°. A sample of the product did not depress the melting point of a sample of *p*-dimethylaminotriphenylmethane.

The Reaction of *p,p'*-Tetramethyldiaminohexaphenylethane with Acetic Acid.—One and seven-tenths grams of *sym.-p,p'*-tetramethyldiaminohexaphenylethane was dissolved in the absence of air in 50 cc. of glacial acetic acid. Solution took place rather slowly, and the solution acquired a deep red color. The solution was allowed to stand for forty-eight hours; it was then poured into 400 cc. of water. A light red precipitate came out; this precipitate was filtered out at once. Crystallization from chloroform–alcohol yielded 0.4 g. of p-dimethylaminotriphenylmethane; the product was identified by a mixed melting point.

The Reaction of *Sym.-p,p'*-Tetramethyldiaminohexaphenylethane with Titanous Chloride.—One and seven-tenths grams of *sym.-p,p'*-tetramethyldiaminohexaphenylethane and 5 g. of sodium acetate were placed in a 50-cc. Erlenmeyer flask. The flask was closed with a one-holed rubber stopper bearing a straight glass stopcock. The flask was swept with nitrogen and evacuated; then 40 cc. of 80% acetic acid and 10 cc. of titanous chloride were drawn into it through the stopcock. The flask was again swept with nitrogen, and was allowed to stand for forty-eight hours. At the end of this time the solution was poured into 300 cc. of 5% sodium tartrate; the resulting suspension was thoroughly extracted with chloroform. The washed and dried chloroform extracts were concentrated and diluted with isopropyl alcohol; on cooling, 1.2 g. of p-dimethylaminotriphenylmethane crystallized. The product was identified by means of a mixed melting point.

***Sym.-p,p',p'',p'''*-Octamethyltetraminohexaphenylethane.**—Two grams of commercial malachite green and 2.0 g. of fused sodium acetate were dissolved in a mixture of 20 cc. of glacial acetic acid and 20 cc. of water. The solution was filtered into the larger chamber of the reduction flask. The system was swept with pure nitrogen; then 20 cc. of 1 N vanadous chloride was pipetted into the smaller chamber against a counter current of nitrogen. The apparatus was again swept with nitrogen; then it was tilted and the two solutions were allowed to mix. The reduction was very rapid. As soon as the deep green color of the solution had disappeared, the lower end of the bottom stopcock was immersed in 200 cc. of freshly boiled and cooled water in which 10 g. of sodium acetate had been dissolved. Nitrogen was blown into the reduction flask, and the reduced solution was forced out of the flask into the sodium acetate solution. The reduction product came out as a light brown amorphous precipitate. The solution was stirred briskly for a few seconds; the precipitate on the surface began to turn green at once. The precipitate was filtered by suction, and washed on the filter with water and very dilute ammonium hydroxide. The moist filter cake, the surface of which was already a bright green, was transferred to a small box made of folded filter paper. The box and its contents were placed directly upon the surface of a layer of calcium chloride in a vacuum desiccator; this was at once evacuated, filled with pure nitrogen and again evacuated to the lowest pressure obtainable. The amorphous free radical was sufficiently dry for ordinary use within twenty-four hours. The procedure outlined above must be followed closely if satisfactory results are to be obtained. Otherwise the product is a brittle black crust, with which very little work can be done.

If the reaction is successful, *sym.-p*-octamethyltetraminohexaphenylethane is obtained as a fluffy amorphous powder, light brown in its interior and bright green on its surface. All manipulations with the radical had to be performed in an atmosphere of carbon dioxide. Exposed to the air, the compound instantly decomposed to a black tar with the evolution of heat and a strong odor of formaldehyde.

Oxygen Absorptions.—In these experiments, the solid ethane was dissolved directly in the chosen solvent. The oxidation product formed a tarry coating over the undissolved ethane; the solubility and the rate of solution of this tar determined the apparent oxygen capacity of the ethane in a given solvent. The first three typical absorptions given below show the varying capacity of the same sample of ethane in different solvents.

Ethane	Solvent	Absorption, cc. (22.5°, 761 mm)	Per cent. absorption
0.16	Bromobenzene	2.0	34
.27	Aniline	5.1	52
.30	Acetic acid	7.5	68
.10	Acetic acid	2.7	73

Decomposition of the Ethane in Acetic Acid.—The same procedure was followed here as in the decomposition of *sym.-p,p'*-tetramethyldiaminohexaphenylethane.

Ethane	Time, minutes	Absorption in cc. (22.5°, 761 mm.)	Per cent. absorption
0.10	3	2.2	60
.10	10	2.7	73
.30	45	2.0	18

A sample of the same ethane absorbed no oxygen whatsoever after ten minutes' solution in a mixture of equal parts of acetic acid and hydrochloric acid.

"Chichibabin Product" from Malachite Green.—Five **grams** of malachite green, dissolved in 100 cc. of concentrated hydrochloric acid, was reduced in an atmosphere of nitrogen with 25 cc. of 1 N chromous chloride. The reaction mixture was allowed to stand for five hours; it was then poured slowly, with constant stirring, into 1000 cc. of water in which 100 g. of sodium acetate was dissolved. The thick white amorphous precipitate which came out was filtered with suction, washed on the filter with water and dried in *vacuo.* The crude product weighed 3.7 g., 84% of the theoretical amount. It was crystallized from boiling n-butyl alcohol. The product weighed 2.6 g. and melted at 231–232°. Further crystallizations did not change this melting point.

The freshly prepared rearrangement product was a white crystalline solid, soluble without coloration in concentrated hydrochloric acid. On standing, the surface of the solid slowly turned green.

Anal. Calcd. for $C_{46}H_{50}N_4$: C, 83.8; H, 7.6. Found: C, 83.5; H, 7.4.

Molecular Weight, Micro Method.—Sample, 0.0150: camphor, 0.1353; average depression, 7.0". Calcd. for $C_{46}H_{50}N_4$: 658.6. Found: 634.

The Reaction of *Sym.-p,p',p'',p'''*-Octamethyltetraminohexaphenylethane with Sodium Amalgam.—Two grams of *sym.-p,p',p'',p'''*-octamethyltetraminohexaphenylethane was placed in a 100-cc. round-bottomed flask corked with a rubber stopper fitted with a straight glass stopcock. The flask was swept with nitrogen and partially evacuated; 40 cc. of anhydrous ether and 15 cc. of 1% sodium amalgam were then drawn into the flask. The flask was again swept with nitrogen, and was then shaken vigorously by hand. The color of the solution, originally light red, faded at once; in two minutes there was a momentary increase of color, which faded at once. A second similar run was made; when the transient color had reached its maximum, carbon dioxide was admitted to the flask. A small volume of gas was absorbed, but no acid could be isolated from the reaction mixture. Benzene was used as the solvent in a third similar run; the results were no more satisfactory. The ethereal solution of the decomposition products was separated from the excess amalgam, filtered and concentrated; the concentrate was diluted with ethyl alcohol. A gray-white crystalline product, melting at 93–95°, was isolated; a mixture of this product with *p,p'*-tetramethyldiaminotriphenylmethane[6] melted at 96–97". The product was apparently an impure sample of the leuco base of malachite green.

Long-Period Reduction of Malachite Green with Vanadous Chloride.—Two grams of malachite green and 2.0 g. of sodium acetate were dissolved in 20 cc. of acetic acid and 20 cc. of water. To this solution 10 cc. of 1 N vanadous chloride was added in the absence of air. The solution was allowed to stand for forty-eight hours; at the end of this time it was poured into 300 cc. of 5% sodium acetate solution. A copious light green precipitate appeared. The mixture was thoroughly extracted with chloroform; the united chloroform layers were washed, dried and concentrated. On dilution with ethyl alcohol, 1.1 g, of white crystals separated; after drying, the product melted at 93–94'. A mixture of these crystals and a known sample of *p,p'*-tetramethyldiaminotriphenylmethane melted at 95–96°.

The Reduction of Malachite Green with Titanous Chloride.—An experiment was carried out under conditions identical with those used in the preparation of *sym.-p-p',p'',p'''*-octamethyltetraminohexaphenylethane. One-half gram of malachite green was reduced with 15 cc. of 20% titanous chloride solution buffered with sodium acetate. The deep color of the malachite green disappeared at once. The solution was allowed to stand for three minutes, and was then diluted with 300 cc. of 5% sodium acetate solution. The precipitate of the free radical was filtered with suction. The filter paper and precipitate were placed in a bottle containing an upright test-tube filled with bromobenzene; this bottle was connected with an absorption buret. When equilibrium was established, the bromobenzene was allowed to flow onto the precipitate, and the absorption of gas was noted. The free radical representing 0.5 g. of the color salt absorbed 8.0 cc. at 21° and 752 mm.; this was 51% of the calculated absorption.

One-half gram of malachite green, dissolved in 45 cc. of water, was reduced in the absence of air with 10 cc. of 20% titanous chloride buffered with sodium acetate. The reduced solution was allowed to stand for forty-eight hours; it was then poured into an excess of alkaline sodium tartrate. The resulting suspension was thoroughly extracted with chloroform. The united chloroform layers were washed, dried and concentrated; on dilution with isopropyl alcohol 0.5 g. of a white crystalline solid came out. This was identified by a mixed melting point as *p,p'*-tetramethyldiaminotriphenylmethane.

Seven-tenths gram of malachite green was dissolved in 45 cc. of boiling water. To the boiling solution 10 cc. of 20% titanous chloride was added. Decolorization took place at once, and an amorphous sandy red precipitate appeared in the solution. The mixture was thoroughly extracted with chloroform; the united chloroform layers, washed and dried, were concentrated and diluted with isopropyl alchol. White crystals appeared in the solution; when isolated, they weighed 0.35 g., and melted at 93°. After one recrystallization their melting point was 95–96°. The product did not depress the melting point of a known sample of *p,p'*-tetramethyldiaminotriphenylmethane.

The Reaction of *Sym.-p,-p',-p'',-p'''*-Octamethyltetraminohexaphenylethane with Titanous Chloride.—A solution of 1.7 g. of *sym.-p,-p',-p'',-p'''*-octamethyltetraminohexaphenylethane and 5 g. of sodium acetate in 50 cc. of 80% acetic acid was treated in

---

[6] Doebner, *Ann.*, 217, 255 (1883).

the absence of air with 10 cc. of 20% titanous chloride. The solution was allowed to stand for forty-eight hours; it was then diluted with sodium acetate solution and worked up in the usual manner. Five-tenths gram of *p,p'*-tetramethyldiaminotriphenylmethane was isolated; this represented 34% of the free radical. The remainder of the product was represented by a dark green tar from which no crystalline products could be isolated.

***p,p'*-Tetramethyldiaminotetraphenylethane.** (a) By Reduction of **Carbinol.**—One gram of p-dimethylaminodiphenylcarbinol was dissolved in 10 cc. of acetone; 5 cc of concentrated hydrochloric acid was added, followed by 10 cc. of 1 N chromous chloride. This mixture was allowed to stand in the absence of air for three hours. The reduction commenced at once, and the originally blue solution was deep green in fifteen minutes' time. When the reaction was complete, the reaction mixture was poured into 150 cc. of water; 20% aqueous sodium hydroxide was added until a precipitate of chromic hydroxide appeared. While still warm from the heat of neutralization, the mixture was thoroughly extracted with warm benzene. The united benzene extracts were washed with warm water, dried over sodium sulfate and concentrated by distillation to a volume of 8–10 cc. This solution was cooled and allowed to stand until crystallization of the high-melting isomer (m. p. 264–267°) was complete. The filtrate was concentrated to about 5 cc. and diluted with 10 cc. of boiling ethyl alcohol. On cooling, the low-melting isomer crystallized. The crude product was suspended in benzene at room temperature for five minutes; the suspension was filtered off and added to the major portion of the high-melting isomer. The low-melting isomer was brought out of the benzene solution by concentration and dilution with hot alcohol. After several such separations the product melted at 206–207°. The yields usually obtained were from 1 g.: 0.3–0.4 g. of low-melting isomer and about 0.2 g. of the other. The ratio of the two products was independent of the time of reduction. The reduction could also be carried out in glacial acetic acid 1.5 N in perchloric acid. The same procedure was followed as is outlined above; the two products appeared in the same ratio.

(b) By the Action of Sodium–Potassium Alloy upon *Sym.-p,p'*-**Tetramethyldiaminotetraphenylethylene.**—Three grams of *sym.-p,p'*-tetramethyldiaminotetraphenylethylene was suspended in a mixture of 15 cc. of anhydrous ether and 15 cc. of anhydrous benzene. This mixture was shaken in the absence of air for forty-eight hours with 3 cc. of sodium–potassium alloy. A greenish-blue color formed at once, which in the course of an hour's time gave place to a bright red coloration. The bright red potassium derivative was decomposed by the introduction of moist benzene. The contents of the flask were allowed to settle, and this crystalline residue was taken up with ordinary ether and treated with small amounts of ethyl alcohol until the alloy was decomposed. The benzene solution was washed thoroughly with water, dried over sodium sulfate and concentrated by distillation. Ethyl alcohol was added to the boiling concentrated solution; on cooling, 0.5 g. of a white crystalline solid came out. This, on recrystallization from benzene–alcohol, yielded 0.3 g. of a product which melted at 205–206°; a mixed melting point of this product and that prepared by reduction of *p*-dimethylaminodiphenylcarbinol with chromous chloride melted at 206–207°.

Anal. Calcd. for $C_{30}H_{32}N_2$: C, 85.7; H, 7.7. Found: C, 85.7; H, 7.7.

Molecular Weight, Cryoscopic, in Ethylene Dibromide.—Solvent, 23.54 g. sample, after preliminary seeding, 0.1518. A second sample did not wholly dissolve. Depression, 0.1795°. Calcd. for $C_{30}H_{32}N_2$: 420. Found: 424.

Molecular Weight, Micro Method.—Sample, 0.0139; camphor, 0.1020; depression, 13.9°. Found: 392.

Preparation of *p,p'*-**Tetramethyldiaminobenzophenone Dichloride.**—Five grams of Michler's ketone was dissolved in 150 cc. of anhydrous benzene. This solution was warmed to 30°; to the warm solution was added 3.5 g. of thionyl chloride. The solution turned an opaque blue and a dark oil separated at once. A slight evolution of sulfur dioxide was observed. The mixture was allowed to stand for a half-hour; during this time the oil crystallized on the bottom and sides of the flask. At the end of a half-hour the crystalline crust on the bottom of the flask was crushed with a stirring rod and the resultant suspension was filtered with suction. The crystalline cake was washed on the filter with benzene and then dried by a short exposure to the air. The yield was almost quantitative. The crude product was a bronze-green crystalline powder, the surface of which rapidly turned deep blue on exposure to the air. The product was used without further purification.

Reduction of the **Dichloride** in Acetone–Hydrochloric **Acid.**—*p,p'*-Tetramethyldiaminobenzophenone dichloride from 2.7 g. of Michler's ketone was dried for a short time, and then suspended in a mixture of 55 cc. of acetone and 5 cc. of concentrated hydrochloric acid. The deep blue solution thus formed was treated with 35 cc. of 1*N* **vanadous** chloride; the deep blue color of the dichloride disappeared at once. The reaction mixture was allowed to stand for two hours. At the end of this time the reaction mixture was diluted to 500 cc. with water, almost neutralized with aqueous sodium hydroxide, and thoroughly extracted with chloroform. The combined chloroform layers were washed with water, dried over sodium sulfate and concentrated. The boiling concentrated solution was diluted with boiling ethyl alcohol and again concentrated until crystals began to appear. The solution was cooled and filtered; the product weighed 1.25 g., representing 60% of the original ketone, and melted at 296°. The product did not depress the melting point of a known sample of *sym.-p*-octamethyltetramethyltetraminotetraphenylethylene prepared by the reduction of Michler's ketone with tin and hydrochloric acid.[7] The use of vanadous chloride and an acetic acid solution of the dichloride as well as chromous chloride in hydrochloric acid–acetone solution also yielded the ethylene.

Reduction of **Octamethyltetraminotetraphenylethylene** Glycol with **Chromous** Chloride.—One-half gram of the glycol was dissolved in 35 cc. of concentrated hydrochloric acid in a 50-cc. Erlenmeyer flask. Four cubic centimeters of *1 N* chromous chloride was added against a stream of carbon dioxide; the salt color disappeared immediately leaving a light green solution which grew deeper with the passage of time. The reaction was allowed to proceed for fourteen hours; then the reaction mixture was diluted. To the resulting solution was added 5.0 g. of sodium acetate; the solution was then almost neutralized with aqueous sodium hydroxide. A yellow amorphous precipitate came out of the solution during the neutralization. The mixture was extracted with chloroform; the united chloroform layers were washed with dilute sodium hydroxide, then with water and were dried over sodium sulfate. The dry filtered solution was concentrated and diluted with boiling ethyl alcohol; on cooling, 0.2 g. of *sym.-p,p'*-tetramethyldiaminotetraphenylethylene crystallized out of the solution. The product was identified by a mixed melting point. Another reduction was carried out under similar conditions, but was worked up after four hours' standing. Although the mother liquors were yellow, no crystalline ethylene could be isolated. A reduction using vanadous chloride was carried out under conditions identical with those described above,

---

[7] Fischl, *Monatsh.,* 35, 525 (1914).

except that 5 cc. of 1 *N* vanadous chloride was used as the reducing agent. The product weighed 0.2 g.; it melted at 218–221°.

Reduction of *p*-**Dimethylaminophenylisopropylcarbinol.**—In a 25-cc. Erlenmeyer flask, 0.8 g. of *p*-dimethylaminophenylisopropylcarbinol[8] was dissolved in 15 cc. of concentrated hydrochloric acid. A vigorous stream of carbon dioxide was blown through the flask to sweep out the air; then 10 cc. of 0.75 *N* chromous chloride was added. The flask was again swept with carbon dioxide; it was then allowed to stand, tightly stoppered, for ten hours. The solution, originally blue, had a distinct greenish cast at the end of a half-hour; in about two hours, needle-shaped crystals of a double salt began to come out. When the reaction was complete, the crystals of the double salt were filtered off; these, after being washed with a little cold hydrochloric acid, were dried and reserved for the preparation of the high-melting isomer. The filtrate was diluted to four times its original volume, and was neutralized with dilute sodium hydroxide until a precipitate of chromic hydroxide appeared. While still warm from the neutralization, the mixture was extracted with warm benzene. The united benzene layers were washed with warm water, dried over sodium sulfate and concentrated. On cooling, a small amount of the high-melting isomer came out which was filtered from the mother liquors. The filtrate was heated to boiling and diluted with twice its volume of boiling ethyl alcohol. On cooling, 0.3 g. of the lower-melting isomer appeared in crystalline form. This product melted at 174°; further recrystallizations did not affect the melting point.

Anal. (low-melting isomer). Calcd. for $C_{24}H_{36}N_2$: C, 81.75; H, 10.3. Found: C, 81.35; H, 10.3.

Molecular Weight **Cryoscopic,** in Ethylene **Dibromide.**—Solvent, 19.75 g.; samples, after preliminary seeding, 0.1192, 0.1386. Depressions, 0.213°, 0.231°. Calcd. for $C_{24}H_{36}N_2$: 352. Found: 338, 350.

One-gram samples of p-dimethylaminophenylisopropylcarbinol were reduced with chromous chloride according to the method outlined above; for various times the yields were: after one hour, 20% low-melting isomer, no high-melting isomer; after four hours, equal amounts (20%) of both isomers; after twenty-four hours, 27% low melting, 38% high melting.

Preparation of High-Melting Isomer.—The double salt mentioned in the preparation of the low-melting isomer was dissolved in hot water, and the solution made strongly alkaline with ammonia. A voluminous white precipitate came out. The suspension was heated for an hour on a steam-bath, cooled and filtered with suction. After drying overnight *in vacuo* the crude product from 1.67 g. of double salt weighed 1.0 g. The product after crystallization from boiling benzene weighed 0.67 g. and melted at 239–240°.

Anal. Calcd. for $C_{24}H_{36}N_2$: C, 81.75; H, 10.3. Found: C, 80.7; H, 10.1.

Molecular Weight, Micro Method.—Sample, 0.0172; camphor, 0.1513; depression, 13.4°. Calcd. for $C_{24}H_{36}H_2$: 352. Found: 335.

Both isomers were unaffected by shaking with sodium–potassium alloy and by the action of concentrated hydrochloric acid.

Summary

1. The action of soluble reducing agents, such as vanadous chloride, on solutions of triphenylmethane dyes has been investigated using malachite green as an example, and *p*-dimethylaminotriphenylcarbinol as a transition compound between the dyes and triphenylcarbinol. The first

---

[8] Sachs and Weigert, *Ber.*, 40, 4365 (1907).

product of the reaction is a free radical which may be isolated in the associated form (derivative of hexaphenylethane); it shows the typical behavior of these compounds. Under the influence of acids the free radical may further undergo rearrangement or reduction and oxidation to the corresponding methane and carbinol.

2. Michler's ketone dichloride and octamethyltetraminotetraphenylethylene glycol are both reduced by soluble reducing agents to octamethyltetraminotetraphenylethylene.

3. Dimethylaminodiphenylcarbinol and dimethylaminophenylisopropylcarbinol are each reduced by powerful soluble reducing agents with the formation of a pair of isomeric dimers.

THE REACTION OF ORGANIC HALIDES WITH PIPERIDINE. I. ALKYL BROMIDES

BY JOSEPH SEMB AND S. M. McELVAIN

RECEIVED NOVEMBER 15, 1930 PUBLISHED FEBRUARY 9, 1931

The reaction between a secondary amine and an organic halide is a common and useful method of preparation of tertiary amines. The reaction, as it is ordinarily carried out, is between two moles of the secondary amine and one mole of the halide with the formation of one mole of the tertiary amine and one mole of the secondary amine hydrohalide

$$2R_2NH + R'X \longrightarrow R_2NR' + R_2NH{\cdot}HX \qquad (1)$$

In a previous communication from this Laboratory[1] it was pointed out that certain halogen compounds did not follow the above reaction course with 3-methylpiperidine, but that the products obtained from the reaction were one mole of the secondary amine hydrohalide and one mole of unchanged secondary amine. No tertiary amine was isolated. Presumably, hydrogen halide had split out of the halogen compound with the formation of an unsaturated compound, thus

$$2R_2NH + R''X \longrightarrow R_2NH + R_2NH{\cdot}HX + (R''\text{—}H) \qquad (2)$$

There are scattered references[2] in the literature to the loss of a molecule of halogen acid from certain halides when they are treated with various organic bases, but apparently no effort has been made to study the reaction from this point of view.

It seemed desirable, therefore, to follow the rate and course of the reaction

[1] Thayer and McElvain, THIS JOURNAL, 50, 3350 (1928).

[2] *Cf.* Houben–Weyl, "Die Methoden der organischen Chemie," Vol. IV, 1924, p. 243; Menschutkin, *Z. physik. Chem.*, 5,589 (1890); Wallach, *Ann.*, 230,233 (1885); Nef, *ibid.*, 309, 164 (1899).

between different types of organic halogen compounds and a representative secondary amine. Piperidine was chosen as the amine to be used on account of its availability in the pure state, high basicity and convenient boiling point. This paper reports the results obtained from the reaction of this secondary amine with eighteen alkyl bromides.

Each reaction was carried out in sealed tubes using two moles of piperidine and one mole of the alkyl bromide in petroleum ether as a solvent. The rate of reaction was followed by opening tubes from time to time and determining the amount of the insoluble piperidine hydrobromide which had precipitated. The course of the reaction was determined at the end of a suitable reaction period by precipitating and weighing the unreacted piperidine as piperidino-formanilide with phenyl isocyanate. The amount of tertiary amine which had formed could then be calculated as the difference between the amount of piperidine which had been put into the reaction and the piperidine which was recovered as the hydrobromide and as piperidino-formanilide. From these data the course of the reaction ((1) or (2) above) was apparent. The results which were obtained are tabulated in the experimental part of the paper.

Experimental

Materials Used

Piperidine.—Piperidine was prepared by the hydrolysis of benzoylpiperidine[3] with 10% sodium hydroxide solution. The piperidine was removed from this alkaline solution by distillation and converted to the hydrochloride by the addition of hydrochloric acid, The solution of the hydrochloride was then evaporated to dryness and the free base liberated from its salt with a saturated potassium hydroxide solution. The piperidine layer was separated, dried with solid potassium hydroxide and finally treated with metallic sodium and distilled. It boiled at 105.4–106".

The Alkyl Bromides.—Ethyl, n-propyl, isopropyl, *sec.*-butyl, *tert.*-butyl, diethylmethyl, *tert.*-amyl, benzyl and I-methylcyclohexyl bromides were prepared from the corresponding alcohols by the Norris procedure.[4] Isobutyl and isoamyl bromides were obtained by the action of phosphorus tribromide on the corresponding alcohols.6 *n*-Butyl, n-amyl, n-hexyl, n-heptyl, cyclohexyl, phenylethyl and phenylpropyl bromides were prepared by the method of Kamm and Marvel[6] from the corresponding alcohols. 1-Methylcyclohexyl bromide apparently has not been prepared before this time. It boiled at 65–66' (19 mm.); Br calcd., 45.1; found, 44.8; M_D calcd., 39.76; found, 39.86.

Phenyl isocyanate was purchased from the Eastman Kodak Company and was distilled before use.

The petroleum ether was washed with sulfuric acid and water. It was finally dried over sodium and distilled. It boiled at 50–75°.

[a] 11.2% in 384 hours. [b] 97.7% in 2 hours.

General Procedure

The determination of the rate of reaction between piperidine and each alkyl bromide was made in the following manner. In a test-tube prepared for sealing was placed 0.02 mole (1.700 g. delivered by a calibrated pipet) of piperidine and a solution of 0.01 mole (1.088–1.985 g.) of the alkyl bromide in 10 cc. of petroleum ether. This latter solution was a 10-cc. aliquot taken from a solution of 0.1 mole (10.88–19.85 g.) of the bromide in 100 cc. of petroleum ether. The tube was then sealed and placed in a thermostat held at 90°. Sufficient such tubes were prepared for each bromide to allow at least two tubes to be taken for the determination of each value given in Table I. When a tube was opened for a determination the precipitated piperidine hydrobromide was filtered off, washed with petroleum ether and dried. A portion of this precipitate was analyzed for its bromine content by titration with standard silver nitrate solution. These analyses showed in every case that the precipitate was practically pure piperidine hydrobromide. The remainder of the precipitate which adhered to the sides of the reaction tube and to the filter paper was washed into the solution resulting from the above titration and further titrated with the silver nitrate solution. From these determinations the amount of piperidine hydrobromide which had precipitated could be determined.

The results of these determinations are shown in Table I. Each value in this table is the average of at least two determinations. The calculation of the percentage reaction is based on the amount of alkyl bromide that was put into the reaction.

The determination of the course of the reaction was made after a sufficient time to allow for a reasonable amount of reaction, as shown by the above data on the rate of the reaction. The reaction tube was opened and the insoluble piperidine hydrobromide filtered off and washed with a few cc. of petroleum ether. The filtrate and washings were placed in a volumetric flask and made up to 50 cc. with petroleum ether. An aliquot, containing not more than 0.170 g.[7] of piperidine, of this solution was used for the determination of the unreacted piperidine. This aliquot was placed in a previously weighed weighing bottle (approximately 4 cm. in diameter and 6 cm. high) and made up to a volume of 30 cc. with petroleum ether. To this solution 1 cc. of phenyl isocyanate was added. A voluminous precipitate of piperidino-formanilide came down immediately. After standing for about ten minutes, the reaction mixture was filtered through a previously weighed Gooch crucible. The weighing bottle was rinsed with 10 cc. of petroleum ether and these rinsings used to wash the precipitate in the Gooch crucible. Since a small amount of the piperidino-formanilide always adhered to the side and bottom of the weighing bottle, it was dried along with the Gooch crucible in an oven at 80° and re-weighed. To the weight of piperidino-formanilide so obtained was added the weight (0.0024 g.) of the anilide which 40 cc. (the volume used in the determination) of petroleum ether was found to dissolve after several hours of shaking. By this procedure 98.5% of the piperidine was found in samples of petroleum ether containing 0.170 g. of the substance.

The results of such determinations for the eighteen alkyl bromides that were reacted with piperidine at 90° are shown in Table II. Each experimentally obtained value is the average of at least two determinations. All weights are expressed in moles X 10^2 in order to allow more ready comparisons and to avoid the use of a larger number of digits. Column B represents the moles of piperidine hydrobromide precipitated from the reaction and column C the moles of unreacted piperidine determined as piperidino-formanilide. Obviously the difference between the amount of piperidine (2 moles) originally put into the reaction and the piperidine recovered as the hydrobromide and as piperidino-formanilide would represent the amount of piperidine which had reacted to form tertiary amine. This value is shown in column D. Column E shows the amount of unsaturated compound formed and represents the difference between the amount of piperidine obtained as the hydrobromide (column B) and that amount of piperidine which was converted into the tertiary amine (column D).

---

[7] Larger quantities of piperidine produced a too voluminous precipitate of piperidino-formanilide to be handled conveniently.

[a] Determined as piperidino-formanilide.

It is seen from Table II that certain secondary and tertiary bromides did not show sufficient reaction at 90° to permit the determination of the course of the reaction to have much meaning. For this reason it seemed desirable to repeat the experiments with these bromides at a higher temperature in the hope of bringing about more complete reaction. This was done by heating the reaction tubes in an oil-bath kept at 125–135° by a hot-plate. No attempt was made to control the temperature as accurately as in the experiments summarized in Table II. After the indicated reaction period the tubes were cooled, opened and the reaction product determined

in the same manner as that described above for the experiments run at 90°. The data for these experiments are summarized in Table III. Each experimentally obtained value in this table is the average of at least two determinations.

Discussion of Experimental Results

It is seen from Table I that there is an enormous difference in the reactivities of the three types of alkyl bromides with piperidine. As a class the primary bromides react quite completely in forty-eight hours. An exception is noted in the case of isobutyl bromide and this is due, no doubt, to the proximity of the branching in the chain to the halogen atom, for isoamyl bromide shows a distinctly greater reactivity than isobutyl bromide. Further, it may be pointed out that there appears to be a distinct alternating effect of the phenyl group on the reactivity of benzyl, phenylethyl and phenylpropyl bromides when they are compared after a four-hour period of reaction. The secondary and tertiary bromides are exceedingly unreactive when compared to the primary bromides. This fact is strikingly shown by the percentage of reaction in the forty-eight hour column of Table I. In this unreactive group cyclohexyl bromide is by far the least reactive. Conant and Hussey[8] have previously noted the extraordinary inertness of cyclohexyl chloride in their study of the rate of reaction of various alkyl chlorides with potassium iodide in acetone solution. They attributed this abnormal behavior to the cyclohexane ring. It is quite possible, however, that the reactivity which the other secondary bromides show may be due to a previous rearrangement to the more reactive primary bromide and that the unreactivity of the cyclohexyl bromide is due to the fact that it cannot rearrange to such a form.

The data summarized in Table II indicate that the primary and secondary bromides react to form tertiary amines, while the three tertiary bromides show a decided tendency to lose hydrobromic acid to form, presumably, an unsaturated compound. A relatively small positive value in column E carries no significance and, traced back to its source, probably means that the value obtained for the moles of unreacted piperidine (column C) rather than the corresponding value in column B was too high. A negative value in column E indicates that the amount of tertiary amine formed (column D) is greater than the amount of piperidine precipitated as the hydrobromide (column B). Obviously, such a ratio of reaction products is theoretically impossible, and when it is indicated it is due to a too low value in column B or C. As a group, however, the primary and secondary bromides in Table II show that there is formed practically the same number of moles of tertiary amine as of piperidine hydrobromide. The tertiary bromides, on the other hand, show a marked difference between the moles of tertiary amine and piperidine hydrobromide produced.

---

[8] Conant and **Hussey, THIS JOURNAL, 47,479** (1925).

The amount of reaction which most of the secondary and tertiary bromides in Table II show is relatively small. **Table** III gives a better view of the behavior of these compounds. At this higher reaction temperature it is seen that isopropyl and secondary butyl bromide definitely react to form a tertiary amine, but that cyclohexyl bromide, which appeared to be showing the same type of reaction in Table II, when forced into a more complete reaction shows practically the same tendency as the tertiary bromides to lose hydrobromic acid and forms only a relatively small amount of a tertiary amine. This fact would seem to lend further support to the suggestion made above that the secondary bromides which react with piperidine to form a tertiary amine probably rearrange to primary bromides before reacting and react as such. This possibility will be tested experimentally in this Laboratory and the results reported later. The tertiary bromides in Table III follow more completely the course which they started in Table II.

Summary

1. The rate and course of the reaction between piperidine and eighteen alkyl bromides has been determined.

2. It has been found that the primary and secondary bromides, with the exception of cyclohexyl bromide, react with piperidine to form tertiary amines. Cyclohexyl bromide and the tertiary bromides which were studied react, in the main, to lose hydrobromic acid and form, presumably, an unsaturated compound.

STUDIES IN PROTEINS.
II. CONCERNING THE UNIFORMITY OF THE PROTEIN FRACTION EXTRACTED FROM ORANGE SEED MEAL BY SALT SOLUTIONS

BY FELIX SAUNDERS

RECEIVED NOVEMBER 15, 1930 PUBLISHED FEBRUARY 9, 1931

Introduction

In a series of recent papers, Gortner and his co-workers[1] have reported the results of studies on the "peptization" of wheat flour proteins. Their figures show a great variation in the fraction of the total nitrogen extracted by various salts. From their data, the authors draw the following conclusions: (1) both anions and cations show a lyotropic series, (2) "protein 'solubility' in neutral salt solutions is, in reality, protein peptization, and

---

[1] Gortner, Hoffman and Sinclair, Cereal Chemistry. 6, 1 (1928); "Colloid Symposium Monograph," The Chemical Catalog Co., Inc., New York, 1928, Vol. V, p 179.

as such it is governed as to rate and extent by the nature of the particular anions or cations present in the salt solution," (3) "we do not believe that any salt used, in any one of the concentrations, extracts a chemical entity which should be designated by the term 'globulin'."[2] While Gortner's conclusions seem entirely justified with respect to the systems with which he worked, they do not seem to apply in the case of a system containing a representative crystalline globulin. In the present paper, studies are reported similar to Gortner's except that they were made on material in which most or all of the nitrogenous substance was crystalline globulin. Furthermore, a crystalline globulin was isolated using the different salts as extracting agents and the percentage of nitrogen in the protein determined in each case.

Material.—The material used in this study was orange seeds,[3] which yield a crystalline globulin, pomelin.[4] The whole seeds were ground in a Wiley mill. The oil was removed by repeated extractions with benzol. The meal which was left after filtering off the benzol was air-dried and then sifted. The fraction which passed through the 40-mesh sieve but not through the 60-mesh was used.

Method.—In order to have the results comparable, Gortner's procedure was followed as closely as possible in the extraction studies. Six grams of the orange seed meal was placed in a centrifuge bottle and covered with 50 cc. of the solution of the salt being investigated. The suspension was shaken mechanically for thirty minutes, centrifuged, and the supernatant liquid was poured into a Kjeldahl flask. Two more extractions were carried out in the same way. The nitrogen in the combined extractions was determined by the usual Kjeldahl procedure.

The pure protein was isolated in the following way. One liter of the salt solution was warmed to 55° and added to 100 g. of the seed meal. The mixture was allowed to stand for about two hours without any further warming. After as much of the liquid as possible had been recovered by centrifuging, solid ammonium sulfate was added to saturation. The globulin which precipitated was separated in the centrifuge and then redissolved by adding distilled water. Any undissolved material was removed by centrifuging and the solution was dialyzed in viscose bags[6] against cold, running, distilled water for about sixty-four hours. The supernatant liquid was separated from the protein precipitate by centrifuging. With-

---

[2] These statements were intended to apply only to wheat flour.

[3] These seeds were supplied by the California Fruit Growers Exchange. It is a pleasure to be able to acknowledge their courtesy in collecting and sending this material.

[4] Pomelin is the name which has been given to the crystalline globulin isolated from citrus seeds. It is easily obtained as octahedral crystals by the dialysis of a salt solution of the protein. A more detailed report on this protein will be published soon.

[5] Grateful acknowledgment is made to the Visking Corporation for furnishing the viscose tubing used in this work.

out being removed from the centrifuge cup, the protein was washed by suspending it in successive portions of alcohol of gradually increasing concentration starting with 40% and running up to absolute. The protein was then filtered off and washed with absolute ether. Finally it was dried to constant weight in a vacuum oven at 50°. The protein prepared in this way is a snow-white powder which easily passes through a 100-mesh sieve without any grinding. Each preparation of protein was examined under the microscope during dialysis to be sure that crystallization was proceeding properly.

As a further check, the residue from the protein extraction was dried on the steam-bath, ground until it all passed through a 60-mesh sieve and then analyzed for nitrogen. Of course, a correction for residual salt had to be made. At first an attempt was made to determine salt directly by ashing but this method proved unsatisfactory. An indirect calculation of the salt content on the basis of the amount of liquid left in the meal after centrifuging was much more trustworthy.

Experimental.—The experimental data are summarized in the following table. The variation in the yield of globulin can be explained by technical difficulties. In the case of the sodium bromide and potassium bromide some of the material was accidentally lost. The discrepancy in the values of the nitrogen in the residue from the extraction with sodium iodide and potassium iodide has been accounted for by difficulties in ash determination.

TABLE I

SOLUTION OF THE PROTEIN OF ORANGE SEED BY NORMAL HALIDES

Salt	% of total N extracted	Grams of N in 100 g. of residue	Yield of globulin, grams	N in protein, %
LiCl	72.5	3.1	7.02	16.9
NaCl	72.5	3.0	5.36	17.1
KCl	73.4	3.0	5.62	17.1
LiBr	73.9	3.0	6.80	16.9
NaBr	73.4	2.8	3.42	16.8
KBr	74.2	2.8	3.56	17.0
NaI	73.9	2.4	5.52	16.8
KI	73.4	3.4	6.90	17.0
Average	73.4	2.9	5.53	16.9

Discussion

The experimental data show very clearly that the alkali halides are alike in their ability to extract the protein of orange seeds. This finding is confirmed by the analysis of the residue. Considered by themselves, the analytical figures would not prove that the protein isolated was always the same. However, when taken in conjunction with the extraction figures, they probably warrant the conclusion that the protein is the same in every case. Furthermore, the crystal form and general behavior were the same in every preparation.

According to Gortner, a normal solution of potassium chloride extracts from wheat flour 23% of the total nitrogen, potassium bromide extracts 37% and potassium iodide extracts 64%. Using the same technique on orange seed meal, the figures obtained were: potassium chloride, 73.4; potassium bromide, 74.2; and potassium iodide, 73.4. The difference between the figures of the two series is of no significance since they were obtained on different materials, but the variation between results within each series is important. The first set shows a definite lyotropic series but the variation within the second series is no greater than the experimental error.

The discrepancy may be the result of differences in the type of materials used. Wheat flour contains a complex mixture of proteins in which gliadin and glutenin predominate. It is, therefore, hardly a suitable substance for the study of the action of salt solutions on globulins, even if we assume that flour contains a globulin fraction. Gortner's results justify the statement that all the material extracted by salt solutions from wheat flour is not necessarily globulin, but they do not force the conclusion that there is no such thing as a chemical entity which we may designate "globulin." In fact, of all the proteins there are probably none better entitled to consideration as chemical entities than the crystalline globulins. The real need is a definition which will distinguish between the crystalline or semicrystalline globulins and the nitrogenous material which can be extracted from almost any biological material.

In a private communication, Dr. Gortner asserts that he had no intention of denying the existence of globulins but was merely questioning the definition of the globulins and the methods for isolating them. Unfortunately many persons have construed his remarks to mean a complete denial of the existence of globulins as a class of proteins. It should be noted that Gortner's statements were made only in connection with the wheat flour system which he studied and it is not intended in this paper to imply that he wished at any time to extend his conclusions to other systems.

The question remains whether the existence of a lyotropic series in the extracting power of various salts may not still be demonstrated even in representative seed materials which are known to yield crystalline globulins. Dr. Gortner has very kindly sent the author a private communication in which he gives some figures from recent work in his laboratory. His results show very conclusively that there may be a series even with seeds which give a crystalline globulin. However, the existence or nonexistence of such a lyotropic series need not affect the other considerations regarding the nature of the protein extracted. In other words, different salt solutions may show a variation in their peptizing power toward a given system and yet be extracting the same protein only in varying amounts.

Unpublished results from this Laboratory show that the foregoing statement is probably true in some cases at least. Of course, the converse may also be true, that is, different salts may extract the same amount of nitrogen from a meal and yet may not be extracting a chemical entity.

This study is being extended to include other seeds known to yield crystalline globulins, and different salts at varying concentrations are also being used.

Conclusions

1. The alkali halide salts in normal concentration all extract the same amount of nitrogen from orange seed meal. There is no evidence for the existence of a lyotropic series in the extracting power of different salts on orange seed meal.
2. The protein isolated from orange seed meal by extraction with different salts is probably the same in every case.

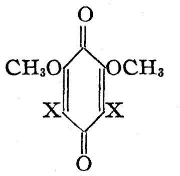
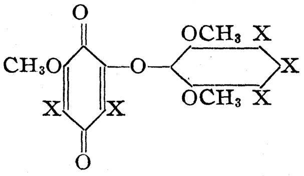
A NEW TYPE OF OXIDATION PRODUCT DERIVED FROM QUINONES[1]

BY W. H. HUNTER AND MURRAY M. SPRUNG

RECEIVED NOVEMBER 17, 1930 PUBLISHED FEBRUARY 9, 1931

During a study of the oxidation of tribromo- and trichloropyrogallol-2,6-dimethyl ether, Hunter and Levine[2] showed that when treated with any of a number of oxidants, these phenols gave both a yellow mononuclear quinone (I) and a red (or purple) phenoxy quinone (II).





I (X = Br or Cl) II

However, when the oxidations were carried out with chromium trioxide in 50% acetic acid[3] there were obtained, in addition to these expected products, small amounts of colorless compounds. These compounds seemed to be of a nature different from any of the oxidation products previously isolated during this series of investigations. Their further study therefore

---

[1] The work described in this paper formed part of a thesis submitted to the Graduate Faculty of the University of Minnesota by Murray M. Sprung in partial fulfilment of the requirements for the degree of Doctor of Philosophy, September, 1928.

[2] Hunter and Levine, THIS JOURNAL, 48, 1608 (1926); cf. Hunter and Morse, *ibid.*, 48, 1615 (1926).

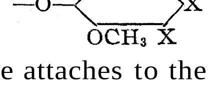
[3] Hunter and Levine, Ref. 2, p. 1612.

appeared to be of interest, and was undertaken, leading to the results described in the present paper.

A quantity of each of the colorless oxidation products was prepared and very carefully purified. On subjecting them to ultimate analyses and molecular weight determinations, a pair of empirical formulas was obtained which at first sight do not seem to be related. For the colorless oxidation product of tribromopyrogallol-2,6-dimethyl ether the best formula is $C_{28}H_{22}O_{15}Br_8$ (calculated molecular weight, 1238); for the colorless oxidation product of trichloropyrogallol-2,6-dimethyl ether the best formula is $C_{14}H_{11}O_8Cl_4$ (calculated molecular weight, 449). Nor do these formulas have any apparent relation to either of the normal products of oxidation of the phenols, for the mononuclear quinones have the composition, $C_8H_6O_4Br_2(Cl_2)$, while the dinuclear quinones have the composition, $C_{15}H_9O_6Br_5(Cl_5)$. Furthermore, the colorless substances are much richer in oxygen than any of the expected products. We were therefore led to suspect that oxidative rupture had occurred at some stage of these oxidations.

It was later discovered that the colorless compounds could also be obtained directly from the corresponding dinuclear quinones (II) of Hunter and Levine, by oxidizing the latter with chromium trioxide under conditions identical with those used in the synthesis of the colorless compounds from the trihalogenated pyrogallol-dimethyl ethers, showing that the colorless compounds are probably secondary products, derived from oxidation of the primary quinones.

A second very significant reaction was found to occur when dilute alkali was added to the colorless substances. Both compounds went into solution quite rapidly. On acidification of the solution, immediate precipitates of colorless materials were produced which were, *in both cases, different from the starting materials.* Investigation proved them to be the *original trihalogenated pyrogallol-dimethyl ethers* from which the colorless oxidation products, themselves, are derived. This action was very rapid, and in the case of the brominated compound it was demonstrated that the yield of phenol obtained was constant, that is, 63.2% of the weight of the brominated oxidation product used. It is therefore evident that the white compounds contain the residue

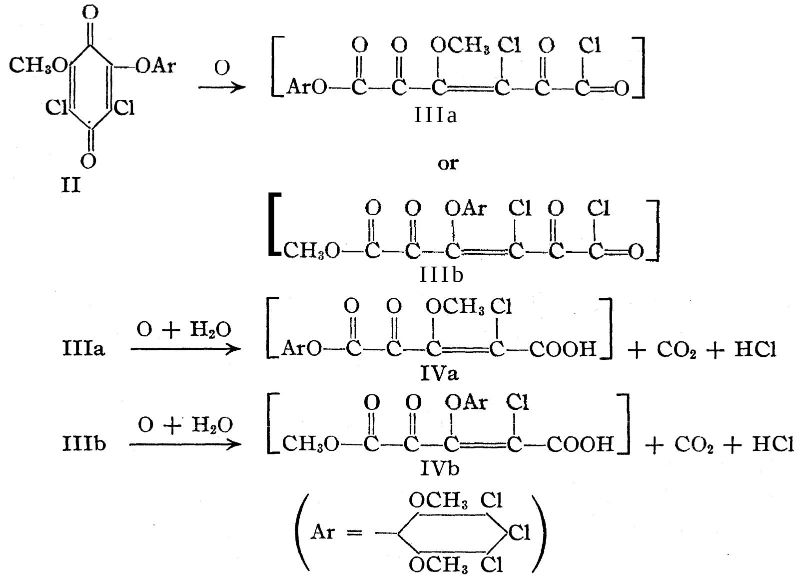


(X = Br or Cl)

and that this residue attaches to the rest of the molecule by some easily saponifiable linkage, for which only two simple possibilities suggest themselves: an ester linkage, and an acetal or hemiacetal linkage.

If now we consider the chlorinated oxidation product first (because of its simpler analytical formula, $C_{14}H_{11}O_8Cl_4$) we may arrive at a theory for its formation on the basis of the above information only. Three significant facts must be accounted for at this time: first, one carbon atom is lost when the white compound is produced from the phenoxy quinone; second, the colorless compound still contains the phenoxy group as a distinct unit, easily lost by saponification; third, when the phenoxy residue is removed from the colorless compound, the resulting residue is easily and apparently completely destroyed by the reagent.[4]

A series of steps leading from the purple dinuclear quinone (II) to a product (IV) of the desired empirical'composition is outlined below.



On the basis of the well-known oxidation of quinone to maleic acid,[5] it might reasonably be expected that if the chlorinated phenoxy quinone (II) were subjected to the action of a sufficiently strong oxidant, the first effect would be to split the quinonoid ring open at one of the double bonds. One oxygen atom would add to each side of the ruptured bond, and there would result one of two compounds, IIIa or IIIb, depending upon which double bond of the quinone ring was ruptured. Either of the hypothetical compounds thus produced is a di-acid derivative: the first a substituted phenyl ester and an acid chloride; the second a methyl ester and an acid chloride. It is important, also, that each is **twice** an *alpha oxo acid* derivative, that is, an alpha oxo acid chloride and an alpha oxo ester. Now alpha oxo esters are quite stable toward oxidation (pyruvic ester, for example). However, we have been able to find no mention in the literature

---

[4] Many attempts were made to isolate this residue after the "hydrolytic" reaction, but in no case could a single, homogeneous product be obtained In all such cases, large amounts of halogen acid and some oxalic acid were found in the solution.

[5] **Kempf,** ***Ber.*,** **39,** 3719 (1906).

of the existence of alpha oxo acid chlorides. We consider it quite probable that such a compound, under the conditions of our experiments, would either be hydrolyzed to the free alpha oxo acid and then further oxidized, or oxidized directly as the oxo chloride. In either case, we should expect to find the carbon chain lessened by one carbon atom, to give a C_{14} compound. There would result, then, a complicated alpha oxo ester of an unsaturated 5 carbon di-acid (IVa or IVb).

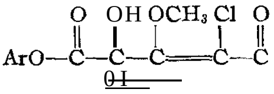
The formulas IVa and IVb are of course isomeric, and correspond empirically to the composition $C_{14}H_{10}O_8Cl_4$. The experimental formula for the chlorinated colorless oxidation product is $C_{14}H_{11}O_8Cl_4$, identical with the above except for one hydrogen, a discrepancy which could easily be accounted for by a relatively slight error in hydrogen analysis.

However, our colorless compound has no effect upon saturated sodium hydrogen sulfide, and it, therefore, cannot be a carboxylic acid. Furthermore, it forms a well-defined acetyl derivative, which can be crystallized unchanged from ethyl alcohol, and is, therefore, not a mixed anhydride. We conclude from this that our acid, which would be a gamma oxo acid, exists in the oxy-lactone form, similar to the alternate formula for levulinic acid, $CH_3\underbrace{C(OH)CH_2CH_2C}_{O}{=}O$. Levulinic acid, too, is known to form an acetyl derivative, which also can be crystallized unchanged from ethyl alcohol, and to which the formula $CH_3\underbrace{C(OCOCH_3)CH_2CH_2C}_{O}{=}O$ has been assigned.[6] Unsaturated gamma oxo acids show the same tendency toward lactone formation. Thus acetone dipyruvic acid exists only in the form of a dianhydro compound to which the formula

$$O{=}\overbrace{C{-}C(CH_3){=}CH{-}C}^{O}\overbrace{{-}CH{=}C(CH_3){-}C}^{O}{=}O$$

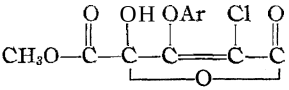
has been assigned.

If our white oxidation product is a gamma oxy lactone, it may have either of the following formulas



$$ArO{-}\overset{O}{\overset{\|}{C}}{-}\underbrace{\overset{OH}{\overset{|}{C}}{-}\overset{OCH_3}{\overset{|}{C}}{=}\overset{Cl}{\overset{|}{C}}{-}\overset{O}{\overset{\|}{C}}}_{O}$$

Va



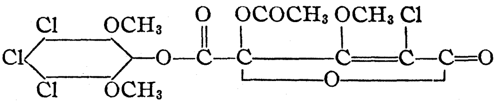
$$CH_3O{-}\overset{O}{\overset{\|}{C}}{-}\underbrace{\overset{OH}{\overset{|}{C}}{-}\overset{OAr}{\overset{|}{C}}{=}\overset{Cl}{\overset{|}{C}}{-}\overset{O}{\overset{\|}{C}}}_{O}$$

Vb

To choose between these two formulas, it need only be remembered that the substituted phenoxy group is easily saponified, the methoxy group not. Therefore the substituted phenyl group must be tied by an ester linkage, and the methyl group by an ether linkage. All this evidence points to formula Va as representing the most probable structure for the colorless oxidation product of trichloropyrogallol-2,6-dimethyl ether. Its acetyl derivative would then have the structure

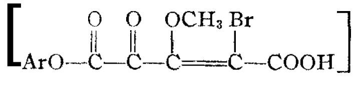
---

[6] Bredt, *Ann.*, 236, 225 (1886); *ibid.*, 256, 314 (1890); Autenrieth, *Ber.*, 20, 3191 (1857); Thiele, Tischbein and Lussow, *Ann.*, 319, 184 (1901).



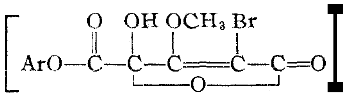
The colorless brominated oxidation product is similar to the chlorinated compound both as regards mode of formation and chemical behavior. The two compounds behave analogously in respect to a variety of chemical reagents. However, a series of carefully checked analytical data and molecular weight determinations has established the previously mentioned C_{28} formula, *i.* e., $C_{28}H_{22}O_{15}Br_8$. Assuming the hydrogen analyses to be high again, we may modify this formula (for reasons which will shortly be clear) to $C_{28}H_{18}O_{15}Br_8$. If the brominated compound were exactly analogous to the chlorinated compound it would have the composition $C_{14}H_{10}O_8Br_4$. It is then evident that the formula $C_{28}H_{18}O_{15}Br_8$ represents a *dimolecular* anhydride of the simpler formula $C_{14}H_{10}O_8Br_4$.

The most reasonable mechanism by which to explain the formation of the brominated oxidation product is as follows: as in the case of the analogous chlorine compound, a monomolecular derivative is first formed. This may possess either the free acid structure (VIa), or the gamma oxy-lactone form (VIb).

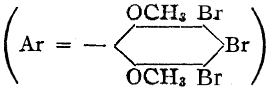


$$\left[ArO{-}\overset{O}{\overset{\|}{C}}{-}\overset{O}{\overset{\|}{C}}{-}\overset{OCH_3}{\overset{|}{C}}{=}\overset{Br}{\overset{|}{C}}{-}COOH\right]$$

VIa



VIb



But, as we have previously mentioned, there is a definite tendency for the hydroxyl group of a gamma oxy lactone to become esterified through dilactone formation. When this is impossible, dehydration sometimes occurs, by loss of the hydroxyl group along with an alpha hydrogen atom. The above hypothetical gamma oxo acid, however, has neither a second gamma carboxyl group nor an alpha hydrogen atom. The tendency toward reaction can only be satisfied, in this case, by elimination of water between two molecules and this leads to the dimolecular anhydride which is actually isolated.[8]

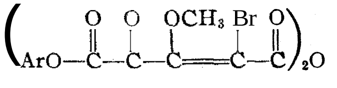
There are at least three possible mechanisms by which the formation of a dimolecular anhydride may be explained, assuming that such anhydride formation actually does occur. There may be formed in the solution both

---

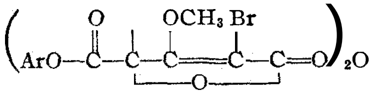
[7] Stating this in another way, the only "available" hydrogen atom which can split out with the hydroxyl group of one molecule is the hydroxyl hydrogen of a second molecule.

[8] The chloro and the bromo hypothetical intermediates, then, behave differently under the same experimental conditions. It is not entirely clear just why they should do so; but there is, on the other hand, no a *priori* reason to assume that they must behave the same.

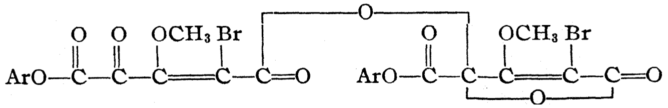
the free acid form and the lactone form (formulas VIa and VIb). The free acid, instead of becoming esterified intramolecularly, as in the case of the analogous chloro compound, may become esterified intermolecularly, and this may occur either by union with a second molecule of the free acid itself, or by union with a molecule in the oxy lactone form. In the first case, the ordinary type of acid anhydride (formula VIIa) would result; in the second case, the product would be an unsymmetrical molecule (formula VIIb).



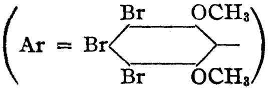
VIIa



VIIc

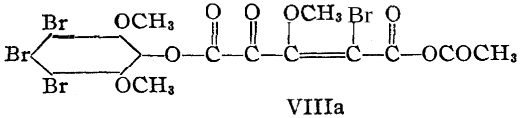


VIIb

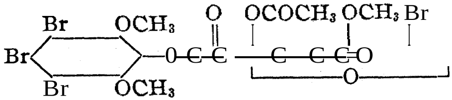


The third possibility is that only the lactone form of the acid (VIb) is involved in intermolecular anhydride formation. The dimolccular anhydride would then have the structure VIIc. It is possible to eliminate the first of these structures (formula VIIa) by virtue of the fact that the compound can be crystallized unchanged from ethyl alcohol, and therefore cannot be a normal acid anhydride. It is impossible at present to make a choice between formulas VIIb and VIIc.

The colorless oxidation product of tribromopyrogallol-dimethyl ether, like the analogous chloro compound, forms an acetyl derivative, when subjected to the action either of acetic anhydride and glacial acetic acid, or acetyl chloride and concentrated sulfuric acid.[9] This acetyl derivative has the composition $C_{16}H_{12}O_9Br_4$, and is therefore derived from the monomeric form of the acid. Its structure may be either that of a mixed anhydride VIIIa or an acetylated gamma oxy lactone VIIIb, again.



VIIIa



VIIIb

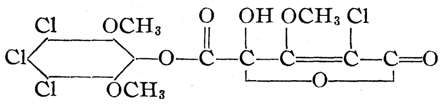
---

[9] The hydrogen necessary for this reaction may come from the sulfuric acid used during the acetylation. Very little water is required, due to the very large molecular weight of the colorless oxidation product.

We are once more inclined to favor the gamma oxy-lactone formula (VIIIb), by analogy with the acetyl derivative of levulinic acid and of our chlorinated oxidation product. Moreover, this acetyl derivative also may be crystallized unchanged from alcohol, which is evidence against the mixed anhydride formula. Further evidence for structure VIIIb is that whereas the acetyl derivative is broken down to the original phenol by dilute alkali, as is the white compound itself, in the former case the hydrolysis requires boiling alkali, while the unacetylated derivative breaks down quite easily in the cold. In formula VIIIb the oxo group alpha to the substituted ester grouping is modified in such a way as would be expected to stabilize the ester group toward hydrolysis, while in formula VIIIa no such modification is suggested.

Conclusions

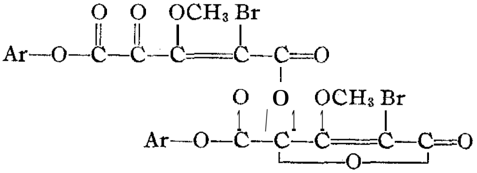
1. From these considerations we suggest IX as the most probable formula for the colorless oxidation product of trichloropyrogallol-2,6-dimethyl ether



IX

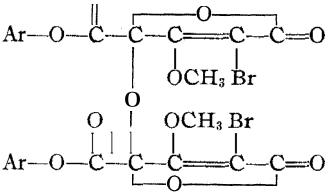
the oxy-lactone of α-chloro-β-methoxyquinonic[10] acid [(3,4,5-trichloro-2,6-dimethoxy)-phenyl ester].

2. Either Xa or Xb then becomes the best formula for the colorless oxidation product of tribromopyrogallol-2,6-dimethyl ether.



Xa

Ester of IX (bromine analog)
keto form



Xb

Ether of IX (bromine analog)
Ar = $—C_6Br_3(OCH_3)_2$

---

[10] In order to simplify the naming of these structures, it is convenient to designate the parent acid (a-keto-glutaconic acid, COOHCOCH═CHCOOH) by some suitable trivial name. We have adopted the name "quinonic acid," since a like oxidation of parabenzoquinone would yield this acid, if it could be carried out.

At the present time we wish to present these formulas provisionally only. Although these structures are as yet by no means rigorously established, we nevertheless consider them to be entirely plausible, in so far as they agree with *every one* of the known experimental facts and satisfy the analytical requirements admirably. We hope to be able to test these suggested structures by further chemical investigation of the substances and of analogous materials.

Experimental Part

Oxidation of Tribromopyrogallol-2,6-dimethyl Ether.—A representative procedure was as follows. Nine grams of tribromopyrogallol-2,6-dimethyl ether (m. p. 134.2°) was covered with 900 cc. of 50% acetic acid and warmed on a water-bath to 80°, at which temperature the dimethyl ether went into solution. Six and six-tenths grams (3 molar equivalents) of chromium trioxide was stirred in. An immediate precipitate of the purple phenoxy quinone was usually obtained. This varied somewhat in quantity, and in one or two cases no phenoxyquinone was formed. The temperature was maintained at 80° for fifteen to twenty minutes, after which the mixture was cooled, and filtered from the phenoxyquinone. It was then poured, slowly and with stirring, into 1200 cc. of cold water, and allowed to stand. The white oxidation product appeared as a very flocculent precipitate, which slowly settled to the bottom of the vessel. After several hours, most of the supernatant liquid was decanted, and the white compound filtered onto a good grade of coarse filter paper made into a "fluted filter." It was washed with dilute acetic acid, water and dilute (ca. 25%) alcohol and allowed to dry between filter papers. Eight oxidations, each starting with 9 *g.* of the phenol, gave an average of 2.9 g. of the colorless compound, or about 32% of the weight of the starting material. The yield was greatly reduced when the oxidation was carried out with larger amounts of the phenol.

The colorless compound melted, when crude, at 193–197°. A sample was purified by recrystalliiation, as follows: four times from dilute ethyl alcohol, once from aqueous ethyl acetate, three times from dilute methyl alcohol, twice from aqueous methyl acetate and finally once again from dilute methyl alcohol. Starting now with a bath temperature of 200°, the substance showed a melting point of 206–206.6" (with decomposition). A sample obtained from the last methyl alcohol–water filtrate by evaporating to dryness melted with decomposition at 206–207° (Jackson's test for purity).

Properties of the Colorless Oxidation Product of Tribromopyrogallol-2,6-dimethyl Ether.—This substance crystallizes from dilute ethyl alcohol in pure white, microscopic needles, melting, when very pure, at 206–206.6° (decomp.). It is very soluble in acetone, acetic acid, ethyl acetate, methyl acetate and chloroform; moderately soluble in methyl alcohol, and ethyl alcohol; slightly soluble in amyl alcohol, toluene, benzene, xylene, ethylene dibromide, acetophenone and hot carbon tetrachloride; practically insoluble in cold carbon tetrachloride, water and ligroin.

It is oxidized only very slowly by hot alkaline permanganate, hot acid permanganate and boiling concentrated nitric acid. Boiling silver nitrate in 95% alcohol produces only a slight murkiness. It dissolves in concentrated sulfuric acid to a clear solution. Such a solution was diluted with water, leading to the precipitation of a white material, which was shown to he tribromopyrogallol-2,6-dimethyl ether (m. p. 131–136°).

The original oxidation product is entirely unaffected by any of the following reagents: boiling bromine in chloroform, phosphorus pentabromide in hot chloroform or carbon disulfide, liquid bromine without a solvent, dilute or concentrated hydrochloric acid, dilute nitric acid, saturated sodium hydrogen sulfide.

The Acetyl Derivative.—One and two-tenths grams of the white oxidation product was covered with acetyl chloride, 2 drops of concd. sulfuric acid added and the mixture heated gently in an acetylation flask for three hours. Fumes of hydrogen chloride were evolved from the start. The contents of the flask, poured into 200 cc. of ice water, gave 1.1 g. of the white acetyl derivative. Three recrystallizations from dilute ethyl alcohol gave a pure white product, m. p. 141–144° (decomp.). A sample recrystallized twice more was used for analysis.

Anal. Subs., 0.1261, 0.1889: AgBr, 0.1437, 0.2146. Subs., 0.1861, 0.1655: CO_2, 0.1964, 0.1743; H_2O, 0.0345, 0.0315. Calcd. for $C_{16}H_{12}O_9Br_4$: C, 28.45; H, 1.81; Br, 47.91. Found: C, 28.78, 28.72; H, 2.07, 2.13; Br, 48.16, 48.34.

The same acetyl derivative is obtained by using acetic anhydride and glacial acetic acid as the acetylating agent. It crystallizes from dilute alcohol in minute, colorless needles. It is moderately soluble in ethyl alcohol, methyl alcohol, glacial acetic acid, chloroform and carbon disulfide; slightly soluble in fractol or ligroin.

Action of Dilute Alkali upon the Acetyl Derivative.—A sample of the acetyl derivative, when boiled with 6% potassium hydroxide, slowly went into solution. When the solution was cooled and acidified with a few drops of concentrated hydrochloric acid, a white material precipitated, which was shown, by the method of mixed melting points, to be tribromopyrogallol-2,6-dimethyl ether.

The Action of Dilute Alkali upon the Colorless Oxidation Product.—An example is given of one of the hydrolytic experiments in which quantitative technique was adopted. Ninety-eight hundredths gram of the pure colorless oxidation compound was dissolved in 90 cc. of cold 6% potassium hydroxide. Solution required only a minute or two. Immediate acidification at this point would give a good yield of the tribromodimethoxyphenol; however, for the sake of quantitative results, the solution was heated gently on the steam-bath for two hours, then nearly neutralized with glacial acetic acid and made slightly acid with dilute (1 normal) acetic acid. The precipitate which resulted was allowed to stand overnight, then filtered onto a weighed Gooch crucible and dried over calcium chloride in a vacuum desiccator. The tribromopyrogallol-2,6-dimethyl ether weighed 0.62 g., or 63.3% of the weight of the starting material. A check determination gave 63.2%.

A sample of the phenol thus prepared was crystallized twice from dilute ethyl alcohol, giving pure white, delicate needles, m. p. 133.8–134.0°; mixed melting point with a known sample of tribromopyrogallol-2,6-dimethyl ether, 134–134.2°. Since it was exceedingly important to establish, without question, the identity of this material, the purified material was subjected to analysis.

Anal. Subs., 0.2002, 0.2037: AgBr (Carius), 0.2881, 0.2943. Subs., 0.0695, 0.0925: CO_2, 0.0664, 0.0841: H_2O, 0.0151, 0.0177. Calcd. for $C_6H_7O_3Br_3$: Br, 61.34; C, 24.87; H, 1.80. Found: Br, 61.24, 61.48; C, 25.00, 24.80; H, 2.35, 2.15.

Investigation of the Filtrate from the Hydrolysis Reaction.—Examination of the solution from which the tribromopyrogallol-dimethyl ether was filtered led to the following results. Silver nitrate and concd. nitric acid gave a heavy precipitate of silver bromide, showing that further decomposition occurred when the phenol was split off.

Chlorine water and chloroform also disclosed the presence of much free bromide ion. From the filtrate from one sample of 0.57 g. of the white oxidation product, 0.25 g. of silver bromide, equivalent to 0.10 g. of bromine or 33% of the total bromine present in the starting material, was obtained. This, plus the bromine content of the dimethyl ether, accounts for approximately the total bromine available. Another portion of the solution, when neutralized with ammonia and treated with a solution of calcium chloride, gave a white precipitate which gradually darkened on standing, indicating the presence of some reducing acid residue. This was confirmed by the fact that permanganate acidified with dilute sulfuric acid was rapidly decolorized.

The filtrate from one hydrolytic experiment was extracted with ether and the ether extracts allowed to evaporate. There was obtained less than 0.1 g. of an impure white material, melting at 150–160°. The substance was exceedingly deliquescent; standing in the air for even a few moments rendered it of a sirupy consistency. It could not again be isolated, even in this state of impurity, although several attempts were made to do so.

Hydrolytic Decomposition by Means of Other Alkalies.—The hydrolysis could be effected by the use of weaker bases than potassium hydroxide, for example, ammonia or aniline. The latter reagent had previously been used in attempts to obtain an anilide of the colorless compound, without success. It was now clear why these experiments had proved fruitless. If heated for a few minutes with aniline in alcoholic solution, the substance was unaffected. If heated for a somewhat longer time, a gummy product resulted, from which a quantity of the tribromodimethoxyphenol could be obtained. The effect of aniline when used without a solvent was either to leave the colorless material unaffected, or to cause deep-seated decomposition of the substance.

Oxidation of 3,5-Dibromo-6-methoxy-2-(3,4,5-tribromo-2,6-dimethoxyphenoxyl)-p-benzoquinone.—A sample of the above compound, obtained as a by-product during the oxidation of tribromopyrogallol-2,6-dimethyl ether to the colorless oxidation product, was recrystallized three times from glacial acetic acid. It melted at 219–219.5° (Hunter and Levine report 214°). When recrystallized again it melted at 219.5° sharply. Thirty-five hundredths gram of this material was suspended in 50 cc. of 50% acetic acid, heated to 80° and 0.2 g. of chromium trioxide added. The heating was continued for one and one-half hours, after which the solution was cooled and the unchanged quinone filtered. The filtrate was diluted with 120 cc. of water. A white substance slowly precipitated. After being filtered, washed and dried at 100°, it showed a melting point of 200.5–201.5° (only the most highly purified samples of the white product melt above this temperature) with decomposition, and was found to be identical with the white oxidation product obtained in the original oxidation experiments.

Oxidation of Trichloropyrogallol-2,6-dimethyl Ether.—A representative procedure was as follows. Three grams of trichloropyrogallol-2,6-dimethyl ether was dissolved in 350 cc. of 50% acetic acid and heated on a water-bath to 78°. Two grams (1.7 molar equivalents) of chromium trioxide was stirred in and the heating continued for ten to fifteen minutes, after which the mixture was cooled and the red phenoxyquinone filtered off. (As in the case of the corresponding bromo compound, this phenoxyquinone usually precipitated immediately upon addition of the oxidant, but it varied in amount, and in one or two cases it failed to appear at all.) The filtrate was poured into 500 cc. of cold water and allowed to stand overnight, when the white oxidation product had settled to the bottom of the beaker. Most of the supernatant liquid was decanted, and the precipitate was filtered onto a fluted filter paper, washed with dilute acetic acid, water and dilute alcohol and dried between sheets of filter paper. The average yield of crude material was 31% of the weight of the starting material. The crude material melted at 177–182° (decomp.). After crystallizing twice from dilute acetic acid, twice from dilute ethyl alcohol and twice from dilute methyl alcohol, it melted at 187.4–187.8°, with decomposition.

Anal. Subs., 0.1059, 0.1003, 0.1391, 0 1270: AgCl (Carius), 0.1380, 0.1284, 0.1779, 0.1627. Subs., 0 1657, 0.1669: CO_2, 0.2300, 0.2297; H_2O, 0.0357, 0.0365. Subs., 0.2040, 0.2027: AgI (Zeisel), 0.3220, 0.3175. Calcd. for $C_{14}H_{10}O_8Cl_4$ (3 OCH_3): Cl, 31.65; C, 37.53; H, 2.25; 0, 28.57; OCH_3, 20.76; mol. wt., 448. Found: Cl, 32.24, 31.67, 3164, 31.69; C, 3785, 37.53; H, 2.41, 2.45; O (by difference), 28.10, 28.33; OCH_3, 20.84, 20.68; mol. wt. (in ethylene dibromide), 525, 476, 460; mol. wt. (in camphor), 515.

Properties of the Colorless Oxidation Product of **Trichloropyrogallol-2,6-dimethyl** Ether.—This substance crystallizes from dilute alcohol in small, white, delicate needles, which melt, when very pure, at 187.4–187.8°, with decomposition. The microscopic crystals are much better developed than those of the bromine analog, which gives reason to suspect, *a priori*, a much smaller molecule in the former case than in the latter. It is readily soluble in ethyl alcohol, methyl alcohol, glacial acetic acid, acetone, chloroform and ether; slightly soluble in carbon disulfide, benzene, toluene, xylene and ethylene dibromide; practically insoluble in water, carbon tetrachloride and fractol.[11]

Like the bromine analog, the substance is inert to most common chemical reagents It is unaffected by dilute or concentrated hydrochloric acid, dilute or concentrated nitric acid, saturated sodium hydrogen sulfide, bromine, pure or in solution, and is attacked only very slowly by hot acid or alkaline permanganate. The pure material dissolves in concentrated sulfuric acid to a clear solution One such solution, on dilution, was found to give a precipitate of trichloropyrogallol-2,6-dimethyl ether (m. p, 121–122°) The same substance was produced by the action of 6% potassium hydroxide on the colorless product, and subsequent acidification, by dilute acetic acid, of the solution produced. It was identified by the method of mixed melting points. A large amount of free chloride ion was found to be produced during the hydrolytic reaction, and there was also present in the solution, after reaction, a substance which reduced acid permanganate. It could not be isolated.

Acetylation.—Fifteen-hundredths gram of the colorless compound and 30 cc. of acetic anhydride, contained in a long-necked flask, was warmed gently over a free flame for two to three hours. The contents of the flask were cooled, neutralized with sodium hydroxide and diluted with water. The brown product was crystallized from dilute alcohol, giving white crystals, m. p. 135–136°, with decomposition. A chlorine analysis on the crude product indicated that it was a monoacetyl derivative.

Anal. Calcd. for $C_{16}H_{12}O_9Cl_4$: Cl, 29.0. Found: 27.7, 29.0.

Oxidation **of 3,5-Dichloro-6-methoxy-2-(3,4,5-trichloro-2,6-dimethoxyphenoxyl)-*p*-benzoquinone.**—Five-tenths gram of the above compound was suspended in 100 cc. of 50% acetic acid, and treated at 78° with 0.35 g. of chromium trioxide. After heating at this temperature for one and one-half hours, the solution was cooled, the excess quinone filtered and the filtrate poured into 200 cc. of cold water. After twenty-four hours, the small amount of white material which had settled to the bottom of the vessel was collected, washed with water and dried. It melted at 186–188°, with decomposition, and was identical with the colorless oxidation product of trichloropyrogallol-2,6-dimethyl ether.

---

[11] The oxidation product sometimes appears in the colloidal condition, either when first precipitated from 50% acetic acid by dilution, or on subsequent recrystallization. Under these circumstances, purification cannot be effected and the material must be discarded.

Summary

The oxidation of halogenated pyrogallol-2,6-dimethyl ethers leads to the formation of colorless products. The same products are likewise obtained by the further oxidation of phenoxy quinones, derived from the halogenated phenols by oxidation. These colorless compounds differ from previously known quinone oxidation products by virtue of the fact that in their formation by rupture of the quinone ring, only one carbon atom of the ring is lost.

Structures are proposed for these compounds, and the mechanism by which they are formed is discussed.

DERIVATIVES OF PHENYLBORIC ACID, THEIR PREPARATION AND ACTION UPON BACTERIA[1]

BY WILLIAM SEAMAN AND JOHN R. JOHNSON

RECEIVED NOVEMBER 17, 1930 PUBLISHED FEBRUARY 9, 1931

The fact that boric acid acts as a very mild antiseptic agent suggested that, in seeking new types of organic antiseptics, an investigation of the organic boric acids, R-B$(OH)_2$, would be of interest. Michaelis and Becker,[2] who first prepared phenylboric acid, observed that this substance was toxic toward microorganisms and relatively harmless toward higher animals. Notwithstanding the promising indications of this early work, no further investigations have been made upon the antiseptic action of the substituted boric acids. The present study was undertaken with the object of preparing a number of derivatives of phenylboric acid containing nitro and amino groups, and testing their action on microorganisms.

Since none of the usual methods for the preparation of aryl boric acids could be adapted readily to the direct synthesis of the nitrophenylboric acids,[3] it seemed desirable to introduce the nitro group by the nitration of phenylboric acid. This compound is prepared conveniently by the interaction of boron trifluoride[4] or methyl borate[5] and phenylmagnesium bromide.

---

[1] This article is an abstract of a thesis submitted by William Seaman to the Faculty of the Graduate School of Cornell University, in partial fulfilment of the requirements for the degree of Doctor of Philosophy, in March, 1929.

[2] (a) Michaelis and Becker, **Ber.,** 13, 58 (1880); (b) *ibid.,* 15, 180 (1882).

[3] An adaptation of the method of preparation of aryl boric acids used by Michaelis and Becker would involve the interaction of boron trichloride or boron tribromide with a bis-(nitrophenyl)-mercury. Although it has been possible to prepare bis-(m-nitrophenyl)-mercury (unpublished work of R. S. Shelton in this Laboratory), the relative inaccessibility of such compounds led us to seek other methods.

[5] **(a)** Khotinsky and Melamed, **Ber.,** 42, 3090 (1909); (b) Gilman and Vernon, THIS JOURNAL, 48, 1064 (1926).

After a preliminary study of the nitration of phenylboric acid, two satisfactory methods of procedure were developed, whereby it was possible to produce the three isomeric nitro compounds. The ortho and meta compounds could be prepared in relatively large amounts but the para isomer was only obtained in very small amounts. Nitration at a low temperature, in the presence of acetic anhydride, with a moderate excess of fuming nitric acid gave a mixture containing about 95% of o-nitrophenylboric acid and 5% of *p*-nitrophenylboric acid. The combined products represented yields of about 65% of the theoretical quantities. Nitration with fuming nitric acid alone, at low temperature, led to the production of a mixture of approximately 85% of m-nitrophenylboric acid and 15% of the ortho isomer.[6] The combined products in this case represented about 80% of the theoretical yield. The separation of the isomeric nitrophenylboric acids was accomplished by fractional crystallizations from aqueous solutions.

In order to establish the structure of the three isomeric nitrophenylboric acids, the boric acid residue was replaced by the chloromercuri- group,? and this in turn by bromine

$$NO_2C_6H_4B(OH)_2\ 4\ HgCl_2 + H_2O \longrightarrow NO_2C_6H_4HgCl + HCl + H_3BO_3$$
$$2NO_2C_6H_4HgCl + 2Br_2 \longrightarrow 2NO_2C_6H_4Br + HgCl_2 + HgBr_2$$

Either the nitrophenylmercuric chlorides or the corresponding bromonitrobenzenes were identified by comparison with authentic specimens.

The o- and m-aminophenylboricacids were obtained by reduction of the nitro compounds by means of freshly precipitated ferrous hydroxide.[8] On account of the small amount of *p*-nitrophenylboric acid at our disposal, the para isomer was not reduced. m-Aminophenylboric acid was isolated as a crystalline solid and was converted to the acetyl and benzoyl derivatives. o-Aminophenylboric acid was not isolated as such, but was converted to the corresponding benzoyl derivative.

Since the positions of the nitro group in the nitrophenylboric acids had been established, further proof of the orientation of the groups in the

---

[6] Since the preparation of this manuscript, Ainley and Challenger [J.Chem. *Soc* , 2176 (1930)] have described the nitration of phenylboric acid to produce *m*-nitrophenylboric acid. These investigators did not isolate the corresponding ortho and para isomers which are described in the present article, but determined the relative proportions of the isomers produced, by examination of the mixed bromonitrobenzenes obtained from them. Their method undoubtedly gives more accurate data concerning this point, but they have dealt only with the nitration technique in which the meta isomer predominates. Their methods of establishing the position of the nitro group were very similar to those used in this investigation.

[7] Michaelis and Becker, ***Ber.***, 15, 182 (1882).

[8] Subsequently, F. R. Bean, in this Laboratory, has shown that catalytic reduction with the platinum catalyst of Adams and Shriner ("Organic Syntheses," John Wiley and Sons, Inc., New York, Vol. VIII, 1928, p. 92) is a simpler method of effecting this reduction.

amino derivatives was unnecessary. However, in order to confirm the structures of the amino derivatives, it seemed desirable to establish the state of combination of the nitrogen atom. This was accomplished readily by elimination of the boric acid residue,[9] and identification of the resulting nitrogen compound

$$CH_3CONHC_6H_4B(OH)_2 + AgNO_3 + NH_3 \longrightarrow CH_3CONHC_6H_4BO_2HAg + NH_4NO_3$$

$$2CH_3CONHC_6H_4BO_2HAg + 2H_2O \longrightarrow 2CH_3CONHC_6H_5 + 2H_3BO_3 + Ag_2O$$

In the course of this work several attempts were made to devise new methods for the preparation of aromatic boric acids. One of these was an attempt to introduce the boric acid residue directly, by heating aniline with boric acid, in a manner analogous to that used for the preparation of arsanilic acid. It has been shown by Chaudhuri[10] that an anilide of boric acid, $C_6H_5NHB{=}O$, can be obtained by heating aniline with boric acid. None of our efforts to effect a rearrangement of the boric acid group from the side chain into the ring was successful, either with boric anilide or with its acetyl and benzoyl derivatives. Experiments were also made upon the replacement of the sulfinic acid group by the boric acid residue. Sodium benzenesulfinate and *p*-toluenesulfinate were heated with boric acid and with borax, but no trace of an organic boric acid could be observed in the products of these reactions.

Work is now in progress on the preparation of hydroxyphenylboric acids, and of other substituted nitro and amino compounds.

Experimental

Methyl Borate.—For use in the preparation of phenylboric acid, methyl borate should be quite free from methyl alcohol, since the latter caused a marked diminution of the yield, apparently greater than could be accounted for on the basis of the Grignard reagent actually destroyed by the alcohol. Diverse boiling points for methyl borate (from 55 to 72°) are reported in the literature,[11] probably due to the fact that methyl borate forms an azeotropic mixture with methyl alcohol[11d] from which it is relatively difficult to remove the last traces of methyl alcohol. To accomplish this, we employed the method of Schiff,[11b] which consists in washing with cold concd. sulfuric acid. The purified methyl borate obtained thus had the following properties: b. p. 67–67.8° at 750 mm.; d^{20}_{4} 0.932; n^{24}_{D} 1.3558.

Phenylboric Acid, $C_6H_5\text{-}B(OH)_2$.—Preliminary tests showed that the yields of phenylboric acid were improved by adding the phenylmagnesium bromide to an ethereal solution of methyl borate, instead of the reverse procedure used by Khotinsky and

Bruxelles*, 47B, I, 63–71 (1927); [*C. A.*, 22, 4296 (1928)]. At the time when this work was started we were not aware of the work of Lecat on the azeotropic mixture, methyl borate + methyl alcohol.

Melamed.[5] Even this modification did not allow us to attain the yields of 50 and 86% which are claimed by previous investigators.[12]

During the course of forty-five minutes, 0.25 mole of phenylmagnesium bromide (in 1 molar solution) was added to a solution of 26 g. (0.25 mole) of methyl borate in 80 cc. of pure ether. The methyl borate solution was maintained at about −12° during this addition, and the reaction mixture was shaken constantly by hand. After all of the Grignard reagent had been added, the reaction mixture was refluxed gently for fifteen minutes. It was then thoroughly chilled in a freezing mixture, and 125 cc. of a cold 1% solution of sulfuric acid was added cautiously. After shaking thoroughly, the ethereal layer was decanted and the aqueous layer was extracted with four 100-cc portions of ether. The combined ethereal solutions were dried and the ether distilled off. The solid residue was crystallized from about 70 cc. of water, with the addition of decolorizing carbon. The average yield of a number of runs was 9 g., which is 30% of the theoretical amount. The product obtained in this way was sufficiently pure to be used for nitration.

For more thorough purification, to obtain specimens for determination of physical constants and for bacteriological tests, the substance was recrystallized from petroleum benzene (b. p. 110–120°). The purified material melted at 215.5–219° by the capillary tube method, in a preheated bath; m. p. 221° (corr.) on the Maquenne block.[13]

Michaelis and Becker[2] reported a melting point of 204" for the sample of phenylboric acid that they tested for antiseptic properties; in a later communication the melting point was recorded as 216°.[15] This discrepancy, together with the fact that they reported that phenylboric acid has a pleasant taste and a phenolic odor, leads us to believe that they did not work with perfectly pure material. Our purified specimens were odorless and tasteless, and showed much less antiseptic action.

The residues from the mother liquors which remained after as much as possible of the phenylboric acid had been recovered, contained a yellow solid which melted incompletely near 300°. This material gave a qualitative test for boron[16] and responded to the usual tests for aromatic boric acids with silver nitrate and with mercuric chloride. This material was not examined further; it may consist in part of diphenylboric acid.[15]

***m*-Nitrophenylboric** Acid.—In an ice–salt freezing mixture, 75 g. of colorless fuming

---

[12] More recent work of F. R. Bean, in this Laboratory, using n-butyl borate and effecting the reaction at a temperature of −50 to −60°, gave yields of 50–60% of the theoretical.

[13] The capillary tube melting points of the aromatic boric acids were found to be greatly influenced by the manner of heating, since the substances are capable of undergoing dehydration and other decomposition in the course of heating. The melting points of these substances are much more characteristic and more constant if the Maquenne block [Houben–Weyl, "Die Methoden der organischen Chemie," Georg Thieme, Leipzig, **1921,** Vol. I, pp. 734–735] is used, so that preliminary heating is avoided. Since the melting points observed on the Maquenne block frequently differ from those obtained by the usual methods, the values are not directly comparable. In Table I, at the end of the experimental section, are tabulated the various melting points of the principal compounds described in this article. A very convenient and elegant modification of the Maquenne block has been devised in this Laboratory.[14]

[15] Michaelis and Behrens, *Ber.*, **27,** 244 (1894).

[16] Two qualitative tests for boron were used in connection with this work: (1) observation of the green color imparted to a Bunsen flame when the compounds were burned upon a foil, and *(2)* fusion with metallic sodium, treating with slightly acidulated water and testing the solution with turmeric paper.

nitric acid (sp. gr. 1.50), to which a little urea had been added, was cooled to −15°. During one and one-half hours, 10 g. of finely powdered, dry phenylboric acid was added, with good mechanical stirring, so that the temperature did not rise above −9° The mixture was stirred for ten minutes after all the phenylboric acid had been added, and was then poured onto 50 g. of ice.[17] The precipitated nitrophenylboric acid (I) was filtered with suction, and recrystallized from *a* small volume of water, with the addition of decolorizing carbon.

The original filtrate was cooled in an ice-bath, neutralized to congo red with strong sodium hydroxide solution, and then slightly acidulated with nitric acid. The solution was extracted thoroughly with ether, and the solvent evaporated off at room temperature. The residue was fractionally crystallized from a small volume of water, with the addition of decolorizing carbon. The crystals (II) which separated before the solution had cooled completely (30°) consisted chiefly of m-nitrophenylboric acid, and were combined with the original precipitate (I) and subjected to further purification. The substance which crystallized upon cooling the filtrate from II, in an ice-bath, consisted largely of o-nitrophenylboric acid. The latter was purified by crystallization from a very small volume of water. The average yield of m-nitrophenylboric was 10 g. (70% of the theoretical); that of o-nitrophenylboric acid was 1.5 g. (10% of the theoretical).

***m*-Nitrophenylboric** Acid.—This substance forms yellow prismatic crystals. It is slightly soluble in cold water, moderately soluble in hot water, soluble in alcohol and ether. It dissolves in aqueous sodium hydroxide, sodium carbonate and ammonia. It gives the characteristic tests for aromatic boric acids with silver nitrate and with mercuric chloride, and the usual qualitative tests for boron. The air-dried purified m-nitrophenylboric acid melted with charring at 275–276.5° (corr.) in a capillary tube placed in a bath preheated to about 250°, and at 273" (corr.) in a bath which was not preheated.[18] On the Maquenne block the melting point was 319° (corr.).

After drying to constant weight in a desiccator, the substance melted with charring at 285–286° (corr.) in a bath not preheated. This is evidently the melting point of the anhydride, $NO_2C_6H_4B{=}O$, since the analytical data on this sample agreed with the theoretical values for the anhydride. All samples for analysis were dried in *vacuo* over concd. sulfuric acid.[19]

Anal. Calcd. for $NO_2C_6H_4BO$: C, 48.37; N, 9.41. Calcd. for $NO_2C_6H_4B(OH)_2$: C, 43.14; N, 8.39. Found: C, 48.05, 48.17; N, 9.90, 9.75.

Determination of the Position of the Nitro Group.—A hot aqueous solution of 1 g. of the nitrophenylboric acid was treated with a concd. aqueous solution of 1.8 g. of mercuric chloride. The resulting precipitate of nitrophenylmercuric chloride was washed with water, and treated with an excess of a solution of bromine in aqueous potassium bromide. The mixture was shaken for two and one-half hours at room temperature and extracted with ether. The residue, after removal of the solvent, was washed free from bromine and recrystallized from 50% alcohol; m. p. 53.7–54.2° (corr.). An authentic specimen of m-bromonitrobenzene (Kahlbaum), used for comparison,

---

[17] A small amount of nitrobenzene is always formed in these nitrations; if the reaction is carried out at higher temperatures, nitrobenzene and boric acid are produced as the principal products.

[18] Ainley and Challenger, Ref. 6, report m. p. 273° for m-nitrophenylboric acid, but do not state the conditions of the melting point determination.

[19] Carbon determinations were made by the Parr total carbon method, which did not prove entirely satisfactory. Ainley and Challenger (Ref. 6) reported that the usual combustion method gave very low results for carbon. The nitrogen determinations were made by the Dumas method,

melted at 54.0–54.2° (corr.); a mixture of the two substances melted at 53.7–54.2° (corr.). The formation of m-bromonitrobenzene establishes the structure of the above acid as m-nitrophenylboric acid.

o-Nitrophenylboric Acid.—Six grams of colorless fuming nitric acid (sp. gr. 1.50), to which a few crystals of urea had been added, was allowed to drop slowly into a suspension of 10 g. of phenylboric acid in 90 cc. of acetic anhydride, cooled to −15°. Mechanical stirring was used throughout the addition, which required about forty-five minutes, and the mixture was stirred for about one and one-half hours after all of the nitric acid had been added. During this period the temperature was allowed to rise slowly to −7°; the freezing-bath was then removed and the stirring was continued until all of the acid had dissolved (about one hour). Occasional cooling was used to keep the temperature below +20°. The reaction mixture was poured slowly into 200 cc. of ice water and the whole was agitated until a clear homogeneous solution was obtained. The solution was concentrated to a small volume at 50°, under reduced pressure; 100 cc. of water was added and the concentration repeated.[20] After cooling, and standing for ten to twelve hours, about 0.3 g. of a crystalline nitrophenylboric acid (III) separated. This was removed by filtration and reserved for examination (see below, *p*-nitrophenylboric acid). The quantity of this product was about 2% of the theoretical yield.

The filtrate was concentrated further, at 50° under reduced pressure, with repeated additions of water, until most of the acetic acid was removed and crystals had separated in the solution. These were separated by filtration, and the mother liquor was concentrated further, until it was reduced to a very small volume After separating the crystals, the final filtrate was made alkaline to congo red with sodium carbonate, slightly acidified with hydrochloric acid, and extracted with ether. Evaporation of the ether extract gave a residue which was combined with the main fractions of *o*-nitrophenylboric acid and recrystallized from a very small amount of water. Approximately 8 g. of crude o-nitrophenylboric acid was obtained (60% of the calculated quantity). This product was sufficiently pure for subsequent syntheses; for further purification the acid was washed with hot carbon tetrachloride and recrystallized from water.
